Results In the derivation cohort, the prevalence of HRN was 15%. The bias-corrected AUC and Akaike Information Criterion (AIC) of a model (Diabetes-HRN index) comprising of variables independently associated with HRN (log-transformed values of ALT, GGT, and BMI along with AST/ULN-to-platelet ratio, HDL-C, and age) were 0.95 (95% CI 0.93–0.97) and 309.6, respectively. A score threshold of >15.82, selected by Youden's index, correctly identified a total of 717 (89%) out of 805 participants, with a sensitivity of 90%, specificity of 89%, NPV of 98%, and PPV of 57%. In the validation cohort, the Diabetes-HRN index yielded an AUC of 0.95 (95% CI: 0.89–0.99), and a score threshold of >15.82 correctly classified a total of 81 (84%) out of 97 participants, with NPV of 74% and PPV of 87%. The Diabetes-HRN index outperformed Fib-4 in predicting HRN in the derivation (AUC: 0.64, 95% CI: 0.61–0.67) and validation (AUC: 0.77, 95% CI: 0.67–0.84) cohorts. The Delong test p values for comparing AUCs between HRN Diabetes and FIB4 was <0.01 (Figure). In a separate analysis consisting of 1237 T2D participants in NHANES 2011–2012 and 2013–2014, our Diabetes-HRN index, after adjusting for age, gender, race/ethnicity, history of CVD and cancer, and smoking status, was significantly associated with overall mortality [HR: 1.6 (95% CI: 1.04–2.3), P = 0.03].
Conclusion: A newly developed and validated Diabetes-HRN index based on 6 bedside variables accurately identifies diabetic patients at high risk of fibrotic NASH. This model significantly outperforms FIB4.

TOP-083

Utility of serum phosphatidylethanol in differentiating NAFLD from alcohol-associated liver disease among individuals with overweight and obesity: the San Diego liver study

Monica Tincopa[1], Ricki Bettencourt[1], Maral Amangurbanova[1], Christian Butcher[1], Christie Hernandez[1], Egbert Madamba[1], Seema Singh[1], Lisa Richards[1], Veeral Ajmera[1], Rohit Loomba[1]. [1]*UCSD, United States*
Email: mtincopa@health.ucsd.edu

Background and aims: Differentiating non-alcoholic fatty liver disease (NAFLD) from alcohol-associated liver disease (ALD) can be challenging in individuals with overweight and obesity. There are limited prospective data from cohorts of individuals with overweight or obesity who have been systematically assessed for hepatic steatosis. This study aimed to evaluate the prevalence of NAFLD and ALD among individuals with overweight and obesity and to

determine the clinical utility of serum phosphatidylethanol (PEth) in differentiating NAFLD from ALD.

Method: This prospective study enrolled adults aged 40–75 with overweight (BMI ≥ 25–<30 kg/m^2) and obesity (BMI ≥ 30). Participants completed a research visit with vibration controlled transient elastography (VCTE) with controlled attenuation parameter, MRI proton-density-fat-fraction (MRI-PDFF) and MR elastography (MRE). Alcohol use was assessed with Alcohol-Use-Disorder-Identification-Test (AUDIT)-C, Skinner Lifetime Drinking History and serum PEth. NAFLD was defined as MRI-PDFF ≥ 5% and AUDIT-C <4 for males and <3 for females with exclusion of other liver diseases and consistent with AASLD Practice Guidance. ALD was defined as MRI-PDFF ≥ 5% with self-reported measures consistent with alcohol use disorder. Advanced fibrosis was defined using established liver-stiffness cut-points on MRE.

Results: The cohort included 278 consecutive individuals, median age 54 years, 46% males, 41% Latinos, median BMI 31 kg/m^2 with 29.5% having diabetes. The prevalence of NAFLD was 68.7% and ALD 11.2%. Median hepatic fat-content by MRI-PDFF was 13.2% in NAFLD versus (vs.) 11% in ALD. Median MRE liver stiffness measures were 2.2 kPa in NAFLD vs. 2.1 kPa in ALD. The prevalence of advanced fibrosis by MRE was 11.5% in NAFLD vs. 12.9% with ALD. PEth >20–40 ng/ml, >40–60 ng/ml and >60 ng/ml was detected in 4.3%, 2.1% and 5.4% of NAFLD patients. Serum PEth correlated with MRE liver stiffness measures in NAFLD (r_s 0.20, p 0.01). A PEth cut-point of <17 ng/ml yielded an AUC of 0.82 with a negative predictive value of 96% to distinguish those with NAFLD from those with ALD (Figure 1).

Figure 1. Clinical Utility of PEth in Differentiating NAFLD from ALD

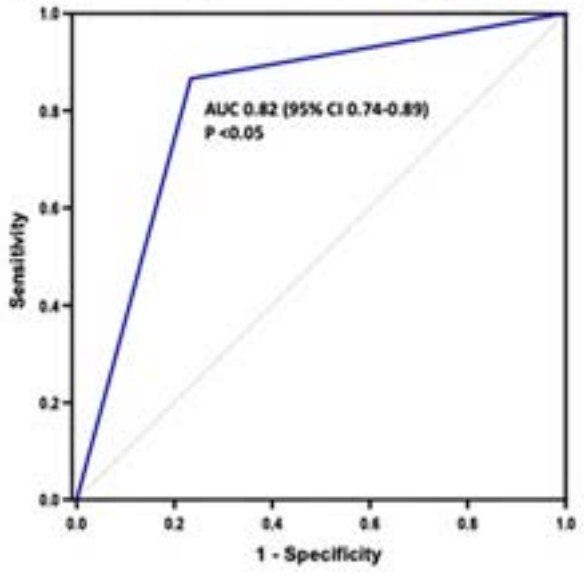

Figure:

Conclusion: Among a well characterized prospective cohort of individuals with overweight and obesity, the prevalence of NAFLD was 69% and ALD 11%. The prevalence of advanced fibrosis was 10%. Serum PEth is associated with increased liver stiffness in NAFLD, raising concern for synergistic effects of even low amounts of alcohol on disease progression in NAFLD. A PEth of <20 ng/ml may serve as a simple serum-based tool to differentiate those with NAFLD from those with ALD in patients with overlapping risk factors. These data have important implications for clinical practice and trials.

TOP-085

Long-term liver-related outcomes in 1,260 patients with non-cirrhotic NAFLD

Camilla Akbari[1], Maja Dodd[1], Xiao Zhang[2], Tongtong Wang[2], Thomas Jemielita[2], Gail Fernandes[2], Samuel Engel[2], Patrik Nasr[1,3], Johan Vessby[4], Fredrik Rorsman[4], Stergios Kechagias[3], Per Stal[1], Mattias Ekstedt[3], Hannes Hagström[1], Ying Shang[1]. *[1]Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden; [2]Merck and Co., Inc., Rahway, NJ, USA, United States; [3]Department of Gastroenterology and Hepatology and Department of Health, Medicine, and Caring Sciences, Linköping University, Linköping, Sweden; [4]Dept of Gastroenterology and Hepatology, Uppsala University Hospital, SE-751 85 Uppsala, Sweden*
Email: ying.shang@ki.se

Background and aims: Non-alcoholic fatty liver disease (NAFLD) can progress to cirrhosis, decompensated cirrhosis and hepatocellular carcinoma (HCC). Previous studies on the prognosis of NAFLD have been limited to less than 1000 patients, have few hard outcomes and frequently short follow-up time or low granularity. Here, we aimed to investigate the long-term prognosis of a large cohort of patients with NAFLD regarding the risk of liver-related outcomes.

Method: We conducted a retrospective cohort study with data from three Swedish university hospitals. Patients were diagnosed with NAFLD through biopsy, vibration-controlled transient elastography (VCTE) or as a clinical diagnosis between 1974–2020 and followed up until 2020. We excluded patients with cirrhosis at baseline. Each NAFLD patient was matched on age, sex and municipality with up to ten reference individuals, identified from the Swedish Total Population Register. Liver-related outcomes were defined as clinically recorded diagnoses of cirrhosis, decompensated cirrhosis, HCC or liver-related death, or ascertained through linkage to Swedish national registers. The risk of liver-related outcomes was estimated by Cox regression, and Harrell's C-statistic was performed to assess model discrimination.

Results: 1,260 non-cirrhotic NAFLD patients and 12,529 matched controls were included. The median age at inclusion was 52 years (IQR: 39–60) and 748 (59.4%) were men. 904 (71.8%) patients were diagnosed through biopsy, 118 (9.4%) through VCTE and 238 (18.9%) through a clinical diagnosis. During follow-up, 339 outcomes occurred in the NAFLD group (IR = 5.9/1000 PY), and 597 in the reference individuals (IR = 1.0/1000 PY). NAFLD was associated with a higher rate of liver-related outcomes (hazard ratio: 6.6; 95% CI 5.2–8.5). The cumulative incidence of liver-related outcomes was highly associated with the stage of fibrosis at diagnosis after considering competing risks (Figure). Around 40% of patients with F3 developed a liver-related outcome after 20 years. In the biopsy subcohort, patients with F3 and NASH had a higher overall mortality than patients with F3 without NASH, mainly from extrahepatic cancers, but there was no difference in the cumulative risk for liver-related outcomes. In patients with biopsy-diagnosed NAFLD, the predictive ability of FIB-4 showed a similar C-statistic as compared to biopsy for prediction of liver-related outcomes at 5 years (0.713 for FIB-4 vs 0.701 for biopsy) and at 10 years (0.728 vs 0.734). In the full cohort, C-statistic reflecting FIB-4′s prediction of liver-related outcomes at 5 years and 10 years were 0.724 and 0.730, respectively.

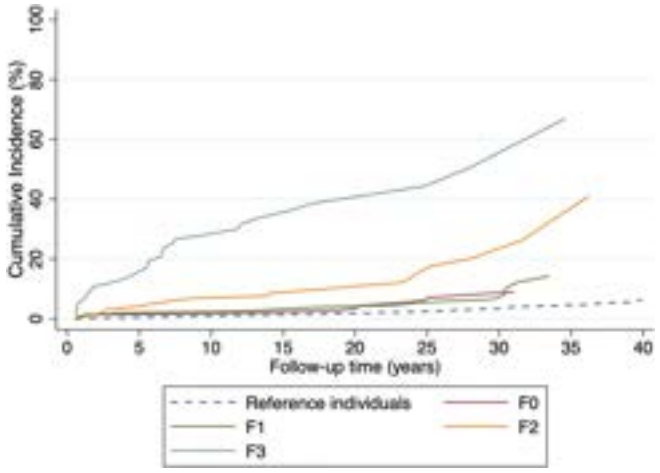

Figure: Cumulative incidence of liver-related outcomes stratified on fibrosis stage and compared against reference individuals from the general population.

Conclusion: The cumulative incidence of liver-related outcomes was considerable in this large cohort of patients with NAFLD and fibrosis stage 2–3. We found some indication of a more severe prognosis in those with F3 and NASH. Prognostic information from biopsy was comparable to FIB-4, although both modalities had modest discriminative ability. New prediction models are needed in NAFLD.

SAT-393

Early aminotransferase improvement in the phase 2b NATIVE study is predictive of response pattern of liver histology as well as hepatic and cardiometabolic health markers at the end of treatment in patients with non-cirrhotic NASH

Quentin Anstee[1], Philippe Huot-Marchand[2], Lucile Dzen[2], Jean-Louis Junien[2], Pierre Broqua[2], Sven Francque[3], Manal Abdelmalek[4], Michael Cooreman[2], Stephen Harrison[5].
[1]Newcastle University, United Kingdom; [2]Inventiva, Research and Development, Daix, France; [3]Antwerp University Hospital, Edegem, Belgium; [4]Mayo Clinic, Rochester, United States; [5]University of Oxford, United Kingdom
Email: michaelpcooreman@msn.com

Background and aims: There is a need to identify non-invasive tests (NITs) that provide an early prediction of evolving histological response/non-response to therapy. Lanifibranor has shown efficacy on liver histology and metabolic-immune markers of NASH. We evaluated the correlation of ALT and AST response at treatment week (TW) 4 with subsequent histological response and change in cardiometabolic health (CMH) in lanifibranor treated patients at TW24 in the ph2b NATIVE trial.

Method: NATIVE evaluated lanifibranor 800 and 1200 mg/d versus placebo in patients with non-cirrhotic NASH over 24 weeks. We assessed the early kinetics of liver biochemistry improvements for AST and ALT at TW4, and their abilities for predicting histological *non-response* at TW24 for 'NASH resolution with no worsening of fibrosis' (E1) and 'improvement of fibrosis with no worsening of NASH' (E2), mainly using the Negative Predictive Value (NPV) but including also Sensitivity (Sens), Specificity (Spec) and Negative Likelihood Ratio (NLR) at TW4. Analyses were performed on data available for transaminases at TW4 and histological response at TW24 (N = 142 pooled lanifibranor treated patients) individually for each NIT. Based on the results, we then analyzed the correlation of early ALT and AST improvement at TW4 and response of CMH markers at TW24.

Results: For E1, an ALT reduction ≥15% from baseline value to TW4 showed Sens 0.90 (95%CI 0.83–0.98), Spec 0.22 (0.13–0.31) for histological response. Reductions <15% were observed in 21.5% of non-responders versus 9.5% of responders, giving a NPV of 0.74 (0.56–0.92) and NLR 0.44. AST reduction ≥15% was less sensitive but more specific: Sens 0.60 (0.48–0.72), Spec 0.47 (0.36–0.58), reductions <15% gave a NPV 0.60 (0.48–0.72), NLR 0.85. For E2, biochemical changes performed less well as predictive markers. Reductions ≥15% showed Sens 0.82 (0.72–0.92), Spec 0.15 (0.08–0.23) and Sens 0.54 (0.41–0.67), Spec 0.42 (0.31–0.52) for ALT and AST respectively. ALT and AST decrease at TW4 correlated with improvement in markers of glucose and lipid metabolism, adiponectin, GGT at TW24, with a correlation more pronounced for ALT than AST.

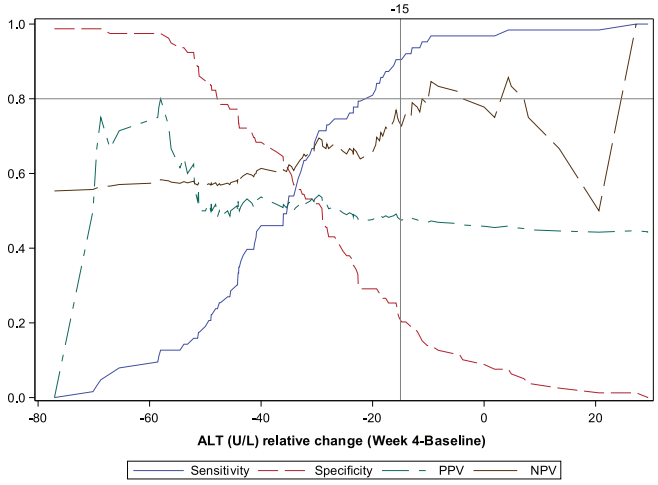

Figure: NASH resolution without worsening of fibrosis.

Conclusion: Considering detection of NASH resolution, absence of a ≥15% reduction from baseline in ALT at TW4 in the NATIVE study was a simple, effective tool to predict non-response to lanifibranor at TW24. Early decrease in ALT or AST correlated with improvement of non-invasive hepatic and CMH biomarkers at TW24.

SAT-394

Novel artificial intelligence-assisted digital pathology quantitative image analysis predicts the occurrence of liver-related clinical events in the multicentric, European, hepatic outcomes and survival fatty liver registry (HOTSURFR) study

Li Chen[1], Louis Petitjean[1], Javier Ampuero[2], Jerome Boursier[3], Stergios Kechagias[4], Salvatore Petta[5], Hannes Hagström[6], Jörn Schattenberg[7], Frederic Charlotte[8], Leila Kara[9], Pierre Bedossa[10], Mathieu Petitjean[1], Vlad Ratziu[11]. *[1]PharmaNest, United States; [2]Hospital Universitario Virgen del Rocío de Sevilla, Spain; [3]CHU Angers, France; [4]Linköping University, Sweden; [5]Università degli Studi di Palermo, Italy; [6]Karolinska University Hospital, Sweden; [7]Mainz Universität, Germany; [8]Assistance Publique Hôpitaux de Paris, France; [9]ICAN, France; [10]Liverpat, France; [11]Sorbonne Université, France*
Email: vlad.ratziu@inserm.fr

Background and aims: Artificial intelligence-assisted digital pathology provides an automated, operator independent, sensitive and quantitative assessment of histological changes with the ability to identify patterns of fibrosis progression or regression. However, its value for predicting clinical events is unknown. We have previously shown that quantitative traits in collagen fiber parameters can be used to build fibrosis scores that are correlated with the semiquantitative histological NASH CRN stages. We aimed to determine if quantitative fibrosis scores from baseline liver biopsies are correlated with incident liver-related events (LRE) in a large, multicentric, European cohort with long-term follow-up.

Method: 304 patients (pts) from 6 European centers with liver biopsy performed for suspected NAFLD before 2011 and clinical follow-up, were retrospectively analyzed. LRE were defined as occurrence of cirrhosis, cirrhosis decompensation events or hepatocellular carcinoma. Formalin-fixed, paraffin-embedded biopsies where stained with collagen stains (Masson Trichrome or Picro Sirius Red) and digitized at 40X. Histology was read centrally (NASH CRN classification). Quantitative image analysis extracted 315 single-fiber quantitative traits (qFTs) to assess fibrosis composition, morphometric and architectural histological phenotypes. The qFTs that exhibited a significant (>50%) mean change between pts with or without events were identified, normalized and combined in a Liver Event Predictive Score (LEPS). A quantitative fibrosis severity score, Ph-FCS, ranging from 1 to 10, previously optimized to model the F0-F4 fibrosis progression, and derived from a selection of the same 315 qFTs was also assessed.

Results: Mean age was 53.5 yrs, 56% were males, mean BMI 30.6 kg/m², 39% had diabetes and 62% arterial hypertension. The proportion of histological fibrosis stages were: 0/1/2/3/4, 53%/17%/8%/14%/8%, respectively. Median follow-up was 11.4 yrs (IQR 4.7). 52 pts (17%) had at least one LRE. Mean (sd) LEPS was 1.88 (0.67) in pts with LRE vs 2.68 (0.78) in pts without LRE ($p < 0.001$). Using a cut-off value of 2.9, LEPS had a sensitivity of 71% and specificity of 68% for the prediction of LRE. When the cut-off value was changed by ± 5% the sensitivity and specificity varied within a – 11% to +6.5% range. Ph-FCS demonstrated a similar performance as LEPS (sensitivity = 79%, specificity = 62%) for a cut-off value of 4. There was a strong correlation between LEPS and Ph-FCS ($r = 0.77$, $p < 0.001$), confirming that fibrosis severity is a major predictor of clinical events.

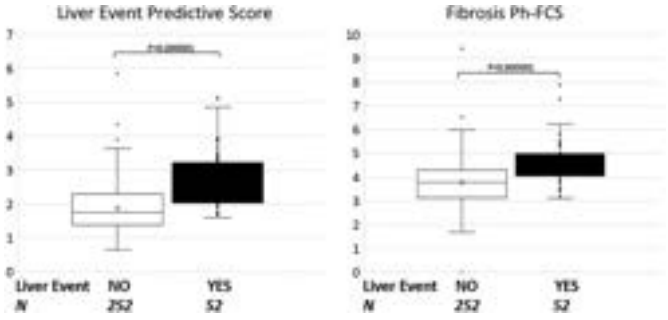

Figure:

Conclusion: Quantitative image analysis by digital pathology performed on stained liver slides provides continuous scores that identify NAFLD patients at risk of incident clinical outcomes. Further validation on additional cases is ongoing, aiming to provide better histological surrogates for therapeutic trials.

SAT-395

Risk-stratification of patients with non-alcoholic fatty liver disease (NAFLD) in primary care: lessons from the Calgary NAFLD pathway

Abdel-Aziz Shaheen[1], Elizabeth Baguley[1], Wendy Schaufert[2], Mark G Swain[1]. [1]*University of Calgary, Canada;* [2]*Alberta Health Services, Canada*
Email: az.shaheen@ucalgary.ca

Background and aims: The Calgary non-alcoholic fatty liver disease (NAFLD) pathway (CNP) is the largest primary care-based NAFLD pathway in North America. We aimed to evaluate the performance of different risk-stratification modalities among CNP patients according to their baseline liver enzymes and metabolic syndrome risk factors.

Method: The CNP uses validated shearwave elastography (SWE) assessment as the primary tool of risk-stratification for patients with a history of fatty liver or 'at-risk' of metabolic syndrome since March 2017. In the CNP, 'at-risk' of advanced fibrosis patients with SWE ≥8.0 kPa or inconclusive results are referred to hepatology. Since only an ALT assessment was mandatory at baseline, some patients did not have all baseline serum fibrosis-4 variables (FIB-4). We compared the performance of both SWE ≥7.0 and 8.0 kPa, and FIB-4 ≥1.3, according to sex, age, rural residence, body mass index (≥35), normal ALT (25 U/L for women and 30 U/L for men), and presence of Type 2 diabetes mellitus (DM).

Results: A total of 12,122 patients completed SWE assessment with a confirmed NAFLD diagnosis in the CNP between March 2017 and June 2022. Baseline FIB-4 was available in 8,590 patients (70.9%). Among those patients with available FIB-4, 2,643 (33.8%) had FIB-4 ≥1.3,402 (4.8%) had an inconclusive SWE, 1,042 (11.9%) SWE ≥7.0 kPa, and 762 (8.9%) SWE≥8.0 kPa. The performance of different modalities among different cohorts is presented in Table 1. Patients with normal baseline ALT levels had FIB-4 ≥1.3 ($p = 0.61$) and SWE ≥8.0 kPa ($p = 0.09$) similar to patients with elevated ALT. While SWE ≥7.0 and 8.0 kPa were significantly higher among patients with a BMI ≥35, these patients had lower advanced fibrosis confirmed by liver biopsy ($n = 232$ patients) compared to patients with BMI <35 ($p < 0.001$). Patients with DM had significantly higher rates of FIB-4 ≥1.3 and SWE ≥7.0 and 8.0 kPa, Table 1.

Table: Comparison of FIB-4 1.3 and SWE 7.0 and 8.0 kPa among different demographic and clinical characteristics.

Modality cut-off	Female cohort N = 4,538 (52.9%)	Age ≥50 yrs cohort N = 5,284 (61.5%)	BMI ≥35 N = 2,085 (30.2%)	Normal ALT N = 2,585 (30.1%)	Elevated ALT N = 6,005 (69.9%)	DM N = 2,922 (34.2%)
FIB-4 ≥1.3	1,289 (28.4%)	2,350 (44.5%)	579 (27.8%)	785 (30.4%)	1,858 (30.9%)	1,081 (37.0%)
SWE ≥7.0 kPa	540 (11.9%)	781 (14.8%)	387 (18.6%)	275 (10.6%)	749 (12.5%)	554 (19.0%)
SWE ≥8.0 kPa	404 (9.0%)	596 (11.4%)	287 (13.9%)	208 (8.1%)	554 (9.3%)	448 (15.5%)

Conclusion: In this primary care-based cohort to risk-stratify NAFLD patients for advanced fibrosis, patients with normal ALT had similar risk of elevated liver stiffness compared to those with elevated ALT. Priority of risk-stratification should be given to patients with DM.

SAT-396

Thrombospondin-2 as a new biomarker for at risk NASH and advanced fibrosis in a large multicentric European cohort

Vlad Ratziu[1], Rambabu Surabattula[2], Elisabetta Bugianesi[3], Jörn Schattenberg[2], Maharajah Ponnaiah[4], Chiara Rosso[3], Angelo Armandi[3], Sudha Myneni[2], Raluca Pais[4], Leila Kara[4], Detlef Schuppan[2]. [1]*Sorbonne Université, Paris, France;* [2]*Mainz Universität, Germany;* [3]*University of Torino, Italy;* [4]*ICAN, France*
Email: vlad.ratziu@inserm.fr

Background and aims: New biomarkers with strong biological rationale are needed for identifying patients with progressive or advanced NASH in clinical practice and for selection in therapeutic trials. Liver transcriptomic data from NAFLD patients identified thrombospondin-2 (TSP2), a matricellular glycoprotein that mediates cell-matrix interactions and collagen fibrillogenesis, as strongly induced in patients with NASH and those with advanced fibrosis. We tested the diagnostic performance of Tsp2, I7 (a matricellular and metabolic marker) and CD163 (a macrophage marker) in a large, multicentric European cohort.

Method: Retrospective study of patients with NAFLD, available liver biopsy and frozen serum collected within 3 months of the biopsy. TSP2 and I7 were measured by validated proprietary ELISAs, and CD163 was determined by commercial ELISA (RandD). FIB4 was calculated. Liver biopsies were graded and staged according to the NASH CRN histological classification. Histological outcomes were at-risk NASH (steatohepatitis with NAS≥4 and fibrosis stage 2–4) and

advanced fibrosis (stages 3–4). We developed combinatorial scores (with clinical variables and/or multi-biomarkers) for NASH and advanced fibrosis using multivariate logistic regression controlling for centers, age, BMI, and gender. Training and validation sets were defined using a machine learning algorithm which randomly split 80% and 20% of the total cohort, for 100 iterations, followed by averaging of the AUROC predictions.

Results: 481 patients were included from Turin (219), Paris (173) and Mainz (89): mean age 51.4 years (s.d. 12.7), 61% males, Mean BMI 30.6 kg/m² (s.d. 5.6), 44% with type 2 diabetes, 53% with arterial hypertension, mean ALT 66 (s.d. 55), mean GGT 113 (s.d. 162). There were no significant differences between the three centers. The proportion of at risk NASH was 45.5%, of advanced fibrosis 30%. Median TSP2 was 55.9 ng/ml [IQR 48.6], median I7: 86 ng/ml [IQR 114], median CD163: 531 [IQR 278], FIB4 1.13 [IQR 0.87]. AUROCs for at-risk NASH were TSP2: 0.823; I7: 0.757; CD163: 0.733 and FIB4: 0.726. AUROCs for advanced fibrosis were TSP2: 0.817; I7: 0.678; CD163: 0.761 and FIB4: 0.726. Combining TSP2 with clinical and biological variables (AST, platelets, albumin, GGT) achieved an AUROC of 0.872 for at risk NASH (Se 0.77, Spe 0.85) and 0.822 for advanced fibrosis (Se 0.72, Spe 0.83) (combined with age and platelets). The addition of I7 and C163 to the TSP2-clinical biological score only marginally improved diagnostic performance: AUROCs 0.884 and 0.829 for at-risk NASH and advanced fibrosis, respectively.

Conclusion: Serum levels of TSP2, a molecule with high biological rationale, have a strong discriminative performance for at-risk NASH and advanced fibrosis, especially when combined with simple clinical and biological variables. TSP2 should be prioritized as a strong biomarker candidate in patients with NAFLD.

SAT-397

Predicting severe liver outcomes in NAFLD using repeated measurements of biomarkers—a cohort study in 1,260 patients

Ying Shang[1], Camilla Akbari[1], Maja Dodd[1], Xiao Zhang[2], Tongtong Wang[2], Thomas Jemielita[2], Gail Fernandes[2], Samuel Engel[2], Patrik Nasr[1,3], Johan Vessby[4], Fredrik Rorsman[4], Stergios Kechagias[3], Per Stal[1], Mattias Ekstedt[3], Hannes Hagström[1]. *[1]Karolinska Institutet, Department of Medicine, Huddinge, Sweden; [2]Merck and Co., Inc., Rahway, NJ, USA, United States; [3]Department of Gastroenterology and Hepatology and Department of Health, Medicine, and Caring Sciences, Linköping University, Linköping, Sweden; [4]Dept of Gastroenterology and Hepatology, Uppsala University Hospital, SE-751 85 Uppsala, Sweden*
Email: ying.shang@ki.se

Background and aims: Non-invasive biomarkers measured at a single timepoint have prognostic information for development of severe liver disease (SLD) in patients with non-alcoholic fatty liver disease (NAFLD), but these biomarkers may change over time and the predictive capacity of changes in biomarkers has yet to be determined. Herein, we aimed to assess if the change in biomarkers could predict SLD in patients with NAFLD better than the same biomarkers measured at a single timepoint.

Method: We used a retrospective cohort of 1,260 patients with non-cirrhotic NAFLD (among which 904 [71.7%] had biopsy-proven NAFLD) from three university hospitals in Sweden between 1974 and 2019. Medical charts were reviewed, and biomarkers were measured at baseline and at follow-up visits. Severe liver disease outcomes including cirrhosis, decompensated cirrhosis, hepatocellular carcinoma, liver failure, liver transplantation or MELD score over 15 were determined through medical charts or linkage to national registers until the end of 2020. We used multivariable Cox regression to determine baseline risk factors and biomarkers associated with SLD. We quantified the associations between the trajectory of biomarkers (including current value and slope) with risk of SLD using a joint modeling approach.

Results: The median age at NAFLD diagnosis was 52 years (IQR: 39–60) and 59% were male. During a median follow-up of 12.2 years, 111 (8.8%) patients developed SLD. Higher aspartate aminotransferase (AST), higher Fibrosis-4 score (FIB-4), and lower platelets at baseline were independently associated with a higher SLD risk after adjusting for metabolic factors and fibrosis stage. The average of log-transformed (log) FIB-4 increased steadily over time whereas the average of platelets count and log (AST) remained roughly constant. The multivariable joint modeling showed that higher current value of FIB-4 (HR 2.96, 95% CI 2.08–4.26), AST (HR 2.48, 95% CI 1.85–3.34) and lower platelets (HR 0.99, 95% CI 0.99–1.00) was associated with increased risk of SLD, whereas the rate of change in these biomarkers had no significant association to the risk of SLD (Table).

Table: The association between repeated values of the AST, platelets, FIB-4 and the event of SLD from joint modeling

Current value of biomarker level*	HR#	95% confidence interval	p value
log (AST), μkat/L	2.96	2.08–4.26	<0.001
Platelets, 10^9/L	0.99	0.99–1.00	<0.001
log (FIB4)	2.48	1.85–3.34	<0.001
Instantaneous slope of temporal pattern**			
log (AST)-slope	0.37	0.11–1.58	0.188
log (AST)-value, μkat/L	3.43	2.38–5.06	<0.001
Platelets-slope	1.00	0.98–1.02	0.618
Platelets-value, 10^9/L	0.99	0.99–1.00	0.002
log (FIB4)-slope	1.40	0.38–5.39	0.591
log (FIB4)-value	2.60	1.84–3.84	<0.001

*The basic joint model, which combines a linear mixed submodel of biomarkers and a survival submodel of time to SLD.
#HR includes the baseline covariates: age, sex, type 2 diabetes, hyperlipidemia, body mass index, fibrosis stage.
**The slope of the marker is modeled and added to the basic joint model.

Conclusion: In addition to the baseline measurement of the non-invasive biomarkers such as FIB-4, AST, and platelets taken at NAFLD diagnosis, monitoring their value over time is important as the current value of them is closely associated with the risk of future SLD. The rate of change may not affect the prognosis to severe liver disease.

SAT-398

Improvements in liver fibroinflammation (as assessed by corrected T1 [cT1]) with HTD1801 (berberine ursodeoxycholate) treatment in patients with non-alcoholic steatohepatitis and type 2 diabetes mellitus

Stephen Harrison[1], Nadege Gunn[2], Guy Neff[3], Abbey Flyer[4], Alexander Liberman[5], Leigh MacConell[5]. *[1]Pinnacle Clinical Research, United States; [2]Impact Research Institute, United States; [3]Covenant Metabolic Specialists, United States; [4]Pacific Northwest Statistical Consulting, United States; [5]HighTide Therapeutics USA, LLC, United States*
Email: sharrison@pinnacleresearch.com

Background and aims: HTD1801 is a new molecular entity consisting of an ionic salt of berberine and ursodeoxycholic acid with a unique microstructure which has been shown to significantly reduce liver fat content (LFC) as determined by MRI-PDFF in an 18-Week, placebo-controlled Phase 2 study in patients with non-alcoholic steatohepatitis (NASH) and Type 2 Diabetes (T2DM) (NCT03656744). cT1 is an MRI-based quantitative metric for assessing liver inflammation and fibrosis. Previous studies have reported that cT1 improvements are moderately correlated with histologic improvements in NAS and fibrosis and cT1 levels are associated with clinical outcomes (liver and CVD) in patients with NASH. The purpose of this post-hoc analysis

was to evaluate the effects of HTD1801 on cT1 in patients with NASH and T2DM.
Method: One hundred patients were randomized and treated with HTD1801 1000 mg BID (n = 34), HTD1801 500 mg BID (n = 33), or placebo (n = 33) for 18 weeks. MRI data was collected prospectively for evaluation of the primary end point (proton density fat fraction), and cT1 was evaluated after the completion of the study for subjects who had been randomized to HTD1801 1000 mg BID or placebo. p values (nominal) were obtained from an ANCOVA model with treatment group as a fixed effect, and baseline ALT and baseline cT1 as covariates. Values are Mean (SD) unless otherwise specified.
Results: On average at baseline, patients were 56 (11) years, 72% female, 91% White, 38% Hispanic or Latino, with an HbA1c of 7.1% (1.0). At baseline, subjects had significantly elevated LFC by MRI-PDFF [19.3% (6.5)] and fibroinflammation by cT1 (942.1 [91.5] ms and 937.5 [97.7] ms for HTD1801 1000 mg BID and placebo, respectively). As shown in Figure 1, after 18 weeks of treatment there was a significant reduction in cT1 with HTD1801 compared to placebo (-60.9 [75.9] ms vs −14.7 [68.9] ms, p < 0.05). Similarly, a significant reduction was observed in ALT, a marker of liver function, in the HTD1801 1000 mg BID group compared to placebo (−19 [27.2] U/L vs −3 [19.2] U/L, p < 0.01). At Week 18, a larger proportion of subjects receiving HTD1801 compared to placebo (39% vs 16%, respectively) experienced at least an 80 ms reduction in cT1, which has been correlated with a 2-point reduction in the NAS.

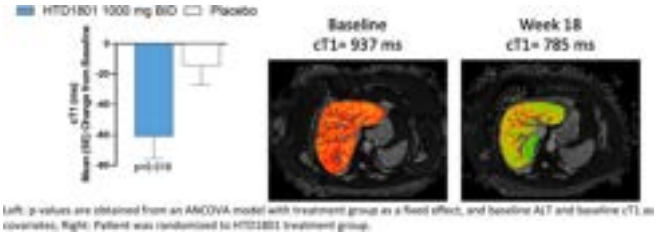

Figure: Subjects Receiving HTD1801 Had Significant Reduction in Fibroinflammatory Disease as Assessed by cT1

Conclusion: These data provide further evidence that HTD1801 may improve measures of disease activity in patients with NASH and T2DM and warrant further investigation. A Phase 2b study is currently ongoing to evaluate the histologic effects of HTD1801 in patients with NASH and confirm the findings of this evaluation (NCT05623189).

SAT-399

Prevalence of NAFLD and advanced fibrosis in Stockholm, Sweden

Emilie Toresson Grip[1,2], Helena Skröder[1], Ying Shang[2], Oskar Ström[1,2], Hannes Hagström[2,3]. [1]*Quantify Research AB, Stockholm, Sweden;* [2]*Karolinska Institutet, Department of Medicine, Huddinge, Stockholm, Sweden;* [3]*Karolinska University Hospital, Clinical Epidemiology Division, Department of Medicine Solna, Stockholm, Sweden*
Email: emilie.toresson-grip@quantifyresearch.com

Background and aims: Estimates of prevalence of NAFLD in Sweden are lacking, despite globally unique register data. Use of invasive or costly diagnostics such as histology or imaging are scarce in primary care, leading to underdiagnosis of NAFLD, and subsequently under-reporting of NAFLD in registers. Therefore, non-invasive measures of NAFLD, such as the commonly used Hepatic Steatosis Index (HSI), can be used to estimate the prevalence of probable NAFLD in broad populations. Here, we used data from the HERALD (Health outcomes and risk assessment in chronic liver disease) cohort to estimate prevalence of NAFLD in primary or secondary care settings in Stockholm, using data from national health registries and regional electronic health records.
Method: All patients with any liver-related tests taken in Stockholm during 2015–2020 were included (n = 715,161). The HSI was calculated using the latest available information on AST, ALT and BMI during 2015–2020, in either primary or secondary care. A cut-off of ≥ 36 was used to define patients with probable NAFLD. Patients with alcohol-related diseases or other liver diseases than NAFLD since 2001 were excluded. The FIB-4 score was calculated using a cut-off of ≥ 1.3 (age <65) and ≥ 2.0 (age ≥ 65) to define intermediate or high-risk (≥ 2.67) of advanced fibrosis among all patients with NAFLD.
Results: In total 341,305 patients with assessable HSI were included, of which 45% (n = 151,939) had probable NAFLD. Among the patients with probable NAFLD, 25% had T2DM, median age was 57 years, and 56% were females. In addition, 23% of patients with probable NAFLD had an intermediate (15%) or high risk (8%) of advanced fibrosis, but only 1.7% had a NAFLD/NASH diagnosis code (ICD-10 K76.0/K75.8) recorded in primary or secondary care, despite allowing for a 19-year look back period for such diagnoses. Of patients with a recorded NAFLD diagnosis, 88% had high HSI, and 32% had intermediate or high risk of advanced fibrosis. Among the patients without a recorded NAFLD diagnosis, the corresponding fractions were 44% for high HSI and 31% for intermediate or high risk for advanced fibrosis.
Conclusion: This study provides an up-to-date estimate of NAFLD prevalence in a unique, unselected heterogenous population of individuals in Stockholm. The results support previous indications that there are many undiagnosed patients with NAFLD. Advanced fibrosis may be equally common in patients with and without a recorded diagnosis of NAFLD, highlighting needs for further improvement of identification of at-risk patients.

SAT-400

Accuracy of 100 Hz transient elastography-based spleen stiffness for the identification of advanced fibrosis in biopsy-proven non-alcoholic fatty liver disease

Background and aims: The non-invasive identification of advanced fibrosis in Non-Alcoholic Fatty Liver Disease (NAFLD) represents an unmet need. In NAFLD, the liver-spleen axis may be affected by the chronic, low-grade splanchnic inflammation, leading to spleen tissue congestion even in the absence of portal hypertension. We aimed to explore the accuracy of spleen stiffness measurement (SSM) as a non-invasive tool to detect advanced fibrosis in individuals with biopsy-proven NAFLD.
Method: Retrospective cohort study of 167 patients with biopsy-proven NAFLD analyzed from 3 centers (Mainz, Rome, Seville). Liver stiffness measurement (LSM) and SSM were collected within 6 months from the index liver biopsy, using the Fibroscan 630 Expert. For SSM, the 100 Hz spleen-specific probe was employed. Patients

Model	AUC	Se (%)	Sp (%)	PPV (%)	NPV (%)	DeLong p
Mainz cohort (n = 50)						
SSM - FIB-4	0.92	82.1	94.1	95.8	76.2	0.69 (with SSM-LSM)
SSM - LSM	0.94	89.3	88.2	92.6	83.3	0.13 (with LSM-FIB-4)
LSM - FIB-4	0.88	92.9	70.6	83.9	85.7	0.39 (with SSM-FIB-4)
Rome/Seville cohort (n = 117)						
SSM - FIB-4	0.84	78.0	80.0	75.0	83.1	0.43 (with SSM-LSM)
SSM - LSM	0.87	82.0	80.6	75.9	85.7	0.41 (with LSM-FIB-4)
LSM - FIB-4	0.85	90.0	70.1	69.2	90.4	0.82 (with SSM-FIB-4)

Table 1. Area Under the Curve (AUC) of the predictive models for the identification of advanced fibrosis. FIB-4: Fibrosis-4 score; LSM: liver stiffness measurement; SSM: spleen stiffness measurement.

Figure: (abstract: SAT-400).

with a history or presence of decompensation were excluded. Advanced fibrosis was defined by histological stages F3 and F4.
Results: Median age was 58 [50–64] years and 50.3% were male. Obesity and type 2 diabetes (T2D) were present in 63.5% and 59% of cases. A total of 83 (49.7%) cases had advanced fibrosis on liver histology. Median LSM was 10.2 [7.0–17.7] kPa and median Fibrosis-4 (FIB-4) score was 1.6 [1.08–2.79]. Median SSM was 30.5 [20.0–45.1] kPa, showing a stepwise increase across fibrosis stages, with higher values in advanced fibrosis, when compared to F0-F2 stages (median 38.4 [32.0–59.3] kPa versus 21.8 [16.4–30.6] kPa, $p < 0.000001$). Overall, SSM correlated with longitudinal spleen size ($r = 0.63$, $p < 0.001$) and inversely with platelet count ($r = 0.44$, $p < 0.001$), and was associated with advanced fibrosis after adjusting for age, sex, Body Mass Index, T2D and transaminases (OR 1.08 [95% CI 1.04–1.13], $p < 0.0001$). In the whole cohort, SSM had AUC of 0.85 for advanced fibrosis (Se 93.6%, Sp 61.9%, PPV 65.2%, NPV 91.2%), which was similar to that of LSM (AUC 0.87, DeLong p for SSM 0.475), and FIB-4 (AUC 0.80, DeLong p for SSM 0.228). In the Mainz cohort (derivation cohort), a model combining LSM and SSM reached the best accuracy for advanced fibrosis (AUC 0.94), when compared to the other models (Table 1). In the combined Rome and Seville cases (validation cohort), the same model reached an AUC of 0.87. In the derivation cohort, the cut-off of 24.6 kPa was identified by the lowest negative likelihood ratio for ruling out advanced fibrosis (Se 92.8%, Sp 58.9%, PPV 79.4%, NPV 90.9%). In the validation cohort, the consecutive use of SSM could identify F3-F4 patients that would have been ruled out by other non-invasive tests (n = 12 FIB-4 <1.3; n = 5 LSM <8 kPa).
Conclusion: SSM displays a progressive increase across fibrosis stages and is associated with advanced fibrosis. In this cohort with high prevalence of advanced fibrosis, the accuracy of SSM is comparable to LSM and FIB-4. The combined use of LSM and SSM in the NAFLD diagnostic algorithm may improve liver disease staging and risk stratification.
Boehringer-Ingelheim sponsored the study.

SAT-401

Performance of non-invasive tests as exclusion criteria for cirrhosis in trials targeting at-risk non-alcoholic steatohepatitis: combined data from multiple trials including more than 5,000 patients (in collaboration with NAIL-NIT consortium)

Naim Alkhouri[1], Julie Dubourg[2], Stephen Harrison[3], Mazen Noureddin[4], Michael Charlton[5], Vlad Ratziu[6], Sophie Jeannin Megnien[2], Jörn Schattenberg[7]. [1]*Arizona Liver Health, Chandler, United States;* [2]*Summit Clinical Research, San Antonio, United States;* [3]*University of Oxford, United Kingdom;* [4]*Houston Methodist Hospital, Houston, United States;* [5]*UChicago Medicine, Chicago, United States;* [6]*Institute for Cardiometabolism and Nutrition, France;* [7]*University medicine at the Johannes Gutenberg University in Mainz, Mainz, Germany*
Email: jdubourg@summitclinicalresearch.com

Background and aims: Non-alcoholic steatohepatitis (NASH) cirrhosis is a distinct group of patients which is usually excluded from NASH with F2-F3 clinical trials for reasons related to safety and efficacy assessments. We aimed to assess non-invasive tests (NITs) including Fibrosis-4 score (FIB-4), vibration-controlled transient elastography (VCTE) and FibroScan-based score Agile 4 to distinguish this group of patients.
Method: We combined screening data from 6 ongoing non-cirrhotic NASH clinical trials (>5,000 patients). Liver histology data were assessed centrally, and cirrhosis was defined as a fibrosis stage of 4 with or without NASH. Diabetes status required by the Agile 4 formula was defined using glycated hemoglobin (HbA1c). Area under the receiver operating characteristic (AUROC) analysis was used to determine the diagnostic accuracy of each test to rule-in cirrhosis. Considering the low prevalence of cirrhosis in NASH with fibrosis stage (F) 2 or 3 trials, we presented the positive likelihood ratio (LR+) as it is independent of the prevalence of cirrhosis, rather than the positive predictive value. We calculated the pre- and post-test probability of cirrhosis to express the clinical utility of each score.
Results: 1,104 patients with histology results were included, with a fibrosis prevalence of: 94 (9%) for F0, 231 (21%) for F1, 294 (27%) for F2, 440 (40%) for F3, and 45 (4%) for F4. AUROC for FIB-4, VCTE and Agile 4 are shown in the Figure. The LR+ of the published Agile 4 rule-in cut-off (≥0.57) was 9.25. This reflects a post-test probability of cirrhosis of 30% compared to a pretest probability of 4%. Among the 1,104 patients included in this analysis, 39 (3.5%) had Agile 4 ≥ 0.57 with 28 of those having no cirrhosis. The LR+ of the published FIB-4 rule-in cut-off (≥3.48) was 1.81. This reflects a post-test probability of cirrhosis of 7% compared to a pretest probability of 4%. Among the 1,104 patients included in this analysis, 12 (1%) had a FIB-4 ≥3.48, with only 1 of those having cirrhosis and 13 having no cirrhosis. The LR+ of the published VCTE rule-in cut-off (≥20) was 4.56. This reflects a post-test probability of cirrhosis of 16% compared to a pretest

probability of 4%. Among the 1,104 patients included in this analysis, 117 (11%) had a VCTE ≥ 20, with 98 of those having no cirrhosis but mainly F2 and F3.

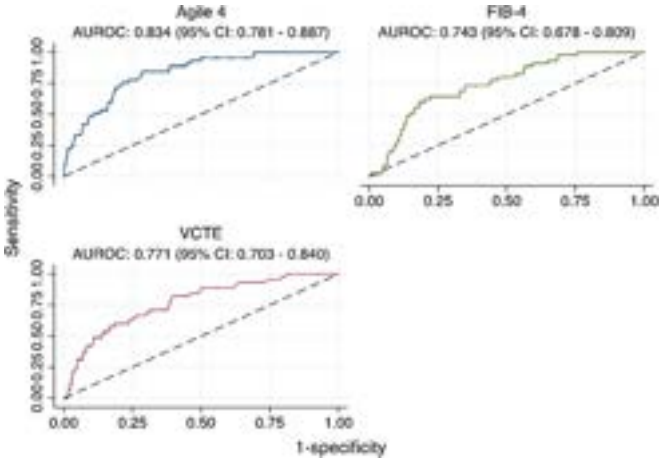

Figure:

Conclusion: In comparison to FIB-4 and VCTE, Agile 4 is the best test to be used as exclusion criteria for cirrhosis in NASH F2-F3 clinical trials.

SAT-402

FIB-4 predicts the risk of hepatocellular carcinoma in patients with type 2 diabetes: a longitudinal multicentre study

Vincent Mallet[1,2], Mathis Collier[3], Nathanael Beeker[3], Lucia Parlati[1,2,4], Stanislas Pol[2,3], Emmanuel Tsochatzis[5]. *[1]AP-HP. Centre, Groupe Hospitalier Cochin Port Royal, DMU Cancérologie et spécialités médico-chirurgicales, Service d'Hépatologie, Paris, France; [2]Université Paris Cité, F-75006, Paris, France; [3]AP-HP.Centre, Groupe Hospitalier Cochin Port Royal, DMU PRIME, Unité de Recherche Clinique, Paris, France; [4]Institut Cochin, Université Paris Cité, CNRS, INSERM, F-75014 Paris, France; [5]UCL Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom*
Email: e.tsochatzis@ucl.ac.uk

Background and aims: Patients with type-2 diabetes (T2D) are at risk for NAFLD and hepatocellular cancer (HCC). FIB-4 is recommended to delineate liver fibrosis in patients with NAFLD. We evaluated the performances of FIB-4 and the FIB-4 variation to predict HCC risk in patients with T2D.

Method: The data source was the Assistance Publique—Hôpitaux de Paris (AP-HP) Clinical Data Warehouse, that contains all clinical and biological data for acute inpatient/day case hospital admissions; post-acute care; and outpatient visits to 36 Greater Paris university hospitals. We selected, among all patients discharged from the AP-HP between August 1, 2017 and March 9, 2022, those with T2D mellitus (ICD-10: E11; n = 144,378). We excluded patients with an extra-hepatic cause of thrombopenia; those without synchronous serum transaminase and/or platelet measurement; and those without any FIB-4 measurement >3 months before censoring. We assessed the ability of a random FIB-4 and of FIB-4 variations to predict hepatocellular cancer (HCC) risk using the c-Index metric. The primary outcome was development of HCC and secondary outcome was liver disease progression to decompensated cirrhosis or HCC. Models were trained with two-third of the dataset and validated in the other third.

Results: 69,225 patients were included, mean age 66.7 years, 57.1% males. The average (standard deviation) number of FIB-4 measurements per patient was 9.3 (14.4), with a total of 643,755 FIB-4 measurements. 408 (0.6%) patients were diagnosed with HCC over 378,734 person-years, corresponding to a median follow-up of 2 years per patients. FIB-4 was associated with HCC risk in Cox univariate [HR 1.668 (1.602–1.738)] and multivariate [aHR 1.52 (1.453–1.59)] analyses in the training set, and yielded concordant predictions in the validation set [c-index 0.804 (0.761–0.847) and 0.83 (0.789–0.871), respectively]. Adding absolute or relative FIB-4 variations, or FIB-4 slope over ≥3 previous FIB-4 measures, to a single, random FIB-4 measure, did not increase the prognostic value. Results were similar in nonparametric machine learning random forest survival models. The areas under the ROC curve (95% CI) of a single, random, FIB-4 measurement to predict 12- and 24-months HCC risk were 0.823 (0.797–0.849) and 0.829 (0.806–0.851). The FIB4 cut-offs for 90% sensitivities were 1.21 and 1.245, respectively. The cut-offs for 90% specificities were 3.075 and 2.954, respectively. Similar results were obtained for the risk of liver disease progression.

Figure: Performance of a single, random, measure of FIB-4 to predict 2-year HCC risk, by strata.

FIB-4 Threshold	Sensitivity	Specificity
Strata = men		
1.045	95.2%	32.6%
1.245	90.3%	44.2%
3.118	54.3%	90%
4.291	40.2%	95%
AUC	0.81 [0.782–0.837]	
Strata = women		
1.094	95.7%	44%
1.21	91%	50.9%
2.742	63.9%	90%
3.761	51%	95%
AUC	0.862 [0.82–0.904]	
Strata = alcohol use disorders		
1.596	95.6%	46.1%
2.111	90.2%	61%
5.798	40%	90%
Inf	0.0%	100.0%
AUC	0.822 [0.782–0.862]	
Strata = no alcohol use disorders		
1.045	95.1%	36.9%
1.183	90.2%	45.4%
2.832	51%	90%
3.834	37.9%	95%
AUC	0.798 [0.77–0.826]	

Strata = liver risk factors

Conclusion: FIB-4 predicts the risk of HCC in patients with T2D. These data support its use as a liver health check measure in this patients' group.

SAT-403

FIB-4 as a screening tool for significant liver fibrosis in a cohort of overweight subjects involved in a weight loss program conducted in a primary care setting

Charlotte Costentin[1], Odile Fabre[2], Remy Legrand[2], Sébastien Bailly[1]. *[1]Centre Hospitalier Universitaire de Grenoble, La Tronche, France; [2]Franchise Groupe Ethique and Santé-Siège social, Aubagne, France*
Email: charlotte.costentin.pro@gmail.com

Background and aims: International societies have issued guidelines supporting systematic screening for liver fibrosis in the primary care setting whenever a risk factor for chronic liver disease is identified. FIB-4 has been selected as the first line tool of choice to stratify patients according to the risk of advanced fibrosis and need for additional liver assessment (FIB-4 > 1.3). The objective of this study was to assess prevalence and characteristics of patients at risk for advanced fibrosis in a cohort of obese and overweight subjects involved in a weight loss program conducted in a primary care setting.

Method: It is a multicenter prospective cohort study including obese and overweight subjects participating in a weight loss program after referral by their physician and conducted in 110 centers distributed across France. Patient characteristics, anthropometrics and biological

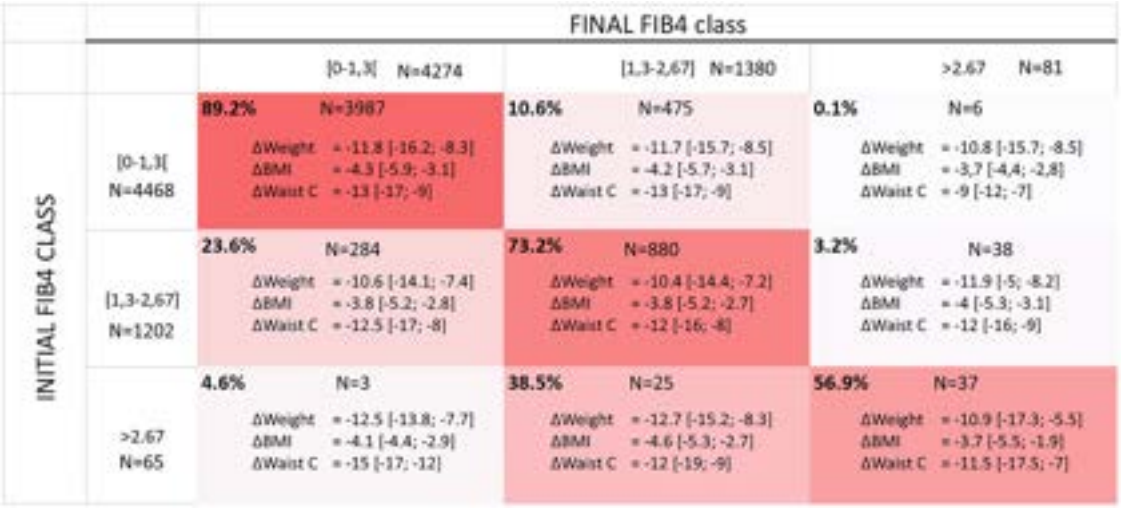

Figure: (abstract: SAT-403).

data were collected in each center by using a single electronic medical record.

Results: From 63 744 adult participants in the RNPC® program, 27 643 had baseline FIB4 data and were included in the subsequent analysis: predominantly women (78.3%), median age of 54 years [IQR 44; 63], median initial body mass index (BMI) was of 32.6 [IQR 29.2; 36.4] kg/m² (70% with BMI ≥30), median initial waist circumference (WC) 107 cm [IQR 97; 117]). Fatty Liver Index (FLI) was available in 12 454 participants, in which steatosis defined by Fatty Liver Index FLI>60 was present in 8 452 subjects (66%). FIB4 at baseline was <1.3 in 22 353 participants (80.9%), and >2.67 in 264 (1%). When moving from the lower risk category (FIB4<1.3) to the intermediate (1.3–2.67) and the higher risk (FIB4>2.67), the population was enriched in male gender (from 19.1, to 32% and 47.3% respectively), waist circumference increased (from 106 to 110 and 116 cm) as well as rates of metabolic comorbidities such as of sleep apnea (from 14.9 to 26.9% and 37.7%), diabetes (from 36.8 to 39.7 and 40.2%), arterial hypertension from 40 to 58.2% and 66.7%) (p <0.01). When available, rates of FLI>60 increased from 65.5 to 69.9% and 77.5%. Diagnosed non-alcoholic fatty liver disease was more prevalent in the higher risk category compared to the lowest (22.3% vs 5.3%; p <0.01). After 5 [3–7] months into the program, all anthropometric parameters improved: median WC decreased from 108.6 to 95.6 cm, fat mass decreased from 40.9% to 37%, muscle mass increased from 29.7% to 30.7% (; p <0.001). A follow-up FIB-4 value was available in 5 735 participants. Among participants from the low-risk category at baseline, 481 (10.6%) changed classes, but only 6 (0.1%) moving to the higher-risk category. Among participants from the high-risk category at baseline, 28 (43%) changed classes, 3 (4.6%) moving to the lower risk-category (Figure 1). In the population with FIB-4 > 1.3 eligible for additional liver assessment, results of specialized second line fibrosis testing were not recorded.

Conclusion: In a cohort of overweight and obese patients from the primary care setting, prevalence of patients at risk for advanced fibrosis according to initial FIB-4 >1.3 was 19.1%. Higher-risk participants (FIB-4 >2.67, 1%) displayed higher rates of metabolic comorbidities. General practitioners and nutrition professionals are important assets to implement the two-steps algorithm to screen for advanced fibrosis in patients at risk. Efforts should be made to improve the care pathway to the second line non-invasive fibrosis tests.

SAT-404

Soluble TREM2 and PRO-C3 as efficacy of intervention markers in NASH

Charlotte Wernberg[1,2], Vineesh Indira Chandran[3], Mette Lauridsen[2], Maria Kløjgaard Skytthe[3], Camilla Dalby Hansen[1], Johanne Kragh Hansen[1], Lea Ladegaard Grønkjær[2], Birgitte Jacobsen[2], Tina Di Caterino[3], Sönke Detlefsen[2], Maja Thiele[1], Alejandro Mayorca Guiliani[4], Diana Leeming[4], Morten Karsdal[4], Ida Villesen[1], Jonas Graversen[3], Aleksander Krag[1]. *[1]Fibrosis, Fatty liver and Steatohepatitis Research Center Odense (FLASH), Denmark; [2]Institute for Regional Health Research, University of Southern Denmark, Denmark; [3]Clinical Institute, University of Southern Denmark, Department of Molecular Medicine, University of Southern Denmark, Odense, Denmark; [4]Nordic Bioscience Biomarkers and Research A/S, Denmark*

Email: charlotte.wilhelmina.wernberg@rsyd.dk

Background and aims: Patients with obesity and type 2 diabetes have a high risk of developing non-alcoholic steatohepatitis. Diet and weight loss are currently the mainstay of treatment in most patients with non-alcoholic fatty liver disease (NAFLD) and some drugs are approved for the use in NAFLD, but multiple drugs are at advanced stages of clinical testing. There is consequently an unmet medical need for non-invasive tests that can help clinicians assess treatment response. Our aim was to explore the ability of NITs to reflect a change of at least one stage in histologic NAFLD Activity Score (NAS).

Method: A longitudinal study of 173 patients with type 2 diabetes or severe obesity, suspected of NAFLD, and ≥6 months follow-up including dual liver biopsies and blood samples. We measured soluble TREM2, collagen formation markers (III, IV, VI, VIII, XVIII) using ELISA assays PRO-C3, PRO-C4, PRO-C6, PRO-C8, and PRO-C18L (Nordic Bioscience), FAST-score using Fibroscan (Echosens), and calculated HOMA-IR. We calculated Fibrosis-4 (FIB-4) and NAFLD Fibrosis Score (NFS). Patients were stratified into three outcome groups according to NAS change between baseline and end of study: worsened ≥1 NAS stage, no change in NAS, and improved ≥1 NAS stage'.

Results: The mean age was 52 years (± 12), 38% were males, 70% had low fibrosis (F0-F1), and 23% had NASH (n = 39) at baseline. Outcome groups were balanced regarding age, BMI, triglycerides, and fibrosis grades; but participants that improved had the highest HOMA-IR of 7.7 (p = 0.002) and a higher prevalence of NASH (p < 0.001). Several NITs were significantly reduced in patients who improved NAS at follow-up, and there was an overall dose-response between outcome groups (worsened (n = 22), no change (n = 50), improved (n = 101)):

sTREM2 ($p < 0.001$), PRO-C3 ($p < 0.01$), HOMA-IR ($p < 0.001$), and FAST-score ($p < 0.001$). On the other hand, levels of PRO-C18L were downregulated in patients that worsened in NAS ($p < 0.01$). Seventy percent of patients that improved had a change in inflammation and/or ballooning. In multivariable analysis, sTREM2 combined with PRO-C3 predicted NAS improvement well (AUROC 0.75) with an OR for every unit decrease respectively of 1.05 (95% CI 1.02–1.09) and 1.13 (95% CI 1.05–1.21) ($p < 0.01$). HOMA-IR also performed well (AUROC 0.76), but even better in combination with sTREM2 (AUROC 0.79). FIB-4 and NFS did not (AUROC <0.60, OR <1.05 $p > 0.5$). The Fibroscan yielded non-valid measurements in 16%, at either one or both visits, making it less ideal for monitoring.

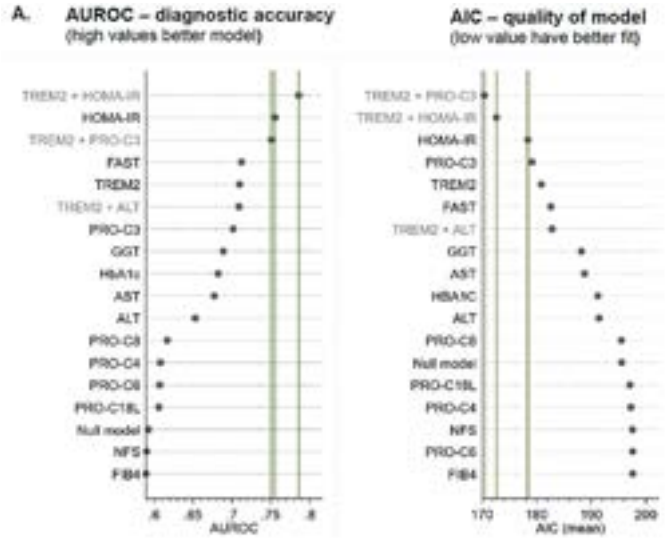

Figure: Figure legend. Logistic regression analysis to assess the probability of NAS improvement ≥1 stage (=1), as opposed to no improvement (no-change and worsened = 0). We include each NITs' units change from baseline in models as a difference. A. Dot plot shows area under the receiver operation characteristic curve (AUROC) diagnostic accuracy and Akaike information Criterion (AIC) estimator of prediction error and, thereby, the relative quality of statistical models for a given set of data for all models (green vertical lines mark the best models).

Conclusion: sTREM2 and PRO-C3 in combination reflect NAS improvement and should be further explored as surrogate markers for efficacy of interventions. Divergently, FIB-4 and NFS showed low accuracy for monitoring histological response in this cohort.

SAT-405

Dynamic changes in liver stiffness assessed by transient elastography as a prognostic factor in NAFLD patients with prediabetes and type 2 diabetes

Elias Maleh[1], Claudia Regina Cardoso[1], Gil Salles[1], Ana Carolina Cardoso[1], Lorrane Santos[1], Henrique Sérgio Coelho[1], Cristiane Villela-Nogueira[1], Nathalie Leite[1]. [1]*Federal University of Rio de Janeiro, Brazil*
Email: nathaliecleite@gmail.com

Background and aims: Baseline liver stiffness measure (LSM) associates with a higher risk of liver events (Les) and mortality in NAFLD patients. We aimed to assess the prognostic value of dynamic changes of LSM for predicting survival and the occurrence of liver (LEs) and cardiovascular events (CVEs) in prediabetes (PreDM) type 2 diabetes (T2DM) NAFLD patients.
Method: NAFLD adults with PreDM or T2DM with two consecutive reliable LSMs by TE were included. Clinical, biochemical and elastography data (Fibroscan Touch 502, Fr) were collected at baseline. Follow-up LSM was recorded accordingly. Dynamic changes in LSM (ΔLSM) were categorized as improvement (LSM reduction of ≥25% from baseline) and impairment (LSM increase of ≥25% from baseline). During follow-up, LEs (ascites, encephalopathy, variceal bleeding, HCC) and CVEs (myocardial infarction, new-onset heart failure, any myocardial revascularization, stroke, any aortic or lower limb revascularization, any amputation above the ankle) were recorded. The follow-up period was from the baseline LSM to the last clinical visit or the outcome. Multivariate cox analysis evaluated the associations between ΔLSM (as continuous and categorized variables) and the occurrence of LEs, CVEs events or mortality.
Results: 301 patients were included (68% female, age 59 ± 10 y): 19% had PreDM and 81% T2DM.
At the first TE examination, 12% had LSM >15kPa [median 6.9 kPa (5.1–10.1)]. Overall, 26% experienced ΔLSM improvement [median 32.7 (22.3–42.2)], and 25% had ΔLSM impairment [median 29.6 (14.6–56.2)] on a 38 (27–55) months interval. During an observation period of 76 (65–86) months (1878 person-years), there were 31 deaths, 24 CVEs and 20 LEs. Cumulative incidences by Kaplan Meier showed a higher incidence of CVEs in those with ΔLSM impairment. (log-rank test: $p = 0.007$), but not for LEs or mortality (log-rank test: $p = 0.449$ and $p = 0.581$, respectively). On multivariate Cox analysis, continuous and categorized ΔLSM were independently associated with CVEs adjusted for age, gender, BMI, diabetes, arterial hypertension, smoking, previous cardiovascular event, statin use, HbA1c levels and baseline LSM. (ΔLSM for each 1% increase HR:1.009; 95% CI, 1.003–1015; $p = 0.004$/ΔLSM 25% impairment HR:3.026; 95% CI, 1.298–7.051; $p = 0.01$). For LEs, adjusting for the same potential risk factors, only continuous and categorized baseline LSM were the independently associated variables (baseline LSM for each 1kPa increase HR:1.115; 95% CI, 1.073–1.158; $p < 0.001$/baseline LSM >15kPa HR:15.927; 95% CI, 5.686–44.61; $p < 0.001$).
Conclusion: Dynamic changes in LSM, more specifically an increase of ≥25% from baseline LSM, can predict adverse CVEs in NAFLD individuals with either prediabetes or type 2 diabetes. In contrast, only baseline LSM is associated with a higher risk of LEs or death. LSM impairment does not seem to be an additional risk of liver events or overall mortality in this population.

SAT-406

Fibrosis-4 score and liver stiffness measurement by vibration-controlled transient elastography predict risk of liver-related events in non-alcoholic fatty liver disease

Esteban Urias[1], Tianyu Qiu[2], Michael Song[3], Tanvi Goyal[3], Jing Hong Loo[4], Yu Jun Wong[4], Vincent Chen[3]. [1]*Michigan Medicine, Department of Internal Medicine, Ann Arbor, United States;* [2]*Changi General Hospital, Department of Gastroenterology and Hepatology, Singapore;* [3]*Michigan Medicine, Department of Gastroenterology and Hepatology, United States;* [4]*Yong Loo Lin School of Medicine, National University of Singapore, Singapore*
Email: uesteban@med.umich.edu

Background and aims: Both the Fibrosis-4 (FIB-4) score and liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) are non-invasive tests used to classify risk of adverse events in patients with non-alcoholic fatty liver disease (NAFLD). Current practice guidelines recommend a sequential approach to risk stratification in NAFLD with FIB4 followed by VCTE. However, whether LSM more accurately predicts risk of liver-related events (LREs) than FIB-4 or outweighs FIB-4 is not known. We sought to determine combined effects of FIB-4 and LSM to predict LREs in NAFLD.
Method: This was a retrospective study of consecutive patients with NAFLD undergoing VCTE and serum testing within 12 months of VCTE at the University of Michigan Health System (USA) and Changi General Hospital (Singapore) from 2015 to 2022. NAFLD was defined by hepatic steatosis without alternative chronic liver diseases or excess alcohol intake. The index date was the date of VCTE. The primary outcome was LREs defined as decompensation or hepatocellular carcinoma. The primary predictors were FIB-4 score, stratified

		LSM						
		< 8 kPa		8 - 12 kPa		> 12 kPa		
		Cumulative Incidence	LRE/total patients	Cumulative Incidence	LRE/total patients	Cumulative Incidence	LRE/total patients	p value
FIB-4	< 1.3	-	0/684	-	0/151	-	0/90	-
	1.3 - 2.67	-	0/263	5.21 (0.63 - 18.82)	2/118	13.17 (4.28 - 30.73)	5/120	0.0061
	> 2.67	18.78 (2.27 - 67.58)	2/33	18.71 (2.27 - 67.58)	2/35	62.44 (34.95 - 102.98)	15/78	0.071
	p value	<0.0001		0.021		<0.0001		

Figure: (abstract: SAT-406).

by low (<1.3), intermediate (1.3–2.67), and high (>2.67); and LSM, stratified by low (<8 kPa), intermediate (8–12 kPa), high (>12 kPa).
Results: We included 1,572 patients meeting inclusion criteria. Median age was 53 years, 54% were male, 57% were White, and 32% were Asian. FIB-4 scores were low, intermediate, and high in 59%, 32%, and 9% of patients, and LSM was low, intermediate, and high in 62%, 19%, and 18%, respectively. Median follow-up was 38 months with 4,969 person-years of follow-up in total. There were no LREs in patients with FIB-4 <1.3 regardless of LSM and no LREs in patients with FIB-4 <2.67 and LSM <8 kPa in 3,321 person-years of follow-up (Figure). Within each FIB-4 category, higher LSM was associated with higher incidence rate of LREs, and similarly within each LSM category, higher FIB-4 was associated with increased risk of LREs. For example, for FIB 1.3–2.67, the incidence rate was 5.2 and 13.2 per 1,000 person-years for LSM 8–12 kPa and >12 kPa, respectively. For FIB-4 >2.67, the incidence rate was 18.7 and 62.4 events per 1,000 person-years for LSM ≤ 12 and >12 kPa, respectively.
Conclusion: FIB-4 and LSM in combination more accurately predict risk of LREs in NAFLD than either alone. However, no LREs occurred in patients with FIB-4 <1.3 regardless of LSM, supporting existing guidelines to not obtain VCTE in this patient population.

SAT-407

A stepwise screening approach using non-invasive tests to identify phenotypic non-alcoholic steatohepatitis (NASH) patients with fibrosis for clinical trials

Naim Alkhouri[1], Rohit Loomba[2], Mazen Noureddin[3], Eric Lawitz[4], Kris Kowdley[5], Hiba Graham[6], Erin Quirk[6], Diana Chung[6]. *[1]Arizona Liver Health, Tucson, United States; [2]University of California San Diego, NAFLD Research Center, La Jolla, United States; [3]Houston Research Institute, Houston, United States; [4]Texas Liver Institute, University of Texas, San Antonio, United States; [5]Liver Institute Northwest, Seattle, United States; [6]Terns Pharmaceuticals, Foster City, United States*
Email: dchung@ternspharma.com

Background and aims: Non-invasive tests (NITs) have become essential to diagnose and stage non-alcoholic steatohepatitis (NASH). Biopsy-based screen failure (SF) rates are high in NASH trials, which lead to increased cost and extended enrollment durations. LIFT and AVIATION were double-blind, placebo-controlled studies in adults with non-cirrhotic NASH evaluating TERN-101, a potent, nonsteroidal farnesoid X receptor (FXR) agonist with enhanced liver distribution, and TERN-201, a highly specific vascular adhesion protein-1 (VAP-1) inhibitor, respectively. A stepwise NIT screening approach was implemented to recruit similar study populations in both trials: patients with presumed NASH and a high degree of liver fat and fibro-inflammation, reflecting F2 and F3 fibrosis.
Method: Screening and baseline characteristics from the phase 2a LIFT and phase 1b AVIATION studies were combined. In screening step 1, both trials required age ≥18, BMI ≥25 kg/m^2, ALT above the median central laboratory normal range, vibration controlled transient elastography (VCTE) of 7.5 (LIFT) and 6.5 (AVIATION) to 21 kPa, and controlled attenuation parameter (CAP) of 280 (AVIATION) and 300 (LIFT) dB/m within 3 months of screening. Neither trial required liver biopsy. Potential subjects remaining eligible after the step 1 screening underwent MRI to assess liver fat content eligibility ≥10% by proton density fat fraction (PDFF) for LIFT or corrected T1 (cT1) >800 msec for AVIATION. Common SF reasons were tabulated, and multiparametric MRI SF rates were calculated.
Results: 567 (446 in LIFT; 121 in AVIATION) patients were screened and 153 (101 in LIFT; 52 in AVIATION) were randomized; overall SF rate was 73%. Recruitment durations were 6 and 3 months for LIFT and AVIATION, respectively. Of the 567 patients, 181 (32%) met step 1 eligibility criteria, with a SF rate of 68%. The most common reason for SF was not meeting the ALT enrollment eligibility threshold value. Of the 181 patients, 155 (86%) met either MRI-PDFF in LIFT or cT1 criteria in AVIATION, resulting in a step 2 MRI SF rate of 14% (26/183; 2 patients not treated for other reasons post step 2). Per baseline characteristics, each study enrolled a population with VCTE ranging from 4.4 to 19.6 kPa, CAP 261 to 400 dB/m, PDFF 6.0 to 48.2% and cT1 721.0 to 1461.0 msec.
Conclusion: A stepwise screening approach first using clinical assessments, laboratory tests and VCTE with CAP allowed for screening of patients that were more likely to meet the MRI eligibility criteria. As a result, this reduced the number of MRI assessments that were required which reduced costs and the need for patients to be scheduled for a separate imaging visit. These NIT-guided studies recruited efficiently and enrolled subjects likely to have presumed NASH. These biomarkers may be used in combination with medical history to identify phenotypic at-risk NASH patients in a non-invasive fashion to enable clinical trials of experimental NASH therapies.

SAT-408

Machine learning with routine laboratory tests and clinical features performs similar to current NAFLD clinical pathways

Devon Y. Chang[1], Emily Truong[2], Ju Dong Yang[3], Naim Alkhouri[4], Stephen Harrison[5], Mazen Noureddin[6]. *[1]Arnold O. Beckman High School, United States; [2]Cedars Sinai Medical Center, United States; [3]Cedars-Sinai, United States; [4]Arizona Liver Health, United States; [5]Pinnacle Clinical Research, United States; [6]Houston Liver Institute, United States*
Email: mazen.noureddin@cshs.org

Background and aims: AGA's NAFLD Clinical Care Pathway (Kanwal, et al. Gastro 2021) screens patients with risk factors for NAFLD with Fibrosis-4 index (FIB-4) to determine risk (low, indeterminate, or high) for clinically significant liver fibrosis. Indeterminate patients subsequently undergo FibroScan® to further stratify risk for clinically significant liver fibrosis. In this study, we assessed the performance of established machine learning (ML) models (Chang et al, Hepatology 2022) versus sequential testing with FIB-4 followed by FibroScan® (STFF) in predicting the risk of clinically significant liver fibrosis.
Method: We implemented ML models including logistic regression (LR), random forests (RF), and artificial neural network (ANN) to predict risk of significant fibrosis (defined by histological stage of fibrosis ≥F3) using 17 routine demographic, clinical, and laboratory features in 1223 NAFLD patients at multiple US centers. These patients had ≥1 risk factors for NAFLD, including ≥2 metabolic risk factors, type 2 diabetes mellitus, steatosis on any imaging modality,

	Correctly Classified (CC) Measurement (%)	Percentage of Indeterminate-Risk Patients (%)
Logistic Regression	63.96 [61.12, 66.8]	8.2 [7.14, 9.26]
Random Forests	67.47 [64.67, 70.27]	14.16 [12.47, 15.86]
ANN	63.06 [60.35, 65.78]	10.41 [8, 12.82]
FIB-4 + FibroScan	70.53 [66.51, 74.55]	11.51 [10.13, 12.89]

Figure: (abstract: SAT-408).

or elevated aminotransferases, and underwent liver biopsy, FibroScan®, and labs within a 6-month period. 29.52% of these 1223 patients had significant fibrosis, according to liver biopsy results. Patients with low, indeterminate, and high risk for significant liver fibrosis were predicted using the ML models and STFF according to the NAFLD Clinical Care Pathway. We used 80% of the cohort to train and 20% to test the ML models. Finally, we used the correctly classified (CC) measurement, defined as (true negative for rule-out cutoff + true positive for rule-in cutoff)/total, to compare the performances of the ML models to STFF. We also used the percentage of indeterminate-risk patients to compare the abilities of the ML models to separate the positive and negative classes to that of STFF.

Results: The performances of the ML models and STFF are shown in Table 1. LR had a CC of 63.96% (confidence interval, or CI: 61.12%–66.8%) and a percentage of indeterminate-risk patients of 8.2% (CI: 7.14%–9.26%). RF had a CC of 67.47% (CI: 64.67%–70.27%) and a percentage of indeterminate-risk patients of 14.16% (CI: 12.47%–15.86%). ANN had a CC of 63.06% (CI: 60.35%–65.78%) and a percentage of indeterminate-risk patients of 10.41% (CI: 8%–12.82%). STFF had a CC of 70.53% (CI: 66.51%–74.55%) and a percentage of indeterminate-risk patients of 11.51% (CI: 10.13%–12.89%). Overall, there was no statistically significant difference when comparing the CCs of LR and RF to that of STFF. While there was no statistically significant difference in percentage of indeterminate-risk patients when comparing RF or ANN to STFF, LR had a statistically significantly lower percentage of indeterminate-risk patients compared to STFF.

Conclusion: There was no statistically significant difference in the performances of LR, RF, and STFF in the prediction of risk of clinically significant liver fibrosis. LR better separated the positive and negative classes compared to STFF. ML may replace STFF in the NAFLD Clinical Care Pathway to predict the risk of clinically significant liver fibrosis.

SAT-409

Validation of elastography criteria and cACLD risk model for diagnosis of compensated advanced chronic liver disease (cACLD) in NAFLD patients

Antonio Liguori[1,2], Mirko Zoncapè[2,3], Roshni Patel[2], Davide Roccarina[2], Nicholas Viceconti[1], Lucrezia Petrucci[1], Laura Iogna Prat[2], Francesca D'Ambrosio[1], Giuseppe Marrone[1], Marco Biolato[1], Anna Mantovani[2,3], Jennifer-Louise Clancy[2], Atul Goyale[2], Antonio Gasbarrini[1], Antonio Grieco[1], Luca Miele[1], Emmanuel Tsochatzis[2]. *[1]Department of Translational Medicine and Surgery, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Università Cattolica del Sacro Cuore, Rome, Italy, Italy; [2]University College London (UCL) Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, UK, United Kingdom; [3]Liver Unit, Division of General Medicine C, Department of Internal Medicine, University and Azienda Ospedaliera Universitaria Integrata of Verona, Verona, Italy*
Email: lig.antonio91@gmail.com

Background and aims: Fibroscan is a well-established NIT for the diagnosis of advanced fibrosis (F≥3) in patients with NAFLD, recently defined as compensated advanced chronic liver disease (cACLD). EASL Guidelines[1] proposed 8 and 12 kPa, respectively, as rule-out and rule-in cut-offs for cACLD. Patients with Fibroscan measurement between 8 and 12 fall in a grey zone where further investigations are recommended. We recently proposed the cACLD Risk Score to further stratify this population. The main aim of this study was to test the diagnostic performance of the main NITs in two European cohorts of patients with histological diagnosis of NAFLD. Secondly, we assessed the performance of the cACLD risk score to further stratify patients in the Fibroscan's grey zone.

Method: This is a retrospective observational study. We enrolled consecutive patients with histological diagnosis of NAFLD/NASH from

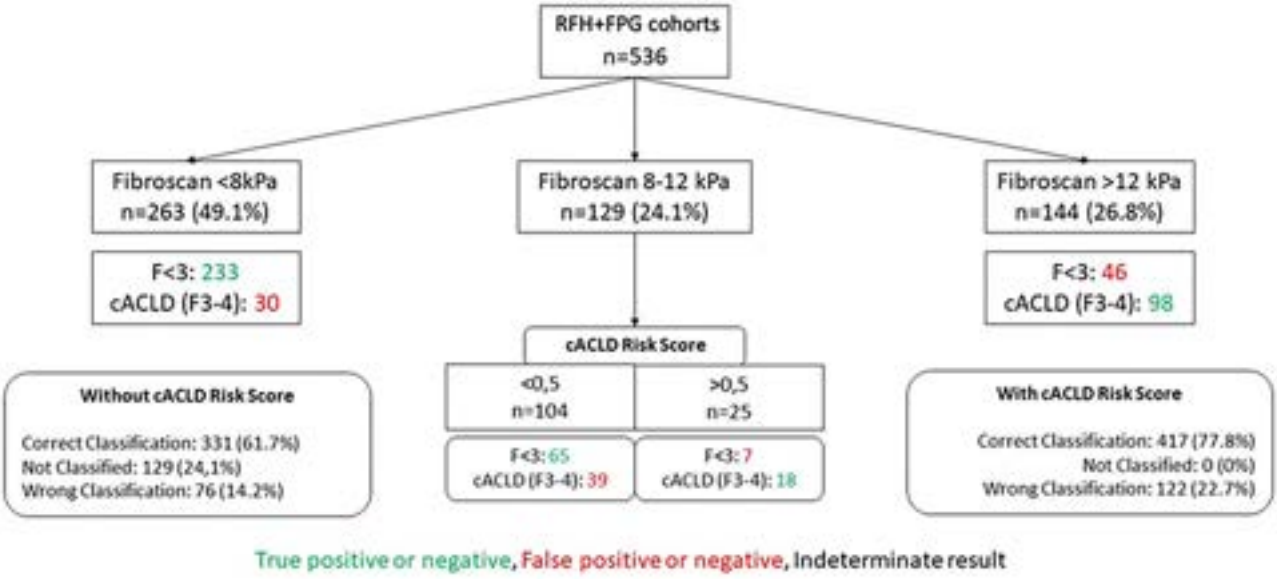

Figure: (abstract: SAT-409).

January 2014 to December 2021 at two tertiary liver units in UK (Royal Free Hospital, London-RFH) and Italy (Fondazione Policlinico Universitario A. Gemelli IRCCS, Rome-FPG). We excluded patients who did not perform at least one of these NITs at time of biopsy (± 6 months): FIB4, NAFLD Fibrosis score (NFS), Fibroscan, APRI, AGILE3+, cACLD Risk Score. We performed a ROC analysis to explore the diagnostic performance of NITs for cACLD (F > 2). Secondly, in patients with intermediate Fibroscan results (between 8 and 12 kPa), we tested the diagnostic performance of cACLD Risk Score, considering the originally proposed cutoff of 0, 5.

Results: We included 536 patients;201 were female, median age was 53 years, and 44% had diabetes. Fibroscan and AGILE3+ score had the best diagnostic performances for cACLD with an AUROC of 0.81 and 0.83 respectively. EASL criteria showed a high sensitivity and high specificity for 8 kPa and 12 kPa Fibroscan's cutoffs, respectively (Sens 84.3%; Spec 86.6%), a wrong classification rate of 14.2%. 129 patients (24.1%) fell in the grey zone (between 8 and 12 kPa). Diagnostic performance of cACLD Risk Score in Fibroscan's grey zone was suboptimal (AUROC: 0.682). The use of Fibroscan+cACLD Risk Score vs Fibroscan alone showed a better overall accuracy (77.8% vs 61.7%) and a slight worsening of overall wrong classification rate (22.7% vs 14.2%) mainly due to a higher number of false negatives than false positives. Among patients with intermediate Fibroscan (8–12 kPa), cACLD risk score correctly classify 64.4% of patients with a PPV of 72.0% and NPV of 62.5%.

Conclusion: Our results suggest that cACLD Risk Score should be used in patients with indeterminate Fibroscan results to further stratify their risk of cACLD. The use of cACLD Risk Score improve the performance in identifying patients with cACLD (high PPV) although its false negative rate could lead to missed diagnosis (suboptimal NPV). Patients with intermediate fibroscan and low cACLD risk score should be still considered for further investigation (liver biopsy).

SAT-410

Predictors of liver stiffness changes in consecutive cohorts of patients with non-alcoholic fatty liver disease and longitudinal follow-up

Mirko Zoncapè[1,2], Antonio Liguori[1,3], Serena Pelusi[4], Cristiana Bianco[4], Roshni Patel[1], Davide Roccarina[1], Laura Iogna Prat[1], Anna Mantovani[1,2], Jennifer-Louise Clancy[1], Atul Goyale[1], Luca Valenti[4], Emmanuel Tsochatzis[1]. *[1]Royal Free Hospital, University College London (UCL) Institute for Liver and Digestive Health, London, United Kingdom; [2]Azienda Ospedaliera Universitaria Integrata Verona, Liver Unit, Division of General Medicine C, Department of Internal Medicine, Verona, Italy; [3]Università Cattolica del Sacro Cuore, 3Department of Translational Medicine and Surgery, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Roma, Italy; [4]Policlinico of Milan, Department of Pathophysiology and Transplantation and Translational Medicine, Department of Transfusion Medicine and Hematology, Milano, Italy*
Email: mirko.zonky@yahoo.it

Background and aims: The serial use of non-invasive fibrosis tests can refine prognosis in patients with non-alcoholic fatty liver disease (NAFLD) and evaluate the progression or improvement of liver fibrosis. We evaluated predictors of improvement or worsening of liver stiffness measurements (LSM) in well characterized cohorts of patients with NAFLD from London (UK) and Milan (Italy).

Method: We included two consecutive cohorts of 405 patients with at least two outpatient visits between 2014 and 2022. The minimum time interval between baseline and follow-up LSM was >6 months. LSM worsening was defined as an increase of >20% kPa if the baseline LSM was ≥5 kPa, or a follow-up LSM >6 kPa if the baseline LSM was <5 kPa. An LSM improvement was defined as an LSM decrease of >20% kPa (if the baseline LSM was >6 kPa). A significant change in weight was defined as a >5% reduction or increase at follow-up, while a

Variable	Multivariate for LSM worsening		Multivariate for LSM improvement	
	OR (95% CI)	p-value	OR (95% CI)	p-value
Age	-	-	1.02 (0.99 – 1.0)	0.16
Weight change, %	-	-	0.93 (0.87 – 0.99)	**0.03**
BMI	-	-	1.00 (0.95 – 1.07)	0.77
DM	-	-	1.92 (0.81 – 4.55)	0.13
Follow up time	1.01 (0.98 – 1.02)	0.48	1.00 (0.99 – 1.02)	0.60
AST/ALT ratio at baseline	1.01 (0.98 – 2.24)	0.28	-	-
Total cholesterol change, %	0.98 (0.95 – 0.99)	**<0.05**	-	-
AST change, %	0.98 (0.96 – 0.99)	**0.04**	1.02 (1.01 – 1.04)	**0.03**
ALT change, %	1.02 (1.01 – 1.03)	**0.02**	0.98 (0.96 – 0.99)	**0.02**
HbA1c change, %	1.03 (1.01 – 1.06)	**0.03**	0.97 (0.95 – 1.00)	0.06
Difference between expected and actual FIB-4 at follow up	1.39 (0.28 – 6.94)	0.68	0.49 (0.21 – 1.20)	0.12

Figure: Multivariate analysis for Fibroscan LSM increase and for LSM decrease.Numbers in bold represent statistical significance.Legend: ALT, alanine amino-transferase; AST, aspartate aminotransferase; BMI, body mass index; DM, type II diabetes mellitus; FIB-4, fibrosis-4 index; HbA1c, glycated hemoglobin.

significant change in glycated hemoglobin (HbA1c) was defined as a >10% reduction or increase. The variation between the true and expected FIB-4 index (based on the patient's age at the follow-up visit, but using the blood tests performed at the first visit) was calculated. A significant improvement or worsening in FIB-4 was defined as a >20% variation between the actual and "expected" FIB-4.
Results: Of the 405 patients, 282 (70%) were males; mean age was 54 ± 11 years. The median time from the first visits was 20.3 (13.9–28.7) months. 128 and 54 patients had an LSM >8 kPa and LSM>12 KPa at follow-up, respectively. 77 patients (19.3%) had an LSM improvement, while 67 (16.8%) had an LSM worsening; 256 patients (63.9%) maintained a stable value. In patients with an LSM improvement, 22 had an improvement, 12 had worsening, while 37 had stable FIB-4. In patients with an LSM worsening, 10 had an improvement, 20 had worsening, while 33 had a stable FIB-4. In multiple logistic regression analysis, LSM worsening was independently associated with an increase in ALT and in HbA1c levels (OR 1.02 and 1.03 respectively), but also with a reduction in total cholesterol and AST levels (OR 0.98 for both). LSM improvement was independently associated with weight and ALT reduction (OR 0.93 and 0.98 respectively), but also with an increased AST level (OR 1.02).
Conclusion: More than 35% of patients with NAFLD have significant changes in their LSM measurements over a period of 20 months, with worsening or improvement at similar rates. Improvement in weight is independently associated with significant improvement in LSM measurements. On the converse, worsening in metabolic comorbidities, particularly glycemic control, could be associated with significant worsening in LSM, further supporting a multidisciplinary model of care.

Association of non-high-density lipoprotein cholesterol trajectories with the development of non-alcoholic fatty liver disease

Jun-Hyuk Lee[1], Jiyeon Kim[2], Jung Oh Kim[2], Yu-Jin Kwon[3], Eileen Yoon[4], Dae Won Jun[4], Sang Bong Ahn[1]. *[1]Nowon Eulji Medical Center, Eulji University School of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [2]Institute of genetic epidemiology, Basgenbio Co., Ltd., Korea, Rep. of South; [3]Yongin Severance Hospital, Yonsei university college of medicine, Family medicine, Yongin-si, Korea, Rep. of South; [4]Hanyang university college of medicine, Internal medicine, Seoul, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: Dyslipidemia including non-high-density lipoprotein (non-HDL) cholesterol can induce hepatic insulin resistance, which contributes to the incidence of non-alcoholic fatty liver disease (NAFLD). To date, the effect of longitudinal trends in non-HDL cholesterol on NAFLD development is unknown. This study aimed to verify relationship between non-HDL cholesterol trajectories and incident NAFLD and identify genetic differences contributing to the development of NAFLD between non-HDL cholesterol trajectory groups.
Method: From a total of 10,030 participants aged 40–69 years who participated in the Korean Genome and Epidemiology Study, we analyzed data from 2203 adults without NAFLD at baseline who consecutively participated in the first, second, and third follow-up surveys. During the 6-year exposure periods (from baseline to third follow-up periods), participants were classified into increasing non-HDL cholesterol trajectory group (n = 934) and stable group (n = 1269). NAFLD was defined as NAFLD-liver fat score >-0.640. Multiple Cox proportional hazard regression analysis was performed to estimate the hazard ratio (HR) and 95% confidence interval (CI) for incident NAFLD of increasing group compared with stable group. For genome-wide association study (GWAS), we applied the interaction polygenic risk scores (PRS) to clarify effects of single-nucleotide polymorphisms (SNPs) on NAFLD phenotypes. For case-control comparison, we set control group by randomly selecting 2203 samples from total participants in the KoGES and calculate interaction PRSs using same difference of effect sizes.
Results: During the median 7.8-year of event accrual period, 666 (30.2%) newly developed NAFLD cases were collected. Incidence rate per 2 years of NAFLD was ranged from 5.03 to 11.14. Kaplan-Meier curves showed significant higher cumulative incidence rate of NAFLD in increasing group than in stable group (log-rank test $p < 0.001$). Compared with stable group, the adjusted HR (95% CI) for incident NAFLD of increasing non-HDL cholesterol group was 1.54 (1.32–1.80, $p < 0.001$). Linear mixed model revealed that increasing group had consistently and significantly higher NAFLD-liver fat score than stable group during the follow-up periods except the baseline. On GWAS, no significant SNPs were identified. PRS was highest in increasing group, followed by stable group and control group.
Conclusion: A trend in increasing non-HDL cholesterol was positively related to incident NAFLD. Results from GWAS suggested that lifestyle (diet) or external environmental factors have a greater effect size of factors involved in NAFLD progression risk than genetic factors. Intensive lifestyle modification could be an effective prevention strategy for NAFLD for people with elevated non-HDL cholesterol.

SAT-412

A gut-mycobiome-derived signature predicts advanced fibrosis in people with diabetes

Daniel Huang[1,2], Tae Gyu Oh[3], Megan Hill[4], Ricki Bettencourt[2], Egbert Madamba[2], Harris Siddiqi[2], Maral Amangurbanova[2], Michael Downs[3], Ronald Evans[3], Jack Gilbert[4], Rohit Loomba[2,5]. *[1]National University of Singapore, Yong Loo Lin School of Medicine, Department of Medicine, Singapore; [2]University of California, San Diego, NAFLD Research Center, Division of Gastroenterology and Hepatology, United States; [3]Salk Institute for Biological Studies, Gene Expression*

Laboratory, United States; [4]University of California, San Diego, Department of Pediatrics and Scripps Institution of Oceanography, United States; [5]University of California San Diego, Division of Epidemiology, Department of Family Medicine and Public Health, United States
Email: roloomba@health.ucsd.edu

Background and aims: One in seven older adults with type 2 diabetes mellitus (T2DM) have advanced liver fibrosis (stage 3–4) due to non-alcoholic fatty liver disease (NAFLD). T2DM is associated with dysbiosis of the gut mycobiome, and emerging data suggest that the gut mycobiome may influence the progression of NAFLD to advanced fibrosis and cirrhosis. However, it is unknown if a stool mycobiome signature can be utilized as a non-invasive test for advanced fibrosis in individuals with T2DM.
Method: This prospective study enrolled participants with T2DM aged ≥50 years from primary care or endocrine clinics. Participants underwent MRI-proton density fat fraction, magnetic resonance elastography (MRE), vibration-controlled transient elastography (VCTE) and controlled-attenuation parameter. The presence of advanced fibrosis was defined by the presence of concordant findings between MRE and VCTE (MRE ≥3.63 kPa and VCTE ≥12 kPa). We performed fungal internal transcribed spacer (ITS) 2 sequencing using stool samples from 186 participants (64% female). A random forest machine learning algorithm and differential abundance analysis were utilized to identify signatures to identify advanced fibrosis.
Results: The mean (SD) age and body mass index (BMI) were 65.3 (8.19) years and 31.8 (6.31) kg/m^2, respectively. The composition of the mycobiome was substantially different in participants with NAFLD and advanced fibrosis, compared to those without advanced fibrosis. Notably, there was an increase in *Candida albicans* (p value = 8.6E-34), *Kazachstania humilis* (p value = 2.6E-03), and *Penicillium concentricum* (p value = 2.4E-16), and a decrease in *Saccharomyces cerevisiae* (p value = 3.7E-07), *Aspergillus versicolor* (p value = 2.1E-04), and *Fusarium fujikuroi* (p value = 2.8E-05). A unique stool mycobiome signature in combination with BMI was able to accurately distinguish the presence of advanced fibrosis (AUC 0.89, CI = 0.87–0.91) (Figure 1) and displayed consistent findings in an ethnically and geographically distinct cohort.

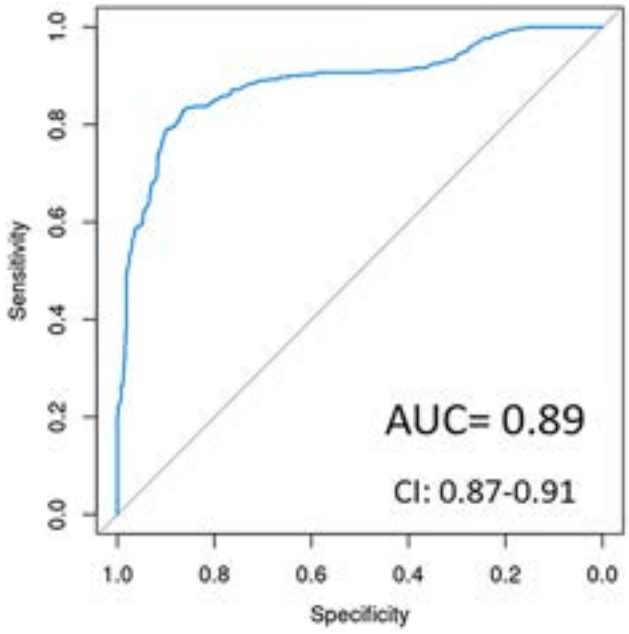

Figure: Diagnostic accuracy of the gut-mycobiome-derived signature in identifying advanced fibrosis.

Conclusion: These findings demonstrate that a core set of gut mycobiome species may be useful as a non-invasive diagnostic test for advanced fibrosis in participants with T2DM.

SAT-413

Diagnostic and prognostic performance of the SAFE score in non-alcoholic fatty liver disease

Guanlin Li[1,2], Huapeng Lin[1,2], Pimsiri Sripongpun[3,4], Yan Liang[1,2], Xinrong Zhang[1,2], Vincent Wai-Sun Wong[1,2], Grace Lai-Hung Wong[1,2], W. Ray Kim[3], Terry Cheuk-Fung Yip[2,5]. *[1]The Chinese University of Hong Kong, Department of Medicine and Therapeutics, Hong Kong; [2]The Chinese University of Hong Kong, Institute of Digestive Disease, Hong Kong; [3]Stanford University, Department of Medicine, United States; [4]Prince of Songkla University, Division of Internal Medicine, Thailand; [5]The Chinese University of Hong Kong, Department of Medicine and Therapeutics, Hong Kong*
Email: tcfyip@cuhk.edu.hk

Background and aims: The steatosis-associated fibrosis estimator (SAFE) was developed for detection of significant (≥stage 2) fibrosis (SF) in patients with non-alcoholic fatty liver disease (NAFLD) for non-hepatologists (Hepatology 2023;77 (1):256–267). We validate the performance of the SAFE score in comparison to other non-invasive tests to diagnose SF, and to assess their performance in predicting liver-related complications in NAFLD patients in Hong Kong.
Method: This is a retrospective cohort study involving two datasets. The first cohort, prospectively recruited between 2006 and 2021, consisted of adult patients who underwent liver biopsy at Prince of Wales Hospital. The second cohort composed of territory-wide adults with NAFLD (ICD-9-CM code 571.8) first diagnosed from January 2000 to July 2021, retrieved from the Clinical Data Analysis and Reporting System (CDARS) under the management of the Hospital Authority, Hong Kong. Diagnostic and prognostic performance characteristics of the SAFE, FIB-4, NAFLD Fibrosis Score (NFS) and AST-plate ratio index (APRI) were compared. Liver stiffness data by transient elastography were also available in the biopsy cohort.
Results: Four hundred and seventy patients of the biopsy cohort and 4603 patients of the territory-wide cohort were included. In the primary analysis detecting SF, liver stiffness had the highest AUROC (0.844), followed by SAFE score (0.773), FIB-4 (0.746), NFS (0.737) and APRI (0.697). Results were similar for the detection of fibrosing NASH and advanced fibrosis (Figure, *p < 0.05 compared to SAFE). Based on cut-off values of SAFE score (0 and 100 points), 854 (18.6%), 1596 (34.6%) and 2153 (46.8%) were in the low-, intermediate- and high-risk groups, respectively. Six (0.7%), 15 (0.9%) and 59 (2.7%) developed liver-related events in these three groups from territory-wide cohort. Among diabetic patients who had liver-related events at 10 years, using the high cut-off, SAFE score could predict 90.7% of patients accurately, compared to 80.6% for FIB-4 and 66.8% for APRI. In subgroup analyses of NAFLD patients with and without type 2 diabetes, SAFE score had consistently good performance in detecting SF and liver-related events.

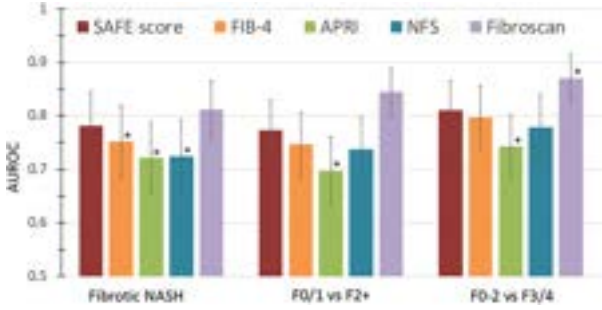

Figure: Comparison of area under the receiver-operating characteristics curves (AUROC) of non-invasive tests in patients with biopsy-proven NAFLD.

Conclusion: The SAFE score has good overall accuracy in diagnosing SF and predicting liver-related events in NAFLD patients. It has similar performance in patients with and without diabetes and is therefore well-suited for initial assessment of a broad spectrum of NAFLD patients to assess liver fibrosis and future risk of liver-related complications.

SAT-414

Standardized non-invasive screening for non-alcoholic fatty liver disease in people with type 2 diabetes identifies a substantial number of individuals with advanced liver disease

Naomi Lange[1,2], Jonas Schropp[1], Martin Hilpert[3], Andreas Melmer[3], Markus Laimer[3], Christoph Stettler[3], Annalisa Berzigotti[1], Jean-François Dufour[4]. *[1]Department of Visceral Surgery and Medicine, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland; [2]Graduate School for Health Sciences, University of Bern, Switzerland; [3]Department of Diabetes, Endocrinology, Nutritional Medicine and Metabolism, Inselspital, Bern University Hospital and University of Bern, Bern, Switzerland; [4]Centre des Maladies Digestives Lausanne, Lausanne, Switzerland*
Email: naomi.lange@insel.ch

Background and aims: International guidelines recommend screening for advanced non-alcoholic fatty liver disease (NAFLD) in high-risk populations using validated, non-invasive tests. We implemented an algorithm to systematically screen and refer people with type 2 diabetes (T2DM), based on the simultaneous use of fibrosis-4 (FIB4) score and vibration controlled transient elastography (VCTE). Our objective was to assess feasibility, and evaluate the prevalence of clinically suspected and histologically assessed liver disease in referred patients.

Method: We included adult people with T2DM from a tertiary care diabetes outpatient clinic. Hepatology referral was recommended to patients who 1.) presented with a high FIB4 and/or VCTE, or 2.) intermediate values of both FIB4 and VCTE using previously validated cut-offs (FIB4: low <1.30, intermediate 1.30–2.67, high >2.67; VCTE [kPa]: low <7.9, intermediate 7.9–9.6, high >9.6). Clinical suspicion of advanced liver disease was defined as indication for the performance of liver biopsy, clinical diagnosis of cirrhosis, and detection of hepatocellular carcinoma (HCC), and significant liver disease was defined as liver disease warranting follow-up. Histological fibrosis was staged according to NASH-Clinical Research Network (CRN) criteria.

Results: Of 840 eligible individuals, 276 (32.9%) were included. Valid screening test results were obtained in 95.7% of participants (1.8% and 2.5% invalid results of FIB4 and VCTE, respectively). Among 261 participants evaluated for hepatology referral, mean age was 60.7 years, 28% were female and prevalence of steatosis assessed by controlled attenuation parameter (CAP) was 76.6%. 16.9% of participants (n = 44) were recommended for hepatology referral due to elevated screening tests and 43 did undergo hepatology work-up (Fig. 1). Referred patients were older (64.4 vs. 59.9 years, p = 0.021), and had higher body mass index (33.6 vs. 31.5 kg/m^2, p = 0.047), CAP (330 vs. 288 dB/m, p = 0.001) and HbA1c (7.6 vs. 7.1%, p = 0.014). Overall, 90.7% (n = 39) of referred patients were clinically diagnosed with advanced (n = 24) or significant (n = 15) liver disease. 75% of cases without identifiable or only mild liver disease in work-up were referred due to high FIB4 in combination with low VCTE. The most common liver-related diagnosis was NAFLD in 60.5% (n = 26) of cases, followed by metabolic liver disease (MAFLD) with dual etiology due to alcohol-related and viral liver disease in 20.9% (n = 9) of cases.

Conclusion: Implementation of an algorithm to screen people with T2DM for liver disease using a combination of FIB4 and VCTE was feasible and identified a large number of clinically relevant liver disease cases in a tertiary care setting. Our data suggest a high prevalence of MAFLD with dual etiology in this population, highlighting the necessity of offering screening to high-risk T2DM populations beyond the suspicion of NAFLD.

SAT-415

Patients with risk factors for liver diseases associated with hepatic steatosis constitute the target population for liver fibrosis assessment in primary care

Email: nfabrellas@ub.edu

Background and aims: Primary care is the ideal setting for early identification of subjects with liver fibrosis before cirrhosis or liver cancer occurs. Early diagnosis is critical to undertake personalized effective therapeutic interventions to stop disease progression and prevent liver-related mortality. However, the target population for liver fibrosis assessment in primary care is not well defined. The objective of this study was to investigate the characteristics of target population for liver fibrosis assessment, particularly the relationship between risk factors of liver fibrosis and presence of steatosis.
Method: Prospective cohort of 5760 subjects without known liver disease randomly selected from primary care. Fibrosis was estimated by liver stiffness (LS) with transient elastograpy. A LS ≥9.2 kPa was considered suggestive of liver fibrosis, as reported by previous studies in population-based cohorts. Hepatic steatosis was estimated with fatty liver index (FLI). A FLI ≥60 was considered suggestive of moderate/severe hepatic steatosis. Risk factors of fibrosis were metabolic syndrome and its components, obesity, type2DM, or risk alcohol consumption.
Results: Out of the 5760 subjects included, 3,614 (63%) had at least one risk factor of liver fibrosis. Among subjects with risk factors, the prevalence of LS≥9.2 kPa was higher compared to that of subjects without risk factors (4.7% vs 0.3%, $p < 0.001$). We then assessed the prevalence of LS≥9.2 kPa in patients with risk factors categorized according to presence/absence of associated hepatic steatosis (FLI≥60). Interestingly, prevalence of LS≥9.2 kPa was higher among subjects with risk factors and steatosis compared to that of subjects with risk factors without steatosis (7.5% vs 0.6%, respectively; $p < 0.01$). Remarkably, the vast majority of subjects with LS≥9.2 kPa belonged to the subgroup of subjects with risk factors and associated steatosis (162 of 178, 91%). By contrast, only a small fraction of subjects with LS≥9.2 kPa had risk factors and increased FIB-4 (>2.67) (23 out of 178, 13%). In subjects with risk factors, FLI had higher accuracy in the diagnosis of LS≥9.2 kPa compared to FIB-4 (AUROC: 0.83 vs 0.62, respectively).
Conclusion: In primary care, the target population for evaluation of liver fibrosis should consist of subjects with risk factors for liver fibrosis and associated hepatic steatosis. In subjects without risk factors or with risk factors but without steatosis, the prevalence of increased LS is very low and does not seem to justify the assessment of liver fibrosis. In subjects with risk factors, FLI is more accurate than FIB-4 to predict individuals with high likelihood of liver fibrosis.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the leading cause of chronic liver disease in Western countries. NAFLD is associated with both liver-related and extrahepatic complications, including cardiovascular disease (CVD). Non-invasive tests (NITs) for advanced fibrosis are increasingly used to identify individuals with NAFLD who are at risk for liver-related complications. Their performance for extrahepatic complications has been recently tested in tertiary care settings and found to be limited. Herein, we investigated the performance of NITs for predicting long-term liver and heart outcomes in individuals with dysmetabolism from the large prospective UK Biobank.
Method: To assess the performance of NITs for liver and heart outcomes, we selected 305,745 Europeans with overweight/obesity and/or type 2 diabetes, without any liver disease at baseline, and 194,236 Europeans with overweight/obesity and/or type 2 diabetes, without chronic viral hepatitis and CVD at baseline, respectively. Then, we estimated the performance of NITs for predicting incident severe liver disease (SLD: cirrhosis, decompensated liver disease, hepatocellular carcinoma, liver transplantation) or incident CVD (angina, myocardial infarction, stroke, transient ischemic attack) by Cox proportional hazards models. Follow-up length was calculated from the date of baseline assessment visit up to the first date of target outcome diagnosis, the date of death, or the date of end of follow-up at the assessment center (July 1st, 2022), whichever occurred first. The following NITs were tested: fibrosis-4 index (FIB-4), NAFLD fibrosis score (NFS), fibrotic NASH index (FNI), AST to platelet ratio index (APRI), BARD.
Results: After a median follow-up of 9 years, FNI was the best score for predicting liver outcomes (area under the curve [AUC] 0.77, $p < 0.05$ vs all the other NITs). After a median follow-up of 13 years, NFS was the best score for predicting heart outcomes (AUC 0.60, $p < 0.05$ vs all the other NITs). All NITs showed a worse and limited performance for heart outcomes compared with that for liver outcomes.

	SLD (N = 305,745)		CVD (N = 194,236)	
Score	AUC	P value	AUC	P value
FIB4	0.75 (0.73–0.77)	0.03	0.59 (0.59–0.60)	<0.001
NFS	0.72 (0.70–0.74)	<0.001	0.60 (0.60–0.61)	reference
FNI	0.77 (0.75–0.79)	reference	0.59 (0.58–0.60)	0.003
APRI	0.75 (0.73–0.77)	0.01	0.53 (0.53–0.54)	<0.001
BARD	0.62 (0.61–0.64)	<0.001	0.55 (0.54–0.55)	<0.001

Conclusion: NITs showed a satisfactory performance for predicting liver outcomes, but a rather limited performance for predicting heart outcomes in individuals with dysmetabolism from the general population.

SAT-417

Impact of age as a confounding factor on non-invasive blood-based tests for the evaluation of non-alcoholic fatty liver disease: comparing NIS2+TM to established tests

Quentin Anstee[1,2], Jeremy Magnanensi[3], Yacine Hajji[3], Alexandra Caron[3], Zouher Majd[3], Christian Rosenquist[3], Dean Hum[3], Bart Staels[4], Margery A. Connelly[5], Rohit Loomba[6], Stephen Harrison[7,8], Vlad Ratziu[9], Arun Sanyal[10]. *[1]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [2]Newcastle NIHR Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Freeman Hospital, Newcastle upon Tyne, United Kingdom; [3]GENFIT S.A., Loos, France; [4]Univ. Email: jeremy.magnanensi@genfit.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is the more progressive form of non-alcoholic fatty liver disease (NAFLD), the leading cause of chronic liver disease. Timely diagnosis of specific conditions associated with higher risk of liver-related/all-cause mortality, such as "at-risk NASH" (NASH with a NAFLD activity score [NAS] ≥4 and a fibrosis stage [F] ≥2) or advanced fibrosis (F ≥3), is critical and different non-invasive tests (NITs) have been developed for these purposes. NAFLD affects patients of all ages, therefore, NITs should perform consistently across age groups to simplify large-scale use in clinical practice. This work investigated the effect of age on several well-established NITs including NIS2+™ and compared it to a histological reference standard.

Method: An analysis cohort (N = 2108; ≤45 years [n = 496], 46–55 years [n = 569], 56–64 years [n = 625], and ≥65 years [n = 418]) containing all patients with liver biopsies and data for NIS2+™, aspartate aminotransferase-to-platelet ratio index (APRI), NAFLD fibrosis score (NFS), Fibrosis-4 (FIB-4), and Enhanced Liver Fibrosis (ELF)) was selected among those screened for the phase 3 RESOLVE-IT clinical trial (NCT02704403). To avoid potential confounding effects and allow for a robust analysis of the age impact on NITs, a well-balanced cohort (N = 800, n = 200 per age group) was obtained by applying a propensity score matching algorithm to the analysis cohort. Baseline values of biomarkers and NITs were compared across age groups using one-way ANOVA, and age impact on NITs distribution was compared to the effect of histology (F, NAS) using 3-way type-2 ANOVA and associated effect sizes. Using derived Youden cutoffs, the impact of age on NITs' clinical performance (sensitivity, specificity) for the diagnosis of targeted condition was analysed.

Results: NIS2+™ and APRI were not impacted by age (p = 0.70 and p = 0.91, resp.), while the means of NFS, FIB-4, and ELF increased significantly with age (p < 0.0001), driven notably by decreasing ALT (NFS, FIB-4) and increasing hyaluronic acid (ELF) concentrations (p <0.0001). Age had a higher effect size for FIB-4, NFS, and ELF than liver fibrosis, the hypothesized main driver of these NITs. The age impact on FIB-4, NFS and ELF led to a decrease in specificity (FIB-4: 0.91–0.34; NFS: 0.81–0.23; ELF: 0.86–0.42) and an increase in sensitivity (FIB-4: 0.26–0.89; NFS: 0.49–0.92; ELF: 0.49–0.93) for the detection of F ≥3 across the different age groups. While not being impacted by age, NIS2+™ was the only NIT for which both F stage and

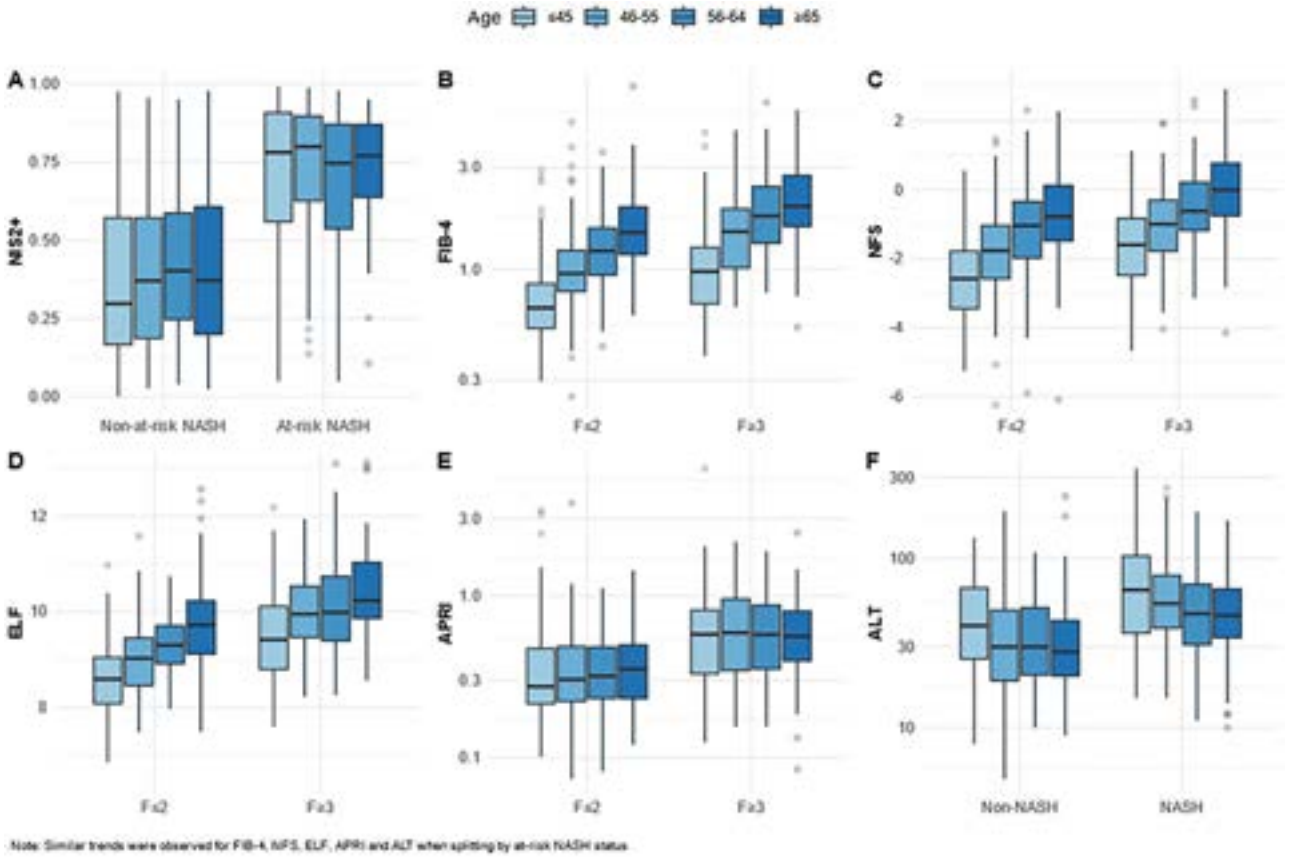

Figure: (abstract: SAT-417).

NAS score had medium to large effect sizes (partial omega squared = 0.16 and 0.12, resp.), confirming its adequacy for the detection of at-risk NASH as a composite end point.
Conclusion: FIB-4, NFS and ELF were impacted by age, therefore consideration should be given to adopting age-adapted cutoffs. NIS2 +™ was not impacted by age, demonstrating robust assay performance for ruling in/out at-risk NASH with fixed medical decision points.

Email: noshin@hanyang.ac.kr

Background and aims: Current guidelines for non-alcoholic fatty liver disease (NAFLD) recommend that the screening test for hepatic fibrosis should be performed to at-risk group for hepatic fibrosis This study aimed to evaluate the cost- effectiveness of screening strategy using sequential combination of FIB-4 followed by transient elastography for advanced hepatic fibrosis in various at-risk populations.
Method: We built a combined model of decision tree model and Markov model to compare expected costs and quality-adjusted life-years (QALYs) between 'screening' and 'no screening' groups from healthcare system perspective. At-risk group was mainly defined as the group of individuals with any of the following risk factors: fatty liver, two or more metabolic abnormalities (three or more in the European Association for the Study of the Liver (EASL)), diabetes mellitus, and abnormal liver function test based on American Gastroenterological Association (AGA) guideline. Patients with pre-diabetes or obesity in American Association for the Study of Liver Diseases (AASLD) and overweight in EASL were additionally added in at-risk group, respectively. Fibrosis distribution of at-risk group was based on real world data from 8,545 health check-up examiners who underwent magnetic resonance elastography. Patients who diagnosed as advanced fibrosis in screening group were applied with intensive life-style intervention (ILI). The model included not only liver disease-related health states, but also cardiovascular disease (CVD) and extrahepatic cancer states that could be affected by NAFLD. Incremental cost-effectiveness ratio (ICER) was calculated for 20-year horizon and evaluated by applying the definition of 'at-risk' population to various guidelines.
Results: The cost-effectiveness analysis showed that screening group had $253 incremental costs and additional 0.0191 QALY per patient compared to no screening group in at-risk population. Through the base-case analysis ICER was $13,234/QALY. The result indicated that screening was cost-effective based on the implicit ICER threshold of $25,000/QALY in Korea. Sequential algorithm based on FIB-4 and transient elastography was more cost-effective considering the effects of ILI on cardiovascular and other malignancy in the 'at-risk group'. In addition to the at-risk group defined by AGA guideline, the screening algorithm with ILI was also cost-effective in the at-risk group definition suggested by other guidelines ($14,211/QALY in EASL, $13,986/QALY in AASLD). Even when replacing medical costs in other countries, they were cost-effective because they were below the ICER threshold ($44,860/QALY in the US and $6147 in Japan).

Figure:

Conclusion: Screening for advanced hepatic fibrosis using FIB-4 in patients with at-risk population would be cost-effective when applying definitions in most of all guidelines about at-risk populations.

SAT-419
Which screening of advanced liver fibrosis in NAFLD?
Paul Cales[1], Clémence M Canivet[2], Lannes Adrien[2], Frédéric Oberti[2], Isabelle Fouchard[2], Charlotte Costentin[3], Victor de Lédinghen[4], Jerome Boursier[2]. *[1]Angers University Hospital, Angers, France; [2]Angers University Hospital, France; [3]Grenoble University Hospital, France; [4]Bordeaux University Hospital, France*
Email: paul.cales@univ-angers.fr

Background and aims: The EASL and AGA guidelines recommend screening advanced fibrosis in patients at risk of NAFLD using sequential tests. Our aim was to compare and improve these algorithms.
Method: 1051 NAFLD patients were divided in derivation (n = 637) and validation (n = 414) sets. The outcome was advanced fibrosis (Kleiner F3+F4). The main descriptors were sensitivity, accuracy, indeterminate rate, liver stiffness measurement (LSM by Fibroscan) recourse and direct costs. The recommended algorithms were evaluated according to cut-offs either original or adapted to derivation set. In the EASL algorithm, we included either the agreement between LSM and Fibrotest (FT) or FibroMeter (FM), or the FM+LSM (EFM) combination. A new 3-steps Fibs algorithm used first FIB9 (using 9 usual liver blood markers), then FIB11 (adding 2 specialized blood markers) and finally FIB-12 (adding LSM). These new FIB tests were obtained by multi-targeting (PMID: 29619423) improved by machine learning in the derivation set.

Results: They are given in the validation set. AUROC were, FIB4: 0.757, FT: 0.766, FM: 0.850, LSM: 0.852, FIB9: 0.863, FIB11: 0.880, EFM: 0.894, FIB12: 0.912 ($p < 0.001$). 1/The recommended algorithms with original cut-offs had the same fair sensitivity (70.3%) but the AGA algorithm had a significantly higher indeterminate rate and cost. The indeterminate rate of EASL algorithm was, FT: 13.5%, FM: 7.5% ($p < 0.001$). 2/Optimized EASL or AGA algorithms by adapted cut-offs improved sensitivity and accuracy vs original algorithms at the expense of increased indeterminate rate and cost. 3/The modified EFM-EASL algorithm significantly reduced the indeterminate rate (5.3%, $p < 0.001$) and cost vs optimized algorithms. The new Fibs algorithm improved all outcomes (Figure), e.g. sensitivity: 82.1% vs AGA: 77.2% or EASL: 74.5% ($p = 0.052$), indeterminate rate: 3.1% vs AGA: 16.4% or EASL: 9.7% ($p < 0.001$), LSM recourse: 15.5% vs AGA: 66.9% or EASL: 49.0% ($p < 0.001$) and mean cost: 57€ vs AGA: 188€, EASL: 134€ ($p < 0.001$).

Figure:

Conclusion: The characteristics of the recommended algorithms show significant differences depending on their type or the patented blood test included. Their sensitivity, indeterminate rate and cost are perfectible. The modified EFM-EASL algorithm, improved by test combination, is immediately applicable. The new Fibs algorithm significantly improved all characteristics including greatly reduced indeterminate rate, LSM recourse (promoting ubiquitous applicability) and cost.

Email: marta.garbin@studenti.univr.it

Background and aims: Non-alcoholic fatty liver disease (NAFLD), mainly in its advanced form with hepatic fibrosis, represents a risk factor for the development of cardiovascular (CV) disease and chronic kidney failure, the latter early expressed by glomerular hyperfiltration (GH). GH shares the same CV and metabolic risk factors with NAFLD, and their association has been already evaluated in adults with metabolic syndrome. However, association between GH and NAFLD fibrosis has not been investigated yet.

Method: 772 patients (mean age 47.3 ± 8.9 (range 40–65 ys), 67.1% male) with non-cirrhotic NAFLD diagnosed by abdominal ultrasound were enrolled at three hepatology centers (Verona, Milan and London). Hepatic fibrosis was diagnosed by Fibroscan (echoSense) by a liver stiffness measurement (LSM) ≥7.2 kPa. Glomerular filtration rate (GFR) was estimated using 2021CKD-EPI formula and GH was defined by GFR ≥ 110 ml/min, whereas normal filtration (nGFR) by GFR 60–110 ml/min. Anthropometric and biochemical data, as well as medical history and current therapy were recorded at enrollment.
Results: In the whole cohort, 152 (20%) belonged to the GH group. Compared to the nGFR, the GH group presented younger age (38.4 ± 8.3 vs 49.5 ± 7.7 years, $p < 0.001$), higher prevalence of severe steatosis (39.9% vs 27.1%, $p = 0.03$) and higher LSM values (8.04 ± 6.15 kPa vs to 7.47 ± 6.12 kPa, $p = 0.023$). In multivariate analysis adjusted for age, sex, type 2 diabetes, hypertension and obesity, age (OR 0.83, CI 95% 0.77–0.89) and LSM (OR 6.6, CI 95% 2.2–19.9) were independent risk factors for GH. LSM remained independently associated with GH even when considered diagnostic for fibrosis (LSM >7.2 kPa) (OR 1.83, CI 95%, 1.10–3.03). These association were maintained even adjusting for diuretic and ACE/ARBs therapy.
Conclusion: GH is associated with hepatic fibrosis by LSM independently of other metabolic alterations. Therefore, GH could be considered an early marker of liver fibrosis in non-cirrhotic NAFLD patients and calculation of a simple index as GFR could suggest the need for a Fibroscan assessment in NAFLD patient even in primary care.

SAT-421

NIS2+™ as a screening tool for optimizing patient selection in non-alcoholic steatohepatitis therapeutic trials

Vlad Ratziu[1], Stephen Harrison[2,3], Yacine Hajji[4], Jeremy Magnanensi[4], Stéphanie Petit[5], Zouher Majd[5], Christian Rosenquist[5], Dean Hum[5], Bart Staels[6], Quentin Anstee[7,8], Arun Sanyal[9]. *[1]Sorbonne Université, Institute for Cardiometabolism and Nutrition, Hôpital Pitié-Salpêtrière, Paris, France; [2]Summit Clinical Research, San Antonio, TX, United States; [3]Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom; [4]GENFIT, Loos, France; [5]GENFIT, Loos, France; [6]Université de Lille, INSERM, CHU Lille, Institut Pasteur de Lille, Lille, France; [7]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [8]Newcastle NIHR Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Freeman Hospital, Newcastle upon Tyne, United Kingdom; [9]Division of Gastroenterology, Hepatology and Nutrition, Virginia Commonwealth University School of Medicine, Richmond, VA, United States*
Email: yacine.hajji@genfit.com

Background and aims: In clinical trials of non-cirrhotic patients with at-risk NASH (NAS ≥4; F ≥2), the screen failure rate of liver biopsy (LB) is unacceptably high. Standard non-invasive fibrosis tests aimed at detecting advanced fibrosis are not optimal to identify at-risk NASH. NIS2+™ is an improved version of the blood-based NIS4® biomarker, designed to identify at-risk NASH. We assessed the potential of NIS2+™ for optimized biopsy referral in therapeutic trials targeting at-risk NASH.
Method: Among >5000 patients who were screened in the RESOLVE-IT Phase 3 trial (NCT02704403), 1929 patients were selected with non-historical LB, available NIS2+ and FIB4 results and less than 3 months between LB and serum samples. This cohort was representative of the overall screening population and was used to perform a simulation to compare the actual screening performance observed in the RESOLVE-IT trial (based on clinical judgment of the investigators and standard local practices) with two simulated pathways using NIS2+™ alone, and FIB4-NIS2+™ sequentially. The number of patients needed to screen, the LB failure rate, and the screening cost (based on average costs of RESOLVE-IT in US sites) were assessed for a range of cutoff values of 0–0.8 for NIS2+™; and 0–2.0 for FIB4.

Performances were estimated for the inclusion of 1000 patients as confirmed by liver biopsy.
Results: The RESOLVE-IT screening process (RSP) cost $15 million per 1000 included patients, with a LB failure rate of 60.3% and 3220 patients needed to screen. Using, NIS2+™ for screening with a cost-optimized cutoff of 0.53, reduced the LB failure rate to 39%, saving 884 unnecessary biopsies (-58%) with a $2.3 million cost reduction (-16%) for only 812 (+25%) additional patients to be screened, corresponding to a NNT (number needed to be tested) of 4. For this cost-optimized cutoff, the sensitivity of NIS2+™ would have been 80%, specificity 66%, NPV 83% and PPV 61%. Compared to NIS2+™ alone, neither FIB4 alone nor FIB4-NIS2+™ would have reduced cost of inclusion or LB failure rates without considerably increasing the number of screenings. Unlike FIB4, NIS2+™ did not alter the demographic profile of patients included, in particular for important stratification parameters such as diabetes, histological activity or advanced fibrosis.
Conclusion: In therapeutic trials of non-cirrhotic at-risk NASH, the NIS2+™ blood-based biomarker would substantially optimize the referral pathway for liver biopsy by reducing unnecessary liver biopsies and overall costs thus greatly improving a major aspect of feasibility of NASH clinical trials.

SAT-422

Abdominal adiposity and insulin resistance are the main predictors of CAP values in individuals with metabolic dysfunction: the liver-bible cohort

Cristiana Bianco[1], Serena Pelusi[1], Sara Margarita[1], Francesco Malvestiti[2], Giulia Periti[1], Jessica Rondena[1], Melissa Tomasi[1], Rossana Carpani[1], Matteo Vidali[3], Ferruccio Ceriotti[3], Daniele Prati[1], Luca Valenti[1,2]. *[1]Fondazione IRCCS Ca' Granda Ospedale Ospedale Maggiore Policlinico di Milano, Precision Medicine-Department of Transfusion Medicine, Italy; [2]Università degli Studi di Milano, Department of Pathophysiology and Transplantation, Italy; [3]Fondazione IRCCS Ca' Granda Ospedale Ospedale Maggiore Policlinico di Milano, Clinical Pathology Unit, Italy*
Email: biancocristiana.md@gmail.com

Background and aims: Evaluation of controlled attenuation parameter (CAP) during vibration controlled transient elastography (VTCE) permits the non-invasive estimation of hepatic fat content and the presence of fatty liver disease (FLD), a key driver of liver disease. Aim of the study was to examine the independent determinants and clinical predictors of CAP values in a cohort of apparently healthy individuals at high risk of FLD due to metabolic dysfunction.
Method: We considered 1230 consecutive blood donors (Liver-Bible cohort up to June 2022) with ≥3 features of metabolic dysfunction (overweight/obesity, hyperglycemia, hypertension, low HDL/high triglycerides), who underwent cardiometabolic evaluation from June 2019 to June 2022. CAP was measured by VTCE with Fibroscan. CAP determinants and predictors were identified by backward stepwise analysis and introduced in generalized linear models.
Results: Among participants, 210 (17.1%) were females, mean age was 53.8 ± 6.4 yrs, BMI 28.6 ± 3.2 Kg/m^2, 600 (48.8%) had steatosis (CAP ≥275 dB/m) and 27 (2.2%) had liver stiffness measurement (LSM) ≥8 kPa. CAP values correlated with higher LSM ($p < 10^{-22}$). At multivariable analysis, independent determinants of CAP values were fasting insulin and abdominal circumference (AC; $p < 10^{-7}$ for both), together with body mass index (BMI; $p < 10^{-4}$), age, diabetes, triglycerides, ferritin, and lower HDL and thyroid stimulating hormone (TSH; $p < 0.05$ for all). AC was also an independent determinant of CAP ≥275 dB/m ($p < 10^{-5}$), with insulin and diabetes, BMI, and lower HDL and TSH ($p < 0.05$ for all). In a subgroup of 592 participants for whom the information was available, we observed an independent association between higher fT3 levels, correlating with higher TSH, and CAP values (estimate 11.78 ± 3.92, p = 0.0027), independently of TSH levels and of levothyroxine treatment. A clinical score based on age, BMI, AC, HDL, HbA1c and ALT predicted CAP ≥275 dB/m with moderate accuracy (AUROC = 0.73), which was better than that of ALT alone and fatty liver index (AUROC = 0.61/0.70 respectively).

Figure: Independent determinants of CAP values in the LIVER-BIBLE-2022 cohort.

	Overall Liver-Bible-2022 cohort (n = 1,230)			Subgroup with fT3/T4 determination (n = 592)

TSH, mU/L	−1.57	0.74	**0.0324**	2.38	1.64	0.1456
fT3, ng/L				11.87	3.93	0.0025

°At GLM, adjusted for ethnicity, Levothyroxine replacement therapy and reported variables (identified at backward stepwise analysis, not shown). AC: abdominal circumference; BMI: body mass index; F: female; fT3: free triiodothyronine; HDL-C: high-density lipoprotein cholesterol; SE: standard error; T2D: type 2 diabetes; TG: triglycerides; TSH: thyroid stimulating hormone.

Conclusion: The severity of insulin resistance and abdominal adiposity were the main independent determinants of CAP in individuals with metabolic dysfunction and may improve the risk stratification of FLD at an early stage of development. CAP values were modulated by hypophysis-thyroid-axis activity.

SAT-423

A cost-effective non-invasive serum test for diagnosing NASH-cirrhosis (NC-3) in high-risk metabolic syndrome and/or type 2 diabetes patients

Shira Shaham-Niv[1], Eldad Kepten[1], Boris Sarvin[1], Avishai Gavish[1], Claudia Filozof[2], Tomer Shlomi[1,3]. *[1]MetaSight Diagnostics, Rehovot, Israel; [2]Labcorp Drug Development, Israel; [3]Technion, Department of Computer Science and Biology, Haifa, Israel*
Email: shira.s@metasightdx.com

Background and aims: Liver cirrhosis is majorly underdiagnosed and with an estimated prevalence of 6% among T2D patients; hence, ~70% of cirrhosis cases are only incidentally found. However, currently high-risk T2D and metabolic syndrome patients are typically not screened for NASH-cirrhosis as part of common general practice. Here, we develop a robust non-invasive test (NIT) for NASH-cirrhosis based on cost-effective metabolomics and lipidomics, amenable for screening asymptomatic high-risk patients.
Method: Serum samples from ~500,000 subjects (>50 years old) were collected as part of standard clinical routine by a central Israeli HMO between July 2021 and January 2023, within the ongoing Israeli multi-OMICS Serum Screening (IMOSS-500 K) study. De-identified electronic health records (EHR) were used to identify ~60,000 samples from patients diagnosed with NAFLD, among which 183 were diagnosed with cirrhosis within ± 6 months from serum collection. Cirrhosis cases were identified based on ICD-9 and were individually validated by a health specialist (based on biopsy, imaging and/or clinical assessment data). Patients with matching age, gender, and metabolic syndrome features (n = 183) were selected as controls. All samples were analyzed with high-throughput liquid-

chromatography mass-spectrometry (LC-MS) based metabolomics and lipidomics. Logistic regression was used to identify a serum molecular signature of NASH-cirrhosis patients.
Results: We identified a novel metabolic signature of NASH-cirrhosis (NC-3) based on 3 serum metabolites and lipids (all of which could be readily associated with liver physiology). In a standard cross-validation test, NC-3 showed high diagnostic performance of liver cirrhosis, with an AUROC of 0.81; versus slightly lower AUROC of 0.78 by FIB-4. However, focusing on patients with intermediate FIB-4 levels (<2.67 and >1.3; cases = 66, controls = 87), the performance of NC-3 remains similarly high (AUROC = 0.81), markedly outperforming FIB-4 (AUROC = 0.68). Accordingly, focusing on matched T2D controls NC-3 shows high diagnostic performance for patients with intermediate FIB-4 levels (NC-3 AUROC = 0.81, compared to FIB-4 AUROC = 0.69, cases = 42 and controls = 45). Importantly, NC-3 performs similarly well when focusing strictly on patients without any sign of NASH-cirrhosis, having diagnosis confirmation within 1 to 6 months after serum collection (NC-3 AUROC = 0.85, compared to FIB-4 AUROC = 0.73).
Conclusion: NC-3 is a novel non-invasive method for the identification of patients with NASH-cirrhosis. The data suggests higher accuracy in FIB-4 indeterminate zone and in asymptomatic metabolic syndrome or T2D patients. The cost-efficiency of the metabolomics method would enable screening large at-risk populations, reducing the current high rates of NASH-cirrhosis under-diagnosis.

SAT-424
Comparison between EASL and AGA algorithms for hepatology referral in 1572 outpatients with type 2 diabetes and suspected NAFLD seen in a diabetes clinic
Laurent Castéra[1], Tiphaine Vidal-Trecan[2], Tania Khoury[3], Jean-Baptiste Julla[2], Jean-Pierre Riveline[4], Valérie Paradis[5], Dominique Valla[1], Jean-François Gautier[4]. *[1]Beaujon hospital, Université Paris Cité, Hepatology, Clichy, France; [2]Lariboisiere hospital, Diabetology, Paris, France; [3]Beaujon hospital, Hepatology, Clichy, France; [4]Lariboisiere hospital, Université Paris Cité, Diabetology, France; [5]Beaujon hospital, Université Paris Cité, pathology, clichy, France*
Email: laurent.castera@bjn.aphp.fr

Background and aims: Recently, two algorithms screening patients at risk for NAFLD and advanced fibrosis to decide if a referral to a hepatologist is needed have been proposed by EASL (J Hepatol 2021) and AGA (Kanwal Gastroenterology 2021). Screening of patients with type 2 diabetes (T2D), who are the most at risk of advanced fibrosis, is an unmet need. We aimed to compare the performance of these two algorithms in term of hepatology referral in a large cohort of T2D outpatients seen in a diabetes clinic.
Method: 1572 T2D outpatients seen in our diabetes clinic between October 2019 and February 2022, were systematically screened for NAFLD (steatosis and/or elevated ALT) and underwent FIB-4 and liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE). Excessive alcohol consumption and viral hepatitis B and C were excluded. According to EASL algorithm, patients with FIB-4 ≥1.3 should undergo VCTE and those with LSM ≥8 kPa should be referred to a hepatologist. According to AGA algorithm, patients with FIB-4 >2.67 or with FIB-4 between 1.3 and 2.67 and LSM ≥8 kPa should be referred to a hepatologist.
Results: The characteristics of the 1572 patients were as follows: male 60%; median age 61 years; BMI 29 kg/m^2; waist circumference 103 cm; HbA1c 7.6%; AST 28 IU/L; ALT 28 IU/L. A liver biopsy (LB) was performed in 163 patients (advanced fibrosis 30%). Comparison of the two algorithms is shown in the Figure. According to EASL, 186 (12%) should be referred to a hepatologist (LSM ≥8 kPa). The 1386 remaining patients were considered at low risk. According to AGA, 227 patients (15%) should be referred (132 at high risk (FIB-4 >2.67 or LSM >12 kPa) and 95 at intermediate risk). The 1345 remaining patients were considered at low risk. Among the 163 patients with LB, the rate of false positive was higher than that of false negative and similar between algorithms (38%, and 15%, respectively).
Conclusion: EASL and AGA algorithms performed similarly allowing to identify 12 to 15% of intermediate-high risk T2D patients, who should be referred to a hepatologist. These numbers are higher than reported in the general population, highlighting the urgent need for screening these patients.

SAT-425
Non-Alcoholic Steatohepatitis impacts on visceral adipose tissue proteomic signature
Cristian Martínez Navidad[1], Cristina Placed[2], Helena Castañé[1], Andrea Jiménez Franco[2], Jordi Camps[3], Jorge Joven[3]. *[1]Fundació IISPV, Unitat de Recerca Biomèdica, Reus, Spain; [2]Universitat Rovira i Virgili, Unitat de Recerca Biomèdica, Reus, Spain; [3]Hospital Universitari San Joan de Reus, Unitat de Recerca Biomèdica, Reus, Spain*
Email: cristian.marnav@gmail.com

Background and aims: Obesity is a major global health concern due to its growing prevalence and associated diseases, leading to reduce the quality and life expectancy of those affected. Non-alcoholic

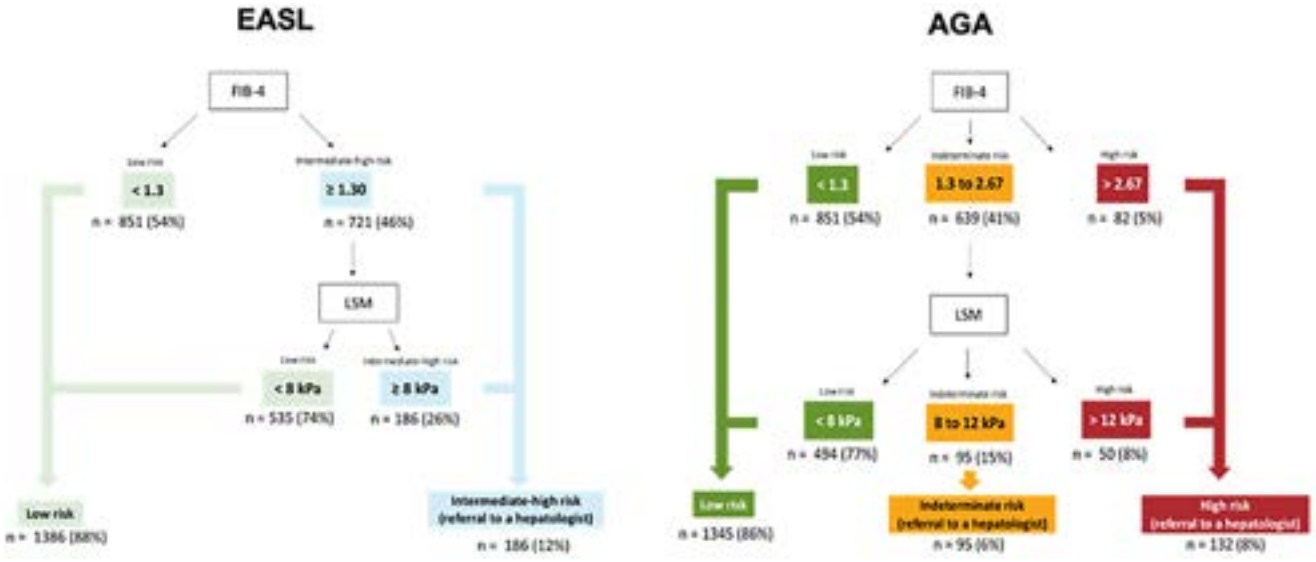

Figure: (abstract: SAT-424): Comparison of AGA and EASL algorithms in 1572 T2D outpatients

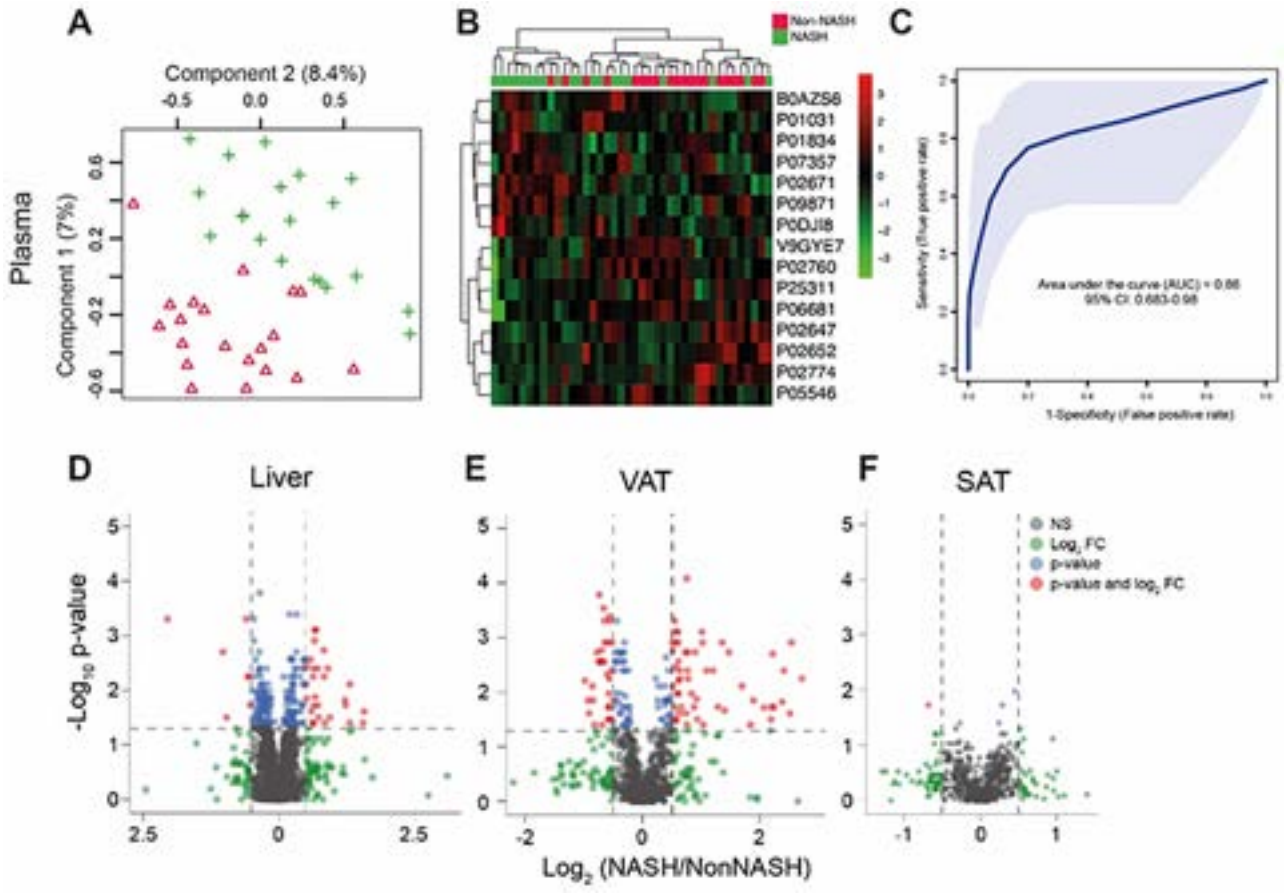

Figure: (abstract: SAT-425).

steatohepatitis (NASH), a form of non-alcoholic fatty liver disease (NAFLD), is commonly linked to obesity and manifests as liver damage and inflammation, caused by the fat accumulation. The diagnosis of NASH is challenging due to its silent and non-specific symptoms, often going undetected until late stages of the disease. Proteomics allows us to examine the mechanisms involved in these biological successes. The objective is to investigate the differences in protein profiles of plasma, liver and adipose tissue between NASH and non-NASH patients using proteomic analysis, with the goal for identifying a biological marker for earlier NASH diagnosis.

Method: To carry out the analyses, plasma samples were collected from patients undergoing bariatric surgery (n = 40), including patients with NASH (n = 20) and patients without NASH (n = 20). Additionally, biopsies of a portion of these (n = 18) were obtained to perform a proteomic analysis of visceral adipose tissue, subcutaneous adipose tissue and liver to determinate possible biomarkers that would differentiate patients with NASH (n = 9) form patients without it (n = 9).

Results: Multivariate analysis revealed differences in plasma proteomic profiles between NASH and non-NASH groups. A PCA showed highlight P09871 to be significantly reduced and P25311 and V9GYE7 significantly increased in NASH patients. PLSDA (A) and heat map (B) analyses provide a separation with almost no overlap between both groups of patients. These results suggest that the difference on the plasma proteomic profile has diagnostic capacity (C). As for the liver (D), multivariate analysis revealed a significantly increasing on P1640 and K7EIV0 and a decreasing of A0A087X1G1 between both groups. These suggest that the liver proteomic profiles also have diagnostic potential. In addition to the impact on plasma and liver, a signature has also been observed in visceral adipose tissue (E), characterized by increasing of P12814 and decreasing P53007. In subcutaneous adipose tissue (F), no NASH proteomic signature is observed.

Conclusion: Patients with NASH present significant differences in the proteome of plasma, liver and visceral adipose tissue compared to patients without the pathology. In the liver, there is an increase in proteins associated with cell growth and inflammation, and a decrease in mitochondrial respiration. In visceral adipose tissue, proteins linked to mitochondrial metabolism decrease and those related to the cytoskeleton increase. However, no proteomic signature is observed in subcutaneous adipose tissue.

SAT-426

AI-enabled virtual hematoxylin and eosin and Masson's trichrome staining for non-alcoholic fatty liver disease activity scoring from single unstained slide

Carson McNeil[1], Pok Fai Wong[1], Niranjan Sridhar[1], Yang Wang[1], Charles Santori[1], Cheng Hsun Wu[1], Andrew Homyk[1], Michael Gutierrez[1], Ali Behrooz[1], Dina Tiniakos[2], Alastair Burt[2,3], Rish Pai[4], Kamilla Tekiela[1], Po-Hsuan Cameron Chen[5], Sudha Rao[1], Debra Hanks[1], Shamira Sridharan[1], Eduardo Bruno Martins[6], Star Seyedkazemi[6], Laurent Fischer[6], Charlie Kim[1], Peter Cimermancic[1]. *[1]Verily Life Sciences, United States; [2]Newcastle University, United Kingdom; [3]The University of Adelaide, Adelaide, Australia; [4]Mayo Clinic, Scottsdale, United States; [5]Google, Mountain View, United States; [6]Allergan, United States*
Email: cpeter@verily.com

Background and aims: Pathologists' interpretation of disease activity using hematoxylin-and-eosin (HandE) and Masson's trichrome (MT) stained slides from liver biopsies is the current gold standard for monitoring response in non-alcoholic steatohepatitis

(NASH) clinical trials. However, staining and scoring variability, and limited tissue availability have created challenges in NASH clinical trials that impact efficiency, cost, and end point assessment. Our aim was to develop a virtual staining approach that relies on digitization and computational prediction of HandE and MT from a single unstained tissue section. This approach reduces the need for chemical staining and the amount of tissue used.

Method: We present a novel digital pathology platform that digitizes information in unstained tissue sections and then uses machine learning to perform virtual staining. The tissue is digitized using autofluorescence (AF) imaging of unstained tissue at hundreds of excitation-emission wavelength pairs using a hyperspectral microscope developed at Verily. The virtual staining step utilizes recent advances in computer vision and deep learning. Importantly, the platform is non-destructive, with the tissue samples remaining unstained and available for other analyses. To develop the virtual staining module, paired AF and stained images of the same tissue sections were collected by imaging 200 unstained liver biopsies from the completed Phase 2b CENTAUR trial, followed by HandE or MT staining and scanning. The virtual stains were evaluated on an independent test set of 45 cases using a reader study with 3 adjudicator hepatopathologists (co-authors of this abstract), as follows: (a) all cases were presented to each pathologist in a randomized order and blinded to the stain modality (real or virtual); (b) consensus scores based on NASH Clinical Research Network (NASH CRN) system were generated via in-person adjudication; (c) the accuracy of virtual stains was measured by computing linearly-weighted Kappa values between adjudicated NASH CRN scores on real versus virtual stains. Additionally, 9 hepatopathologists (not authors) scored the same set of chemically stained cases to measure inter-observer variation on real stains. We define success of virtual staining by real versus virtual kappa values being non-inferior to those from inter-observer variation on real stains.

Results: In the blinded and randomized adjudication reader study, concordance (linearly-weighted kappa) of NASH-CRN scores derived from virtual stains versus real stains were 0.86 (95% CI [0.74, 0.96]), 0.33 (95% CI [0.06, 0.57]), 0.76 (95% CI [0.61, 0.88]), and 0.55 (95% CI [0.35, 0.70]) for steatosis, lobular inflammation, ballooning, and Ishak fibrosis stage, respectively. The Kappa values for inter-observer variability were 0.57 (95% CI [0.49, 0.65]), 0.28 (95% CI [0.17, 0.40]), 0.31 (95% CI [0.22, 0.40]), and 0.50 (95% CI [0.39, 0.61]), respectively.

Conclusion: The virtual staining platform generates HandE and MT images equivalent to chemical stains as demonstrated by the equivalence of hepatopathologist NASH-CRN scoring of liver biopsies. This demonstrates the high potential for improving efficiency and maintaining consistency of histopathologic end point assessment. Furthermore, the tissue-sparing stain-free system conserves tissue for downstream analyses.

SAT-427

Practical diagnosis of cirrhosis by liver specialists in non-alcoholic fatty liver disease using currently available non-invasive fibrosis tests

Jerome Boursier[1], Marine Roux[1], Charlotte Costentin[2], Julien Chaigneau[1], Céline Fournier-Poizat[3], Aldo Trylesinski[4], Clémence M Canivet[1], Sophie Michalak[5], Brigitte Le Bail[6], Valérie Paradis[7], Pierre Bedossa[8], Nathalie Sturm[2], Victor de Lédinghen[6], Philip N Newsome[9]. *[1]Angers University, France; [2]Grenoble University Hospital, France; [3]Echosens, France; [4]Advanz Pharma, United Kingdom; [5]Angers University Hospital, France; [6]Bordeaux University Hospital, France; [7]APHP Beaujon, France; [8]Liverpat, France; [9]Birmigham University, United Kingdom*
Email: jeboursier@chu-angers.fr

Background and aims: Unlike for advanced liver fibrosis, the practical rules for the early non-invasive diagnosis of cirrhosis in NAFLD remain not well defined. We aimed to develop and validate an accurate diagnosis of cirrhosis in NAFLD using the best non-invasive tests currently available to liver specialists.

Method: Patients with NAFLD and liver biopsy from four independent cohorts were allocated to derivation and validation sets according to a phase 3 TRIPOD design. All patients had six non-invasive fibrosis tests utilizing different modalities (elastography, blood tests) and dedicated to different diagnostic targets (advanced liver fibrosis, cirrhosis): FIB4, FibroMeter^{V3G}, CirrhoMeter^{V3G}, Fibroscan, Agile3+, and Agile4. Cirrhosis was defined as fibrosis stage F4 according to the NASH CRN staging.

Results: 1,568 patients were included (872 in the derivation set, 696 in the validation set). Median age was 57.6 years, 59.1% of the patients were male, median biopsy length was 25 mm, and the prevalence of cirrhosis was 12.1%. AUROC for cirrhosis were: 0.816 ± 0.016 (FIB4), 0.820 ± 0.016 (FibroMeter^{V3G}), 0.812 ± 0.017 (CirrhoMeter^{V3G}), 0.870 ± 0.013 (VCTE), 0.893 ± 0.011 (Agile3+), and 0.893 ± 0.012 (Agile 4). However, despite this good to very good global accuracy, fibrosis tests showed an imbalance with a much better accuracy to rule out cirrhosis than to rule-in the diagnosis. A stepwise algorithm, using first the Agile3+/Agile4 elastography-based tests and then the FibroMeter^{V3G}/CirrhoMeter^{V3G} specialized blood tests, was developed in the derivation set. This algorithm applied fibrosis tests in the same order as recommended by the 2021 EASL guidelines and provided stratification in four groups, the last of which being enriched in cirrhosis (71% prevalence in the validation set). We also derived a risk prediction chart to allow estimation of the individual

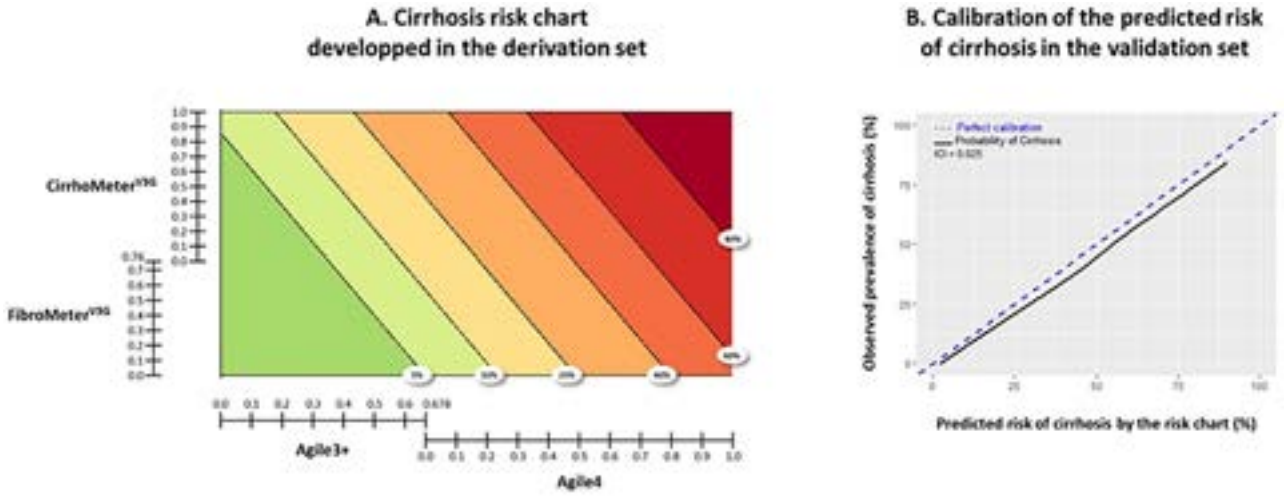

Figure: (abstract: SAT-427).

probability of cirrhosis (Figure). In the validation set, calibration of the predicted risk was excellent: the integrated calibration index was 0.025, and mean difference with perfect prediction was only −2.9% (extremes: −5%; −2%). Quantitative morphometric analysis confirmed that both approaches (sequential algorithm, risk prediction chart) stratified patients into subgroups with significantly different amounts of liver fibrosis.
Conclusion: The new tools we developed improve the personalized non-invasive diagnosis of cirrhosis in NAFLD patients.

SAT-428
Associations of genetic risk panel with enhanced liver fibrosis scores among patients with non-alcoholic fatty liver disease
Zobair Younossi[1,2,3], James M Estep[3], Sean Felix[3], Elena Younossi[3], Nagashree Gundu Rao[3], Leyla Deavila[3], Huong Pham[3], Rebecca Cable[3], Jillian Price[3], Andrei Racila[3], Maria Stepanova[3,4]. *[1]Inova Health System, Medicine Service Line, United States; [2]Inova Health System, Department of Medicine, Center for Liver Diseases, United States; [3]Beatty Liver and Obesity Research Program, Inova Health System, United States; [4]Center for Outcomes Research in Liver Disease, United States*
Email: zobair.younossi@inova.org

Background and aims: Genetic risk factors have been linked to advanced histologic stage of fibrosis among patients with NAFLD. It is unknown if these genetic risk factors are also associated with non-invasive biomarkers such as enhanced Liver Fibrosis (ELF) and FIB-4. Our aim was to assess the associations of select SNPs with the risk of having elevated ELF and FIB-4 in NAFLD.
Method: After informed consent, clinical data, serum and whole blood were collected from patients with NAFLD. In addition to standard laboratory test (liver enzymes, platelet count, to calculate FIB-4), ELF score was measured (ADVIA Centaur, Siemens Healthineers). Genomic DNA was extracted from the whole blood [QIAamp DNA Blood Mini Kit (Qiagen)] and used for determination of minor allele frequency for genomic loci rs641738 (MBOAT7), rs58542926 (TM6SF2), rs738409 (PNPLA3), rs62305723 (HSD1713B) using CFX96 (BioRad). Individual alleles were evaluated for the association with elevated (≥9.8) and high (≥11.3) ELF, elevated FIB-4 (>2.67) in NAFLD.
Results: There were 953 NAFLD patients included: 57 ± 14 years, 57% male, BMI 34.0 ± 9.1, 33% type 2 diabetes. Of those, 83% had low ELF (<9.8), 14.5% had elevated ELF (9.8–11.2) and 2.5% had high ELF (≥11.3). Furthermore, 6.9% had elevated FIB-4 score (>2.67). Of the studied four SNPs, only PNPLA3-rs738409 (51% CC, 42% CG, 7% GG) was significantly ($p < 0.05$) associated with elevated and high ELF scores: elevated ELF 12% in CC vs. 19% in CG/GG, high ELF 0.7% in CC vs. 4.1% in CG/GG (both $p < 0.01$). In multivariate analysis adjusted for age, sex, BMI and type 2 diabetes, having PNPLA3-rs738409 CG/GG genotype was independently associated with increased risk of elevated and high ELF: odds ratio (OR) = 1.87 (1.25–2.78) for elevated ELF, OR = 5.82 (1.67–20.30) for high ELF (both $p < 0.01$). Similarly, only PNPLA3-rs738409 CG/GG was associated with elevated FIB-4: 5.1% in CC vs. 8.0% in CG vs. 13.7% in GG ($p = 0.05$). In multivariate analysis, having PNPLA3-rs738409 CG/GG genotype was independently associated with a higher risk of elevated FIB-4: odds ratio (OR) = 2.10 (1.13–3.90) ($p = 0.019$).
Conclusion: The well-known SNP in the PNPLA3 gene linked to advanced histologic fibrosis is also associated with elevated/high ELF and FIB-4 scores in NAFLD. These data validate the association of non-invasive biomarkers with the genetic risks in NAFLD.

SAT-429
Morphometric analysis of sonic hedgehog in non-alcoholic fatty liver steatohepatitis patients by MorphoQuant: a potential biomarker of disease severity
Cindy Serdjebi[1], Bastien Lepoivre[1], Florine Chandes[1], Linda Willis[2], Julé Yvon[1]. *[1]Biocellvia, Marseille, France; [2]Histologix Ltd, United Kingdom*
Email: cindy.serdjebi@biocellvia.com

Background and aims: Sonic hedgehog (Shh) is an important pathway activated in non-alcoholic fatty liver diseases and its expression is known to increase along with the severity of non-alcoholic steatohepatitis (NASH). In addition, computer-assisted morphometry previously demonstrated that Shh expression was associated with ballooning degeneration score as well as fibrosis grading. Yet, the use of this immune-histo-chemistry (IHC) has long been ignored in the current general practice and/or in clinical trials. In this study, we have developed and a fully automated morphometry software to detect and quantify Shh expression and investigated the interest of measuring the area of active injury in patients' liver biopsies.
Method: Liver biopsies were scored by a blinded expert pathologist according to the NASH CRN for steatosis, inflammation, ballooning and fibrosis. Shh labeling was developed using SG vector as chromogen. MorphoQuant, a fully automated and deterministic artificial intelligence, based on morphometry and expert system-completely independent from pathologist's annotations, was developed to specifically detect Shh and areas of active liver injury from whole slide images. As an edge effect was seen on a significant number of labeled slides, a 150-µm safety margin was automatically removed from all biopsy fragments before analysis. The quantitative data of Shh expression and areas of active injuries were thus compared to the pathologist's reading and correlations were calculated using the Spearman correlation test for fibrosis, steatosis, lobular and portal inflammation, Mallory-Denk bodies, interface hepatitis, NAS and NASH status.
Results: A total of 271 slides were processed for quantitative image analysis by MorphoQuant. Results are presented in Table 1. Shh was expressed in all patients, 5.49 ‰ in average, ranging from 0.046 to 44.88 ‰ while active injury area ranged from 0 to 82.06 ‰ with a mean at 5.239 ‰. Both Shh and active injury area were higher in NASH than in non-NASH patients (6.428 vs 3.270; 6.632 vs 1.943, respectively; p values <0.0001 for both). Shh was significantly associated with fibrosis, ballooning, lobular inflammation, interface hepatitis, Mallory-Denk bodies, NAS and NASH status. Active injury area also correlated with the same items, though the strength of the correlation was systematically higher for all the compared items.
Conclusion: The current study demonstrates the utility of Shh IHC to discriminate NAFLD from NASH patients. Active injury always correlated more with the histopathological reading than Shh, identifying this new readout as a potential biomarker for disease activity.

SAT-430
Burden of non-alcoholic fatty liver disease and usefulness of non-invasive tests to identify advanced liver disease in patients with type 2 diabetes mellitus: interim analysis of an Italian prospective multicentre study

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is closely associated with type 2 diabetes mellitus (T2DM). However, systematic data on the epidemiology and severity of NAFLD in T2DM are scarce and mostly relying on data from gastroenterological referral centers.
In a cohort of diabetic patients consecutively referred by Diabetes Units, we aimed to assess a) the prevalence of NAFLD and the prevalence of advanced liver fibrosis and compensated advanced chronic liver disease (cACLD) and b) to investigate the efficacy of a model of care based on the sequential use of non-invasive tests (NITs) and vibration controlled transient elastography (VCTE) for the identification of patients at risk of advanced liver disease.
Method: From April 2021 to August 2022, a total of 461 consecutive patients with T2DM attending 6 different diabetes referral centers were prospectively enrolled. Liver stiffness (LS) was assessed by VCTE and liver steatosis by controlled attenuation parameter (CAP). Liver steatosis was defined according to CAP values ≥275 dB/m. AVTCE cut-off value of 8.0 kPa was used to rule out advanced liver fibrosis, while cACLD was defined according to liver stiffness (LS) values ≥10.0 kPa. The following NITs were calculated: AST-to-platelets ratio (APRI), Fibrosis-4 (FIB-4), and NAFLD fibrosis score (NFS). The cut-offs adopted to rule-out advanced liver disease were 0.5 for APRI, 1.3 for FIB-4, and −1.455 for NFS.
Results: Overall 413 out of 461 patients underwent VCTE + CAP. Patients' median age was 58 (52–63) years and 241 (58.4%) of them were males; 288 (69.7%) patients were obese (BMI >30 kg/m^2) and 245 (59.3%) had arterial hypertension. Elevated liver enzymes (ALT and/or AST and/or γGT) were found in 116 (28.1%) patients. Liver steatosis by CAP was detected in 257 (62.2%) patients, among them 57 (22.2%) had a LS ≥8 kPa, while 36 (14.1%) had a LS ≥10 kPa. In our cohort of T2DM patients, the sequential use of NITs followed by VCTE would have resulted in the highest hepatologist referral rate for NFS (20.0%), followed by FIB-4 (11.9%) and APRI (5.5%). The lowest probability of missing advanced liver fibrosis was observed for NFS (5.8% of patients with NFS <-1.455 and LS ≥8.0 kPa) in spite of the highest VCTE referral rate (71.1% vs 32.6% for FIB-4 and 9.7% for APRI, respectively). On the contrary, screening by FIB-4 could spare a substantial number of VCTE (Table 1).

Figure:

NITs	VCTE referral rate	Hepatologist referral rate (LS ≥8.0 kPa)	False negative (LS ≥8.0 kPa)
APRI ≥0.5	9.7%	5.5%	16.9%
FIB-4 ≥1.3	32.6%	11.9%	10.6%
NFS ≥-1.455	71.1%	20.0%	5.8%

Conclusion: In patients with T2DM and NAFLD, the prevalence of advanced liver fibrosis by VTCE is approximately 22%, while cACLD can be found in 14% of subjects. In Diabetes Units, pre-screening by NFS or FIB-4 is the most convenient referral approach to hepatologists for the identification of T2DM patients at risk of advanced liver fibrosis by VTCE.

SAT-431

LIVERFASt GP+, first-line screening tool in at-risk MAFLD patients outperforms the standard-of-care (SOC) FIB-4

Ronald Quiambao[1], Paul Hermabessière[2], Adele Delamarre[3], Imtiaz Alam[4,5], Juan Manuel Minoz Perez[6], John Lee[7], Mona Munteanu[1], Victor de Lédinghen[8]. *[1]Fibronostics, Medical Affairs, United States; [2]CHU Bordeaux, Hepatology Department, United States; [3]CHU Bordeaux, France; [4]Austin Hepatitis Center, United States; [5]Dell Medical School, United States; [6]Fibronostics, IT, United States; [7]Fibronostics, IT, Singapore; [8]CHU Bordeaux, Hepatology, France*
Email: mona_munteanu@hotmail.com

Background and aims: LIVERFASt GP+ (GP+) is a AI-based blood test conceived for the screening of MAFLD at risk subjects. GP+ combines common blood biomarkers (lipid panel, liver enzymes, glucose and bilirubin) with patient's anthropometrics. Recently, GP+ has been validated to predict the short-term severe outcomes in those patients infected with SARSCov-2 virus and liver fibrosis. (Hepatology-Suppl2022). The primary aims of this retrospective analysis was: 1/ to construct and validate a new MAFLD screening test, GP+, noninferior to the SOC reference, FIB-4, for bridging fibrosis (F3F4 stages), and 2/with less drawbacks related to age-adapted cutoffs.
Method: N = 580 MAFLD patients prospectively included with liver biopsy and concomitant GP+ and FIB-4 were randomly assigned in

two subsets. GP+ was trained to identify the presumed MAFLD clinical stages: N0 no-fibrosis/steatosis, N1 steatosis only, N2 fibrosis non-bridging, N3 fibrosis bridging with reference the liver biopsy and using AUROCs (95%CI).
Results: Characteristics: 56% males, median age 59.5yo, BMI 31.5, ALT 55IU/l. The AUROCs for F3F4, for GP+ and FIB-4 in the subsets 1 and 2 were, respectively: 0.806 (0.737–0.841) vs. 0.807 (0.630–0.756, p = NS) and 0.759 (0.701–0.808) vs. 0.757 (0.698–0.805, p = NS) in the subset 2. FIB4 underperformed in males aged ≥65yo for identifying F3F4 stages in both subsets 1 and 2: 0.586 (0.451–0.695, p = NS vs. hazard and p = 0.02 vs GP+).

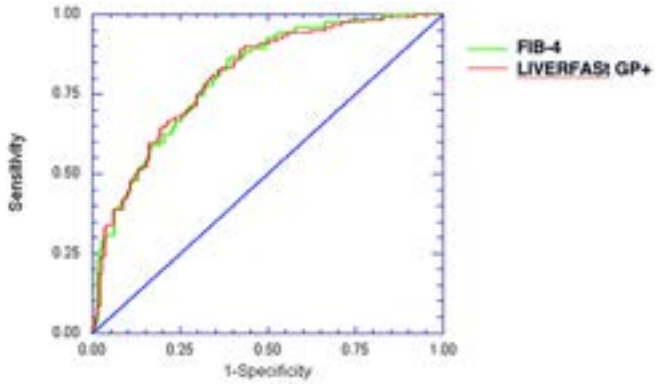

Figure: AUROCs (95%CI) for bridging fibrosis in the subset 1 of FIB-4 and LIVERFASt GP+

Conclusion: In a MAFLD cohort LIVERFASt GP+, compared to FIB-4, demonstrated several advantages to identify MAFLD from steatosis to bridging fibrosis without grey zone and no drawbacks related to age and male gender.

SAT-432

Velacur ACE outperforms CAP for liver fat quantification using MRI PDFF as the gold standard

Rohit Loomba[1], Alnoor Ramji[2], Tarek Hassanein[3], Emily Peng[4], Caitlin Schneider[5], Michael Curry[6]. *[1]University of California San Diego, La Jolla, United States; [2]The University of British Columbia, Vancouver, Canada; [3]Southern California Research Center, United States; [4]Vancouver Coastal Health (VCH), Vancouver, Canada; [5]Sonic Incytes Medical Corp., Vancouver, Canada; [6]Beth Israel Deaconess Medical Center, Boston, United States*
Email: caitlin@sonicincytes.com

Background and aims: With the global rise of non-alcoholic fatty liver disease (NAFLD) and the potential new therapeutics, it is imperative to accurately measure the amount of fat in the liver. Although Magnetic Resonance Imaging Proton Density Fat Fraction (MRI PDFF) has become the gold standard in non-invasive liver fat assessment, two point of care methods are presented here in comparison to MRI PDFF; Velacur's Attenuation Coefficient Estimation (ACE) and FibroScan's Controlled Attenuation Parameter (CAP).
Method: Velacur ACE was compared to CAP in patients with clinically proven NAFLD or non-alcoholic steatohepatitis (NASH). The study was completed at five sites in the US and Canada. All patients received a contemporaneous magnetic resonance imaging proton density fat fraction (MRI PDFF) scan. Using the MRI PDFF cut offs of 5%, 15%, and 20%, the AUROC and 95% confidence intervals were computed for both ACE and CAP, allowing for the optimal cutoff for this set of patients. Delong's test was used to compare the AUC's. The overall correlation coefficient and correlation for BMI categories for both ACE and CAP to MRI PDFF was calculated.
Results: A total of 164 patients were enrolled into this study. Of these, 132 had complete data sets. The average MRI PDFF for all patients was 13.8 ± 8.7%, with the average for ACE and Cap being 310. ± 54 dB/m and 304. ± 60 dB/m respectively. There were 21, 56, 26 and 29 patients in the ≤5%, 5–15%, 15–20% and >20% groups respectively. Using the MRI PDFF cut offs of ≤5%, ≤15%, and ≤20%, ACE was able to separate the patients with AUROC [95% confidence interval] of 0.816 [0.715, 0.907], 0.878 [0.823, 0.940] and 0.902 [0.846, 0.945] respectively. CAP has AUC's of 0.859 [0.766, 0.919], 0.820 [0.731, 0.891] and 0.797 [0.700, 0.864]. DeLong's test showed that the AUC of ACE and CAP were statistically different for separation patients with >20% fat. The correlation coefficient (r) between ACE and PDFF was 0.69, while r for CAP and PDFF was 0.59. When separating the patients into <27 kg/m^2, 27–33 kg/m^2, and ≥33 kg/m^2, the correlation coefficients were 0.71, 0.68, and 0.68 for ACE, and 0.60, 0.58, and 0.59 for CAP respectively.

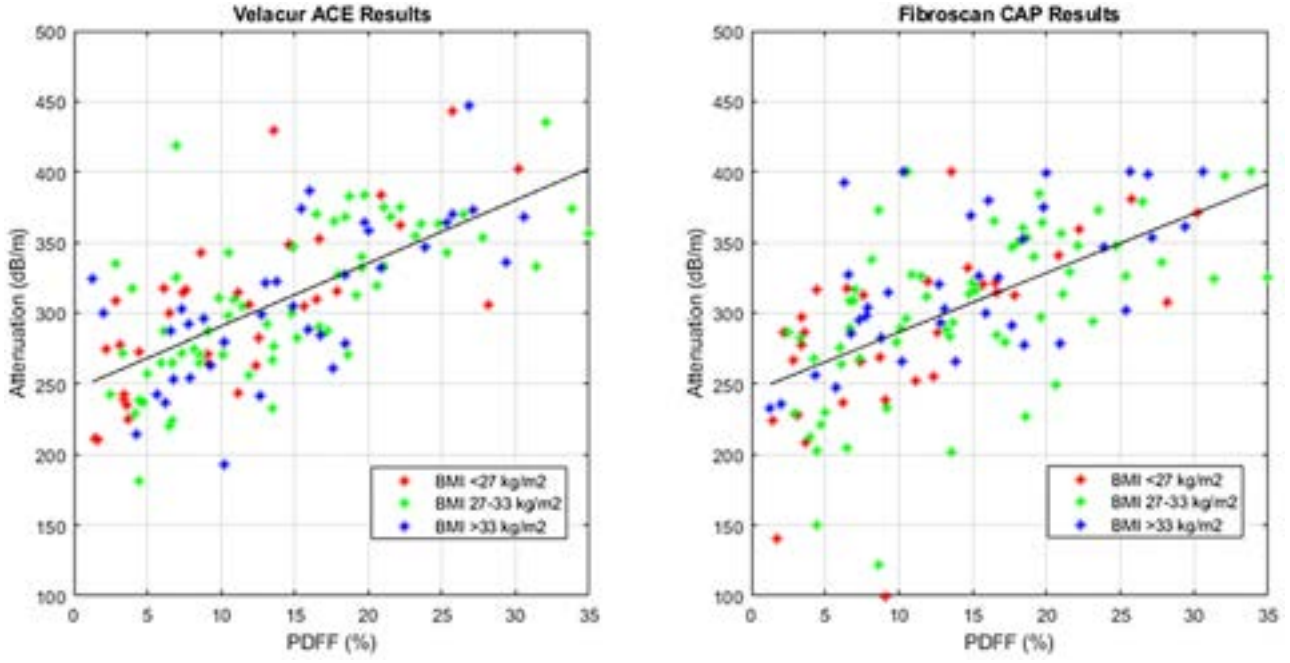

Figure: (abstract: SAT-432).

When examining the graph, colored by BMI category, there were 5 patients with CAP of 390 dB/m or more but MRI PDFF ≤20% indicating a possible overestimation by CAP. Of these, 60% were in the highest BMI category.

Conclusion: At each fat percentage, Velacur ACE shows a numerically higher AUC than FibroScan CAP and was statistically different for patients with the highest measures of liver fat.

The correlation coefficients between ACE and MRI PDFF were greater than that of CAP, in all patients and in each BMI category.

Velacur ACE was shown to be a superior point-of-care method for measuring liver fat in patients with NAFLD and NASH.

SAT-433

Assessing the role of organokines as biomarkers for diagnosing non-alcohol related liver disease

Andrea Jiménez Franco[1], Cristian Martínez Navidad[2], Cristina Placed[1], Helena Castañé[2], Jordi Camps[3], Jorge Joven[3]. [1]*Universitat Rovira i Virgili, Unitat de Recerca Biomèdica, Reus, Spain;* [2]*Fundació IISPV, Unitat de Recerca Biomèdica, Reus, Spain;* [3]*Hospital Universitari Sant Joan de Reus, Unitat de Recerca Biomèdica, Reus, Spain*
Email: andreajfranco99@gmail.com

Background and aims: Non-alcoholic Fatty Liver Disease (NAFLD) and obesity are widespread global health issues. NAFLD starts as simple fat buildup in the liver and can progress to non-alcoholic

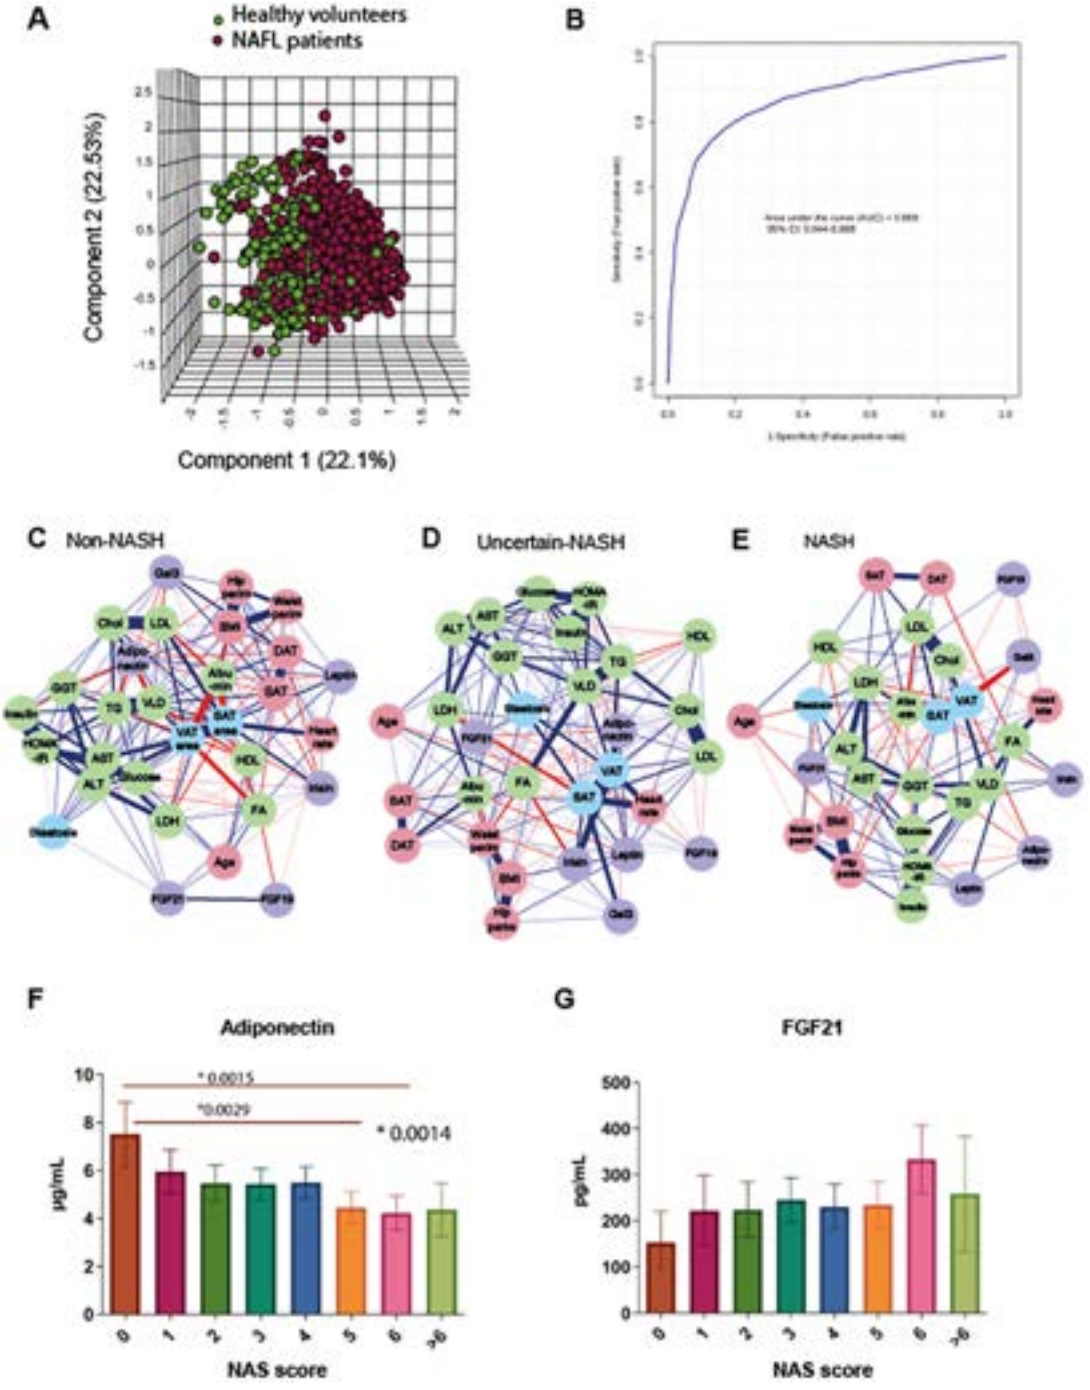

Figure: (abstract: SAT-433).

steatohepatitis (NASH), a more severe stage that involves inflammation and tissue damage. The gold standard for diagnosing NAFLD/NASH progression is liver biopsy. As the disease progresses, the body regulates metabolic and physiological changes in organs through cytokines or organokines, but the intricacy of this inter-tissue communication remains unclear. This study aims to measure the concentration of six organokines in plasma and evaluate their role in the progression of obesity-related NAFLD.

Method: Plasma samples from 1068 NAFLD patients with obesity and different stages and 414 healthy volunteers were analyzed using sandwich Enzyme-Linked ImmunoSorbent Assay (ELISA) to determine the concentration of Adiponectin, Leptin, Irisin, Galectin2, Fibroblast growth factor 19 (FGF19), and Fibroblast growth factor 21 (FGF21).

Results: We identified significant differences in the organokines profile between healthy volunteers and patients with obesity-related NAFLD (Figure A). Combining the six organokines produced an Area under de Curve (AUC) of 0.860 in the Receiver Operating Characteristics (ROC) curve, suggesting their potential as a diagnostic biomarker (Figure B). Correlation network showed different associations between clinical variables and organokines on the different stages of NAFLD (Figure C, D, and E). Adiponectin and FGF21 demonstrated the ability to differentiate between NASH, uncertain NASH, and non-NASH groups (Figure F and G). Although Adiponectin and FGF21 showed significant differences in classifying patients based on liver histology, they were not strong enough as fibrosis biomarkers

Conclusion: Significant differences were found between healthy volunteers and NAFL patients regarding the analyzed organokines' profile. However, only Adiponectin and FGF21 were found to be associated with NAFLD progression. Organokines' concentration was not significantly related to hepatic histological features.

SAT-434

Evaluating the prevalence of liver fibrosis in children with non-alcoholic fatty liver disease using transient elastography, Dutch Fibrokids cohort

Jalina Rooseboom[1], Laura Draijer[1], Malika Chegary[2], Marc Benninga[1], Bart Koot[1]. *[1]Amsterdam University Medical Centre, Pediatric Gastroenterology, Amsterdam, Netherlands; [2]OLVG Hospital, General Pediatrics, Netherlands*
Email: j.b.rooseboom@amsterdamumc.nl

Background and aims: Major international guidelines currently recommend screening for non-alcoholic fatty liver disease (NAFLD) in children with obesity, but the method for screening is not forthright due to insufficient evidence. This study evaluates the screening for advanced NAFLD guided by alanine aminotransferase (ALT) based screening algorithm and identifies additional risk factors for probable significant fibrosis.

Method: A prospective cohort study in children (8–18 years) with obesity or overweight with at least one metabolic risk factor visiting our University Clinic after referral from local obesity outpatient clinics. Referral was based on the three ALT thresholds defined in the NASPGHAN 2017 Clinical Practice Guideline. Additionally, a fourth group of children with obesity and normal ALT was analysed. Transient elastography (Fibroscan) was used to detect probable significant fibrosis with a cut-off of 7.4 kPa.

Results: Our cohort consisted of 322 children, 64% male. Median age 13 years [11.00, 15.75], BMI z-score 3.5 (0.63). The prevalence of probable significant fibrosis differed significantly from 1.9% in the normal ALT group and 16.3%, 18.6% and 41.2% in three elevated ALT groups ($p < 0.001$). (Figure 1). Lasso regression for variable selection with subsequent logistic regression showed that fibrosis was correlated with male gender (OR = 2.98) higher age (OR = 1.39), ALT>80 IU/L (OR = 15.66), higher BMI z-score (OR = 3.20) and presence of acanthosis nigricans (OR = 5.67).

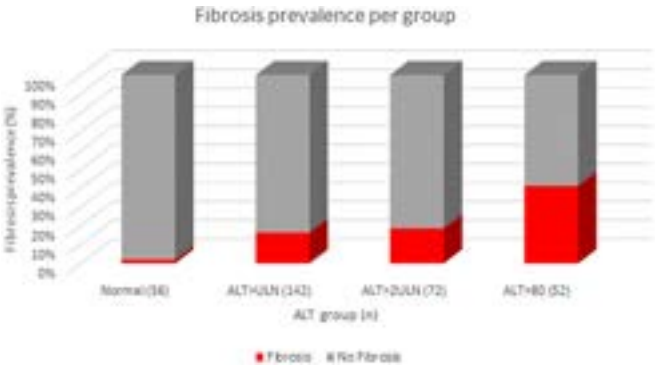

Figure:

Conclusion: ALT is a strong predictor of probable significant fibrosis in screening population of children with obesity and overweight, supporting its use as a primary screening test. Fibrosis evaluation for children with obesity with ALT>80 IU/L seems warranted. In children with lower elevated ALT levels this needs further evaluation balancing risk, benefits and costs. Gender, age, BMI and presence of acanthosis nigricans could be taken into account in this consideration.

SAT-436

The impact of projected increases in obesity prevalence on incident liver disease in the UK: insights from bayesian-network modelling

Tom Waddell[1,2], Ana Namburete[3], Paul Duckworth[1], Daniel Cuthbertson[4], Celeste McCracken[5], John Michael Brady[2]. *[1]The University of Oxford, Department of Engineering Science, Oxford, United Kingdom; [2]Perspectum Ltd, United Kingdom; [3]The University of Oxford, Department of Computer Science, Oxford, United Kingdom; [4]University of Liverpool, United Kingdom; [5]The University of Oxford, United Kingdom*
Email: tom.waddell@perspectum.com

Background and aims: Obesity is a complex multi-system disease and a growing public health challenge. Recent projections estimate that 71% of adults living in England will be overweight or obese by 2040, with the percentage of people living with obesity (37%) surpassing that of those of a 'healthy weight'. Obesity is associated with non-alcoholic fatty liver disease and non-alcoholic steatohepatitis (NASH) and a complex set of variables that interact in myriad ways. We use Bayesian-network (BN) analysis applied to a large UK-based cohort, specifically magnetic resonance imaging (MRI) derived measures of liver steatosis and fibroinflammation, both to explore likely projected increases in obesity prevalence and to illustrate the power of BN methods to address such complexity.

Method: Proton density fat fraction [PDFF]) and corrected T1 (cT1) were obtained from 27,002 UK Biobank cases (application 9914). These were combined with additional participant data to construct a BN. Each directed edge is supported by medical literature, making it a "semantic" BN. BNs explicitly model conditional dependencies as a directed acyclic graph, where network variables denote biomarkers and the directed edges connecting such variables the direction of *causality.* The probabilities of being normal weight, overweight, obese, and severely obese in this dataset were then fixed to 2040 projections (29%, 27%, 37% and 7%, respectively), and conditional probability queries explored the resultant changes in the probability of liver steatosis and NASH (defined by PDFF >10% and cT1 >800 ms).

Results: The rate of obesity in the study population was substantially lower than the UK population estimate (16% vs 29%). Fixing the variable 'Obesity' to 2040 projections resulted in an 8% (2160 participants), 5% (1350) and 3% (800) increase in the probability of severe steatosis (PDFF >10%), moderate steatosis (PDFF 5.6–10%) and NASH, respectively. We observed a 2% (470 participants) and 6% (1620 participants) increase in the probability of elevated blood glucose (HbA1c >42 mmol/mol) and hypertension, respectively.

Furthermore, when fixing the value of 'Obesity' to projected obesity estimates in areas of low socioeconomic status (46%), we observed an additional 1440 and 550 participants with severe steatosis and NASH, respectively, above our previous estimates for the entire UK population. Such increases equate to an additional £~7.5 million in direct NASH-related costs within our population of 27,002 participants, only <1% of the entire UK population.

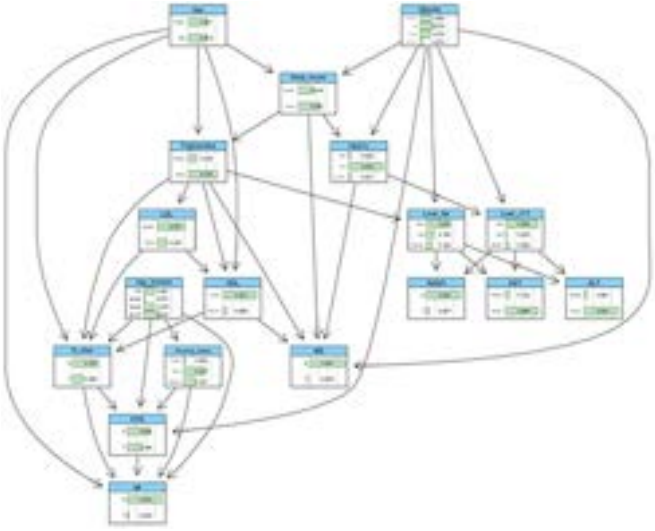

Figure: Bayesian-network structure (here the probabilities of 'Obesity' have been fixed to 2040 projections). Waist circum = waist circumference; LDL = low density lipoprotein; HDL = high density lipoprotein; H_chol = high cholesterol; HTN = hypertension; MI = myocardial infarction; MS = metabolic syndrome.

Conclusion: BN analysis models the complexity of liver disease and, in this case, illustrates a 'best case scenario' of the impact of projected increases in obesity on liver disease. This disproportionately impacts areas of low socio-economic status, and the cost associated with increasing rates of NASH.

SAT-437

The prevalence and predictors of non-alcoholic fatty liver disease by vibration controlled transient elastography among lean adults in the United States

Ifrah Fatima[1], Mohamed Ahmed[1], Wael Mohamed[1], Alisa Likhitsup[2]. [1]*University of Missouri- Kansas City School of Medicine, United States;* [2]*Saint Luke's Hospital System, United States*
Email: ifrahfatima@umkc.edu

Background and aims: Non-Alcoholic Fatty Liver Disease (NAFLD) affects about 25–30% of individuals worldwide. About 16.7% of all NAFLD individuals are lean. This study aims to identify the prevalence and predictors of NAFLD among lean United States (US) adults.

Method: Lean adults ≥18 years of age from the National Health and Nutrition Examination Survey (NHANES) 2017–2018 with BMI <25 in Asians and <30 in other races were included. NAFLD was identified according to the controlled attenuation parameter (CAP) score ≥248 dB/m. Viral hepatitis, significant alcohol use history (>1 drink/day in women, >2 drinks/day in men) were excluded. The sample weights were utilized according to the complex survey analysis guidance. Characteristics were compared using Fisher's exact test/Chi-square and Student's t-test/Mann-Whitney test. Odds ratios and 95% confidence interval were calculated for the association between chronic medical conditions and DS use adjusted for confounding variables. Two-sided p <0.05 were considered statistically significant. Statistical analyses were conducted using STATA/SE version 16.1 (StataCorp, College Station, TX)

Results: A total of 2629 observations representing an underlying population of 123,341,002 were included. 40% of lean adults had NAFLD identified by Vibration-controlled Transient Elastography (VCTE) (CAP score ≥248 dB/m). The mean age in the NAFLD group was 54.1 ± 0.50 versus 42.4 ± 0.85 years in the non-NAFLD group. Predictors associated with NAFLD were older age (aOR 1.91; 95% CI 1.4–2.6 for age 40–59 and 2.22; 95% CI 1.59–3.11 for age ≥60), male (aOR 1.47; 95% CI 1.04–2.06), non-Hispanic Asian (aOR 1.85; 95% CI 1.26–2.70), Mexican or other Hispanic (aOR 1.41; 95% CI 1.02–1.96), BMI 25–29.9 (aOR 3.13; 95% CI 2.33–4.21) but not education level, marital status, or the presence or absence of hypertension, diabetes, prediabetes, dyslipidemia or cardiovascular disorders. Hemoglobin A1C and triglyceride levels were associated with NAFLD among lean US adults with aOR 1.54; 95% CI 1.25–2.91, and 1.006; 95% CI 1.004–1.009, respectively.

Conclusion: 40% of lean US adults have NAFLD based on VCTE evaluation. Age ≥40 years, male, non-Hispanic Asian or Mexican/other Hispanic, BMI 25–29.9, HbA1C, and triglyceride levels were predictors for NAFLD among lean US adults.

SAT-438

Utility of SomaSignalTM panels for drug response and monitoring disease progression in patients with advanced fibrosis due to non-alcoholic steatohepatitis

Background and aims: Non-alcoholic steatohepatitis (NASH) is characterized by liver steatosis, inflammation, and hepatocellular ballooning and may lead to progressive fibrosis and cirrhosis. Changes in NASH activity score (NAS) and fibrosis stage by histology are commonly used to assess treatment response in clinical trials. However, liver biopsy is subject to sampling variability, invasive, and expensive; thus reliable non-invasive tests to measure treatment response are needed. SomaSignal™ NASH scores provide a predictive probability and binary classification of the presence of the individual histological components of liver biopsy (Fibrosis, Inflammation, Steatosis, Ballooning). Our study aimed to apply composite serum biomarker panels, SomaSignal™ scores, to evaluate hepatic steatosis, lobular inflammation, hepatocyte ballooning and liver fibrosis in a randomized, placebo-controlled, phase 2b NASH clinical study.

Method: A total of 198 patients with bridging fibrosis or compensated cirrhosis (F3-F4) due to NASH were randomized to placebo, cilofexor (CILO) 30 mg or firsocostat (FIR) 20 mg alone, or two-drug combination groups. Fibrosis stage and NAS were staged according to NASH CRN. Serum proteome was analyzed in 166 subjects with paired baseline (BL) and Week 48 (W48) samples via SomaScan® (SomaLogic, Boulder, CO). Associations of SomaSignal™ scores with NAS components and fibrosis stage were assessed by Jonckheere's trend test, and the binary classification results were evaluated by Fisher's exact test. The changes in SomaSignal™ NASH scores at W48 from BL (on the logit scale) among the treatment groups were compared by a linear model adjusting for age, gender, diabetes, and baseline cirrhosis status.

Results: NASH SomaSignal™ scores showed strong correlation with histologic features ($p < 0.001$), and the binary classification prediction results were largely consistent with biopsy histology (AUC >0.72; $p < 0.005$). At W48, combination therapy significantly reduced all SomaSignal™ scores compared to placebo (all $p < 0.05$). FIR monotherapy significantly reduced the SomaSignal™ fibrosis and hepatocyte ballooning scores but not the other SomaSignal™ scores; CILO monotherapy numerically reduced the SomaSignal™ score (Figure). Through W48, 15 of 67 NASH patients had reduced (reduction ≥1) fibrosis stage by biopsy in the combo cohort. Compared to patients without histological improvement, NASH patients with improved

Figure: (abstract: SAT-437).

The least square means with the 95% confidence interval (CI) of the predicted NASH SomaSignal score changes at W48 from BL (**A**. Fibrosis **B**. Lobular inflammation **C**. Hepatocyte ballooning **D**. Steatosis) are shown for each treatment arm. Statistical significance of each treatment arm against placebo is annotated as follows: "***" for $P < 0.001$, "**" for $P < 0.01$, "*" for $P < 0.05$, "ns" for $P > 0.05$.

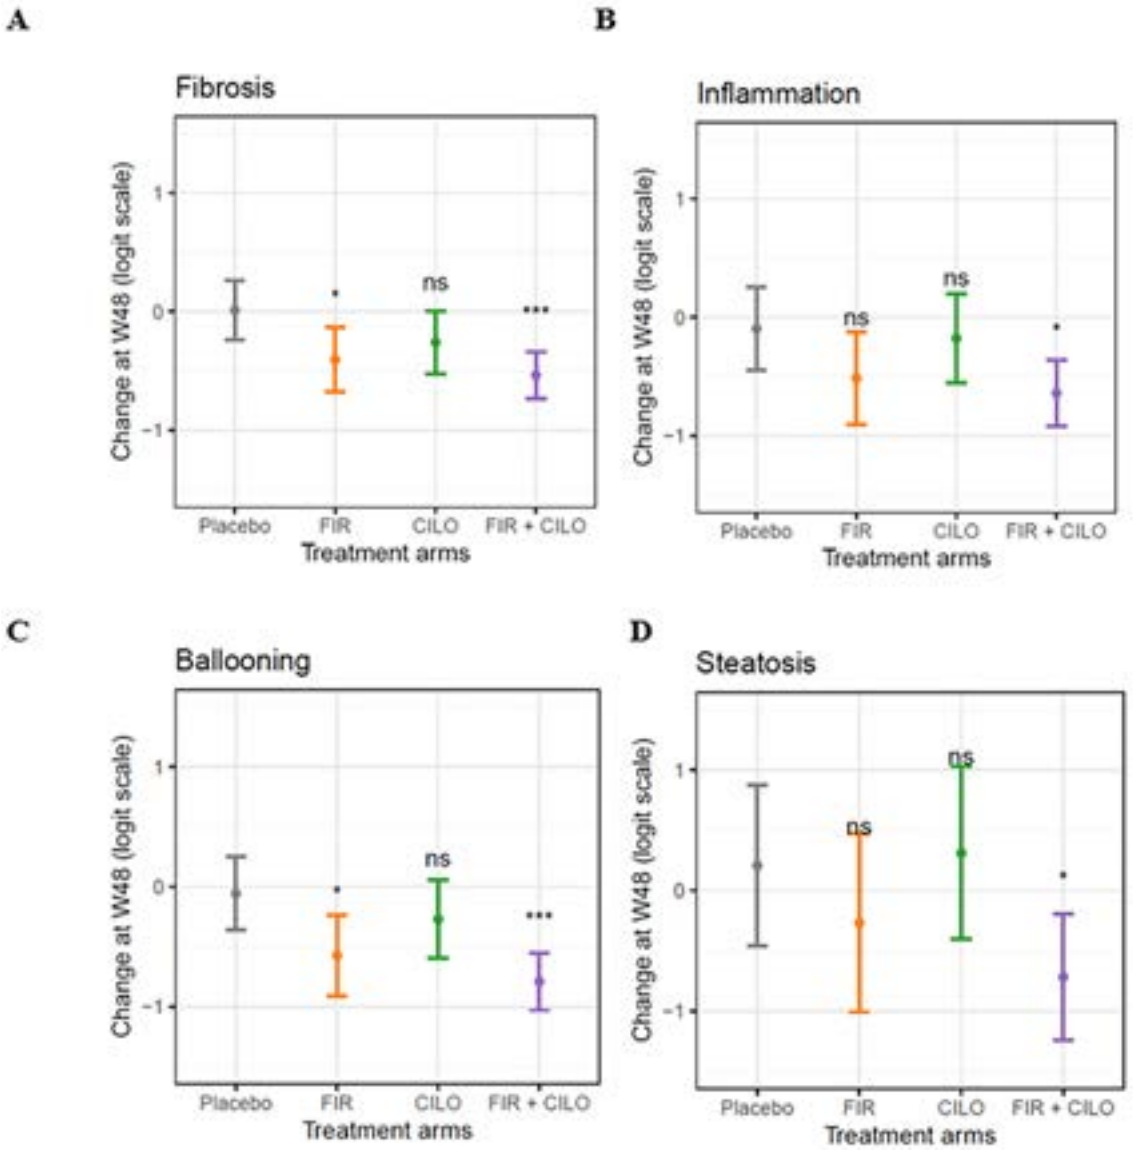

Figure: (abstract: SAT-438): Combination Therapy with Cilofexor and Firsocostat Reduced SomaSignal™ NASH Scores Compared to Placebo

fibrosis stage had greater reductions in the SomaSignal™ fibrosis scores (Wilcoxon test $p < 0.05$). The AUROC for the SomaSignal™ fibrosis score to predict histological improvement was 0.67 (95% CI: 0.52–0.82).

Conclusion: The proteomic SomaSignal™ NASH scores including measures of hepatic steatosis, lobular inflammation, hepatocyte ballooning and liver fibrosis showed significant correlations with NASH CRN fibrosis stage and NAS components. Greater reductions of SomaSignal™ fibrosis and NAS scores were observed in the combo treatment group, consistent with the observed histological changes. We propose that SomaSignal platform may be useful to assess treatment responses in NASH trials.

SAT-439

Wearable technology utilizing an electrical impedance tomography (EIT) system for hepatic steatosis quantification and the role in ambulatory monitoring

Lung Yi Loey Mak[1], James H.W. Li[2,3], Adrien Touboul[3], Fedi Zouari[3], Pak-To Cheung[3], Eddie Wong[1,3], Iris Y. Zhou[4], Ellie Wei[1], Man-Fung Yuen[1], Russell Chan[3], Wai-Kay Seto[1]. *[1]The University of Hong Kong, School of Clinical Medicine, Hong Kong; [2]The Hong Kong University of Science and Technology, Hong Kong; [3]Gense Technologies Ltd, Hong Kong; [4]Massachusetts General Hospital and Harvard Medical School, Radiology, Massachusetts, United States*

	Pilot 1*	Pilot 2	Pilot 3**	Pilot 4*	Pilot 5*	Pilot 6	Pilot 7	Pilot 8**
Week 0 CAP	229	198	373	244	216	156	277	347
Week 8 CAP	175	192	320	158	172	277	299	293

*Subjects with significant CAP reduction at week 8 (defined as ≥40 dB/m); corresponding to dashed lines in the graph
* Known NAFLD

Figure: (abstract: SAT-439).

Background and aims: The current effective treatment for patients with non-alcoholic fatty liver disease (NAFLD) is achieving weight loss through lifestyle modifications. We developed a wearable device using the electrical impedance tomography (EIT) technology to quantify hepatic steatosis (part 1). In this pilot study, we then explored the role of ambulatory monitoring of hepatic steatosis using the EIT system (part 2).
Method: In part 1, 21 healthy controls and 43 patients with known NAFLD were recruited for cross-sectional evaluation by vibration controlled transient elastography (VCTE), which can measure hepatic steatosis by controlled attenuation parameter (CAP). The EIT examination was performed after VCTE with a 16-electrode belt worn on the waist connected to a portable non-ionizing non-invasive system, which is designed for use without the need of trained operators. A random subgroup of subjects with NAFLD (n = 27) also underwent magnetic resonance imaging proton density fat fraction (MRI-PDFF) to further validate the accuracy of the wearable EIT system (Figure A). In part 2, 8 subjects (2 with NAFLD, 6 healthy controls) were recruited and underwent EIT scan at baseline and every 2 weeks. VCTE was performed at baseline and week 8 for CAP values. Significant CAP reduction was defined as ≥40 dB/m decline from baseline.
Results: Part 1: The predicted CAP by EIT system achieved area under the receiver-operating characteristic curve (AUROC) of 0.799 (Figures B and C), with 86.1% sensitivity and 71.4% specificity. The predicted MRI-PDFF score by EIT system achieved AUROC of 0.782 (Figures D and E), with 77.8% sensitivity and 80% specificity. Part 2: All 8 subjects underwent ambulatory monitoring using the EIT system at a frequency of ≥3 times over the 8-week observation period, confirming feasibility of this approach. 5/8 (62.5%) subjects, including the 2 subjects with known NAFLD, achieved significant CAP reduction (Figure F). EIT and CAP values at baseline and week 8 yielded 8 pairs of values, with 14/16 (87.5%) concordance in categorizing liver fat quantity. Most subjects agreed the wearable was easy to use (87.5%), confident to self-administer at home (75%), and accept the need to use on a long-term basis (62.5%). No subjects experience intractable discomfort.
Conclusion: The novel portable EIT system can predict VCTE-derived CAP and MRI-PDFF, allowing a safe, well-tolerated and low-cost ambulatory alternative for hepatic steatosis quantification.

Head-to-head comparison of Agile 3+, LSM-VCTE, NFS, and FIB-4 scores for detecting advanced fibrosis in patients with type 2 diabetes seen in diabetes clinic

Laurent Castéra[1], Tiphaine Vidal-Trecan[2], Tania Khoury[3], Jean-Baptiste Julla[2], Valérie Paradis[4], Jean-Pierre Riveline[5], Dominique Valla[1], Jean-François Gautier[5]. [1]*Beaujon hospital, Université Paris Cité, Hepatology, Clichy, France;* [2]*Lariboisiere hospital, Diabetology, Paris, France;* [3]*Beaujon hospital, Hepatology, Clichy, France;* [4]*Beaujon hospital, Université Paris Cité, Pathology, Clichy, France;* [5]*Lariboisiere hospital, Université Paris Cite, Diabetology, Paris, France*
Email: laurent.castera@bjn.aphp.fr

Background and aims: Among patients with type 2 diabetes (T2D), prevalence of NAFLD and advanced fibrosis is high. Identification of these patients is a priority as advanced fibrosis is the main prognostic factor associated with liver outcomes and overall mortality. Non-invasive tests (NITs) based on vibration-controlled transient elastography (VCTE), including Agile 3+, LSM (liver stiffness measurement), and serum-based scores such as FIB-4, and NAFLD fibrosis score (NFS) have been proposed recently for this purpose. Data comparing the performance of these tests in patients with T2D are lacking. The aim of this study was to compare head-to-head, the performance of Agile 3+, LSM, FIB-4 and NFS, for detecting advanced fibrosis in a large cohort of T2D patients with suspected NAFLD.
Method: Among 1620 T2D outpatients seen in a diabetes clinic between June 2019 and February 2022 screened for NAFLD (steatosis and or elevated ALT) who had VCTE, 174 underwent a liver biopsy (LB). Agile 3+, FIB-4, and NFS scores were calculated according to published formula and cutoffs used were those published for Agile 3+ (<0.351, ≥0.679) as well as those recommended by guidelines for NFS (<-1.455, >0.676), FIB-4 (<1.3, >2.67) and LSM (<8, ≥12 kPa)), Comparison of performance was done by comparing AUROCs using the DeLong's test for paired data, and percentage of correctly

classified patients (true positive and true negative) taking liver biopsy as a reference.

Results: 163 patients had all data available for head-to-head comparison. Their characteristics were as follows: male 58%; median age 59 years; BMI 32 kg/m^2; waist circumference 108 cm; HbA1c 7.7%; AST 35 IU/L; ALT 47 IU/L; advanced fibrosis 30%. Performances of scores are shown in the Table. LSM and Agile 3+ had similar accuracy (AUROCs 0.87 vs. 0.85, p = 0.43) but LSM outperformed FIB-4 (0.87 vs. 0.75; p = 0.009) and NFS (0.87 vs. 0.66; p <0.0001). The grey zone (patients between the two cutoffs) was higher for NFS than for Agile 3+, LSM and FIB-4. LSM and Agile 3+ had a higher rate of correctly classified patients than NFS and FIB-4

Table: Comparison of performance of Agile 3+, NFS, FIB-4 and LSM in 163 T2D patients with liver biopsy

Scores	AUROC (95% CI)	P value*	Cut-offs	Se	Sp	PPV	NPV	Grey Zone	Correctly classified
Agile 3+	0.85 (0.79–0.91)	0.43	<0.351 ≥0.679	0.94 0.69	0.47 0.87	 0.69	0.95	35%	54%
NFS	0.66 (0.56–0.75)	<10–4	<-1.455 >0.676	0.82 0.33	0.30 0.90	 0.59	0.79	57%	31%
FIB-4	0.75 (0.66–0.83)	0.009	<1.3 >2.67	0.69 0.20	0.63 0.98	 0.83	0.83	39%	50%
LSM	0.87 (0.82–0.93)	ref	<8 KPa ≥12 KPa	0.96 0.51	0.60 0.92	 0.74	0.97	36%	57%

*Performance comparisons of NITs with respect to histologic results using De Long's test for paired data.

Conclusion: LSM and Agile 3+ score outperformed FIB-4 and NFS for identifying advanced fibrosis in T2D patients with suspected NAFLD.

SAT-441

Screening for advanced fibrosis due to NAFLD in patients with type 2 diabetes in a retina scanning facility

Andrea Lindfors[1,2], Rickard Strandberg[1], Hannes Hagström[1,2].
[1]*Karolinska Institutet, Department of Medicine, Huddinge, Sweden;* [2]*Karolinska University Hospital, Division of Hepatology, Department of Upper GI Diseases, Stockholm, Sweden*
Email: andrea.lindfors@ki.se

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is prevalent in patients with type 2 diabetes (T2D), and international guidelines suggest specific screening for advanced fibrosis. However, how this should be implemented is less clear. Here, we evaluated the feasibility of offering patients with T2D that attended a retina scanning facility as part of their routine care to also undergo vibration-controlled transient elastography (VCTE) to detect NAFLD and advanced fibrosis.

Method: Patients with T2D who attended retina scanning at a single facility between 2020 and 2022 were asked for participation. Patients were assessed for clinical characteristics and underwent VCTE after a two-hour fasting period. NAFLD and advanced fibrosis were defined as controlled attenuation parameter (CAP) values of ≥280 dB/m and ≥12 kPa, respectively. Patients with liver stiffness ≥8 kPa were referred to the Karolinska University Hospital for a liver evaluation, a second VCTE examination and offered standard clinical care.

Results: 1102 eligible patients were asked for participation, of which 818 (74%) were included. The mean age was 65 years (SD 9.6) and 62% were men. 51% had a CAP value of 280 dB/m or more, indicating NAFLD, and 137 (17%) had a liver stiffness above or equal to 8 kPa, with 45 (6%) having values suggestive of advanced fibrosis (≥12 kPa). Of those with values above or equal to 8 kPa, 93/137 patients (68%) have so far accepted and been referred for a liver evaluation, while 28 (20%) were lost to follow-up and 16 (12%) are waiting for a follow-up. At repeat VCTE measurement, 41/93 persons (44%) had a normal VCTE (<8 kPa), and 29 (31%) had values between 8 and 11.9 kPa, while advanced fibrosis was found in 23/93 persons (25%).

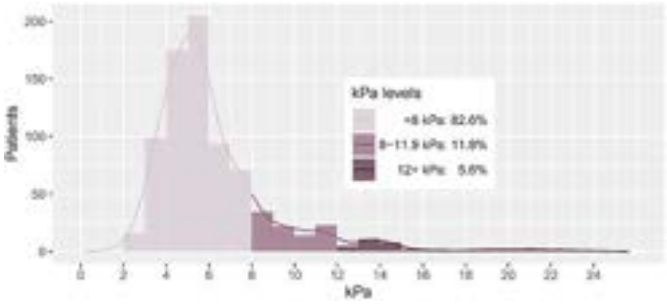

Figure: Distribution of liver stiffness in included patients with type 2 diabetes.

Conclusion: Offering patients with T2D opportunistic screening with VCTE at the time of routine retina scanning is accepted by a high proportion. NAFLD and advanced fibrosis are common in this population, however false-positive findings are also frequent and risks of overdiagnosis needs to be considered if implementing this in routine clinical care.

SAT-442

MRI-PDFF captures the whole spectrum of lipid composition beyond traditional histological evaluation of macrosteatosis

Email: davidmmaa@gmail.com

Background and aims: The histologic evaluation of hepatic steatosis is based on the percentage of hepatocytes with macrovesicular steatosis, ignoring the lipid composition. MRI-PDFF is the most accurate non-invasive method for detecting hepatic steatosis. We aimed to evaluate the influence of lipid droplets composition in PDFF values.

Method: Prospective, multicenter study including chronic liver disease patients with paired liver biopsy and MRI between 2017–2022. MR examination included the MECSE sequence to measure PDFF after automatic whole-liver segmentation. Histologic samples were evaluated with conventional microscope and digital image analysis (Ventana iScan HT). Slides were stained with HandE for semiquantitative scoring of steatosis according to NAS-CRN system (S0–3 macrosteatosis grade and presence/absence of microsteatosis) and IHQ adipophilin for digital pathology assessment. Lipid droplets were categorized as large macrovesicular steatosis (≥80 µm2), small

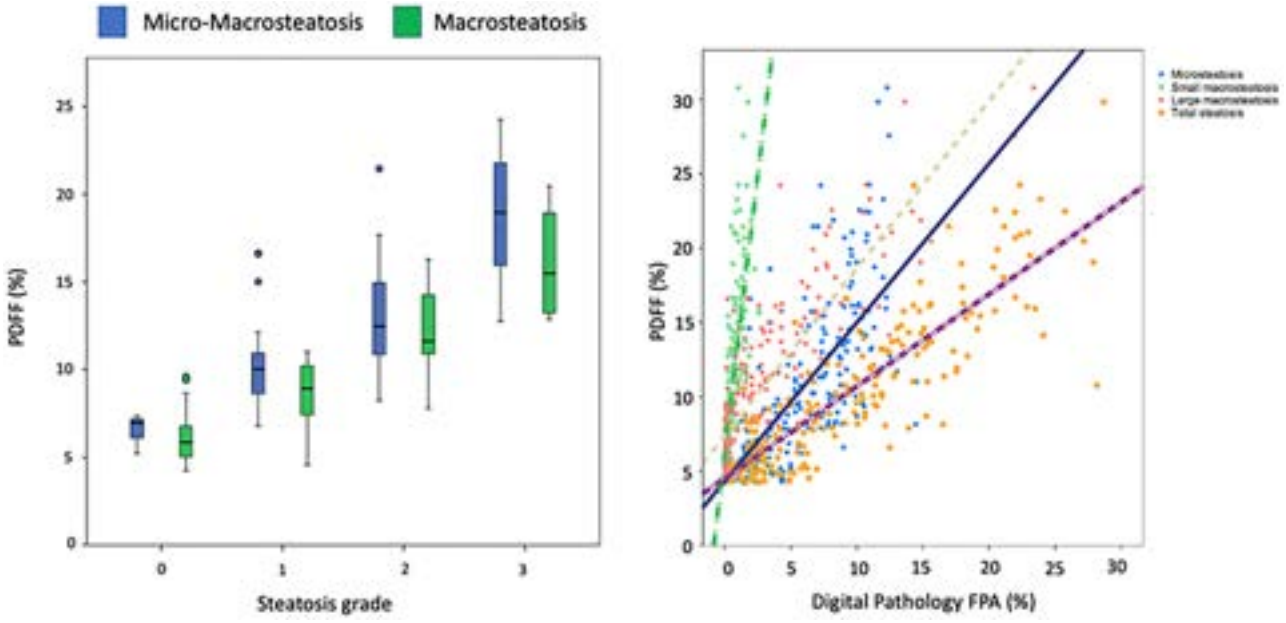

Figure: (abstract: SAT-442).

macrovesicular (<80 µm2) and microsteatosis (non-droplet positive adipophilin). Fat proportionate areas (FPA) and number of lipid droplets were measured with digital pathology. Total FPA was calculated as: large-droplet FPA + small-droplet FPA + microsteatosis FPA. Total lipid droplets were calculated as: number of large-droplets + small-droplets macrovesicular steatosis.

Results: There were 206 patients (57% women; 55 ± 12 years) with mean PDFF of 11.9 ± 4.9%. Main liver disease aetiology was fatty liver (61% NAFLD, 6% ALD), followed by autoimmune diseases (22%) and viral hepatitis (6%). Histologic steatosis distribution included 37% S0, 23% S1, 19% S2, 21% S3. The strength of PDFF-FPA correlation increased with lipid droplet size as follows: r = 0.74 for microsteatosis, r = 0.78 for small-droplet macrovesicular, r = 0.84 for large-droplet macrovesicular; being higher (r = 0.88) for total FPA. The correlation between PDFF and number of lipid droplets also increased as follows: r = 0.70 for small-droplet macrovesicular, r = 0.85 for large-droplet macrovesicular; being higher (r = 0.87) for total lipid droplets. In all steatosis grades (S0-S3) PDFF values were higher if microsteatosis was present (Figure 1). Overall, mean PDFF was 10.8% if microsteatosis was absent vs. 14.3% if microsteatosis was present (p <0.01).

Conclusion: Pathologists grading system of steatosis should consider lipid droplet composition, unifying macro and microsteatosis assessment, as MRI-PDFF correlates with the whole spectrum of hepatic steatosis.

SAT-443

Two steps algorithm for the diagnosis of advanced liver fibrosis in general population. Real-life data

Ana Pérez[1], Marta Hernández Conde[1], Christie Perelló[1], Diana Karen Tapia Calderón[2], Elba Llop[1], Francisco A. Bernabeu-Andreu[1], Javier Vega[1], Marta López-Gómez[1], Natalia Fernández Puga[1], Javier Abad Guerra[1], Carlos Fernández-Carrillo[1], José Luis Martínez Porras[1], Maria Trapero[1], Enrique Fraga[1], José Luis Calleja Panero[1]. *[1]Hospital Universitario Puerta de Hierro, Spain; [2]Guadalajara, Guadalajara, Mexico*
Email: ana.perez.gs96@gmail.com

Background and aims: Chronic liver disease is an increasingly prevalent entity. Additionally, due to its silent evolution, it is an underdiagnosed disease.

Method: In this cohort study, Fibrosis-4 index (FIB4) was performed on all patients between 18 and 65 years old from area 6 of Madrid Community with a request for glycated hemoglobin in the routine analysis of primary care. We suggested the request of a transient elastography (TE) by the primary care physician in patients with FIB4≥1.3 in a medium time of 1 month. If TE was >8kPa, patient was referred to the Hepatology consultation. According to medical indication, a complete study was performed on those patients.

Results: Between April and September 2022, 1,635 patients were included (1,155 patients –70.6%- with low-risk FIB4, 439–26.9%- with indeterminate FIB4 and 41–2.5%- with high-risk FIB4). Of the 480 patients (29.4%) with FIB4≥1.3, TE was requested for 400 patients (83.3%). Of which, 376 TE (94%) were performed. The reasons for not performing TE were: not attending the appointment (22 patients), technical limitations due to obesity (2 patients). The data of the first 166 patients with TE were analyzed. The baseline characteristics are detailed in Table 1. The prevalence of significant fibrosis (TE>8 kPa) was 15.5% in the indeterminate FIB4 group and 55.6% in the high-risk FIB4 group (p < 0.01). In addition, the prevalence of advanced fibrosis (>9.6 kPa) was significantly higher in the high-risk FIB4 group in relation to the indeterminate FIB4 group (50 vs. 10.3%; p < 0.01).

Figure:

Baseline Characteristics (n = 383)	Results
Sex (male), n (%)	107 (73.8)
Age (years), mean (SD)	58 (6.4)
TE (F0–1, F2, F3, F4), %	80.3/5.3/5.9/8.6
TE (Kpa), medium (P25; P75)	5.8 (4.4;7.8)
Hypertension, n (%)	72 (50)
Type II Diabetes Mellitus (DM2), n (%)	42 (29.2)
Dyslipidemia, n (%)	71 (49.3)
Cardiovascular disease, n (%)	17 (11.8)
Mass corporal index (kg/m^2), mean (SD)	29.7 (5.3)
Overweight, n (%)	25 (46.2)
Obesity, n (%)	30 (38.5)
Ceruloplasmin (mg/dl), mean (SD)	24.9 (4.2)
Cholesterol- HDL (mg/dl), mean (SD)	50.5 (16.7)
Cholesterol-LDL (mg/dl), mean (SD)	98.6 (34.8)
Triglycerides (mg/dl), medium (P25; P75)	124 (90; 186)
Hemoglobin (g/dl), mean (SD)	15.4 (1.4)
Platelets (10E3/microL), mean (SD)	202.5 (51.2)
Albumin (g/dL), mean (SD)	4.5 (0.3)
Glucose (mg/dl), mean (SD)	109 (37.9)
Glycohemoglobin (%), mean (SD)	6 (1.2)
Bilirubin (mg/dl), mean (SD)	0.8 (0.4)
ALT (U/L), mean (SD)	69.8 (46.5)
AST (U/L), mean (SD)	54.9 (37)
ALP (U/L), mean (SD)	84.3 (34.1)
GGT (U/L), medium (P25; P75)	47 (30;93)

Conclusion: The sequential FIB4-TE algorithm is an adequate initial tool for the screening of liver fibrosis. However, only 15.5% of patients with indeterminate FIB4 had significant fibrosis. To improve the cost-effectiveness of screening, it is necessary to increase the diagnostic yield of elastography, probably by adding a second serological test in that group of patients before performing TE.

SAT-444

Imaging and biomarker thresholds to accurately diagnose NASH cirrhosis in a 180 patient biopsy confirmed cohort

Rohit Loomba[1], Mazen Noureddin[2], Rebecca Taub[3], Naim Alkhouri[4], Kris Kowdley[5], Greg Everson[6], Stephen Harrison[7,8]. *[1]UCSD, United States; [2]CSHS, United States; [3]Madrigal Pharmaceuticals, United States; [4]AZ Liver, United States; [5]Liver institute NW, United States; [6]HepQuant, United States; [7]Oxford, United States; [8]Pinnacle Research, United States*
Email: rebeccataub@yahoo.com

Background and aims: MAESTRO-NAFLD-1 (NCT04197479) is a 52-week study that includes an open label active resmetirom treatment arm in 180 patients with well-compensated Child-Pugh A NASH cirrhosis, treated for 52 weeks with daily oral 80 mg resmetirom. A goal of the study was characterization of non-invasive baseline measures to diagnose and stage NASH cirrhosis.
Method: Eligibility required at least 3 metabolic risk factors (metabolic syndrome), and NASH cirrhosis diagnosed on liver biopsy or according to accepted criteria. A series of non-invasive biomarkers and imaging procedures at baseline and during the study was used to help define criteria to diagnose NASH cirrhosis non-invasively including FibroScan, MRE, MRI-PDFF, ELF and other laboratory parameters. A subset of patients had HepQuant analyses conducted to measure their hepatic functional capacity and estimate shunting.
Results: 180 patients with well-compensated CP-A NASH cirrhosis were enrolled, most with history of diagnosis by liver biopsy, 70% confirmed F4 on biopsy score reports. Demographics included mean age 61.5 (9.3 (SD)), female 62%, BMI 35.5 (7.5), diabetes 69%, hypertension 79%, dyslipidemia >70%, ASCVD score 15.2%, hypothyroid 23%, statin use 51%, MRE 5.5 kPa (2.1), FibroScan VCTE 25.6 kPa (15.4), CAP 322 dB/m (56), MRI-PDFF 8.1% (5), ELF 10.7 (1.1), FIB-4 2.3 (median) mean 2.8 (1.6), platelets 143 (median), mean 159 (65). Based on literature guidelines, thresholds were assessed for prediction of NASH cirrhosis; approximately 89% met criterion of FibroScan ≥15 kPa and at least one additional test (Table, "MRE/Plts/ELF"). About half of the 10% of patients excluded by these tests had confirmed F4 on biopsy. The threshold, FIB-4 ≥3.25, was not independent of low platelet criteria and was not a useful index for this CP-A population. Statin use was associated with reduced AST (AST, mean 42 (28) (no statin) vs 35 (16) (statin)) and FIB-4 in this population. Highly significant correlations with increasing FIB-4 (rho = 0.7), reduced platelet count (rho = –0.4), and other markers of cirrhosis progression were observed in the subpopulation of patients as a function of reduced liver function as determined by HepQuant. NASH resolution without worsening of fibrosis.

	Met Criterion	Confirmed by additional criteria	Did not meet criterion	Did not meet criterion but met other criteria	Total meeting any cirrhosis criteria
FibroScan (FS) ≥15 kPa	79%	94% (MRE/Plts/ELF)	21%	10% (MRE/Plts/ELF)	89%
FibroScan≥20 kPa	53%		47%		
MRE≥4.2, and/or platelets<140 K, and/or ELF≥10.25 (MRE/Plts/ELF)	87%	87% (FS≥15)	13%	5% (FS≥15)	92%
MRE≥4.2	74%		26%		
ELF≥10.25	66%		34%		
Platelets<140 K	49%		51%		
FIB-4≥3.25	32%		68%		

Conclusion: NASH cirrhosis may be predicted using imaging and biomarker tests in the absence of liver biopsy. Patients with metabolic syndrome and a history consistent with NASH and VCTE of kPA ≥15 could be screened with other tests (ELF, MRE, platelet level) to determine a likelihood of NASH cirrhosis.

SAT-445

Assessment of hepatic fibrosis screening in primary care using the FIB-4 score, followed in second line by an ELF (Enhanced liver Fibrosis) test

Denis Ouzan[1,2], Guillaume Penaranda[3], Jlaiel Malik[4], Corneille Jeremie[5]. *[1]Instutut Arnault Tzanck, France; [2]RHECCA, France; [3]BIOGROUP ALPHABIO-Laboratoire Européen, France; [4]BIOGROUP BIOESTEREL-Laboratoire Mandelieu-Passero, France; [5]BIOGROUP BIOESTEREL-Laboratoire Mougins-L'espérance, France*
Email: denis.ouzan@wanadoo.fr

Background and aims: Screening for liver fibrosis in the general population is a public health issue. We have shown in a previous study (1) that FIB-4, a simple score combining age, ALT, AST, and platelet, can detect liver fibrosis in general practice and identify a possible cause of liver disease. The FIB-4 thresholds usually used are: low risk if <1.30, intermediate risk between 1.3 and 2.67, and high risk if ≥2.67. The objective of our work was to evaluate the screening of hepatic fibrosis in general practice using the FIB-4 score, followed in second line if ≥1.3 by an ELF test.
Method: The FIB-4 score was performed prospectively from March to September 2022 in all consecutive patients seen by 17 general practitioners (GP), outside the emergency. When the FIB-4 was ≥1.3, it was defined as positive and confirmatory ELF test was systematically performed. The positive FIB-4 test was confirmed when the second line ELF test was ≥9.8 (indicating an advanced fibrosis).
Results: Among the 3427 patients included, 869 (25%) had a positive FIB4 score, which was confirmed by the ELF test in 509 (59%) of cases. 35% of them were older than 65 years. Among the 869 FIB-4 positive patients, 784 (90%) were at intermediate risk (FIB-4 between 1.3 and 2.67) and 85 (10%) %at high risk of fibrosis (FIB-4 ≥2.67). FIB-4 positivity was significantly linked to age over 65 years, ASAT >N and

platelets levels <150 000 p < 0.001. Confirmation by ELF was observed among 80% of the patients with high risk of fibrosis, and among 51% of the patients with intermediate risk of fibrosis (p < .0001).. Clinical information was obtain in 680 out of 869 (78%) of the FIB-4 positive patients. The confirmation by ELF test was significantly higher in patient with patients over 65 years (83 vs 57%, p < .0001), in patients with FIB-4 ≥2.67 (80 vs 56%, p < .0001), BMI >25 (47 vs 37%, p = 0.0121), and in those with a diabetes (24 vs 14%, p = 0.0010), but not in those with excessive alcohol consumption (15 vs 14%, p = 0.9283). Only 8% of the patients were known to have a liver disease. In the patients without known liver disease (92%), the GP define a cause in 28% of cases: Nash 67%, Alcohol 23%, NASH+ Alcohol 9%, other 5% and requires an specialized advice in one third of cases.

Conclusion: Liver fibrosis was suspected by FIB4 score in 25% of patients who consulted a GP. The percentage of confirmation by the second line ELF test was significantly higher in patients with a FIB4 ≥2.67 and in those with a risk factor of liver disease overweight or diabetes, who need to be confirmed in priority. For FIB-4 positive patients without known liver disease, the FIB-4 allow the GP to recognize a liver disease in nearly one third of cases, mainly NASH.

Fully automated approach of machine learning combined with deep learning to forecast the coronary artery disease in patients with non-alcoholic fatty liver disease

Antonio Cirella[1], Gaia Sinatti[1], Angelica Bracci[1], Laura Evangelista[1], Pierangela Bruno[2], Silvano Junior Santini[1], Gianluigi Greco[2], Antonella Guzzo[2], Francesco Calimeri[2], Ernesto di Cesare[1], Clara Balsano[1]. *[1]Università degli studi di L'Aquila, Italy; [2]Università della Calabria, Italy*
Email: cirella.nt@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become the most prevalent liver disease worldwide, affecting a quarter of world's population. Growing evidence indicates that in these patients, the presence of NAFLD increases the risks cardiovascular disease (CVD) and morbidity and mortality. CVD represent the principal outcome greater than the progression of liver disease. Coronary arteries disease (CAD) is detected by Coronary CT, moreover CT is used also for the determination liver steatosis. The aim of our study was to implement ML/DL models to analyse CT images integrated with clinical parameters, in order to develop a comprehensive prognostic stratification model to forecast, in NAFLD patients, the onset of CAD.

Method: Our retrospective study analyzed clinical data and CT images of 401 patients (217 males and 184 females), who underwent coronary CT between 2017 and 2021. Images were acquired by cardio-synchronous technique. Hounsfield Unit (HU), Agatston score, Fib-4 score were used to measure radiodensity, calcium score (CS) and the degree of fibrosis, respectively. In order to perform disease classification, we used a combination of Machine Learning (ML) and Deep Learning (DL) algorithms. In particular, the algorithms are first trained on clinical data and CT images, respectively, and then the obtained models are properly combined. We performed an ablation study to identify the most appropriate methods, resulting in Densely Connected Convolutional Networks (Densenet-169) and K-nearest neighbors (KNN).

Results: In order to show the viability of our approach, we first test the ML algorithm on the task of binary classification using clinical data of 84 patients and, then, the DL algorithms using CT images. The results reveal that our combined approach is able to predict absent and severe CAD with a mean accuracy of 94% in NAFLD and healthy patients. Furthermore, we tested ML and DL algorithms in the task of multi classification using only clinical data of 401 patients. Our algorithms were able to distinguish patients in 5 classes from healthy patients to patients affected by NAFLD and CVD, with a mean accuracy of 87% and a mean specificity of 86% for ML and a mean accuracy of 77% and a mean specificity of 76% for DL. To improve the performance of these prediction models, we are integrating them with DL algorithms for liver CT images for all the patients.

Figure:

Conclusion: Our integrated ML/DL approach could be used in practice to flag NAFLD patients at high risk of CVD.

Low risk FIB-4 results in patients under 50 years accurately risk assessed patients for adverse liver outcomes over a follow-up of up to 35 years

Jenny Gallacher[1,2], Stuart Mcpherson[1,2], Quentin Anstee[1,2]. *[1]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [2]Liver Unit, Newcastle NIHR Biomedical Research Centre, Newcastle upon Tyne Hospitals Foundation Trust, Newcastle upon Tyne, United Kingdom*
Email: jennifer.gallacher@nhs.net

Background and aims: Non-invasive tests of fibrosis such as the FIB-4 score are routinely used by clinicians to assess patients with NAFLD and guide management. Current EASL and AASLD guidelines suggest those who fall into the "low risk" category (FIB-4 <1.30) can be managed in a primary care setting, with advice to repeat these tests every 2 years. This practice has been widely adopted as a way to cost effectively screen for advanced fibrosis, from an ever-growing number of patients with NAFLD, given the components of FIB-4 are routinely clinically available and the high negative predictive value of the score. However, there are few long-term studies which explore the outcomes of those deemed "low risk." This study aims to review outcomes of interest including incident HCC, liver transplantation and mortality in "low risk" patients aged <50yrs over a period of up to 35 years.

Method: Participants with biopsy proven NAFLD were prospectively recruited from the Newcastle Hospitals, U.K., between 1990 and 2018 with a minimum of 12 months follow-up. Data was collected at clinical events and outcomes explored including survival analysis with Kaplan Meier log-rank tests.

Results: 158 participants were included with a mean follow-up of 14.3 ± 7.2 years (1–35.4 years). 74.1% were male, mean age 37 ± 9 and BMI 34.3 ± 5.6 kg/m^2. T2DM was present in 24.7% (39), HTN 24.8% (34) and MetS 63.8% (74). The prevalence of these co-morbidities increased over the course of the follow-up to 55.3% (84) T2DM, 51.0% (76) HTN and 87.1% (81) MetS. Five patients died, with cardiovascular disease, the most common cause (60%). Mean time to death was 11.7 ± 7.2 years. No liver related deaths, incident HCC or liver transplantation were observed in the cohort. Survival of this cohort was compared to a larger cohort of patients aged <50 years from the same centre, recruited during the same time frame but including all FIB-4

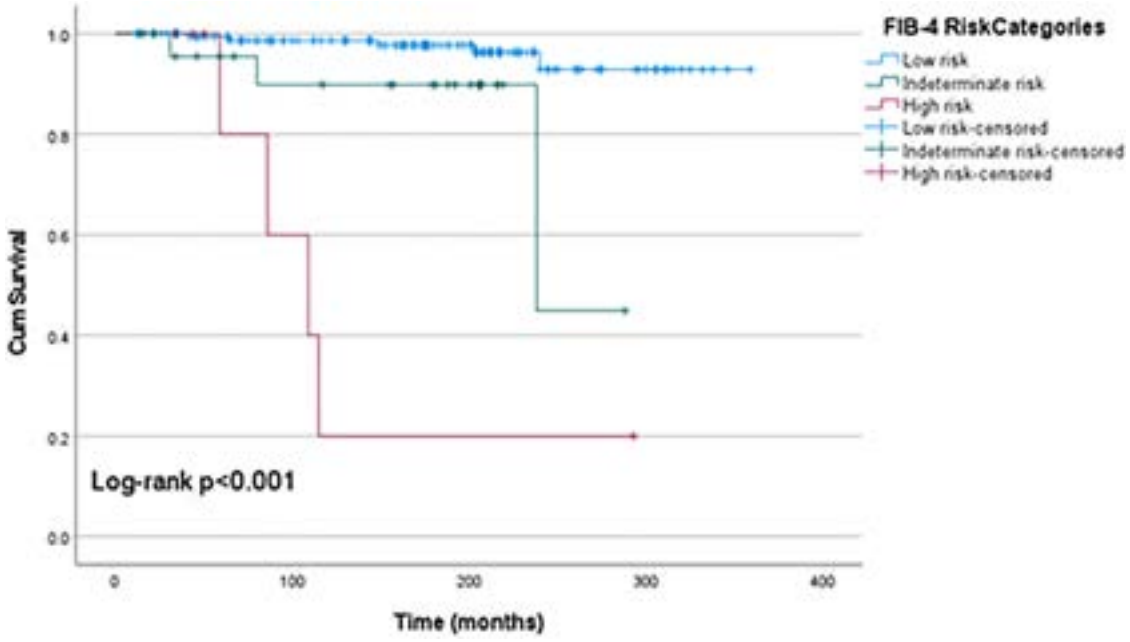

Figure: (abstract: SAT-447): Kaplan Meier survival curves of patients <50 years stratified by FIB-4 risk categories.

risk strata (n = 191). Significant differences in survival were observed, p < 0.001. 80% of FIB4 "high risk" patients were dead at 10 years, and 55% of "indeterminate risk" cases were dead by 20 years. In contrast, the majority (93%) of "low risk" individuals were still alive at up to 35 years follow-up.

Conclusion: These results require further independent validation in large prospective cohorts but indicate that patients under 50 years of age with low-risk FIB-4 are unlikely to experience liver-related hard clinical outcomes over an extended follow-up period.

Background and aims: Type IV collagen 7S (COL4–7S) is one of the simple non-invasive tests for detecting liver fibrosis. However, it was not clarified whether COL4–7S can detect the advanced fibrosis (stage 3/4) and predict the prognosis of non-alcoholic fatty liver disease (NAFLD). In this study, we estimated the clinical efficacy of COL4–7S for detection of advanced fibrosis and prognosis of NAFLD.
Method: The total of 881 Japanese patients with biopsy-prove NAFLD from 1994 to 2020 were enrolled. Serum levels of COL4–7S were determined by the method of radioimmunoassay. Two cutoff points were set on specificity 90% and sensitivity 90% by ROC analysis of COL4–7S for detecting advanced fibrosis. This clinical utility was validated by the 10-fold cross validation. Patients were assigned to three groups on the settled cutoff points. Cox regression analysis were performed to estimate the predictive capacity of COL4-7S for liver-related mortality (LRM) and events (LREs).
Results: The median follow-up period were 4.3 years. 31 patients developed liver-related events and 9 patients died by LREs. The AUROC of COL4–7S was 0.847. The low and high cutoff points were set on 4.8 and 6.8 ng/ml, respectively. The adjusted hazard ratio (aHR) of the high-risk group by COL4–7S for LRM was 46.22 (p < 0.01), while aHR of advanced fibrosis was 1.38 (p = 0.683). The aHR for LREs of the intermediate and high-risk by COL4–7S were 5.94 (p < 0.01) and 27.17 (p < 0.01). The aHR of advanced fibrosis by liver biopsy was 1.61 (p = 0.248). In the same fibrosis stage, the incidence of LRM/LREs was more frequent with a higher risk stratification.
Conclusion: Serum levels of COL4–7S has good diagnostic accuracy for predicting advanced fibrosis and can accurately predict LRM and LREs. COL4–7S help physicians estimate both fibrosis stage and patient prognosis in clinical practice.

The genetic background of NAFLD patients markedly affects their metabolomic and lipidomic signatures

Lina Jegodzinski[1], Ashok Rout[2], Friedhelm Sayk[1], Franziska Schmelter[3], Bandik Föh[4], Henrike Dobbermann[1], Monika Herr[1], Sebastian Meyhöfer[1,5], Svenja Meyhöfer[1,5], Monika Rau[6], Susanne N Weber[7], Marcin Krawczyk[7], Andreas Geier[6], Ulrich Gunther[2], Jens Marquardt[1]. *[1]University Hospital Schleswig-Holstein, Lübeck, Department of Medicine I, Lübeck, Germany; [2]University of Lübeck, Institute of Chemistry and Metabolomics, Lübeck, Germany; [3]University Hospital Schleswig-Holstein and University of Lübeck, Institute of Nutritional Medicine, Lübeck, Germany; [4]Gemeinschaftspraxis im Gesellenhaus, Lübeck, Germany; [5]University of Lübeck, Institute for Endocrinology and Diabetes, Lübeck, Germany; [6]University Hospital Würzburg, Department of Medicine II, Würzburg, Bayern, Germany; [7]University Hospital Saarland, Department of Medicine II, Homburg, Germany*
Email: lina.jegodzinski@uksh.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) encompasses a heterogeneous spectrum of patients with different clinical and molecular characteristics. Pathophysiologically, obesity, diabetes and the metabolic syndrome are major exogenous determinants for metabolic liver diseases. In recent years, several common genetic variants have been identified with significant impact on NAFLD development and progression. Herein, the *patatin*-like phospholipase domain-containing 3 (PNPLA3) p.I148M was identified as a major genetic risk factor for NAFLD. While its impact on clinical progression is well established, metabolomic and lipidomic profile of *PNPLA3* variants are not fully understood.
Method: In this bi-centric study, a total of 256 NAFLD patients were recruited. Chronic and acute liver disease other than NAFLD were excluded in all patients. Genotyping of the *PNPLA3* p.I148M polymorphism was performed using TaqMan assays. Proteo-metabolomics of patient sera was performed by NMR spectroscopy, covering a range of ca. 30 metabolites as well as 100 lipoprotein and glycoprotein parameters.
Results: Homozygous *PNPLA3* p.148MM variant was present in 42 patients (16.4%), whereas 90 patients (35.2%) carried the p.148IM genotype. We were able to show clear differences in analysed serum metabolites as well as in lipoprotein subtype profiles between patients with different PNPLA3 genotypes. For example, there was a significantly higher proportion of LDL triglyceride and VLDL cholesterol subfractions in serum of patients carrying the p.148MM genotype. Additionally, we observed differences in the amino acid status of the patients, especially in the levels of phenylalanine, tyrosine and glutamine.
Conclusion: The *PNPLA3* p.I148M polymorphism has a profound impact on metabolomic and lipidomic profil of NAFLD patients. Results might contribute to our understanding how the variant affects progression in NAFLD patients. A detailed characterization of key molecules could provide a useful tool for the identification of patients at risk in the future.

SAT-450

Prevalence of diagnosed advanced liver fibrosis in high-risk population with metabolic-dysfunction associated fatty liver disease screened in diabetology using transient elastography

Adrien Aubin[1], Marianne Maynard[2,3], Bérénice Ségrestin[1], Yasmina Chouik[2], Laurent Milot[4], Valerie Hervieu[5], Fabien Zoulim[2,3], Emmanuel Disse[1,6], Massimo Levrero[2,3], Cyrielle Caussy[1,6]. *[1]Hospices Civils de Lyon, Endocrinology, Diabetes and Nutrition, Pierre Bénite, France; [2]Hospices Civils de Lyon, Hepatology, Lyon, France; [3]Centre de Recherche sur le Cancer de Lyon, INSERM 1052, Lyon, France; [4]Hospices Civils de Lyon, Radiology, Lyon, France; [5]Hospices Civils de Lyon, Pathology, Lyon, France; [6]Université Lyon 1, CarMen Laboratory, Pierre-Bénite, France*
Email: cyrielle.caussy@chu-lyon.fr

Background and aims: The systematic screening for advanced fibrosis (AF) is recommended in high-risk population such as patients with type 2 diabetes (T2D) and/or obesity and metabolic dysfunction-associated fatty liver disease (MAFLD). However, there are limited data regarding clinical care pathways using liver assessment by transient elastography (TE) performed in diabetology. Therefore, we aimed at assessing the prevalence of diagnosed AF in patients with MAFLD screened for the presence of AF in diabetology prior to hepatology referral.
Method: This is a cross-sectional study including consecutive adult patients with T2D and/or obesity and MAFLD who underwent a liver assessment by TE using a Fibroscan® performed at the Department of Endocrinology, Diabetes and Nutrition, Lyon South Hospital at Hospices Civils de Lyon, France between January 2020 and October 2022. Pseudonymized clinical data, fasting labs including a Fibrotest® and TE reports were systematically extracted from medical electronic records and informed consents were obtained. The presence of suspected AF was defined by a reliable TE≥8 kPa. The confirmed presence of AF was recorded according to assessment in hepatology defined as composite end point including either histological fibrosis stage ≥F3 or overt imaging diagnosis of cirrhosis on magnetic resonance imaging (MRI) or concordant TE≥8kPa and Fibrotest®≥F3 according to EASL guidelines. Patients with discordant TE and Fibrotest® without histological assessment that underwent a

third line magnetic resonance elastography <3.62 kPa were considered as patients without AF in the analysis.
Results: The study included 727 patients with DT2 and/or obesity and MAFLD. The mean age was 54.3 years (± SD 13.6) and the BMI 37.2 kg/m^2 (± 7.9), 50.3% were female, 36.6% had a BMI≥40 kg/m^2, 69.9% had T2D. Sixty-one patients (8.4%) had an unreliable TE. Among the 666 patients with reliable TE, the prevalence of suspected AF with TE≥8kPa was 28.4% (n = 189) and 10.2% (n = 68) had a TE≥12 kPa. In the whole population, the prevalence of confirmed AF was 7.4% (n = 54) including 24 patients with histological stage≥F3, 23 with concordant TE and Fibrotest® for stage≥F3, and 7 with a diagnosis of cirrhosis by MRI. In this population, 18.8% (n = 137) had an undetermined stage of fibrosis. Severe obesity BMI≥40 kg/m^2 was significantly associated with increased odds of undetermined stage of fibrosis (OR 3.4; 95%CI: 2.27–5.09; p < 0.001) in a multivariable model adjusted for age and sex and remained significant even when excluding individuals with unreliable TE (OR 4.4; 95%CI: 2.65–7.40; p < 0.001).
Conclusion: In high-risk individuals with MAFLD consecutively enrolled in a screening for AF in diabetology using TE, the prevalence of diagnosed AF was 7.4%. Severe obesity was significantly associated with undetermined status of AF highlighting the need to optimize the screening strategy in these individuals.

SAT-451

Serological biomarkers of extracellular matrix related disease activity are elevated in patients at risk of NASH with significant liver stiffness

Thomas Møller[1,2], David Provenghi[3], Peder Frederiksen[1], Heidi Guthrie[3], Morten Karsdal[1], Marcus Hompesch[3], Diana Leeming[1]. *[1]Nordic Bioscience A/S, Denmark; [2]University of Copenhagen, Department of Biomedical Sciences, Denmark; [3]ProSciento, Inc, United States*
Email: twm@nordicbio.com

Background and aims: In non-alcoholic steatohepatitis (NASH), inflammation of the hepatic tissue leads to an increased formation and deposition of extracellular matrix proteins, such as collagens. Over time accumulation of collagens causes hepatic fibrosis, which is associated with increased liver stiffness (LS). Type III, IV, and VI collagen formation may be assessed non-invasively using PRO-C3, PRO-C4, and PRO-C6 assessing the pro-peptide of type III and VI collagen, and the 7S domain of type IV collagen. We aimed to investigate how PRO-C3, PRO-C4, and PRO-C6 may identify patients with increased liver stiffness measure (LSM), in patients identified as at risk of NASH, due to obesity and presence of type 2 diabetes (T2D).
Method: 958 patients from the NASH-PASS study, were identified as at risk of NASH due to being obese and presence of T2D, whom all had LSM using vibration-controlled transient elastography (VCTE) by Fibroscan. Blood samples were collected at the time of LSM. PRO-C3 and PRO-C6 were assessed using fully validated competitive immunoassays, and PRO-C4 was assessed using a fully validated automated competitive chemiluminescent immunoassay. Between groups comparisons of biomarker levels were performed using Mann-Whitney or Kruskal-Wallis test.
Results: The median (Q1, Q3) age and BMI of the 958 included patients were 56.4 (48.3, 63.7) years and 35.1 (31.7, 38.9) kg/m^2, respectively, and 473 patients had T2D. 22% of the patients had significant LS (VCTE >8 kPa). While weak Spearman correlation between LS and our biomarkers was observed, the levels of PRO-C3, PRO-C4, and PRO-C6 were significantly elevated in patients with significant LS, compared to those without (VCTE <8 kPa), (p < 0.0001, p < 0.05, and p < 0.0001), (AUROC = 0.672, 0.546, and 0.623).

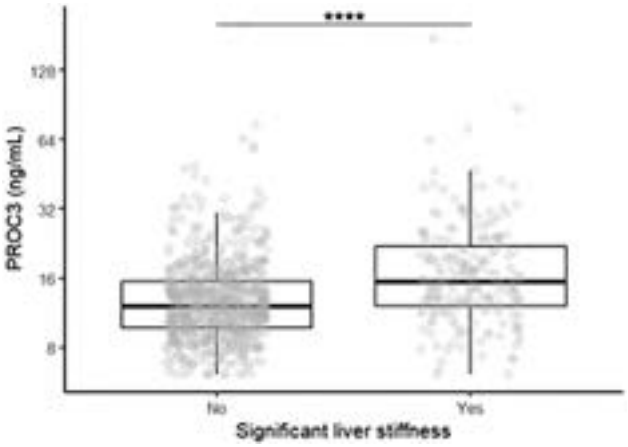

Figure:

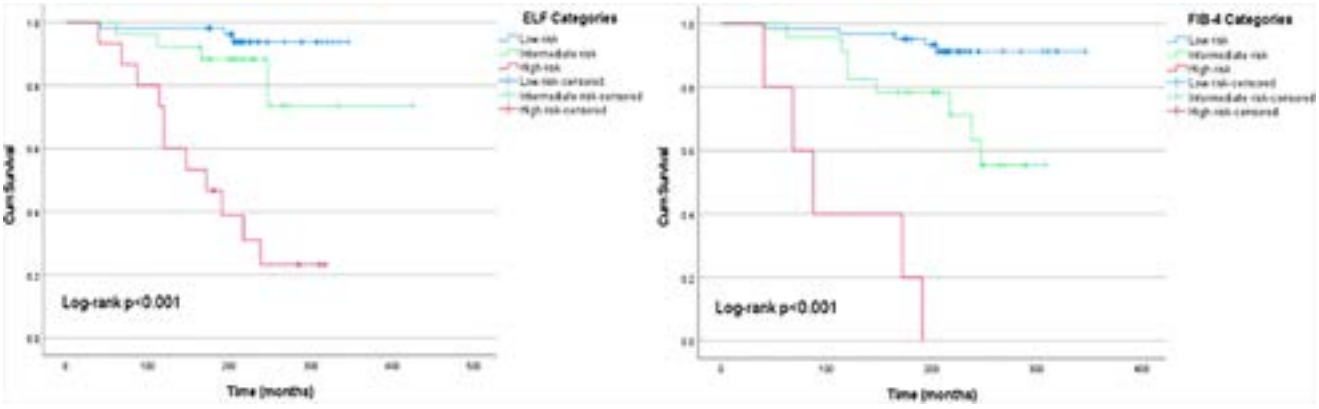
Conclusion: This study did not find strong correlation between LS and the PRO-C3, PRO-C4, and PRO-C6 biomarkers. This was expected as such biomarkers are related to ECM related disease activity rather than status of LS. However, patients with increased LSM (VCTE >8 kPa) had significantly increased disease activity assessed as the formation of type III, IV, and VI collagens, compared to patients without (VCTE <8 kPa).

SAT-452

Prognostic value of the Enhanced Liver Fibrosis (ELF) test to predict long-term outcomes in a NAFLD cohort with up to 35 years follow-up

Jenny Gallacher[1,2], Stuart Mcpherson[1,2], Quentin Anstee[1,2]. *[1]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [2]Liver Unit, Newcastle NIHR Biomedical Research Centre, Newcastle upon Tyne Hospitals Foundation Trust, Newcastle upon Tyne, United Kingdom*
Email: jennifer.gallacher@nhs.net

Background and aims: There are emerging data that non-invasive tests (NIT) can predict long-term clinical outcomes and mortality however the majority of studies are of short duration. ELF is an established biomarker panel, developed to detect advanced fibrosis (≥F3). Fifteen years after the original publication demonstrating the performance of ELF as a *diagnostic* biomarker in NAFLD[1], we report the long-term follow-up of the same cohort of patients and assess the performance of ELF in comparison to FIB-4 as *prognostic* biomarkers for predicting liver-related and all-cause mortality.
Method: Patients recruited at a UK tertiary centre in the original NAFLD-ELF study[1] were followed until 2020 to explore outcomes of interest including progression to cirrhosis, incident HCC and mortality. Cox regression analysis was performed to explore the prognostic ability of ELF and FIB-4 to predict mortality.
Results: 95 patients were included (mean follow-up 17.9 ± 5.3 years [3.3–35.4 years]; 62% male; mean age at baseline 47 ± 13 years). Using cut-offs to group patients as "low," "intermediate" and "high" risk (ELF = <9.80, 9.80–11.1, >11.1. FIB-4 = <1.30, 1.30–2.67, >2.67) the distribution of ELF results in the cohort were 56.8% (54) low, 27.4% (26) intermediate and 15.8% (15) high at baseline. FIB-4 results were similar with 68.9% (62), 25.6% (23) and 5.6% (5) respectively. 17.9% (17) of patients had advanced fibrosis (F3–4) at baseline, with 11.6% (11) being classed as cirrhotic. ELF performed well at identifying presence of advanced fibrosis (AUROC 0.954, 95% CI 0.91–1.00; FIB-4 AUROC 0.824, 95% CI 0.72–0.93). The number of patients with cirrhosis by the end of the study increased to 24.1% (21), 8.4% (8) developed HCC and 18.9% (18) died. Liver-related death was the most common cause (44.5%), followed by extrahepatic malignancy (16.7%) and cardiovascular disease (11.1%). Hazard ratios for all-cause mortality were generated using the risk categories above and



adjusted for age. Patients in the "high risk" categories had an increased association with all-cause mortality compared to those "low risk": ELF aHR 9.05, 95% CI 2.35–34.88, p = 0.001, FIB-4 aHR 16.04, 95% CI 3.46–74.33, p < 0.001. 10 year survival rates were 98%, 92% and 60% in those with low, intermediate, and high ELF results.
Conclusion: Consistent with the recognised link between fibrosis stage and outcomes, ELF and FIB-4 exhibited prognostic value for prediction of mortality in patients with NAFLD. These NITs offer clinically utility for both the diagnostic and prognostic contexts of use in NAFLD.

SAT-453

Utilization of fibroscan-AST scoring system to risk-stratify non-alcoholic steatohepatitis patients for clinical trials and novel therapies

Phillip Leff[1,2], Prido Polanco[1], Rida Nadeem[1], Aria Raman[1], Gagana Ameneni[1], Shray Patel[1], Rayan Ahmed[1], Anushka Kadharia[1], Naim Alkhouri[1]. [1]*Arizona Liver Health, United States;* [2]*Creighton University, United States*
Email: phillipleff@creighton.edu

Background and aims: The Fibroscan-AST (FAST) score is a non-invasive test that utilizes liver elastography with a complex formula to determine a patient's risk of progressive Non-Alcoholic Fatty Liver Disease (NAFLD). Multiple studies have validated the FAST score at predicting the patient's risk of progressing to Non-Alcoholic Steatohepatitis (NASH) more accurately than other non-invasive tests (NIT) i.e. NAS, FIB4, and the APRI score. The aim of this study was to determine if the FAST score would be an effective NIT to stratify high risk patients to receive medical therapies for NASH in conjunction with the AGA guideline for hepatology referrals for NAFLD.
Method: This was a retrospective chart review, in the setting of an outpatient hepatology clinic. Patients 18 years and older who presented to the outpatient clinic that underwent liver elastography, with a complete metabolic panel were included. Patients that did not undergo liver elastography were excluded from the study. NAFLD fibrosis score was calculated using: FAST = {exp (-1.65 + 1.07 × ln (LSM) + 2.66 × 10^{-8} × CAP^3–63.3 × AST^{-1})}/{1 + exp (-1.65 + 1.07 × ln (LSM) + 2.66 × 10^{-8} × CAP^3–63.3 × AST^{-1})}. AGA guidelines were followed, patients were initially screened using Fib-4, Fib-4 > 1.6 underwent elastography. Fib-4 was calculated using Fib-4 = age×AST/PLT×ALT. Elastography cut-off was kPa ≥8. In addition to this protocol, patients with kPa ≥8 were selected for FAST scoring.

Results: Our cohort included 925 patients. 593 were female (64.11%), 499 were Caucasian (53.95%), 25 were African American (2.70%), 19 were Asian (2.05%), 6 were Native American (0.65%), 172 were other (18.59%), and 172 declined to answer (18.59%). 377 (40.76%) patients were non-Hispanic, 192 (20.76%) were Hispanic, and 356 (38.49%) were unknown/declined to answer. 350 (37.84%) had diabetes mellitus, 288 (31.14%) had dyslipidaemia, and 420 (45.41%) had hypertension. The average FAST score was 0.45. 263 had a FAST score ≥0.67 (28.43%). 662 (71.57%) were <0.67. 492 patients had Fib-4 ≥1.3, of those 492 patients 367 had a kPa ≥8. Out of those 367 patients, 207 patients had a FAST score ≥0.67.

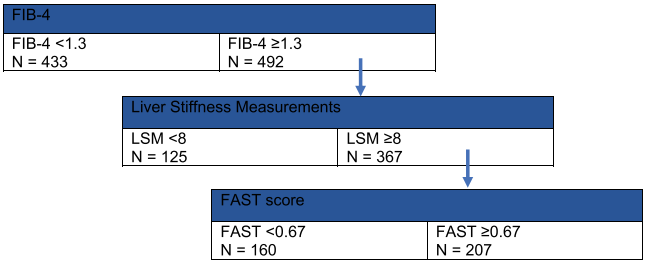

Figure:

Conclusion: With the advent of new therapies currently in clinical trials awaiting approval for commercial use, there is need for a standardized method of risk stratifying patients to receive these limited therapeutics. The FAST score with a cut-off of ≥0.67 had a high specificity and PPV compared to biopsy. This notion implies patients with high FAST scores have a high risk of f2 or greater fibrosis. The decision to start new/limited medication should be reserved for the highest-risk patients, the results of this study conclude patients should follow the AGA guidelines but could consider adding a FAST score to screen for patients that would be the most at need for pharmaceutical therapy.

SAT-454

A screening strategy of hidden compensated advanced chronic liver disease in diabetic outpatients using sequential and automatic fibrosis-4 and enhanced liver fibrosis scores

Clara Amiama Roig[1], Miriam Romero[1], María Sanz de Pedro[2], Alexa Pamela Benitez Valderrama[3], Cristina Suárez Ferrer[1], Carlota Siljestrom Berenguer[1], Mariana Serres Gómez[2], Carmen Amor[1], Irene Gonzalez Diaz[1], Noemi González Pérez de Villar[3], Antonio Buño Soto[2], Antonio Olveira Martín[1]. *[1]La Paz University Hospital, Gastroenterology and Hepatology Department, Madrid, Spain; [2]La Paz University Hospital, Laboratory Medicine Department, Madrid, Spain; [3]La Paz University Hospital, Endocrinology Department, Madrid, Spain*
Email: camiamaroig2@gmail.com

Background and aims: The high prevalence of metabolic liver disease (MAFLD) requires efficient screening and referral strategies. Probably a high number of patients are suffering unknown advanced chronic compensated liver disease (cACLD). The usual non-invasive tests have low positive predictive value, so that the referral of patients based exclusively on one of them is an inefficent overload for our offices. Objective: to efficiently stablish the prevalence of unknown cACLD in a cohort of patients with type 2 diabetes.

Method: Ongoing prospective study. In the Diabetes analytical requests the Laboratory determined, automatically and without specific medical request, both FIB4, and ELF in those with FIB4 >1.3 (>2 in >65 years). In agreement with Endocrinology and with the Ethics Committee approval, the Laboratory generated a referral to Hepatology in those with FIB4 >1.3/2. According to Baveno VII, cACLD was considered absent if Fibroscan <10 kPa and cACLD if >15 kPa. Between 10–15 kPa (suggestive of cACLD) we considered cACLD when ≥12 kPa (Papatheodoridi. J Hepatol 2020). ELF cut-off for cACLD was >9.8. Exclusion criteria were age <35/>80 years, already diagnosed MAFLD or other liver diseases, patient refusal and severe comorbidities (advanced cancer, degenerative diseases…). Normally distributed quantitative variables were described using the mean; otherwise, the median was calculated. Diagnostic performance of ELF was assessed with receiver operating characteristic curves (AUROC).

Results: Between March and November 2022 FIB4 was performed in 1958 patients, 491 (25.1%) with FIB4 >1.3/2. Of these, only 43 (8.8%) were already diagnosed with cACLD (MAFLD 19), being excluded along with 130 other patients (comorbidities, refusal, etc). Of the remaining patients, we have hitherto studied 121 (Table). Twenty-five patients (20.6%) had unknown cACLD. The AUROC for ELF >9.8 was 0.82 (S 95%, E 51%, NPV 97.5%, PPV 32%). The sequential use of FIB4 and ELF would have missed only 1 patient with cACLD and 1 out of 3 referred patients would have cACLD.

Conclusion: the prevalence of unknown cACLD is high in Diabetes outpatient clinic. The sequential use of FIB4 and ELF is very effective in its detection. Its automated determination would be very efficient avoiding unnecessary referrals.

SAT-455

Diagnostic efficacy of Mac-2 binding protein glycosylation isomer for predicting liver fibrosis in patients with metabolic associated fatty liver disease: multicenter cohort study

Dae Won Jun[1], Se Young Jang[2], Ki Tae Yoon[3], Young Youn Cho[4], Hoon Gil Jo[5], Yang-Hyun Baek[6], Sang Yi Moon[6], Aejeong Jo[7]. *[1]Hanyang University College of Medicine, Department of Internal Medicine, Korea, Rep. of South; [2]Kyungpook National University Hospital, Department of Internal Medicine, Korea, Rep. of South; [3]Pusan National Univeristy Hospital, Department of Internal Medicine, Korea, Rep. of South; [4]Chung-Ang University Hospital, Department of Internal Medicine, Korea, Rep. of South; [5]Wonkwang University College of Medicine and Hospital, Department of Internal Medicine, Korea, Rep. of South; [6]Dong-A University College of Medicine, Department of Internal Medicine, Korea, Rep. of South; [7]Andong National University, Department of Information Statistics, Korea, Rep. of South*
Email: gongori1004@gmail.com

Background and aims: The definition of metabolic associated fatty liver disease (MAFLD) has newly been proposed. We aimed to investigate the efficacy of Mac-2 binding protein glycosylation isomer (M2BPGi), non-invasive fibrosis marker, for discriminating significant and advanced fibrosis, and cirrhosis, respectively according to MAFLD and NAFLD definitions.

Method: Serum M2BPGi levels were collected and analyzed from 2,177 patients among 6 tertiary hospitals between April 2020 and May 2021. Liver fibrosis was graded by transient elastography. Diagnostic efficacy of serum M2BPGi and other serum based liver fibrosis markers [AST to platelet index (APRI), fibrosis index based on four factors (FIB-4), and NAFLD fibrosis score (NFS)] was evaluated using area under the ROC curve (AUC) and Delong's test.

Results: There were 1,379 patients and 1,194 patients by the MAFLD and NAFLD definition, respectively. The AUC values of M2BPGi were 0.682, 0.715, and 0.834 for predicting fibrosis (F) >1, F >2, and F >3, respectively in NAFLD group. The AUC values of M2BPGi were 0.68, 0.711, and 0.814 for predicting F >1, F >2, and F >3, respectively in MAFLD group. The AUC values of M2BPGi for predicting severity of fibrosis were greater than those of serum based liver fibrosis markers. The diagnostic efficacies of M2BPGi predicting significant and advanced fibrosis, and cirrhosis in NAFLD and MAFLD patients, respectively, were not statistically different according to Delong's test (p value; 0.94, 0.90, 0.60, respectively).

Figure: Table 1: (abstract: SAT-454): Baseline patients' characteristics.

Sex		Age	BMI (kg/m²)	GPT (U/L)	GOT (U/L)	Fibroscan (kPa)	CAP (dB/m)	Diabetes Comorbidities		Treatment	
Women 43(35.5%)	Men 78(64.5%)	67.3±3.7	29.7±5.3	34.1±18.2	35.3±16.8	9.8±9.3	274±67	Nephropathy	31 (25.6%)	Metformin	68 (56.2%)
								Neuropathy	13 (10.7%)	SGLT2 Inhibitors	50 (41.3%)
								Peripheral Arterial Disease	10 (8.3%)	DPP4 Inhibitors	29 (23.9%)
								Stroke	11 (9.1%)	GLP1 Agonists	30 (24.7%)
								Coronary Syndrome	26 (21.5%)	Insulin	59 (48.7%)

(BMI: Body Mass Index, GPT: Glutamic-pyruvic transaminase, GOT: glutamic-oxaloacetic transaminase, SGLT: Sodium-glucose cotransporter-2, DPP4: Dipeptidyl peptidase-4, GLP1: Glucagon-like peptide 1).

Conclusion: M2BPGi showed better diagnostic efficacy for diagnosing the severity of liver fibrosis in MAFLD patients, as well as in NAFLD patients, comparing with other liver fibrosis markers.

SAT-456

Shortcomings of "FIB-4 First" strategy in screening for non-alcoholic fatty liver disease (NAFLD) patients at risk for disease progression in a real life setting: will we be detracting therapeutic opportunities from patients?

Simone Cappelli[1], Antonio Salvati[1], Giovanni Petralli[2], Laura De Rosa[3], Gabriele Ricco[1], Lidia Surace[1], Piero Colombatto[1], Barbara Coco[1], Veronica Romagnoli[1], Filippo Oliveri[1], Ferruccio Bonino[4], Maurizia Brunetto[1,4]. *[1]Hepatolgy Unit, Pisa Univesity Hospital, Italy; [2]Department of surgical, Medical, Molecular and Critical Area Pathology, Univesity of Pisa, Italy; [3]Department of Information enginneering and computer Science, University of Trento, Italy; [4]Biostructure and bio-imaging institute of National reasarch council of Italy, Italy*
Email: brunettomaurizia@gmail.com

Background and aims: The Fibrosis 4 score (FIB-4) is a non-invasive scoring system derived from Age, Aspartate aminotransferase (AST), Alanine aminotransferase (ALT) and Platelets (PLts), that has been recently promoted in AASLD guidelines as a tool in the Primary Care setting to screen for clinically significant fibrosis (CSF) in NAFLD patients (pts); A value ≥1.30 identifies pts at a higher risk for progressive liver disease that need a hepatologist referral for Liver Stiffness Measurement (LSM).
In this retrospective study, we evaluated the overall performance of the score among different clinical sub-groups.
Method: 367 NAFLD pts between 35 and 65 years (yrs) (M : F = 213 : 154; 51.7 yrs ± 7.5) followed at the Hepatology Unit in Pisa from January 2017 to October 2022 underwent clinical evaluation including: AST, ALT, GGT, ALP, blood count, p.glucose, insulin, HBa1c, lipid profile, body mass index (BMI), waist circumference (WC) and LS by transient elastography (TE, Fibroscan®)
Results: 262 pts (71.3%) had FIB-4 <1.30 (M : F = 149 : 113, 50.5 yrs ± 7.6), among them 34 (13%) had a TE >8 kPa, of which 18 (7% of the total) even higher than 9.7 kPa, indicative of CSF. Compared to the general population, in this group of pts where the FIB-4 score failed in identify CSF we found a statistically significant higher prevalence of Obesity, Type 2 Diabetes Mellitus (T2DM), and T2DM along with Obesity, with a Risk Ratio of 2.3 (CI 95%, 1.1–4.9, p = 0.026), 4.4 (CI 95%, 2–9.6, p < 0.0001) and 5.5 (CI 95%, 2.3–12.8, p < 0.0001), respectively. Given an overall prevalence of TE >8 kPa of 21.1%, the FIB-4 held a negative predictive value (NPV) of 88.5% in non diabetic and lean/overweight pts, 78.3% in diabetic pts, 75.6% in obese pts, while the performance of the score dropped to a NPV of 65.4% in obese and diabetic pts.

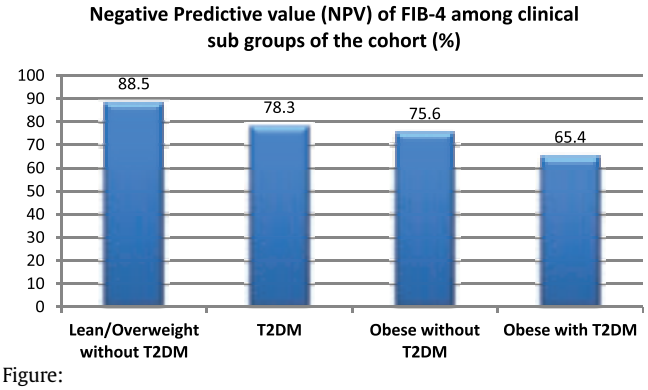

Figure:

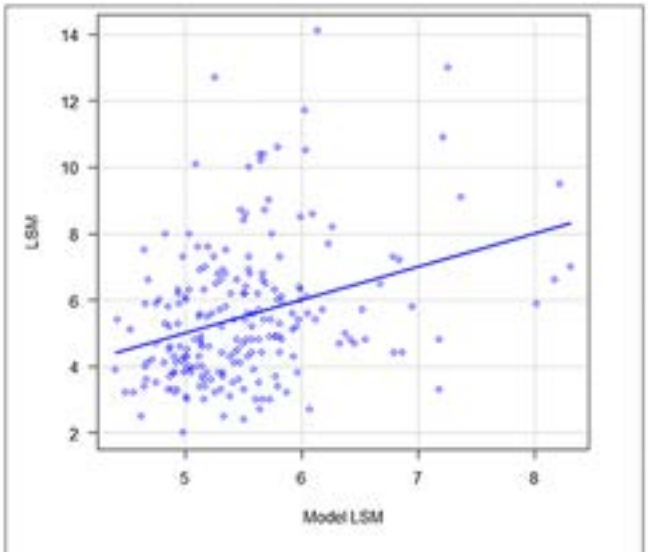
Conclusion: These data show that the categories of patients where the proposed "FIB-4 first" strategy has a worse screening performance are also the one that could benefit more from a specialist referral for the inclusion in a lifestyle change program, a tailoring of their therapy, or even bariatric surgery. These findings should guide the physician not to rely on the FIB-4 score alone when screening NAFLD patients, but rather on a more comprehensive evaluation of the patients clinical characteristics and comorbidities.

SAT-457

Analysis of correlation and predictive ability of oral glucose tolerance tests with insulin assays for liver stiffness measurement in non-cirrhotic overweight and obese patients

Valentino Osti[1,2], Michele Stecchi[2], Michela Genovese[2], Lucia Brodosi[2,3]. *[1]Azienda USL di Bologna, Department of Public Health, Bologna, Italy; [2]University of Bologna, Department of Medical and Surgical Sciences, Bologna, Italy; [3]IRCCS Azienda Ospedaliero-Universitaria di Bologna, Department of Digestive, Liver and Endocrine-Metabolic Diseases, Bologna, Italy*
Email: valentino.osti@ausl.bologna.it

Background and aims: Non-Alcoholic and Metabolic Associated Fatty Liver Disease (NAFLD/MAFLD) is the leading cause of steatohepatitis and end-stage liver disease. Aberrations of glucose metabolism, such as insulin-resistance, Impaired Glucose Tolerance (IGT), Impaired Fasting Glucose (IFG) or Type 2 Diabetes Mellitus (T2DM), and obesity are described as the main metabolic diseases related to NAFLD; to the best of our knowledge, there's no evidence of a quantitative relationship between the post-prandial glucoinsulinemic response in obese patients and Liver Stiffness Measurement (LSM). As an audit in our third level nutrition center in Italy, we investigated the potential of data extraction from Oral Glucose Tolerance Tests (OGTTs) with insulin assay in predicting liver stiffness measured with an elastography.
Method: We analyzed data from 267 non cirrhotic patients with obesity or morbid overweight (Body Mass Index, BMI ≥27 kg/m^2) who underwent both a 75 g OGTT with insulin assay at 0′, 60′ and 120′, and a liver elastography (FibroScan) within a 12 week window. The analysis was performed with R, and we excluded subjects who reported significant alcohol consumption (>1 IU/day women, >2 IU/day men), and those who lost weight or underwent metabolic or weight pharmacotherapy in that time window. After data collection, total insulin and glucose (0′-120′) were calculated with the trapezoidal rule, including baseline determinations. Data are reported as median ± IQR (Interquartile Range), hypothesis testing was lead with a 1% alpha error, and 95% confidence intervals are identified as [CI95].
Results: We evaluated several linear regression models derived from the analysis of the OGTTs. Considering the most practical and efficient model, FIB4 and fasting insulin are necessary, and it has a 33% [20.2–44.1] correlation coefficient, and a median difference of 0.52 ± 0.25 kPa, between estimated and measured LSM. When compared to the measured LSM as a reference, the model predicts subjects with significant liver stiffness (LSM ≥8.0 kPa) with a 4% [1–20.4] sensibility and a 98.4% [95.5–99.7] specificity. Post-prandial insulin-resistance MATSUDA index displays a high diagnostic accuracy for an LSM ≥8.0 kPa, as expressed by an AUC of 0.7 [0.598–0.802], with a Youden's best cut-off of 1.82 associated to a 76.4% specificity and a 63% sensibility. When considering the subgroup of patients with NAFLD (as by Controlled Attenuation Parameter, CAP ≥249 dB/s), the model predicts subjects with LSM ≥7.0 kPa with a 16% [4.5–36.1] sensibility and a 100% [92.8–100] specificity.



Linear regression model (LSM ~ FIB-4 + Insulin 0')

	Estimate	2.5%	97.5%	Std. Error	p value
Intercept	3.9127059	3.18074515	4.6446666	0.37132427	3.784032e-21
FIB-4	0.5214975	0.05651553	0.9864795	0.23588575	2.811815e-02
Insulin 0'	0.0696208	0.04019870	0.0990425	0.01492575	5.475524e-06

Figure:

Conclusion: Our results support the relationship between fasting and post-prandial insulin levels and liver stiffness in subjects with obesity and morbid overweight. The key strength of our work lies in the innovation of finding a formula that could potentially help rule out significant liver stiffness, strongly linked to fibrosis and advanced liver disease. The main limitations of this work are the relatively small sample size and the possible interaction between hypolipidemic agents and glucose homeostasis. The most practical model to predict liver stiffness in dysmetabolic subjects needs a single blood test with liver enzymes, blood count and fasting insulin, but further studies are needed to either verify our formula or to create more accurate algorithms to screen patients with obesity at risk for advanced metabolic liver disease.

SAT-458

Lower ALT levels are associated with increased all-cause and cardiovascular mortality in patients with NAFLD in the United States population

Bo Feng[1], Zheng Jiarui[2]. [1]*Peking University Hepatology Institute, Peking University People's Hospital, Bejing, China;* [2]*Peking University Hepatology Institute, Peking University People's Hospital, Beijing, China*
Email: fengbo@pkuph.edu.cn

Background and aims: The serum alanine aminotransferase (ALT) level is often considered as a marker to evaluate the activity of liver disease and the severity of liver injury. In this study, we aimed to investigate the association between ALT levels and all-cause and cause-specific mortality in non-alcoholic fatty liver disease (NAFLD) patients.
Method: National Health and Nutrition Examination Survey (NHANES)-III from 1988 to 1994 and NHANES-III related mortality data from 2019 were used. NAFLD was defined as hepatic steatosis diagnosed by ultrasound, without other liver diseases. ALT levels were categorized into four groups according to different recommended upper limit of normal in men and women: <0.5 upper limit of normal (ULN), 0.5–1 ULN, 1–2 ULN, ≥2 ULN. The hazard ratios (HRs) for all-cause mortality and cause-specific mortality were analyzed with Cox proportional hazard model.
Results: Multivariate logistic regression analysis demonstrated odds ratio of NAFLD correlated positively with increasing serum ALT levels. In patients with NAFLD, all-cause mortality and cardiovascular mortality are the highest when ALT<0.5ULN, yet cancer-related mortality is the highest when ALT ≥2ULN. The same results could be found in both men and women. Univariate analysis showed that severe NAFLD with normal ALT level had the highest all-cause and cause-specific mortality, but the difference was not statistically significant after adjustment for age and multivariate factors.
Conclusion: The risk of NAFLD was positively correlated with ALT level, but all-cause and cardiovascular mortality were the highest when ALT<0.5ULN. Regardless of the severity of NAFLD, normal or

Note: The multivariate model was adjusted for age, sex, race/ethnicity, body mass index, waist circumference, AST, Alb, TG, TC, HDL, smoking status, diabetes, hypertension, and sedentary lifestyle.
Others: chronic lower respiratory diseases, accidents (unintentional injuries), cerebrovascular diseases, Alzheimer's diseases, diabetes mellitus, influenza and pneumonia, nephritis, nephrotic syndrome and nephrosis and all other causes (residual).
Abbreviations: CI, confidence interval; HR, hazard ratio; NAFLD, nonalcoholic fatty liver disease.

Figure: (abstract: SAT-458).

lower ALT levels are associated with higher mortality than elevated ALT levels. Clinicians should be aware of not only high ALT, indicating liver injury, but also low ALT associated with higher risk of death.

SAT-459

ABDA score: a non-invasive model to identify subjects with fibrotic non-alcoholic steatohepatitis in the community

Shalimar[1], Abhinav Anand[1], Sagnik Biswas[1], Manas Vaishnav[1], Nikhil Tandon[2]. *[1]All India Institute of Medical Sciences, New Delhi, Gastroenterology and Human Nutrition, Delhi, India; [2]All India Institute of Medical Sciences, New Delhi, Endocrinology, Delhi, India*
Email: drshalimar@yahoo.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and steatohepatitis (NASH) are prevalent in the community, especially among those with metabolic syndrome. Patients with fibrotic NASH are at increased risk of liver-related-events. Currently available non-invasive tests have not been utilized for screening for fibrotic NASH among the community. We aimed to develop a screening tool for fibrotic NASH among community members.
Method: We included two large cohorts aimed at assessing cardiovascular disease among community members. Fibrotic NASH was defined using FibroScan-AST (FAST) score of ≥0.67 that identifies ≥F2 fibrosis and NAFLD activity score ≥4 with a specificity of 90%. Metabolic parameters, biochemical tests, and anthropometry were used to develop a multivariate model.
Results: The derivation cohort (n = 1660) included a population with median age 45 years, 42.5% males, metabolic syndrome in 66%, and 2.7% (n = 45) with fibrotic NASH. Multivariate analysis identified 4 significant variables (Age, BMI, Diabetes and ALT levels) used to derive the ABDA score. The score had high diagnostic accuracy (area under receiver-operating characteristic curve, AUROC 0.952) with adequate internal validity (Figure). ABDA score ≥-3.52 identified fibrotic NASH in the derivation cohort with a sensitivity and specificity of 88.9% and 88.3%. The score was validated in a second cohort (n = 357) that included 21 patients (5.9%) with fibrotic NASH, where it demonstrated a high AUROC (0.948), sensitivity (81%) and specificity (89.3%).
Conclusion: ABDA score utilizes four easily available parameters to identify fibrotic NASH with high accuracy in the community.

SAT-460

Evaluation of serum biomarkers for the diagnosis of non-alcoholic fatty liver disease in the general population: a cross-sectional Spanish population-based study

Jesús Rivera[1,2,3], Paula Iruzubieta[4], Alba Jiménez-Masip[1], Ramiro Manzano[1,2], Elba Llop[5], Christie Perelló[5], Marta Hernández Conde[5], María Teresa Arias Loste[4], María Del Barrio Azaceta[4], Desamparados Escudero-García[6], Miguel Serra[6], Juan M Pericas[1,2], José Luis Calleja Panero[5], Javier Crespo[4]. *[1]Vall d'Hebron Hospital Universitari, Liver Unit, Spain; [2]Vall d'Hebron Institut of Research (VHIR), Spain; [3]Universitat Autònoma de Barcelona, Bellaterra, Barcelona, Spain; [4]Hospital Universitario Marqués de Valdecilla, Spain; [5]Hospital Universitario Puerta de Hierro, Spain; [6]Hospital Clinico de Valencia, Spain*
Email: jesusriveraest@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a highly prevalent entity that relies on non-invasive tests (NITs) for disease detection and stratification. Serological NITs for steatosis are useful tools for the initial assessment of NAFLD, whereas validation studies in different populations are needed. The study aimed to evaluate the diagnostic accuracy of serological NITs in the general population from Spain and to investigate the correlation between these tests and the controlled attenuation parameter (CAP) of transient elastography (TE).
Method: Multicentric, cross-sectional study based on a representative cohort of the general adult population in Spain (PREVHEPETHON) with TE and CAP data. We excluded subjects with suspected viral hepatitis or excessive alcohol consumption (≥15 units/day). The reference test was the TE-CAP and a value ≥275 dB/m was considered diagnostic of NAFLD. A liver stiffness ≥8 kPa was considered suggestive of significant fibrosis. We evaluated the diagnostic ability of Fatty Liver Index (FLI), Fatty Liver Disease (FLD) index, Hepatic Steatosis Index (HSI), Lipid Accumulation Product (LAP) index, NAFLD index, Visceral Adiposity Index (VAI), and Zhejiang University (ZJU) index. The area under the curve (AUC) and the predictive values (PV) for NAFLD applying the foreknown cut-offs were calculated in the overall cohort and specifically in obese patients (body mass index ≥30 kg/m^2). In addition, we assessed the concordance to confirm or exclude NAFLD using Cohen's Kappa index (k) and the correlation between the different indices and TE-CAP using Pearson's linear test (r).

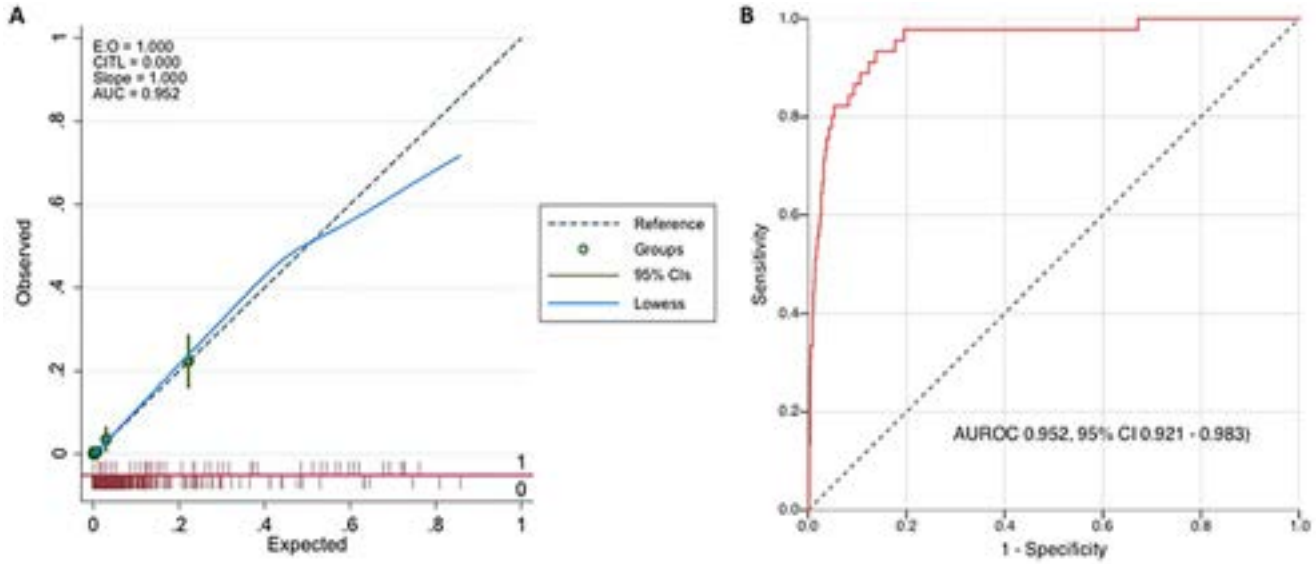

Figure: (abstract: SAT-459): (A) Hosmer Lemeshow calibration plot, with Loess smoothing, for the prediction model in the overall derivation cohort showing satisfactory fit. EO: expected/observed ratio; CITL: calibration-in-the-large; AUC: area under the curve; Loess (B) Receiver operating characteristic (ROC) curve for the ABD score in predicting fibrotic non-alcoholic steatohepatitis (NASH) in the derivation cohort.

Results: We included 9637 patients, 4268 (44.2%) of whom had TE-CAP data. The estimated prevalence of NAFLD was 33.0%. NAFLD subjects were predominantly male (54.8 vs 37.5%; p < 0.001), had a higher median age (55 (47–64) vs 48 (42–57) years; p < 0.001), and a higher metabolic burden than those without NAFLD (p < 0.001 for all metabolic diseases). Overall, serological NITs showed an adequate diagnostic ability (AUC >0.70), showing FLI the highest diagnostic accuracy (AUC 0.81; 95%CI 0.79–0.82), a NPV of 89.6% and a PPV of 63.2% for FLI 30 and 60, respectively. Besides, FLI had a proper concordance (k = 0.45) and linear correlation (r = 0.55) with TE-CAP. In obese individuals, the diagnostic accuracy of serological NITs decreased significantly, presenting FLI an AUC of 0.72 (95%CI 0.69–0.76), and an AUC <0.70 for the rest of the indices. Finally, when tested for significant fibrosis evaluation, FLI showed the highest AUC (0.72–95%CI 0.67–0.76-) of the studied NITs.

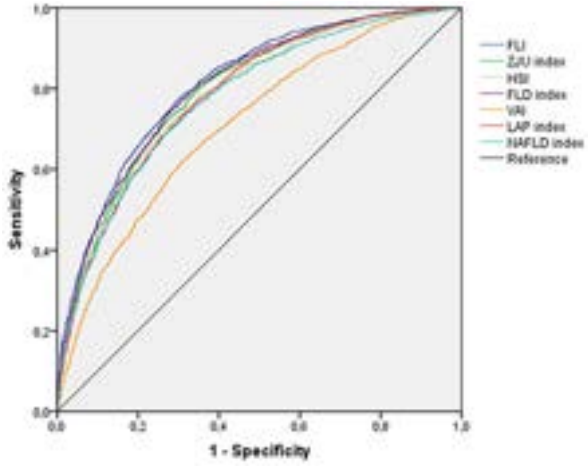

Figure: ROC curves of the serologic indices for NAFLD detection in the general population from Spain.

Conclusion: The serological indices of steatosis, particularly FLI, represent a valid option for NAFLD approaches in the general Spanish population. Further data are needed in high-risk populations, such as people living with obesity, along with histologically-back tested and cost-effectiveness studies to define the best diagnostic strategy for NAFLD at the population level.

SAT-461

MorphoQuant, the first fully-automated morphometric software for the assessment of liver biopsy, identified significant differences between non-alcoholic fatty liver disease and steatohepatitis biopsies

Cindy Serdjebi[1], Bastien Lepoivre[2], Florine Chandes[2], Linda Willis[3], Julé Yvon[2]. *[1]Biocellvia, Marseille, France; [2]Biocellvia, Marseille, France; [3]Histologix Ltd, United Kingdom*
Email: cindy.serdjebi@biocellvia.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is the most severe form of fatty liver diseases, and no treatment has been approved so far. Among the reasons for this lack of valid pharmacological treatment, the subjectivity and variability in the pathology reading has been identified as a confounding factor, probably weakening the ability to assess a treatment effect. We have developed the first fully-automated user-independent morphometric software (MorphoQuant) allowing the assessment of liver biopsies and investigated its performance.

Method: 271 liver biopsies were collected and analyzed. Patients were scored by a blinded expert pathologist according to the NASH CRN for steatosis, inflammation, ballooning and fibrosis using hematoxylin-eosin (HandE) and Masson's trichrome stained slides. MorphoQuant, a fully automated and deterministic artificial intelligence, based on morphometry and expert system-completely independent from pathologist's annotations, was developed to assess NASH features. For digital quantification, slides were stained with HandE (inflammation area, and number of foci), picrosirius red (PSR) alone or combined with CK19 (steatosis, vesicle size, total

Table(abstract: SAT-461): Comparison of MorphoQuant readouts in non-NASH versus NASH biopsies

MorphoQuant Readout	Non-NASH biopsies* (mean; min-max; n)	NASH biopsies** (mean; min-max; n)	Mann-Whitney p-value
Steatosis S (%)	7.89 (081 - 23.55; 74)	10.24 (1.186 - 28.23; 175)	***0.0001***

* NAFLD Activity Score (NAS) < 5

** NAS >=5

bold italic: significant

hCLS: hepatic crown-like structures

collagen, periductular, perisinusoidal, perivascular and septal collagens), labelled with CD68 (CD68 and hepatic crown-like structures) or with Sonic hedgehog (Shh and ballooning/injury), and digitized as whole slide images. MorphoQuant readouts of NASH (NAS ≥5) and non-NASH (NAS <5) biopsies were compared using a Mann-Whitney test.

Results: A total of 929 slides were processed for histology and digitized for quantitative image analysis by MorphoQuant. Steatosis and size of lipid vesicles were significantly higher in NASH patients. The inflammation area, the number of foci and of hepatic crown-like structures were also higher in NASH patients, while CD68 expression did not increase. Ballooning, as investigated through the expression of Shh and injury area, were also shown to be significantly higher in NASH patients. Regarding collagen, collagen proportionate area and perivascular collagen was equivalent in both NASH and non-NASH patients, while perisinusoidal collagen was lower in NASH patients. Periductular and septal collagen were more important in NASH patients, along with CK19 expression.

Conclusion: The current study demonstrates that MorphoQuant is a powerful image analysis tool, using current and original histological methods. In addition, this study highlights that a reliable digital pathology software can be developed independently from pathologist's annotations.

SAT-462

Diagnostic performance of fibrosis-4 index and NAFLD fibrosis score in at-risk group from low prevalence population

Huiyul Park[1], Mimi Kim[2], Sang Bong Ahn[3], Hyo Young Lee[4], Jun-Hyuk Lee[5], Eileen Yoon[6], Chul-min Lee[2], Bo-Kyeong Kang[2], Joo Hyun Sohn[1], Jihyun An[6], Joo Hyun Oh[3], Hye-Lin Kim[7], Hyunwoo Oh[4], Jang Han Jung[8], Dae Won Jun[6], Eun Chul Jang[9].

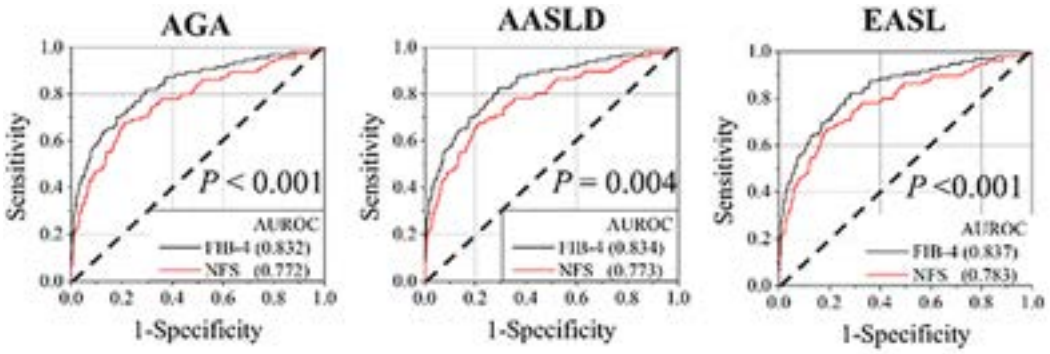
Email: noshin@hanyang.ac.kr

Background and aims: A non-invasive screening test for hepatic fibrosis is recommended in at-risk group (those with fatty liver, elevated liver enzymes, diabetes, and ≥2 metabolic risk factors). The performances of fibrosis-4 index (FIB-4) and non-alcoholic fatty liver disease (NAFLD) fibrosis score (NFS) have not been evaluated in at-risk group. We aimed to evaluate the diagnostic performance of FIB-4



Populations	Risk factors				
	Fatty liver	Diabetes	Abnormal liver enzyme	Metabolic risk factors	Obesity
At risk group in AGA	o	o	o	o (≥2)	x
At risk group in AASLD	o	o (Prediabetes)	o	o (≥2)	o
At risk group in EASL	o	o	o	o (≥3) or CVD	o (Overweight)

Figure 1. Receiver operating characteristic (ROC) curves for diagnosis of advanced fibrosis by FIB-4 or NFS in at-risk group in various guidelines.
The definition of at-risk group according to different guidelines was summarized at table.
P-value when ROC curve by FIB-4 was compared with ROC curve by NFS in at-risk population
Abbreviation: AASLD, American Association for the Study of Liver Diseases; AGA, American Gastroenterological Association; AUROC, area under receiver operating characteristic; CVD, cardiovascular disease; EASL, European Association for the Study of Liver; LFT, liver function test; NFS, NALFD, non-alcoholic fatty liver disease; NAFLD fibrosis score; FIB-4, fibrosis-4 index.

Figure: (abstract: SAT-462).

and NFS in at-risk group with advanced hepatic fibrosis in a population with low prevalence of hepatic fibrosis.
Method: This retrospective, cross-sectional study included 8,545 participants who underwent magnetic resonance elastography (MRE) at 13 nationwide health-promotion centers during a routine health check-up. The area under the receiver-operating characteristic (AUROC) curves of FIB-4 and NFS were compared using DeLong's test.
Results: Overall, 67.4% of individuals in health check-up cohort without the risk of viral or alcoholic hepatitis was at-risk group. At-risk group and those with NAFLD had comparable rates of significant and advanced (9.2% vs. 8.9% and 2.8% vs. 2.3%, respectively) hepatic fibrosis; furthermore, the AUROCs of FIB-4 (0.832 vs. 0.826, respectively; p = 0.873) and NFS (0.772 vs. 0.803, respectively; p = 0.457) in advanced hepatic fibrosis were similar them. However, the AUROC (0.772 vs 0.832, respectively; p < 0.001) and sensitivity (61.7% vs 71.6%, respectively) in the at-risk group were lower for NFS than those for FIB-4. This feature was consistently observed, regardless of the kinds of guidelines such as American Gastroenterological Association (AGA) (0.832 in FIB-4 vs. 0.772 in NFS, p < 0.001), American Association for the Study of Liver Diseases (AASLD) (0.834 in FIB-4 vs. 0.773 in NFS, p = 0.004), and European Association for the Study of Liver (EASL) (0.837 in FIB-4 vs. 0.783 in NFS, p < 0.001).
Conclusion: The diagnostic performance of FIB-4 in at-risk group in a low-prevalence population is comparable to that in individuals with NAFLD. However, the diagnostic performance and sensitivity of NFS in at-risk group were low.

SAT-463

A diagnostic non-invasive model for liver advanced fibrosis and cirrhosis in chronic hepatitis B (CHB) concurrent with non-alcoholic fatty liver disease (NAFLD) based on machine learning (ML)

Jie Li[1], Yayun Xu[2], Fajuan Rui[1], Xiaorong Tian[3], Qi Xue[4], Qi Zheng[5], Qing-Lei Zeng[6], Zebao He[7], Jian Wang[1], Weimao Ding[8], Chuanwu Zhu[9], Yuanwang Qiu[10], Yunliang Chen[3], Junqing Fan[3], Junping Shi[11], Chao Wu[1]. *[1]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Nanjing, Jiangsu, China, China; [2]Shandong Provincial Hospital, Shandong University, Ji'nan, Shandong, China; [3]School of Computer Science, China University of Geosciences, Wuhan, China; [4]Shandong Provincial Hospital Affiliated to Shandong Frist Medical University, Ji'nan, Shandong, China; [5]Hepatology Research institute, the First Affiliated Hospital, Fujian Medical University, Fuzhou, China; [6]The First Affiliated Hospital of Zhengzhou University, Zhenghzhou, Henan, China; [7]Taizhou Enze Medical Center (Group) Enze Hospital, Taizhou, Zhejiang, China; [8]Huai'an No. 4 People's Hospital, Huai'an, Jiangsu, China; [9]The Affiliated Infectious Diseases Hospital of Soochow University, Suzhou, Jiangsu, China; [10]The Fifth People's Hospital of Wuxi, Wuxi, Jiangsu, China; [11]The Affiliated Hospital of Hangzhou Normal University, Hangzhou, Zhejiang, China*
Email: lijier@sina.com

Background and aims: As NAFLD is prevalent globally, the concurrence of chronic hepatitis B (CHB) with non-alcoholic fatty liver disease (NAFLD) is increasing. But there are still lack of non-invasive models to accurately evaluate liver advanced fibrosis and cirrhosis in those patients. This study aimed to establish a novel diagnostic model for liver advanced fibrosis and cirrhosis in CHB patients concurrent with NAFLD based on machine learning (ML).
Method: This study consecutive enrolled CHB patients concurrent with NAFLD underwent liver biopsy and laboratory examination from six medical centers of China between April 2004 and September 2021 as training cohort and patients from other three medical centers of China between April 2004 and October 2020 as independent external validation cohort. We implemented ML models including gaussian naive bayes (GNB) and logistic regression (LR) to predict advanced fibrosis (S≥3) and cirrhosis (S = 4). Pearson correlation coefficient was used to explore the correlation between 29 clinical features and fibrosis grade. The features with the absolute value >0.2 of Pearson correlation coefficient were included in the diagnostic model. To avoid overfitting, 5-fold cross validations were used in the ML models building process. Model performance was compared to fibrosis index based on the four factors (FIB-4), activated partial thromboplastin time (APRI), and NAFLD Fibrosis Score (NFS) in patients of CHB concurrent with NAFLD.
Results: A total of 1427 CHB patients with NAFLD underwent liver biopsy were enrolled, with a average age of 38 (32–47) years (1093 males and 334 females). 298 cases (20.9%) have advanced fibrosis (S≥3), and 118 cases (8.3%) have cirrhosis (S = 4). Prothrombin time (PT) was positively associated with advanced fibrosis and cirrhosis, and albumin (ALB), platelet (PLT) were negatively associated with advanced fibrosis and cirrhosis. GNB model had the best performance, and its AUC for the diagnosis of advanced fibrosis and cirrhosis were 0.770 (0.714–0.827), 0.844 (0.795–0.893) in training cohort, and 0.716 (0.669–0.762), 0.812 (0.772–0.853) in validation cohort, which was significantly better than that of FIB-4, APRI and NFS (all $P < 0.05$).
Conclusion: GNB model performed better overall than FIB-4, APRI, and NFS. ML could be an effective tool for identifying clinically liver fibrosis and cirrhosis in CHB patients concurrent with NAFLD.

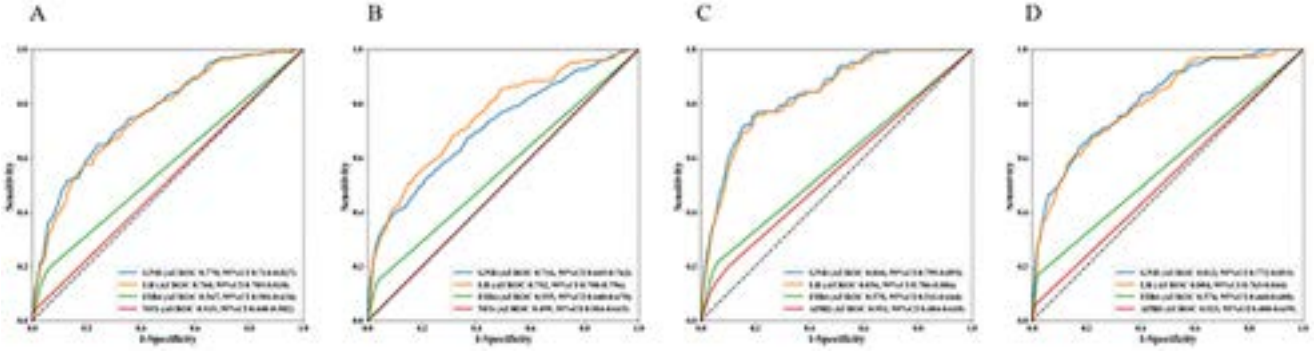


Figure: (abstract: SAT-463): AUC of machine learning models for fibrosis grade in training cohort and validation cohort: A. Advanced fibrosis (≥S3) in training cohort; B. Advanced fibrosis (≥S3) in validation cohort; C. Cirrhosis (S = 4) in training cohort; D. Cirrhosis (S = 4) in validation cohort.

SAT-464

Effect of diabetes mellitus and fatty liver on hepatic fibrosis

Byung Ik Kim[1], Yong Kyun Cho[1], Jung Hee Kim[2], Ju-Yeon Cho[3], Jae Yoon Jeong[4], Won Sohn[1]. [1]*Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Korea, Rep. of South;* [2]*Hallym University Dongtan Sacred Heart Hospital, Korea, Rep. of South;* [3]*Chosun University Hospital, Korea, Rep. of South;* [4]*National Medical Center, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: Diabetes mellitus is associated with fatty liver and hepatic fibrosis. However, it is unclear whether there is a risk of hepatic fibrosis in diabetes without fatty liver or no diabetes with fatty liver. This study aimed to investigate the risk factors for significant fibrosis in patients according to the presence of diabetes and fatty liver.

Method: A cross-sectional study was conducted based on a cohort from a health examination program which included magnetic resonance elastography (MRE). We classified four groups according to diabetes mellitus and fatty liver: Group 1, no diabetes without fatty liver; Group 2, no diabetes with fatty liver; Group 3, diabetes without fatty liver; Group 4, diabetes with fatty liver. Fatty liver was evaluated by ultrasonography. Significant fibrosis was defined as liver stiffness measurement (LSM) ≥2.97 kPa on MRE. We evaluated the difference in significant fibrosis by four groups and analyzed the risk factors for significant fibrosis after adjusting for confounding factors.

Results: A total of 1,899 subjects were included. The number of Group 1, Group 2, Group 3, and Group 4 was 902 (47%), 796 (42%), 47 (3%), and 154 (8%), respectively. Mean values of LSM in Group 1, 2, 3, and 4 were 2.34 ± 0.31 kPa, 2.42 ± 0.37 kPa, 2.49 ± 0.51 kPa, and 2.66 ± 0.70 kPa, respectively ($p < 0.001$). There was a significant difference in significant fibrosis (≥2.97 kPa) between four groups: 2.3%, 3.6%, 6.4%, and 19.5% in Group 1, 2, 3, and 4, respectively ($p < 0.001$). The multivariable-adjusted hazard ratios (aHR) with 95% confidence intervals (CI) for significant fibrosis comparing Group 4, Group 3, and Group 2 to Group 1 were 4.35 (2.14–8.85), 2.43 (0.65–9.12), and 0.96 (0.50–1.85), respectively ($p < 0.001$, $p = 0.197$, and $p = 0.907$).

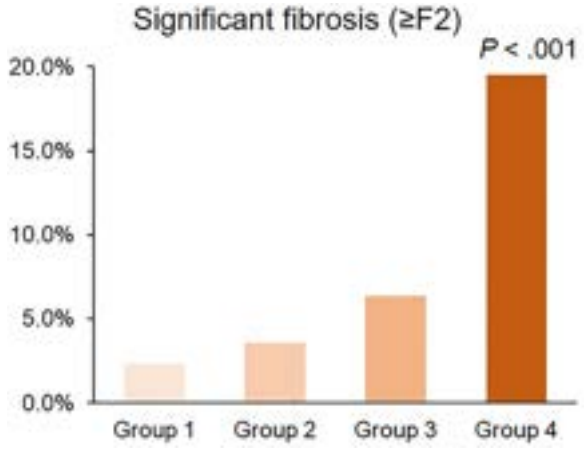

Figure:

Conclusion: The risk of significant fibrosis is high in patients with diabetes and fatty liver rather than those who have one of each. Although all patients with fatty liver have the risk of hepatic fibrosis, it is needed to assess and manage hepatic fibrosis in patients accompanied by diabetes in particular.

SAT-465

High performance of serological indexes in the non-invasive assessment of liver steatosis

Beatriz Pillado Pérez[1], Carlota Siljestrom Berenguer[1], Luis Eduardo Pariente Zorrilla[1], Marta Abadia[1], Gloria Ruiz-Fernandez[1], Joaquin Poza[1], Eva Marín[1], Carmen Amor[1], Clara Amiama Roig[1], Irene Gonzalez Diaz[1], Miriam Romero[1], Araceli García-Sánchez[1], Maria Dolores Martin-Arranz[1], Antonio Olveira Martin[1]. [1]*Hospital La Paz, Spain*
Email: beapillado@gmail.com

Background and aims: steatosis biomarkers are well validated by clinical guidelines but are not used frequently in daily practice. They are mainly used for epidemiological studies or in situations in which other techniques such as ultrasound or controlled attenuation parameter (CAP) are not available. Their real diagnostic value is limited because most studies compare them with ultrasound, CAP or magnetic resonance imaging (MRI) and not with liver biopsy which is still currently the gold standard. We aimed to determine diagnostic value and limitations of steatosis biomarkers using liver biopsy as reference.

Method: we performed a prospective study that included all patients undergoing hepatic biopsy. Clinical, anthropometric, laboratory, ultrasonographic and CAP (EchoSens' Fibroscan 502 Touch) were measured on the same day before the liver biopsy. Hepatic Steatosis Index (HSI: sex, body mass index [BMI], alanine aminotransferase [ALT], aspartate aminotransferase [AST], diabetes), Fatty Liver Index (FLI: BMI, waist circumference, gamma-glutamyl transferase [GGT], triglycerides) and TyG (triglycerides, glucose) were calculated. Biopsies were performed percutaneously using Tru-cut 16/18G needles. Exclusion criteria were biopsy length <1.5 cm or <11 portal tracts, focal lesions, acute hepatitis. Steatosis was diagnosed if liver fat content >5% on biopsy. Receiver operating characteristic (ROC) curves were performed to calculate the performance of the three steatosis biomarkers and CAP.

Results: 245 patients were included between March/20 and October/22. The majority of patients were male (59.8%), and the mean age was 54 years. Mean BMI was 27.4 kg/m2. With regard to liver histology, 42% of patients did not have steatosis, mil steatosis (6–33%) was detected in 23% and moderate (33–66%) or severe steatosis (>66%) in the remaining 35%. Liver fibrosis was not present in 48.4% of patients, mild fibrosis (F1/F2) was detected in 33.9% and advanced fibrosis (F2/F4) was seen in 17.7%. According to the aetiology, 44% of patients had Metabolic-associated Fatty Liver Disease, 18.5% autoimmune diseases, 2.4% genetic diseases, 1.6% alcoholic diseases, 22% normal biopsies and 11.5% other findings. Figure 1 summarises results.

Figure:

N = 245	Optimal cut-off value	Sens (%)	Spec (%)	PPV (%)	NPV (%)	AUC	CI 95%
CAP (dB/m)	254	78	78	81.1	74.6	0.83	0.78–0.88
FLI	60.2	74.8	75.9	78.5	71.9	0.81	0.76–0.87
TyG	4.42	91	58	72	84.4	0.81	0.75–0.86
HSI	41.8	60.9	73.2	73	61.2	0.72	0.66–0.79

Sens: sensitivity, spec: specificity, PPV: positive predictive value, NPC: negative predictive value, AUC: area under the curve, CI: confidence interval, CAP: Coeficient Attenuated Parameter, FLI: Fatty Liver Index, TyG: triglycerides, glucose, HSI: Hepatic Steatosis Index.

Conclusion: steatosis biomarkers FLI and TyG are an excellent tool for the non-invasive diagnosis of steatosis

SAT-466

Fibrosis-4 and M2BPGi combination screening algorithm for screening advanced hepatic fibrosis in diabetes is cost-effective

Mimi Kim[1], Dae Won Jun[1], Hye-Lin Kim[2], Eileen Yoon[1], Se Young Jang[3], Ki Tae Yoon[4], Young Youn Cho[5], Hoon Gil Jo[6], Yang-Hyun Baek[7], Sang Yi Moon[7], Aejeong Jo[1]. *[1]Hanyang University, College of Medicine, Korea, Rep. of South; [2]Sahmyook University, College of Pharmacy, Korea, Rep. of South; [3]Kyungpook National University, Kyungpook National University Hospital, Daegu, South Korea, Korea, Rep. of South; [4]Pusan National University, Korea, Rep. of South; [5]Chung-Ang University Hospital, Seoul, Korea, Korea, Rep. of South; [6]Wonkwang University College of Medicine and Hospital, Korea, Rep. of South; [7]Department of Internal Medicine, Dong-A University College of Medicine, Busan, South Korea, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: The advanced hepatic fibrosis screening strategy using FIB-4-based non-invasive tests (NITs) in diabetes has been shown low sensitivity and specificity, so it is recommended to perform transient elastography (TE) or MR elastography (MRE) first, or combination with NITs. However, TE or MRE is often not available to primary care physicians (PCPs), and screening algorithm in which PCPs first use NITs followed by further evaluation at a tertiary hospital may increase the rates of unnecessary referrals. This study aimed to find out whether the FIB-4 and M2BPGi combination screening algorithm reduces unnecessary referral rates and is cost-effective for diabetic patients in PCPs settings.
Method: We constructed a combined model of the decision tree model and Markov model to compare expected costs and quality-adjusted life-years (QALYs) between 'screening' and 'no screening' groups from healthcare system perspectives. CVD and extrahepatic malignancy conditions potentially related to diabetes and hepatic fibrosis were also included in the model. Patients diagnosed with advanced fibrosis in the screening group were given intensive lifestyle intervention (ILI). Screening strategies compared in our model were (1) M2BPGi, (2) Fibrosis-4 (FIB4), (3) NAFLD fibrosis score (NFS), (4) AST to platelet ratio index (ARPI) (5) FIB4+M2BPGi (6) NFS +M2BPGi (7) APRI+M2BPGi. The prevalence of advanced fibrosis (7.9%) and diagnostic performance of each screening strategy were obtained from cohort data of 9,850 health check-up examiners from 13 health examination centers, and 809 diabetes patients from six tertiary hospitals, respectively. The incremental cost-effectiveness ratio (ICER) was calculated for 20-year horizon. We conducted various sensitivity analyses for varying input values and assumptions.
Results: In the base-case analysis, the estimated ICERs for all the screening strategies were shown below $25,000/QALY which is regarded as an implicit ICER threshold in Korea. FIB-4 with M2BPGi combination screening was not only cost-effective but also was shown to have a lower false positive rate than others, which led to decreasing referral rate to a tertiary hospital. This tendency was more pronounced when the MRE, which has a more precise performance than the TE, was used in the second step. The unnecessary referral rate was 45.4%-46.3% in the single algorithm of M2BPGi and FIB-4, but it decreased to 23.0% in their combination.
Conclusion: The FIB-4 and M2BPGi combination screening algorithm reduces 23.3% unnecessary referral rate compared to FIB-4 screening and is cost-effective for diabetic patients in PCPs setting.

SAT-467

Performance of non-invasive markers in evaluating presence and severity of liver fibrosis in non-alcoholic fatty liver disease: results from a multi-ethnic Asian cohort of biopsy-proven non-alcoholic fatty liver disease patients

En Ying Tan[1], Sin Hui Melissa Chua[1], Eunice Tan[1], Daniel Huang[1], Jonathan Lee[1], Margaret Teng[1], Nur Halisah Binte Jumat[1], Yock Young Dan[1], Mark Muthiah[1]. *[1]National University Hospital (NUH)-Singapore, Department of Gastroenterology and Hepatology, Singapore, Singapore*
Email: tanenying@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease worldwide. It is an umbrella term for a spectrum of disease including hepatic steatosis, non-alcoholic steatohepatitis, fibrosis and cirrhosis. Evaluation for presence and degree of fibrosis is essential in prognostication, determining treatment plans and monitoring response to therapy. Historically, liver biopsy has been the gold standard for achieving this. However, significant shortcomings such as procedural complications, poor patient acceptance, cost and availability issues, sampling error and intra/inter-observer variability have driven development and adoption of non-invasive tests. We aim to evaluate the performance of various NITs in evaluating fibrosis in a multi-ethnic Asian cohort of biopsy-proven NAFLD patients.

Table 1. Base-case analyses by screening strategy (compared to 'No screening')

Strategy	Sensitivity	Specificity	ICER ($/QALY)	TP	FP	TN	FN	Refer rate	Unneccessory referal proportion
Followed by MRE (Sensitivity 88%; Specificity 90%)

Figure: (abstract: SAT-467).

Method: Patients with biopsy-proven NAFLD were enrolled from National University Health System, Singapore to undergo various non-invasive tests. Patients with any other causes for their liver disease were excluded. Fibrosis-4 index (FIB-4), AST to Platelet Ratio Index (APRI), NAFLD Fibrosis Score (NFS), BMI AST/ALT ratio and Diabetes score (BARD), as well as vibration-controlled transient elastography (VCTE), AGILE 3+ and FibroScan-AST score were evaluated for performance in assessment for fibrosis. These NITs were evaluated for performance in identifying clinically significant (F2–4) or advanced (F3–4) fibrosis and "at-risk NASH," a commonly used cutoff for recruitment into clinical trials.
Results: 399 multi-ethnic Asian patients with biopsy-proven NAFLD were recruited to undergo non-invasive tests from 2014 to 2021. Area under receiver-operator-characteristics (AUC) values for identifying clinically significant fibrosis for FIB-4, APRI, NFS, VCTE, AGILE 3+ and FAST were 0.769, 0.785, 0.688, 0.827, 0.806 and 0.797 respectively. AUC values for identifying advanced fibrosis were 0.860, 0.858, 0.760, 0.841, 0.872 and 0.828. AUC values for identifying at-risk NASH were 0.727, 0.793, 0.578, 0.624, 0.581 and 0.770. BARD performed poorly across all analyses, with AUCs of 0.435 to 0.569. Analysis on subgroups with different histological score of steatosis revealed that FIB-4, APRI and NFS performed worse with increasing steatosis, while the performance of VCTE appeared better preserved across grades of steatosis.
Conclusion: VCTE, FIB-4 and APRI performed significantly better than NFS and BARD in identifying clinically significant and advanced fibrosis. VCTE performed well in identifying fibrosis of all severities but performed poorer in identifying at-risk NASH. APRI and FAST were superior to all other indices in prediction of at-risk NASH. FAST and AGILE 3+ scores did not otherwise show benefit over VCTE alone. Composite scores performed worse with more severe steatosis, suggesting VCTE may be the preferred NIT in such cases.

SAT-468

Impact of obesity on transient elastography accuracy among patients with non-alcoholic fatty liver disease

Figure: (abstract: SAT-468).

Background and aims: Liver stiffness measurement by transient elastography (TE) is the most widely used and validated non-invasive method for the assessment of liver fibrosis in non-alcoholic fatty liver disease (NAFLD). However, the presence of obesity can affect the result of TE. Our aim was to evaluate the impact of obesity in the diagnostic performance of TE for NAFLD patients in specialized care centres.
Method: Multicentre and cross-sectional study with biopsy-proven NAFLD patients from the national HEPAmet registry. Inclusion criteria: Non-surgical liver biopsy and valid TE measure, with less than 6 months of difference from the biopsy. Exclusion criteria: Hepatocellular carcinoma, liver transplantation, portal thrombosis and use of beta-blockers.
Results: A total of 1,124 NAFLD patients were included (mean age 55.7 ± 11.0 years, 47% diabetic, 65.7% obese, 11.9% morbid obese). Advanced fibrosis (F3-F4) was present in 32.8% of patients. The 8 kPa cut-off point for advanced fibrosis had a sensitivity, specificity, PPV, and NPV of 94.6%, 39.6%, 43.3%, and 93.7%, respectively. The figure shows the distribution of fibrosis stages among different TE ranges in the overall cohort and according to the presence of obesity/morbid obesity. TE values of 10–15kPa overestimates advanced fibrosis with more frequency among obese patients than non-obese (68.5% vs. 54.3%; p = 0.03). Obesity and controlled attenuation parameter (CAP) were associated with overestimation of advanced fibrosis by TE. The areas under the curve for diagnosis of advanced fibrosis in non-obese, obese, and morbidly obese patients were 0.84 ± 0.02, 0.80 ± 0.02 and 0.76 ± 0.04, respectively. Among patients with a TE ≥15 (n = 273), 33 patients had gastroscopy, of whom 12 (36.4%) presented oesophageal varices and/or portal hypertensive gastropathy. Of these 12 patients, 2 (16.7%) had F2 and both were obese.
Conclusion: In NAFLD patients, obesity may overestimate the value of TE and decrease its accuracy to detect advanced fibrosis. However, TE would predict liver-related outcomes better than liver biopsy.

SAT-469

A sequential use of transient elastography followed by Agile 3+ score significantly improves the screening of advanced fibrosis in patients with NAFLD with or without severe obesity

Adrien Aubin[1], Marianne Maynard[2,3], Bérénice Ségrestin[1], Yasmina Chouik[2], Laurent Milot[4], Valerie Hervieu[5], Fabien Zoulim[2,3], Emmanuel Disse[1], Massimo Levrero[2,3], Cyrielle Caussy[1,6]. *[1]Hospices Civils de Lyon, Endocrinology Diabetes and Nutrition, Pierre-Bénite, France; [2]Hospices Civils de Lyon, Hepatology, France; [3]Centre de Recherche sur le Cancer de Lyon, INSERM-1052, Lyon, France; [4]Hospices Civils de Lyon, Radiology, Lyon, France; [5]Hospices Civils de Lyon, Service d'Anatomie Pathologique, Lyon, France; [6]Université Lyon 1, Medicine School, Pierre-Bénite, France*
Email: cyrielle.caussy@chu-lyon.fr

Background and aims: The Agile 3$^+$ (A3$^+$) score has been proposed to reduce the false positive (FP) rate for the diagnosis of advanced fibrosis (AF) in non-alcoholic fatty liver disease (NAFLD). There are limited data on A3$^+$ diagnostic performance applied in its clinical context of use. Therefore, we aimed at comparing the diagnostic performance of A3$^+$ and vibration controlled transient elastography (VCTE) in patients with NAFLD with or without severe obesity and screened for liver fibrosis.
Method: This cross-sectional study included adult patients with NAFLD followed at the Lyon Hepatology Institute consecutively presented at a monthly multidisciplinary board for suspected fibrotic NASH between March 2020 and December 2022. Other causes of liver diseases were systematically excluded. Pseudonymized clinical data, fasting labs and non-invasive tests (NITs) including Fibrotest®, VCTE, magnetic resonance elastography (MRE) and liver biopsy reports were systematically extracted from medical electronic record. The presence of AF was determined by a composite end point: histological fibrosis stage ≥F3 or overt imaging diagnosis of cirrhosis by MRE or concordant VCTE and Fibrotest® for ≥F3 according to EASL guidelines. Patients with uncertain stage of fibrosis due to discordant NITs and no histological results were excluded from the analysis.
Results: The study included 368 patients with NAFLD, mean (± SD) age was 57.2 (± 12.3) years and BMI 34.5 (± 7.1) kg/m^2, 21.5% (n = 79) had severe obesity (BMI≥40 kg/m^2). The overall prevalence of AF was 38.9% (n = 143) and was significantly lower in patients with BMI≥40: 22.8% versus 43.2% in patients with BMI<40, p = 0.001. The FP rate of VCTE ≥8kPA was significantly higher in severe obesity compared to non-severe obesity: 38.1% vs 18.3%, p < 0.001. Overall, the area under the ROC (AUROC) of A3$^+$ for the detection of AF was significantly higher: 0.85 (95%CI: 0.81–0.89) compared to VCTE: 0.80 (95%CI: 0.75–0.84), p < 0.01 with an indeterminate rate of 20.6%. A sequential use of VCTE, followed by A3$^+$ for VCTE≥8 kPa significantly increased the AUROC: 0.87 (0.83–0.90), p < 0.001 with a high specificity: 88.7% and lower indeterminate rate 16.8%. These results were observed in patients with and without severe obesity (Table).

AUROC (95% CI)	AUROC (95%CI)	Sensitivity (%)	Specificity (%)	Indeterminate (%)
Overall				
VCTE cut-off 8kPA	0, 80 (0, 75–0, 84)	97, 2	62, 7	NA
A3$^+$ cut-offs 0, 45/0, 68	0, 85 (0, 81–0, 89)	88, 1	85, 6	20, 6
Sequential VCTE/A3$^+$	0, 87 (0, 83–0, 90)	88, 2	88, 7	16, 8
BMI <40 kg/m^2				
VCTE	0, 82 (0, 82–0, 91)	97, 2	62, 7	NA
A3$^+$	0, 87 (0, 77–0, 86)	88, 4	88, 8	20, 2
Sequential VCTE/A3$^+$	0, 89 (0, 85–0, 92)	88, 5	91, 7	16, 2
BMI ≥40 kg/m^2				
VCTE	0, 75 (0, 69–0, 87)	100	49, 2	NA
A3$^+$	0, 80 (0, 69–0, 89)	85, 7	76, 6	22, 8
Sequential VCTE/A3$^+$	0, 81 (0, 71–0, 89)	85, 7	80, 0	18, 9

Conclusion: A sequential use of VCTE followed by Agile 3+ score significantly improves the detection of AF in patients with or without severe obesity.

SAT-470

Cost-effectiveness of screening for advanced hepatic fibrosis by non-invasive test in general population

Bo-Kyeong Kang[1], Mimi Kim[1], Hye-Lin Kim[2], Huiyul Park[3], Eileen Yoon[1], Jun-Hyuk Lee[4], Joo Hyun Oh[4], Chul-min Lee[1], Joo Hyun Sohn[1], Jihyun An[1], Hyo Young Lee[5], Hyunwoo Oh[5], Jang Han Jung[6], Dae Won Jun[1], Eun Chul Jang[7]. *[1]Hanyang University, College of Medicine, Korea, Rep. of South; [2]Sahmyook University, College of Pharmacy, Korea, Rep. of South; [3]Myoungji Hospital, Hanyang University College of Medicine, Korea, Rep. of South; [4]Nowon Eulji Medical Center, Eulji University School of Medicine, Korea, Rep. of South; [5]Uijeongbu Eulji Medical Center, Eulji University College of Medicine, Korea, Rep. of South; [6]Dongtan Sacred Heart Hospital of Hallym University Medical Center, Korea, Rep. of South; [7]Soonchunhyang University College of medicine, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: The prevalence of advanced fibrosis in the general population of Koreans is significant at 2.2%, and diagnosis of advanced fibrosis is important for the prognosis of patients. However, the diagnostic performance of non-invasive tests [Fibrosis-4 (FIB4), and NAFLD fibrosis score (NFS)] differs according to age in the general population, and there is insufficient evidence for screening for advanced fibrosis in the general population. This study aimed to evaluate the cost effectiveness of screening strategy using sequential combination of non-invasive test followed by transient elastography (TE) for advanced hepatic fibrosis in the general population, as well as evaluating whether there is an optimal age for effective screening.
Method: We constructed a combined model of decision tree model and Markov model to compare expected costs and quality-adjusted life-years (QALYs) between 'screening' and 'no screening' groups from healthcare system perspectives. CVD and extrahepatic malignancy conditions that potentially lead to advanced hepatic fibrosis were also

included in the model. Patients diagnosed with advanced fibrosis in the screening group were given intensive lifestyle intervention (ILI), and the failure rate of ILI was assumed to be 60%. According to the age of the population (30 s to 70 s), the prevalence of advanced fibrosis was applied as 1.2% to 6.9%. The sensitivity/specificity of test was applied as 37.5% to 81.8%/44.0% to 96.7% in FIB4 and 16.7% to 73.5%/62.3% to 96.3% in NFS based on a data from 9850 health check-up examiners who underwent magnetic resonance elastography. Other input parameters applied to the model were obtained from literature review. Incremental cost-effectiveness ratio (ICER) was calculated for 20-year horizon. We conducted various sensitivity analyses for varying input values, including the screening starting age.

Results: In the base-case analysis, the estimated ICERs (for FIB4 and NFS) were $28,609 and $27,963 per QALY, which exceeded the $25,000 which is regarded as an implicit ICER threshold in Korea. However, considering the effects of CVD and extrahepatic cancer, the ICERs were decreased under the threshold, which indicates screening is cost-effective. In the subgroup analysis for screening starting age, the ICER of the age group over 40 years old was calculated below the cost-effective threshold. In the various sensitivity analyses, the most influential parameters on cost-effectiveness were the ILI failure rate and effect of CVD and extrahepatic cancer.

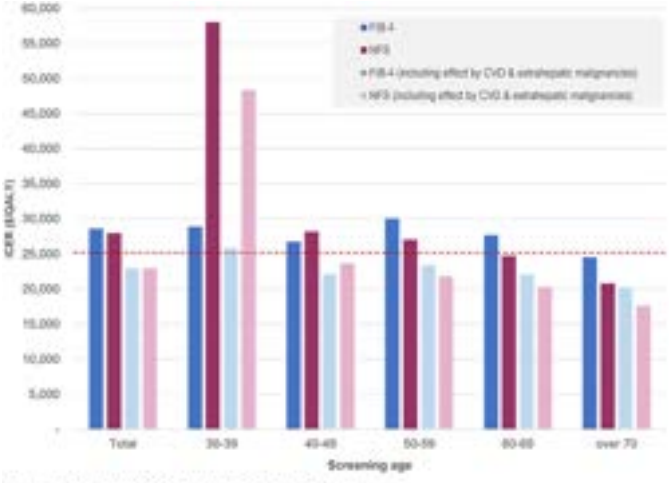

Figure 1. Estimated ICERs by screening starting age.

CVD, cardiovascular disease; FIB-4, fibrosis-4 score; ICER, incremental cost-effectiveness ratio; NFS, NAFLD fibrosis score; QALY, quality-adjusted life year

Figure:

Conclusion: Screening using non-invasive tests followed by TE in the general population is not cost-effective, but, it could be cost-effective, considering not only the liver-related condition but the effects of CVD and extrahepatic malignancies aged over 40.

SAT-471

Using elevated plasma alanine transaminase to screen for non-alcoholic fatty liver disease in overweight and obese individuals from the Danish general population

Elias Rashu[1], Mikkel Werge[1], Mira Thing[1], Liv Hetland[1], Puria Nabilou[1], Anders Junker[1], Anne-Sofie Houlberg Jensen[1], Børge Nordestgaard[2], Stefan Stender[3], Lise Lotte Gluud[1]. *[1]Gastro Unit, Copenhagen University Hospital Hvidovre, Denmark, Denmark; [2]Department of Clinical Biochemistry, Copenhagen University Hospital-Herlev and Gentofte, Denmark; [3]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, Denmark*

Email: elias.badal.rashu@regionh.dk

Background and aims: Affecting up to 30% of the general population, non-alcoholic fatty liver disease (NAFLD) is one of the leading causes of liver disease. The disorder covers a broad clinical spectrum ranging from hepatic steatosis through non-alcoholic steatohepatitis (NASH) to fibrosis and cirrhosis. A major unresolved issue is whether (and if so: how) to screen for NAFLD in the general population. We tested the hypothesis that elevated plasma alanine transaminase (ALT) can be used as a screening tool for NAFLD in overweight and obese individuals from the Danish general population.

Method: This study screened adults in the Copenhagen General Population Study (CGPS), a population-based cohort of the Danish general population. Individuals with a body mass index (BMI) above 25 kg/m^2 and elevated plasma ALT at baseline (>71 U/L for men and >51 U/L for women) were invited to a hepatological evaluation, including a detailed medical history, extensive blood tests, and fibroscan. Individuals with clinical sign of NASH, evidence of fibrosis on fibroscan or elevated fibrosis-4 score (FIB-4), were offered further clinical assessment with a liver biopsy. Those who fulfilled the inclusion criteria for FLINC, an ongoing prospective NASH-cohort were included in this study. We aim to follow the participants from FLINC for >5 years.

Results: Of 997 individuals invited from the CGPS, 344 were enrolled (51.5% male, mean age: 60.6 years, mean BMI: 30.9 kg/m^2). A total of 204 individuals (59.3%) were diagnosed with simple steatosis, whereas 61 (17.8%) had no sign of liver disease, and 15 were diagnosed with alcohol-related liver disease. A total of 53 (15.4%) had clinical signs of NASH fibrosis on fibroscan. Of these, 20 underwent liver biopsy, which identified various degrees of NASH fibrosis, that is, 5 with F0, 5 with F1, 3 with F2, and 7 with F3. In addition, 6 participants were diagnosed with advanced fibrosis and cirrhosis by biopsy due to alcohol-related liver disease (3 with F3 and 3 with F4). Finally, two serious incidental findings of cancer (premalign colon cancer and multiple myeloma), and one case of previously undiagnosed hepatitis C and autoimmune hepatitis were identified.

Figure: Characteristics and findings in the examined individuals.

N	344
Age (years)	60.6
Male	177 (51.5)
BMI (kg/m^2)	30.9
Type 2 diabetes	86 (25)
ALT (U/L)	43.4
Fibroscan median (kPa)	5.9
CAP value (dB/m)	293
Steatosis on Fibroscan (CAP > 260 dB/m)	204 (59.3)
NASH fibrosis on Fibroscan, (kPa>8 kPa)	53 (15.4)
-Biopsy available in n = 20 out of the 53 with NASH fibrosis on Fibroscan	
-F0	5 (25)
-F1	5 (25)
-F2	3 (15)
-F3	7 (35)
-F4	0 (0)
No liver disease	61 (17.8)
Advanced alcohol-related liver disease fibrosis/ cirrhosis*	7 (2.0)
Hepatitis C	1 (0.3)
Autoimmune hepatitis	1 (0.3)
Cancer	2 (0.6)

Values are number and (%) or means. *F3 (n = 3) or F4 (n = 3) on histology.

Conclusion: Screening individuals from the Danish general population with BMI>25 kg/m^2 and elevated ALT identified approximately 15% with NASH fibrosis on fibroscan and FIB-4 score.

SAT-472

Analysis of the diagnostic accuracy of the non-invasive fibrosis indices NFS, HFS, and FIB-4 in the staging of advanced fibrosis in patients with metabolic fatty liver: meta-analysis of comparative studies

Carmen Lara Romero[1,2], Jia-Xu Liang[1], Javier Ampuero[1,2], Javier Castell[3], Isabel Fernández-Lizaranzu[4], Manuel Romero Gomez[1,2]. *[1]Hospital Universitario Virgen del Rocío, Department of Digestive and Liver Diseases, Sevilla, Spain; [2]Institute of Biomedicine of Seville, Sevilla, Spain; [3]Hospital Universitario Virgen del Rocío, Department of Radiology, Spain; [4]Institute of Biomedicine of Seville, Interdisciplinar physics group, Spain*
Email: carmenlararomero@gmail.com

Background and aims: Advanced fibrosis is related to a greater number of liver-related outcomes in patients with Metabolic Associated Fatty Liver Disease. Several non-invasive tests (NITs) have been developed to evaluate liver fibrosis in these patients to minimize the number of liver biopsies. We have performed a metanalysis to evaluate the diagnostic performance of the following NITS: Fibrosis-4 (FIB-4) NAFLD Fibrosis Score (NFS) and Hepamet Fibrosis Score (HFS).
Method: We have analyzed 4 databases until December 2022. Data has been taken from original studies showing data about the diagnostic accuracy of FIB-4, NFS and HFS, using standard cut-offs of biopsy-proven MAFLD patients. We extracted data according to the lower cut-off, higher cut-off and double cut-off methods. We included data of true positives, true negatives, false negatives and false positives patients. ROC curves were estimated using a random effects model.
Results: We included 7 studies with 5143 patients with MAFLD biopsy-proven patients. In the FIB-4 group, for the lower cut-off: S = 0.76[0.67–0.84], E = 0.65[0.49–0.78]; for the upper cut-off (2.67): (S:0.34[0.28–0.40], E:0.96[0.92–0.98]). In the NFS group, for the lower cut-off (-1.455) : (S:0.80[0.71–0.87], E = 0.48[0.34–0.62]); for the upper cut-off (0.675): (S:0.37[0.28–0.47], E = 0.94[0.87–0.97]). In the HFS group, for the lower cut-off (0.12): (S: 0.78[0.70–0.84], E: 0.66 [0.49–0.80]); for the upper cut-off (0.47): (S: 0.43[0.38–0.49], E: 0.92 [0.87–0.95]]. ROC curves for FIB-4, HFS, NFS to predict advanced fibrosis (≥F3) were 0.80 [0.76–0.83], 0.78[0.74–0.81], 0.73 [0.69–0.77], respectively. With the double cut-off method, we found a lower prevalence of indeterminate values for HFS (27% [20%-34%]).
Conclusion: In our metanalysis, HFS and FIB-4 showed higher diagnostic accuracy than NFS to identify advanced fibrosis in MAFLD patients, while HFS showed a lower rate of patients in the grey zone (indeterminate values).

SAT-473

Correlation between serial Fibrosis-4 scores and liver stiffness measurements in patients with low-risk non-alcoholic fatty liver disease

Tanvi Goyal[1], Jing Hong Loo[2], Michael Song[1], Tianyu Qiu[3], Esteban Urias[1], Yu Jun Wong[3], Vincent Chen[1], Karn Wijarnpreecha[4]. *[1]Michigan Medicine, Internal Medicine, Ann Arbor, United States; [2]National University of Sinapor, Yong Loo Lin School of Medicine, Singapore; [3]Changi General Hospital, Singapore; [4]Unviersity of Arizona, United States*
Email: tagoyal@med.umich.edu

Background and aims: In patients with non-alcoholic fatty liver disease (NAFLD) at baseline low risk, major professional societies recommend risk stratification using non-invasive tests such as Fibrosis-4 (FIB4) score in lieu of liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE). However, there are limited data on how changes in FIB4 and LSM correlate, and on whether meaningful changes in LSM can occur without changes in FIB4. Here, we evaluated associations between changes in FIB4 and LSM in NAFLD patients with serial VCTE studies.
Methods: This was a retrospective study of consecutive patients at Michigan Medicine in the United States with NAFLD who had at least two VCTE studies, spaced at least two years apart. We excluded patients with baseline LSM ≥20 kPa. The primary predictors were change between follow-up FIB4 (FIB4–2) and initial FIB4 (FIB4–1), which we call delta-FIB4. The primary outcome was a ≥25% increase in the second LSM (LSM-2) relative to baseline (LSM-1). The secondary outcome, which was applied to only patients with LSM-1 <8 kPa, was disease progression defined as a ≥25% increase in LSM-2 vs. LSM-1 and new advanced fibrosis (LSM-2 ≥8 kPa).
Results: We included 311 patients. Median age was 54 years, 53% were male, and 84% were white. Median follow-up time between VCTEs was 38.6 months. On follow-up, 30% of patients had a ≥25% increase in LSM, 24% had a ≥25% decrease, and 46% had a <25% change. 15% of low-risk NAFLD patients developed incident advanced fibrosis (LSM-2 ≥8 kPa and ≥25% increase vs. LSM-1). Delta-FIB4 correlated strongly with delta-LSM: r = 0.31 ($p < 0.0001$). Among patients with ≥25% increase in LSM, FIB4 did not change over time (delta-FIB4 = 0.15, p = 0.025 for difference from 0). In contrast, among patients with no LSM change or with LSM decrease, FIB4 did not change (delta-FIB4 = 0.02, p = 0.61 for difference from 0). Similarly, among patients with baseline LSM <8 kPa and disease progression, FIB4 increased over time with delta-FIB4 = 0.31 ($p = 0.044$ for difference from 0), but there was no change in FIB4 in those with baseline LSM <8 kPa and without disease progression (delta-FIB4 = 0.04, p = 0.31).

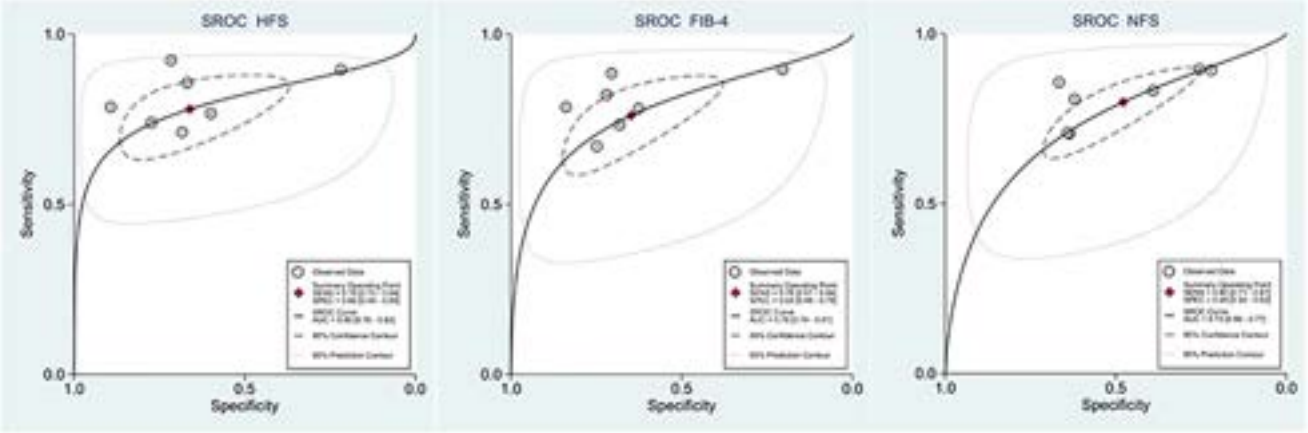

Figure: (abstract: SAT-472): Summary Receiving Operator Curves of the different non-invasive tests: FIB-4, NFS and HFS.

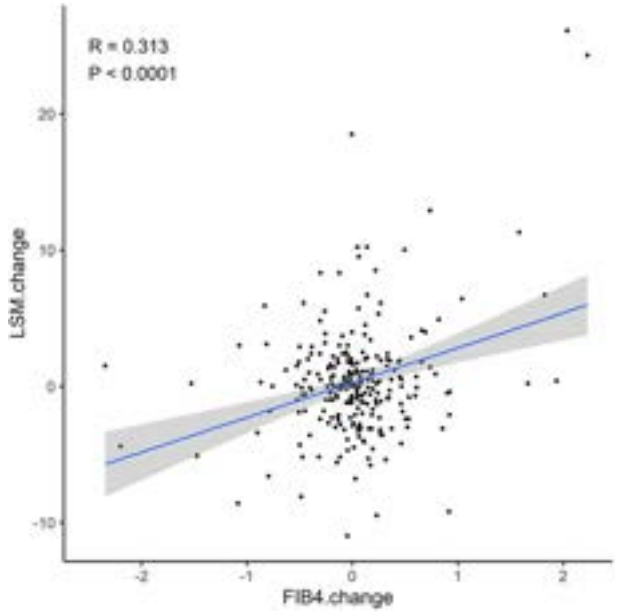

Figure:

Conclusion: Among patients with NAFLD and serial VCTEs, changes in FIB4 correlate strongly with changes in LSM. These findings support current guidelines to obtain serial serum non-invasive tests in patients with low-risk NAFLD.

SAT-474

AGILE 3+ and AGILE 4 scores for the diagnosis of advanced fibrosis and cirrhosis in patients with non-alcoholic fatty liver disease

Kamela Gjini[1], Angelo Armandi[1,2], Gian Paolo Caviglia[1], Chiara Rosso[1], Daphne D'Amato[1], Amina Abdulle[1], Gabriele Castelnuovo[1], Nuria Pérez Diaz del Campo[1], Marta Guariglia[1], Elisabetta Bugianesi[1].

Email: kamelagjini@gmail.com

Background and aims: non-invasive assessment of advanced fibrosis in Non-Alcoholic Fatty Liver Disease (NAFLD) is crucial for the identification of patients at greatest risk of progression. Among non-invasive tests, AGILE3+ and AGILE 4 have been recently proposed, combining liver stiffness measurement (LSM) by vibration-controlled transient elastography (FibroScan) with clinical-biochemical variables. We aimed to assess the accuracy of AGILE 3+ and AGILE 4 for the identification of advanced (F3-F4) and cirrhosis (F4), respectively, against LSM in individuals with biopsy-proven NAFLD.
Method: we retrospectively included 315 biopsy proven-NAFLD patients. No clinical, radiological or biochemical signs of cirrhosis were present at inclusion. Clinical-biochemical data and LSM were collected at time of the biopsy.
Results: median age was 48 (IQR 38–47) years, 62% of patients were male. Median LSM was 7.5 kPa (IQR 5.8–10.1). Advanced fibrosis was present in 28%, cirrhosis in 10% and NASH in 28% of cases. Eighty subjects had type 2 diabetes. At Area Under the Curve (AUC) analysis, LSM had a value of 0.807 (Se 70%, Sp 80%) for advanced fibrosis and 0.877 for cirrhosis (Se 88%, Sp 76%). AGILE 3+ had AUC of 0.77 for advanced fibrosis (cut-off by Youden Index 0.30, Se 68%, Sp78%), while AGILE 4 had AUROC 0.78 for cirrhosis (cut-off by Youden Index 0.11, Se 55%, Sp 89%). Comparison of AUC showed that AGILE 3+ was similar to LSM for identifying advanced fibrosis (DeLong p = 0.254). Similarly, AUC comparison between AGILE 4 and LSM for cirrhosis was not different (DeLong p = 0.739).
Conclusion: when compared to LSM, AGILE3+ and AGILE 4 had similar accuracy for the detection of advanced fibrosis and cirrhosis in NAFLD patients. This research has been supported by the Italian Ministry for Education, University and Research (MIUR) "Dipartimenti di Eccellenza 2018–2022" Project code D15D18000410001.

Email: noshin@hanyang.ac.kr

Background and aims: Diagnostic performance of fibrosis-4 index (FIB-4) and non-alcoholic fatty liver disease (NAFLD) fibrosis score (NFS) for advanced fibrosis in lean patients with NAFLD is limited. We aimed to evaluate the diagnostic performance and current cut-offs of FIB-4 and NFS in individuals with NAFLD.
Method: This multicenter, retrospective, cross-sectional study analyzed 1,501 patients with biopsy-proven NAFLD. The difference in diagnostic performance of FIB-4 and NFS between lean (body mass index (BMI) <23 kg/m^2) and non-lean (BMI ≥23 kg/m^2), and their sensitivity and specificity at the current cut-off value were also evaluated.
Results: Diagnostic performance and area under the receiver operating characteristic curves (AUROCs) of FIB-4 and NFS were comparable between the lean and non-lean groups. The AUROC of FIB-4 and NFS were not different in the lean group (0.807 vs. 0.790). The sensitivity and specificity of the current FIB-4 cut-off values did not change. But, the sensitivity of the current NFS cut-off values was lower in the lean group than in the non-lean group (54.4% vs. 72.7%). The NFS sensitivity decreased with the BMI quartiles. The FIB-4 sensitivity and specificity did not change according to BMI quartiles.

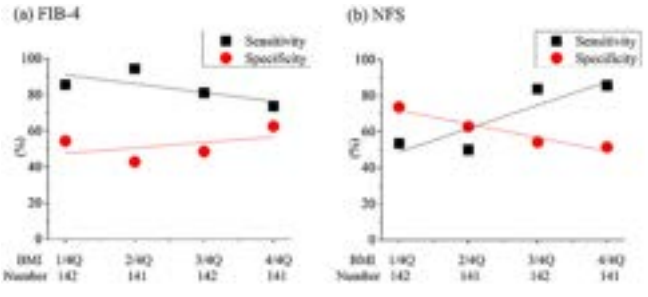

Figure 1. Sensitivity (black square) and specificity (red circle) trend of FIB-4 (a) and NFS (b) for diagnosing patients with advanced hepatic fibrosis by using their lower cut-off values according to BMI quartiles.
Abbreviation: BMI, body mass index; FIB-4, fibrosis-4 index; NFS, NAFLD fibrosis score.

Figure:

Conclusion: The overall diagnostic performance (AUROC) of FIB-4 and NFS in diagnosing advanced fibrosis did not differ between the lean and non-lean groups. However, the sensitivity of NFS at the current cut-off value decreased in lean individuals. FIB-4 at the current cut-off value would be a better screening parameter of advanced NAFLD fibrosis in lean individuals.

SAT-476

Fatty liver score: a novel fatty liver index based on magnetic resonance imaging-proton density fat fraction

Chul-min Lee[1], Bo-Kyeong Kang[1], Mimi Kim[1], Eileen Yoon[2], Sang Bong Ahn[3], Jun-Hyuk Lee[4], Joo Hyun Oh[3], Joo Hyun Sohn[5], Jihyun An[5], Dae Won Jun[5]. Email: noshin@hanyang.ac.kr

Background and aims: We aimed to develop a simple and intuitive model with high accuracy for predicting hepatic steatosis based on the gold standard method.
Method: We collected retrospective data from 2,111 participants who underwent magnetic resonance imaging-proton density fat fraction (MRI-PDFF) at six referral centers in three countries (Korea, Japan, and the United States). The full cohort was randomly assigned to a training cohort and a validation cohort at a ratio of 7:3. Variables were selected via multivariate logistic analysis, and additional linearity was confirmed using the smoothing spine method. Finally, a model maintaining a reasonable area under the receiver operating characteristics (AUROC) with minimum variables was presented; it compared diagnostic performance with the pre-existing model.
Results: We developed new Fatty liver score (FLS) was using male sex, age, diabetes mellitus, alanine aminotransferase, triglyceride, and body mass index. FLS showed good diagnostic performance for predicting fatty liver with an AUC of 0.841 in the training cohort. The AUC of the FLS in the validation cohort was 0.848, higher than Fatty liver index (FLI) (0.796, p = 0.014), and similar to Hepatic steatosis index (HSI) (0.810, p = 0.058) for predicting fatty liver. The best cut-off for FLS was 3.0, with a sensitivity of 80.0% and specificity of 71.6%.

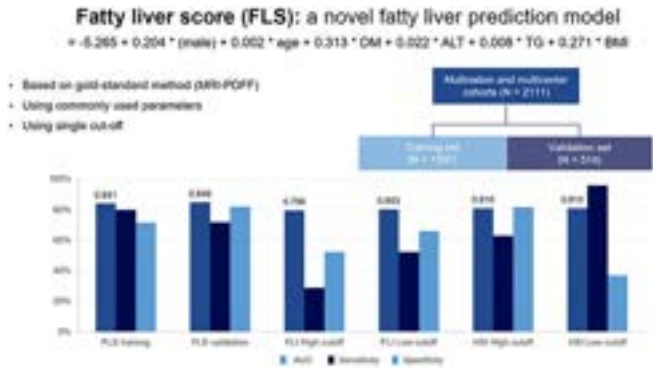

Figure:

Conclusion: A new simplified prediction model, FLS, showed good diagnostic performance for predicting fatty liver with high sensitivity in large cohorts from multinational and multicenter studies using MRI-PDFF as the reference standard.

SAT-477

The role of M2BPGi in screening for advanced hepatic fibrosis in diabetic patients

Mimi Kim[1], Hye-Lin Kim[2], Eileen Yoon[1], Se Young Jang[3], Ki Tae Yoon[4], Young Youn Cho[5], Hoon Gil Jo[6], Yang-Hyun Baek[7], Sang Yi Moon[8], Dae Won Jun[1], Aejeong Jo[1]. Email: noshin@hanyang.ac.kr

Background and aims: There is a lack of algorithms that can identify and predict advanced hepatic fibrosis in diabetic patients, despite much evidence of a high rate of hepatic fibrosis in subjects with diabetes. The purpose of this study is to determine whether Mac-2-binding protein glycan isomer (M2BPGi) and other non-invasive test (NIT) and their combinations can help to exclude advanced hepatic fibrosis in diabetic clinics.
Method: 2,177 patients visiting the endocrinology clinic of six tertiary hospitals and performing M2BPGi and transient elastography (TE) between April 2020 and May 2021 were included. Of them, only patients with diabetes were included. FIB-4 and NAFLD fibrosis score (NFS) were calculated for all subjects and evaluated the diagnostic performance of single or combined tests for advanced fibrosis. Advanced fibrosis was defined by TE ≥8.0kPa.
Results: Of them, 641 diabetic patients with mean age, of 58.5 ± 12.6 years were included. Diagnostic performance of predicting advanced hepatic fibrosis was highest in FIB4 (the area under the receiver operating characteristics curve [AUROC] = 0.756), followed by M2BPGi and NFS (AUROC = 0.702 and 0.690, respectively). The multivariate regression analysis revealed that M2BPGi was an independent risk factor for advanced liver fibrosis (odds ratio (OR): 1.33, p < 0.001). M2BPGi at a cut-off of 0.6 showed a similar diagnostic performance to the low cut-off of other NITs (sensitivity: 85.4% in M2BPGi vs. 84.4–85.3% in other NITs; specificity: 34.8% in M2BPGi vs. 27.3–44.3% in other NITs). The sequential combination of FIB4 followed by M2BPGi showed the sensitivity, specificity, positive predictive value, and negative predictive value of 94.4%, 19.1%, 38.5%, and 86.5%, respectively.
Conclusion: A combination of M2BPGi and APRI can help to exclude advanced hepatic fibrosis in diabetic patients. Through the two-step pathway, diabetic patients with advanced fibrosis could be referred to liver specialists.

SAT-478

One-step diagnosis: detection and stratification of incidental hepatic steatosis by multiparametric abdominal ultrasound

Irene Gonzalez Diaz[1], Carlota Siljestrom Berenguer[1], Luis Eduardo Pariente Zorrilla[1], Marta Abadia[1], Eva Marín[2], Gloria Ruiz-Fernandez[1], Joaquin Poza[1], Clara Amiama Roig[1], Carmen Amor[1], Maria Dolores Martin-Arranz[1], Antonio Olveira Martin[1]. [1]*Hospital la Paz, Gastroenterology and Hepatology Service, Spain;* [2]*Hospital la Paz, Spain*
Email: irenegonzalezdiaz@gmail.com

Background and aims: The high prevalence of hepatic steatosis requires an efficient screening and stratification strategy. Non-invasive tests have low positive predictive value, and the referral of patients based exclusively on one of them is an excessive, inefficient overload for Liver Clinics. Within this broad population, a specific subgroup is incidental hepatic steatosis (IncHS) or hepatic steatosis not previously suspected on imaging tests, in which the risk of advanced liver fibrosis strategy is unknown (AASLD Guidelines 2018). Our aim was to determine the prevalence of IncHS, its characteristics, and the most efficient referral strategy of these patients from an Ultrasound Unit.
Method: Longitudinal and prospective study between November 2021 and June 2022. Consecutive patients presenting for abdominal ultrasound (Aplio i800, Canon) with criteria of hepatic steatosis: 1) Liver hyperechogenicity with respect to renal cortex plus at least one of the following: Posterior beam attenuation, portal or hepatic veins blurring, gallbladder wall blurring or 2) Attenuation Imaging (ATI) ≥0.63 dB/cm/MHz. Steatosis not previously diagnosed and not suspected based on the ultrasound request was considered

incidental. Patients with a previous diagnosis of steatosis, liver disease, or any reason for suspecting a liver disease according to the ultrasound request were excluded. Simultaneously, shear-wave elastography (2D-SWE) was performed, with a risk of advanced fibrosis if ≥7 kPa. In the same ultrasound room, the FIB-4 index was calculated according to available results (<1 year).

Results: 1724 patients were included in the study period. 762 (44.2%) showed steatosis, of which 198 (26%; 95%CI: 23–29.2) were considered incidental: mean age 58 years, women 56.5%, liver test alteration 25%. Factors associated with steatosis were: metabolic dysfunction 48% (obesity 77.9%, diabetes 13%, hypertension/dyslipidaemia 45.5%), alcohol 6.5%, steatogenic medication 0.5%. The most frequent reasons for ultrasound requests were biliopancreatic (31%) and abdominal pain (19.6%). In the 198 with IncHS, the mean elastography value was 4.7 ± 1.5 kPa, 87 (44%) had FIB-4 >1.3 and 17 (8.6%) 2D-SWE ≥7 kPa. Only 11/198 patients (5.6%; 95%CI: 3.1–9.7) had FIB-4 >2.67 and 2D-SWE ≥7kPa, and were referred primarily to the Liver Clinic; the remaining 187 (94.4%) followed their standard pathway.

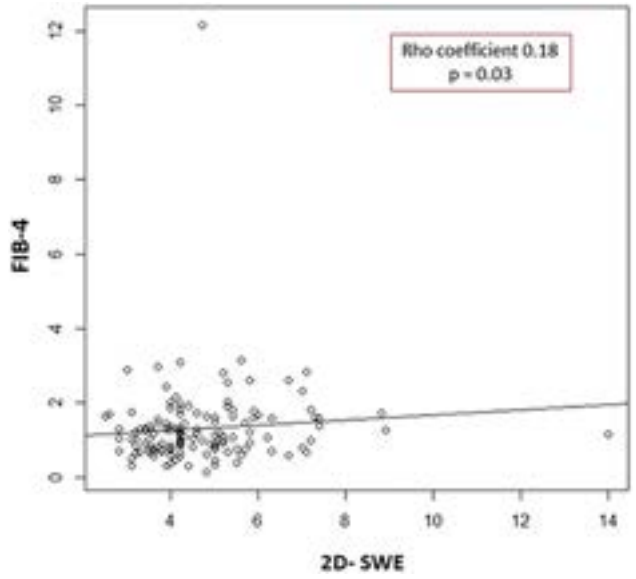

Figure 1: Linear regression model between 2D-SWE and FIB-4

Conclusion: Incidental hepatic steatosis is frequent in a Gastroenterology Ultrasound Unit. As expected, the prevalence of risk of advanced fibrosis is low. Multiparametric ultrasound allows for a one-step diagnosis, and stratification, avoiding unnecessary referrals.

SAT-479

High performance of new multiparametric ultrasound in the non-invasive assessment of liver disease

Gloria Ruiz-Fernandez[1], Marta Abadia[2], Miriam Romero[1], Cristina Suárez[1], Joaquin Poza[1], Eva Marín[1], Clara Amiama Roig[1], Carmen Amor[1], Irene Gonzalez Diaz[1], Carlota Siljestrom Berenguer[1], Beatriz Pillado Pérez[1], Luis Eduardo Pariente Zorrilla[1], Maria Dolores Martin-Arranz[1], Antonio Olveira Martin[1]. *[1]Hospital La Paz, Gastroenterology, Spain; [2]Hospital La Paz, Spain*
Email: gloria.ruizf@gmail.com

Background and aims: Liver diseases affect millions of people worldwide. There is an increasing interest in accessible, reliable tools in the non-invasive assessment of liver disease. We assessed the performance of new Attenuation Imaging and Shear-Wave elastography multiparametric ultrasound tools for the diagnosis of steatosis and advanced fibrosis.

Method: Adult patients consecutively programmed for liver biopsy were prospectively included between February 2020-November 2022. On the same day of percutaneous liver biopsy and prior to it, we conducted the following procedures: transient elastography (TE) and controlled-attenuation parameter (CAP): Fibroscan 502 Touch, EchoSens, France; and bidimensional shear-wave (2D-SWE) and Attenuation Imaging (ATI): Aplio i800, Canon, Japan. We excluded patients with acute liver disease, biopsy <11 portal tracts, and contraindication for liver biopsy. 16–18G Tru-cut needle was used under ultrasound guidance. Metabolic-associated fatty liver disease (MAFLD) was staged according to non-alcoholic steatohepatitis Clinical Research Network scoring (NASH CRN). Chronic hepatitis was classified according to METAVIR. Normally distributed quantitative variables were described using the mean. Diagnostic performances for steatosis (fatty content >5%) and advanced fibrosis (F3-F4) were assessed with receiver operating characteristic curves.

Results: A total of 249 patients were included, the mean age was 51 years, 60% were female, the mean BMI was 27, 4 kg/m^2, and the mean GPT was 70UI/L. The mean biopsy length was 25 mm, 15 portal tracts. The distribution of final diagnosis after biopsy was as follows: MAFLD (n = 115, 46%) of which steatohepatitis 68 (60%), AIH (n = 32, 13%), CBP (n = 10, 4%), others or minimal changes (n = 92, 37%). Fibrosis grades were: F0 123 (49%), F1/F2 82 (33%), F3/F4 44 (17, 7%). Considering the liver biopsy as reference variable, for steatosis the performances were: CAP 0.83, ATI 0.91. For advanced fibrosis (F3/F4), the performances were: TE 0.93, 2D-SWE 0.95. In the subgroup of MAFLD, the performances for advanced fibrosis were: TE 0.89, 2D-SWE 0.95 (table 1)

Table: ATI and CAP accuracy for >5% steatosis detection. ET, 2D-SWE accuracy for advanced fibrosis detection in the total group and in the MALD subgroup.

N = 249	AUROC	95% CI; p	Best cut-off	Sensitivity (%)	Specificity (%)	Accuracy (%)
>5% Steatosis						
CAP (dB/m)	0.83	0.78–0.88; 0.0001	254	78	78	78
ATI (dB/cm/MHz)	0.91	0.87–9.95; 0.0001	0.62	82.7	90.2	86.1
F3/F4 Fibrosis						
TE (kPa)	0.93	0.90–0.97; 0.0001	7.75	90.9	82.7	84, 1
2D-SWE (kPa)	0.95	0.91–0.99; 0.0001	7.15	93.2	92.6	92, 7
F3/F4 Fibrosis MAFLD (N = 115)						
TE (kPa)	0.89	0.82–0.96; 0.0001	8.1	80	80	80
2D-SWE (kPa)	0.95	0.91–1; 0.0001	7.1	96	92	92.9

AUROC: area under the receiver operating characteristic curve; CI: confidence interval; CAP: controlled-attenuation parameter; ATI: attenuation imaging: TE: transient elastography; 2D-SWE: bidimensional shear wave elastometry; MAFLD: metabolic-associated fatty liver disease.

Conclusion: Bidimensional shear-wave and Attenuation Imaging technologies using multiparametric ultrasound are very reliable tools in the non-invasive assessment of liver disease, including MAFLD.

SAT-480

Inclusion of the fatty liver-associated variants in the clinical workup of patients: results of an eight years' experience in a tertiary referral center with genotyping facility

Susanne N Weber[1], Mathias Straub[1], Frank Lammert[2], Marcin Krawczyk[1,3]. [1]*Department of Medicine II, Saarland University Medical Center, Homburg, Germany;* [2]*Hannover Medical School (MHH), Hannover, Germany,* [3]*Laboratory of Metabolic Liver Diseases, Medical University of Warsaw, Warsaw, Poland*
Email: marcin.krawczyk@uks.eu

Background and aims: Genetic testing has become increasingly available in clinical practice. In our center we have introduced the genotyping of fatty liver-associated variants in the clinical work-up of patients with chronic liver diseases in 2013. Here, we present the genotyping results of patients treated in our department up to the year 2021.
Method: In total, we analysed 462 patients with fatty liver phenotypes who were referred by the physicians working in our department for genetic testing of the two common fatty liver-associated variants, namely *PNPLA3* p.I148M and *MBOAT7* p.E17G. In addition to our panel, we genotyped the newly detected *MTARC1* rs2642438 variant that was recently shown to have protective effects on liver status (Fairfield et al. *Hepatol Commun* 2022). Genotyping procedures were performed using allelic discrimination assays. Liver steatosis and fibrosis were quantified non-invasively using controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) by transient elastography.
Results: The results of genotyping procedures were provided to the admitting physicians within an average time of 24 days from blood sampling. The minor allele frequencies (MAF) of the *PNPLA3*, *MBOAT7* and *MTARC1* variants were 25.2%, 40.8%, and 21.5%, respectively, and did not significantly differ from reference data available for Europeans. Among the three tested variants, the *PNPLA3* p.I148M genotype correlated with increased serum ALT, AST as well as serum transferrin (all $p < 0.01$) and iron concentrations ($p = 0.02$) in carriers of the homozygous [MM] genotype. These patients also presented with significantly ($p < 0.01$) higher CAP values (299 ± 62 dB/m) as compared to carriers of the common allele (267 ± 74 dB/m), but we did not find any major effect of this variant on LSM ($p = 0.09$). The only correlation for *MBOAT7* p.E17G was found with increased levels of leukocytes ($p = 0.02$), but not with liver phenotypes (all $p > 0.05$). Finally, we did not find any relevant associations between the *MTARC1* variant and liver steatosis, fibrosis markers or other patient characteristics.
Conclusion: Our data underscore the central role of *PNPLA3* p.I148M variant in the fatty liver phenotype. Routine genotyping of this variant in clinical practice can be rapidly performed and might help to identify at-risk patients with worse liver status.

SAT-481

Performance of novel collagen turnover biomarkers in relation to FIB-4 to detect advanced fibrosis in NAFLD

Hannes Hegmar[1], Thomas Møller[2], Patrik Nasr[3], Johan Vessby[4], Stergios Kechagias[3], Nils Nyhlin[5], Hanns-Ulrich Marschall[6], Åsa Danielsson Borssén[7], Morten Karsdal[2], Diana Leeming[2], Mattias Ekstedt[3], Hannes Hagström[1]. [1]*Karolinska Institutet/Karolinska University Hospital, Department of Medicine, Huddinge, Sweden;* [2]*Nordic Bioscience Biomarkers and Research A/S, Denmark;* [3]*Department of Health, Medicine and Caring Sciences, Linköping University, Sweden;* [4]*Department of Medical Sciences, Gastroenterology Research Group, Uppsala University, Sweden,* [5]*School of Medical Sciences, Örebro University, Sweden;* [6]*Department of Molecular and Clinical Medicine, University of Gothenburg, Sweden;* [7]*Department of Public Health and Clinical Medicine, Umeå University, Sweden*
Email: hhegmar@gmail.com

Background and aims: Cleavage products from different types of collagens that reflect the formation, and degradation, of fibrosis are potential novel biomarkers to detect advanced fibrosis in patients with non-alcoholic fatty liver disease (NAFLD). Here, we investigated the diagnostic performance of PRO-C3, PRO-C6, C4M, PRO-C18L, ADAPT, a score based on PRO-C3 and clinical parameters, and FIB-4 to diagnose advanced fibrosis, based on liver biopsy or liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE).
Method: Serum from 299 patients with NAFLD from six Swedish university hospitals were analyzed with an ELISA-based method for PRO-C3, PRO-C6, C4M and PRO-C18L. LSM by VCTE was performed at inclusion, and when clinically motivated, a liver biopsy was performed (n = 134). Blood samples were collected at the time of the LSM. FIB-4 and ADAPT scores were calculated. Advanced fibrosis was defined as fibrosis stage 3–4 on liver biopsy, or an LSM ≥15 kPa in patients without biopsy data. The area under the receiver operating characteristic curve (AUROC) were calculated for all biomarkers to evaluate their ability to diagnose advanced fibrosis.
Results: Advanced fibrosis was found in 48 (14.6%) patients. These were older than patients without advanced fibrosis (64.5 years vs 55 years, $p < 0.001$) and more commonly had type 2 diabetes (75% vs 43%, $p < 0.001$). When investigating the diagnostic performance of advanced fibrosis, PRO-C3 had an AUROC of 0.73 (95% Confidence Interval [CI] = 0.65–0.80), PRO-C6 0.56 (95%CI = 0.48–0.64), C4M 0.57 (95%CI = 0.48–0.66), and PRO-C18L 0.46 (95%CI = 0.38–0.54). The ADAPT score had the highest AUROC for diagnosis of advanced fibrosis (0.85 (95%CI = 0.79–0.90). However, ADAPT was not significantly better than the FIB-4 score (AUROC 0.83, 95%CI = 0.78–0.89, p = 0.54) (Figure). None of the biomarkers could accurately diagnose presence of NASH.

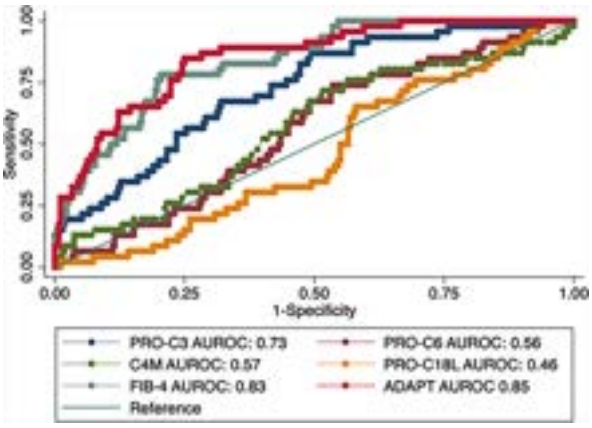

Figure:

Conclusion: Among the evaluated novel biomarkers in this cohort, PRO-C3 had a good diagnostic performance, which improved when implemented in the score ADAPT. FIB-4 and ADAPT had an excellent performance in detecting advanced fibrosis. These results suggests that FIB-4 remains a favorable biomarker to, as a first-line test, predict presence of advanced fibrosis in patients with NAFLD.

SAT-482

Evaluating the role of novel magnetic resonance imaging-based biomarkers in non-invasive assessment of hepatic fibrosis and activity in non-alcoholic fatty liver disease

En Ying Tan[1], Sin Hui Melissa Chua[1], Eunice Tan[1], Daniel Huang[1], Jonathan Lee[1], Margaret Teng[1], Nur Halisah Binte Jumat[1], Yock Young Dan[1], Mark Muthiah[1]. [1]*National University Hospital (NUH)-Singapore, Department of Gastroenterology and Hepatology, Singapore, Singapore*
Email: tanenying@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) encompasses a spectrum of disease including hepatic steatosis, non-alcoholic steatohepatitis, fibrosis and cirrhosis. It is the most common

liver disease worldwide. Identification of those with significant fibrosis and disease activity is the cornerstone of risk stratification of NAFLD patients and preventing progression to irreversible liver disease. Liver biopsy is considered the gold standard for diagnosis and assessment of NAFLD, but drawbacks such as procedural risks, sampling error, cost, poor acceptability and limited availability highlight the need for robust non-invasive tests (NITs). We aimed to evaluate the performance of LiverMultiScan (LMS) and Body Composition Profiling (BCP). We also aimed to correlate BCP to disease activity to generate novel associations in the disease.

Method: Patients at the National University Health System, Singapore who had NAFLD and underwent liver biopsy were recruited to undergo LMS and BCP. All patients were extensively evaluated for alternative causes of liver disease and results were negative. LMS cT1 and various BCP indices were evaluated for their performance in assessment of fibrosis and activity.

Results: 106 multi-ethnic Asian patients with biopsy-proven NAFLD were recruited from 2020 to 2022 to undergo the two scans. PDFF had AUCs of 0.979 for any steatosis, 0.867 for S2–3 steatosis and 0.906 for S3 steatosis. AUC values for cT1 were 0.702, 0.740, 0.702 and 0.714 for identifying NAFLD Activity Score (NAS) of at least 5, SAF activity score of at least 3, NASH and at-risk NASH respectively. cT1 appeared to perform well for the above metrics regardless of grade of steatosis. AUCs improved when combining cT1 with some NITs (PDFF, FIB-4, APRI) via logistic regression modelling, but this did not reach statistical significance. In particular, cT1 with APRI achieved the highest AUC of 0.824. Logistic regression models including all BCP indices achieved much higher performance compared to individual indices, with AUCs of 0.803, 0.846, 0.846 and 0.780 for at-risk NASH, advanced fibrosis, NAS ≥5 and SAF ≥3. BCP indices relating to visceral adiposity had the largest AUCs for predicting fibrosis, activity and steatosis. HOMA-IR score is correlated to visceral adipose tissue index (VATi). On multiple linear regression, VAT ratio (VATr) and HOMA-IR both independently correlate with stage of fibrosis, while VATr correlates independently with activity.

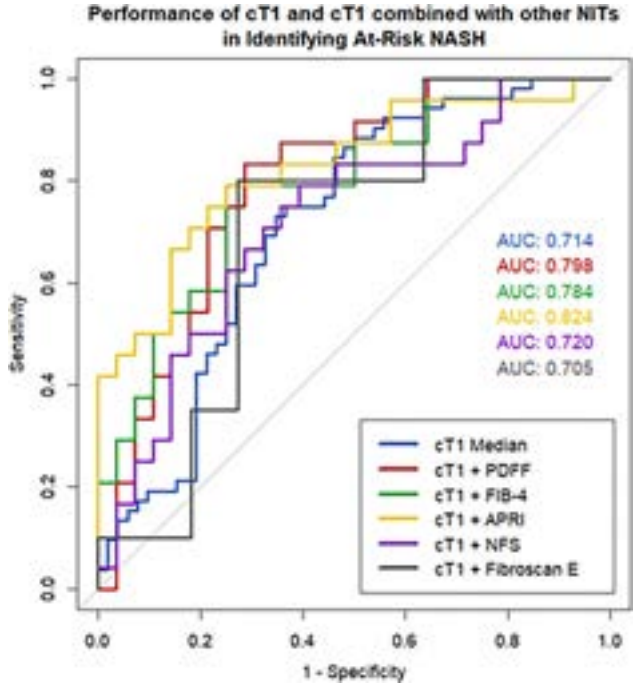

Figure:

Conclusion: Quantitative MRI-based biomarkers from both LMS and BCP scans were able to identify patients with more advanced or more aggressive NAFLD. There may be a role for novel predictive models that combine multiple biomarkers to enhance diagnostic performance. BCP has a role in investigating the mechanisms linking NAFLD, visceral adiposity and insulin resistance.

Email: hamish.miller@nhs.net

Background and aims: Despite increasing evidence demonstrating a strong relationship between poor glycaemic control and NAFLD severity, routine assessment to diagnose and stage NAFLD is not included in national UK guidance in the management of type 2 diabetes (T2D). As a consequence, liver chemistry and platelet counts (critical components of many non-invasive risk scoring systems, including NAFLD Fibrosis Score and Fib-4) are often not measured. We therefore assessed whether age and HbA1c alone could be used to rule out advanced fibrosis in people with T2D.

Method: Data from 324 patients (181 male) with and without T2D from 4 different UK secondary care cohorts were retrospectively analysed. These cohorts comprised patients recruited to a urinary biomarker study (TrUSt NAFLD: Translating the potential of the urinary steroid metabolome to diagnose and stage NAFLD) and its pilot phase in Oxford, the DRWF (Diabetes Research and Wellness Foundation) NAFLD study and a bariatric study in London. All subjects had liver biopsy proven and staged NAFLD and had available HbA1c and Fib-4 data. Data were collected within 12-months of the liver biopsy.

Results: 141/324 (44%) participants had T2D, and advanced fibrosis (F3-F4) was identified in 58% of biopsies. After adjustment for both age and BMI, HbA1c positively correlated with the degree of fibrosis on liver biopsy ($R = 0.479$, $R^2 = 0.229$, $p = 0.023$). A binomial logistic regression model was developed that included the following variables; Fibrosis (absent/mild vs severe) as the dependent variable, HbA1c and age as independent variables. The model demonstrated a significant relationship of HbA1c and age with the severity of fibrosis on liver biopsy (AUROC = 0.77, $p < 0.001$, C.I.95% [0.71–0.82]). There was no correlation between the severity of fibrosis and BMI. The performance of this model to identify advanced fibrosis was similar to that of the established non-invasive risk stratification score, Fib-4 (AUROC = 0.81, $p < 0.001$, C.I.95% [0.75–0.86]).

Conclusion: A regression model based on HbA1c and age is similar to Fib-4 in predicting the risk of advanced fibrosis in a population of subjects with and with-out T2D attending a secondary care metabolic hepatology clinic. Whilst there is a need for validation in an independent cohort, use of simple non-invasive tests to exclude significant disease and focus attention on those at increased risk is desirable. More work is needed to consider the impact of HbA1c and age on risk of fibrosis in clinical care models.

SAT-484

Diagnostic performance of non-invasive fibrosis markers in patients with immune-mediated disease and hepatic steatosis

María Del Barrio Azaceta[1], Paula Iruzubieta[1], Juan Carlos Rodriguez Duque[1], Carolina Jiménez-González[1], Marta Hernández Conde[2], Coral Rivas[1], Álvaro Santos-Laso[1], Laura Rasines[1], Lorena Cayon[1], Ana Álvarez Cancelo[1], Sara Arias-Sánchez[1], Andrea Fernández-Rodríguez[1], Christie Perelló[2], María Teresa Arias Loste[1], José Luis Calleja Panero[2], Javier Crespo[1].

Email: javiercrespo1991@gmail.com

Background and aims: High prevalence of non-alcoholic fatty liver disease (NAFLD) has been evidenced in patients with immune-mediated diseases (IMID), regardless of classical metabolic factors. However, the performance of non-invasive fibrosis tests in these patients is unknown. Our aim was to assess the accuracy of non-invasive tests in identifying advanced fibrosis (AdF) among patients with NAFLD and IMID.
Method: Multicentre, cross-sectional study that included patients with IMID (inflammatory bowel disease, psoriasis, hidradenitis suppurativa, and/or spondyloarthritis) who attended to two university hospitals (Santander and Madrid) between March 2018 and December 2019. Liver stiffness was obtained using FibroScan (FS) and the following tests were calculated: NAFLD Fibrosis Score (NFS), Fibrosis Index-4 (FIB-4), AST to Platelet Ratio Index (APRI), Hepamet Fibrosis Score (HFS). Fatty liver was defined as CAP ≥248 dB/m. The sensitivity, specificity, positive (PPV) and negative (NPV) predictive value of the tests were calculated considering the liver histological result as reference in patients with liver biopsy.
Results: Among the 1,535 patients with valid FS, fatty liver without other causes of liver disease was detected in 668 (43.5%) (mean age 54 ± 11.5 years; 57% men; 41.2% obese; 12.1% diabetics). A FS ≥8kPa was detected in 20.2% of patients, while a FS ≥12kPa was evidenced in 5.5% of patients. Risk of AdF measured by NFS, FIB-4, APRI, and HFS was obtained in 1.7%, 4.9%, 0.5%, and 0.5% of patients, respectively. Liver biopsy was proposed to all patients with FS≥8 kPa and/or increased ALT values (n = 217), accepting a total of 85 patients (mean age 55.3 ± 8.8 years; 49.4% men; 76.5% obese; 28 0.2% diabetics; 18.8% with advanced fibrosis). The table shows the diagnostic accuracy for AdF of each of non-invasive test.
Conclusion: APRI, FIB-4, and FS are the most useful screening tools for the detection of AdF among patients with NAFLD and IMID.

The liver worsens in non-alcoholic fatty liver disease patients as diabetes mellitus worsens and lasts longer

Zülal İstemihan[1], Fatih Bektaş[2], Ali Emre Bardak[3], Cansu Kızıltaş[3], Gamze Kemeç[3], Ziya Imanov[1], Volkan Senkal[1], Kanan Nuriyev[1], Aynure Rüstemzade[1], Sezen Genç[1], Hülya Hacışahinoğulları[2], Kubilay Karşıdağ[2], Bilger Çavuş[1], Aslı Çifcibaşı Örmeci[1], Filiz Akyuz[1], Kadir Demir[1], Fatih Besisik[1], Sabahattin Kaymakoglu[1]. *[1]Istanbul University, Istanbul Faculty of Medicine, Department of Internal Medicine, Division of Gastroenterohepatology, Istanbul, Turkey; [2]Istanbul University, Istanbul Faculty of Medicine, Department of Internal Medicine, Division of Endocrinology and Metabolic Diseases, Istanbul, Turkey; [3]Istanbul University, Istanbul Faculty of Medicine, Department of Internal Medicine, Istanbul, Turkey*
Email: kaymakoglus@hotmail.com

Background and aims: Type 2 diabetes mellitus (T2DM) is a major driver of non-alcoholic fatty liver disease (NAFLD). It was aimed to investigate the frequency of NAFLD with non-invasive tests and the factors affecting liver fibrosis in type 1 diabetes mellitus (T1DM) and T2DM patients.
Method: We prospectively evaluated the frequency of NAFLD and liver fibrosis with biomarkers based on blood tests and FibroScan® in adult (≥18 years) patients with T1DM and T2DM who were followed up from the diabetes mellitus (DM) outpatient clinic in a tertiary center. ≥8 kPa was accepted as significant fibrosis (F2), and ≥9.6 kPa was accepted as advanced fibrosis (F3-F4) in FibroScan® measurements. The cut-off value of the CAP score was accepted as 274 dB/m in FibroScan® measurements. Fibrosis and steatosis was compared with FibroScan® and with scores based on blood tests.
Results: A total of 520 diabetic patients (55.6% female, 82.1% T2DM) who follow-up consecutively were included in our study. The mean age of the patients was 56.28 ± 14.78 years, DM duration was 13.27 ± 8.96 years, body mass index (BMI) was 28.63 ± 6.06 kg/m2, waist circumference was 101.38 ± 14.27 cm, hip circumference was 107.76 ± 12.87 cm. Liver stiffness measurements (LSM) and CAP scores with serum scores of the study group are summarized in Fig. The frequency of NAFLD was higher in patients with T2DM than in patients with T1DM (48.7%, 12.9%, respectively, p = 0.01). When fibrosis scores were compared with non-invasive fibrosis markers of patients with T1DM and T2DM, fibrosis values in patients with T2DM were found to be significantly higher in all kinds of non-invasive biomarkers (p = 0.001). When the factors affecting fibrosis are investigated; age, BMI, waist/hip ratio, and DM duration were found to be significantly corraleted with fibrosis. The incidence of significant fibrosis was higher in patients with T2DM compared to T1DM (29%, 5%, respectively, p = 0.01). Advanced fibrosis rate was found to be higher in patients with T2DM than in T1DM (20%, 5%, respectively, p < 0.05). Microvascular complications of diabetes mellitus were observed more frequently in the presence of significant fibrosis (p = 0.03). The mean CAP score in patients with and without microvascular complications was 267.24 ± 56.74, 256.51 ± 58.13 dB/m (p < 0.05), and in patients with and without macrovascular

Figure: (abstract: SAT-484).

complications, the mean CAP score was 266.44 ± 54.01, 260.9 ± 58.78 dB/m (p < 0.05), respectively. While LSM was most significantly correlated with FIB4 and NAFLD fibrosis scores (p <0.01, r = 0.518; p <0.01, r = 0.361, respectively), CAP score was correlated with fatty liver index and hepatic steatosis index (p < 0.01, r = 0.6; p <0.01, r = 0.583, respectively).

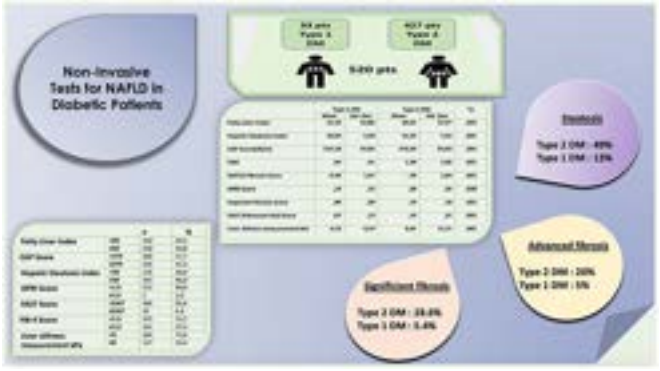

Figure:

Conclusion: NAFLD was detected more frequently in patients with T2DM than in T1DM. BMI, waist/hip ratio, age, duration of DM and complications of DM were found to be the main factors affecting liver fibrosis in T2DM. Microvascular and macrovascular complications of DM are significantly more common in diabetic patients with NAFLD.

SAT-486

Implementing a clinical care algorithm for screening of liver fibrosis in specialist diabetes care

Muna Tajudin[1,2], Johan Hoffstedt[1], Hannes Hagström[1,2], Sophia Rössner[1]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Sweden;* [2]*Karolinska University Hospital, Department of Upper GI Diseases, Sweden*
Email: muna.tajudin.2@ki.se

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease, affecting approximately one third of the global adult population. Patients with type 2 diabetes (T2D) constitute a risk group for presence and severity of NAFLD. Yet, there are few published examples of collaborations between endocrinologists and hepatologists in caring for patients with T2D and NAFLD. Here, we describe preliminary results and patient characteristics from a novel pathway for screening of liver fibrosis in routine specialist diabetes care at a tertiary care hospital.
Method: Patients with T2D seen at the Endocrinology department at Karolinska University Hospital, Stockholm, Sweden, during a structured intervention for T2D between October 2016 and December 2022 were eligible for inclusion. These were patients with complicated T2D referred for a comprehensive assessment. Subjects with excessive alcohol consumption, viral hepatitis or other chronic liver diseases were excluded. Liver stiffness measurement (LSM) and Controlled attenuation parameter (CAP) was obtained utilizing vibration-controlled transient elastography (VCTE). A LSM cut-off to exclude advanced fibrosis was set to 8 kPa.
Results: A total of 167 patients with a valid LSM were included. The median age was 59 years and 39% were women. The mean LSM was 8.3 (SD 6.4) kPa, and the median CAP was 317 dB/m. In total, 32% had LSM ≥8 kPa; 19% had LSM ≥10 kPa; and 11% had LSM ≥15 kPa. NAFLD defined as CAP ≥280 dB/m was present in 94 (66%) patients. Baseline characteristics stratified on a LSM measurement of 8 kPa are presented in Table 1.

Variable	All patients (N = 167)	LSM <8 kPa (N = 113)	LSM ≥8 kPa (N = 54)	p value	Missing data, n
Age (years)	59 (50–67)	59 (49–66)	60 (52–68)	0.36	0
Sex (female, %)	65 (38.9%)	45 (39.8%)	20 (37.0%)	0.73	0
CAP (dB/m)	317 (263–364)	297 (258–345)	344 (292–384)	**0.003**	24
Hypertension	115 (68.9%)	75 (66.4%)	40 (74.1%)	**0.048**	2
BMI (kg/m^2)	30.0 (27.4–34.3)	29.2 (26.5–32.4)	32.0 (29.1–37.1)	**<0.001**	5
HbA1c (mmol/mol)	68 (59–81)	67 (59–81)	70 (59–80)	1.00	4
Glucose (mmol/L)	9.40 (7.6–11.5)	9.2 (7.1–12.1)	9.8 (8.0–11.4)	0.32	44
Creatinine (µmol/L)	73 (60–90)	73 (61–90)	69 (55–91)	0.44	6
Low-density lipoprotein (mmol/L)	2.30 (1.60–3.10)	2.34 (1.80–3.12)	2.30 (1.40–2.90)	0.27	30
Platelet count (10^9/L)	251 (207–318)	248 (212–321)	251 (189–312)	0.53	9
Non-smoker	71 (42.5%)	51 (45.1%)	20 (37.0%)	**0.040**	3
Former smoker	78 (46.7%)	54 (47.8%)	24 (44.4%)		
Current smoker	15 (9.0%)	8 (7.1%)	7 (13.0%)		
Excessive alcohol consumption	57 (34.1%)	37 (32.7%)	20 (37.0%)	0.22	10

Figure:
Data are presented as median (IQR) for continuous measures, and n (%) for categorical measures.

Conclusion: The prevalence of NAFLD and elevated LSM, indicative of advanced fibrosis, in this cohort of patients with advanced T2D was high. CAp values, BMI, hypertension and smoking might be potentially interesting parameters to further identify patients with elevated LSM. Based on these results, a clinical care algorithm is now being introduced in our hospital, offering patients with advanced T2D a VCTE measurement and hepatological evaluations in those with values ≥8 kPa. We hope to spread this model to other hospitals in Sweden through local collaborations between hepatology and endocrinology services.

SAT-487

The use of non-invasive tests compared with histological fibrosis stage in predicting liver-related events in metabolic dysfunction-associated fatty liver disease

Wah Loong Chan[1], Shi-En Chong[1], Felicia Chang[1], Kee Huat Chuah[1], Nik Raihan Nik Mustapha[2], Sanjiv Mahadeva[1], Wah-Kheong Chan[1]. [1]*Universiti Malaya, Gastroenterology and Hepatology Unit, Department of Medicine, Faculty of Medicine, Kuala Lumpur, Malaysia;* [2]*Hospital Sultanah Bahiyah, Department of Pathology, Alor Setar, Malaysia*
Email: wljack90@gmail.com

Background and aims: To study the use of non-invasive tests (NITs) compared with histological fibrosis stage in predicting liver-related events in adults with metabolic-dysfunction-associated fatty liver disease (MAFLD).
Method: This is a single-centre prospective study of a well-characterized cohort of biopsy-proven MAFLD patients who were followed for liver-related events. The patients were followed every 6–12 months for cardiovascular events, liver-related events, malignancy, and mortality. The performance of NITs was evaluated using area under receiver operating characteristic curve (AUROC).
Results: The data for 202 patients were analyzed (median age 55.0 years old, male 47.5%, steatohepatitis 76.7%, advanced liver fibrosis 27.3%). The median follow-up interval was 7 years (range 1–9 years). Seven liver-related events (ascites, n = 1; hepatocellular carcinoma, n = 1; variceal bleeding, n = 1; gastroesophageal varices, n = 4) occurred in 2.5% (5/202) of patients. LSM and histological fibrosis stage were good predictors of liver-related events with AUROC of 0.88 and 0.89, respectively, while NFS was fair with AUROC of 0.78. FIB-4 and APRI performed poorly with AUROC of 0.63 and 0.56, respectively. The optimal cut-off for each of the NITs (based on Youden index), and its sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for liver-related events are shown in Table 1.

Using the 10 kPa cut-off, the sensitivity, specificity, PPV and NPV of LSM for liver-related events were 100%, 65.5%, 6.7% and 100%, respectively. Using the 15 kPa cut-off, the corresponding values were 60%, 84.3%, 8.8% and 98.8%, respectively.

Table 1 The optimal cut-off for each of the noninvasive tests (based on Youden index), and its sensitivity, specificity, positive predictive value, and negative predictive value for liver-related events

	Histological fibrosis stage	LSM	APRI	FIB-4	NAFLD fibrosis score (NFS)
AUROC	0.89 (0.81-0.96)	0.88 (0.78-0.98)	0.56 (0.26-0.83)	0.63 (0.39-0.87)	0.78 (0.66-0.91)
Optimal Cut-off	F3	11.1 kPa	0.81	0.89	-0.930
Sensitivity	100%	100%	40%	100%	100%
Specificity	75%	70%	89%	36%	62%
PPV	9%	8%	9%	4%	6%
NPV	100%	100%	98%	100%	100%

LSM, liver stiffness measurement; APRI, aspartate aminotransferase to platelet ratio index; FIB-4, fibrosis-4 index; NAFLD, nonalcoholic fatty liver disease; AUROC, area under the receiver operating characteristic curve; 95% CI, 95% confidence interval; PPV, positive predictive value; NPV, negative predictive value

Figure:

Conclusion: LSM, but not simple blood-based fibrosis scores, appeared to be as good as histological fibrosis stage in predicting liver-related events in MAFLD patients.

SAT-488

LIVERFASt GP+ (GP+), a non-invasive blood testing for NAFLD staging, improves risk stratification of patients with indeterminate FIB-4 results

Naim Alkhouri[1], Anita Kohli[1], Phillip Leff[1], Rida Nadeem[1], Mona Munteanu[2]. [1]*Arizona Liver Health, United States;* [2]*Fibronostics, United States*
Email: mona_munteanu@hotmail.com

Background and aims: GP+, an AI-based blood test, was validated against liver biopsy (LB) to identify the presumed NAFLD clinical stages. GP+ clinical variables are: total bilirubin, liver enzymes, glucose and lipid panel. The aim was to assess retrospectively the GP+ performance and concordance rate (CR) as second step after FIB-4 for the assessment of advanced fibrosis (F3-F4) in NAFLD patients.
Method: Patients included from a tertiary hepatology clinic had LB-proven NAFLD and concomitant FIB-4, GP+ and liver stiffness measurement (LSM). AUC (SE) and C-statistics were used to assess the accuracy of each no-invasive test (NIT) against LB.
Results: 176 patients were included [mean (se) age 57.2 (0.8) years, BMI 37.7 (0.6)kg/m2, ALT 52 (3)U/L, diabetes 47.4%]. AUC (SE) for F3-F4 for FIB-4, GP+ and LSM, respectively, were 0.76 (0.04), 0.69 (0.04), 0.76 (0.04), all p values = ns. 27 patients had FIB-4≥2.67; the LB CRs for F3-F4 and all NITs were 68%; LB CRs for F3-F4 with LSM and GP+, respectively, were higher (68% each) than with FIB-4 (58%). In 64 patients FIB-4 ranged 1.30–2.67; LB stage was F1-F2 in 34 and F3-F4 in 26. For F1-F2, LB CR with GP+ was 60%, significantly higher than with LSM (28%, $p < 0.001$). For F3-F4, LB CRs with LSM and GP+ were similar (43%). 85 patients had FIB-4 < 1.3; LB CR with FIB-4 for ruling out F3-F4 was 17%; LB CR with GP+ for F1-F2 staging was 71%, higher than with LSM (31%).
Conclusion: GP+ is readily available and can be used to identify F3-F4 as a second step in patients with indeterminate FIB-4.

SAT-489

Assessing the feasibility of AI-based Hamaguchi score estimation for NAFLD diagnosis using ultrasound images

Alessia Visintin[1], Mauro Giuffrè[2,3], Francesca Dottor[2], Christian Francescut[2], Flora Masutti[1], Lisa Rebuzzi[2], Marco Sartori[2], Massimiliano Loddo[2], Caterina Zoratti[2], Simone Kresevic[4], Silvia Palmisano[2,3,5], Saveria Lory Croce'[1,2,3]. [1]*Azienda Sanitaria Universitaria Giuliano Isontina (ASUGI), Clinica Patologie del Fegato, Trieste, Italy;* [2]*Università degli Studi di Trieste, Dipartimento di Scienze Mediche, Trieste, Italy;* [3]*Fondazione Italiana Fegato Onlus, Trieste, Italy;* [4]*Prodigys, Trieste, Italy;* [5]*Azienda Sanitaria Universitaria Giuliano Isontina (ASUGI), Clinica Chirurgica, Trieste, Italy*
Email: gff.mauro@gmail.com

Background and aims: NAFLD is a liver disease caused by fat accumulation and ranges from simple steatosis to NASH with increasing liver damage. 25% of the world population has NAFLD and is projected to rise to 33.5% by 2030. Ultrasound B-mode imaging is the preferred diagnostic method but has limitations. This study aims to improve diagnosis using ML and DL algorithms to estimate scores for US images using the Hamaguchi Score and provide a new approach for automatic analysis.
Method: The study evaluated 220 patients with NAFLD who underwent US assessment at Trieste University Hospital. The clinical and radiological data were analyzed to create the study dataset, divided into 3 datasets (Hepatorenal, Diaphragm, Vessel) based on the visibility of liver and renal parenchyma, intrahepatic vessels, and the diaphragm. The Hamaguchi score was assigned to each dataset by 4 physicians, and pre-processing was applied to locate the US cone containing the info. The study proposed a framework for automatic estimation of Hamaguchi score based on semiautomatic analysis of US images using 3 sub-score related algorithms. The liver brightness score was calculated using clustering and K-means, while diaphragm and vessel scores were evaluated using 2 CNNs with transfer learning. To prevent overfitting, data augmentation was used to balance the datasets. Ten CNNs were implemented with transfer learning (VGG-16 and VGG-19) and the best performing network was selected. The development was implemented using Python and Tensorflow/Keras libraries.
Results: A predictive model for liver brightness contrast score was developed and had a 90.5% classification accuracy using sub-scores labeled by physicians. For misclassified cases, the maximum error was one point. The best models for diaphragm deep attenuation and vessel blurring sub-scores based on their performance on the validation dataset. For diaphragm deep attenuation: accuracy 83.25%, loss 0.48, AUC 0.93, precision 83%. Whereas for vessel blurring: accuracy 84.05%, loss 0.44, AUC 0.89, precision 89%.
The algorithm for diaphragm deep attenuation showed an accuracy of 81.8% with misclassified scores under- or over-estimated by one point. The vessel blurring sub-score model had an accuracy of 86.4% on the test dataset, maintaining its performance from training and validation.
Conclusion: This study aimed to assess the possibility of estimating Hamaguchi's score for NAFLD diagnosis using advanced image analysis. The results showed that AI-based methods can estimate the three sub-scores that determine the score with high classification accuracy. These results suggest that such decision support systems could support liver disease diagnosis in the future and reduce intra- and inter-operator assessment error. However, the study had limitations such as a moderate sample size and a retrospective nature that limited the possibility of building a balanced dataset. Further studies with larger samples and clinically balanced datasets are needed to confirm and improve these preliminary results. An automatic tool for ROI selection could also enhance the presented approach.

SAT-490

Metabolic and adipocytokine disorders as a background cause of the progression of non-alcoholic steatohepatitis in obese patients depending on comorbidity with chronic obstructive pulmonary disease

Olha Hryniuk[1], Oksana Khukhlina[1], Olha Mandryk[1], Ivanna Rachynska[1]. [1]*Bukovinian State Medical University, Department of Internal Medicine, Clinical Pharmacology and Occupational Diseases, Chernivtsi, Ukraine*
Email: olha.hryniuk@bsmu.edu.ua

Background and aims: The aim of the research was to analyze changes in glycemia, blood lipid profile and their endocrine (insulin, leptin, adiponectin) regulation during the isolated and combined course of non-alcoholic steatohepatitis (NASH) and chronic obstructive pulmonary disease (COPD) against the background of obesity.
Method: The study involved 160 patients: 35 patients with NASH and obesity of the 1st stage (1 group), 90 patients with NASH, obesity of the 1st stage and COPD 2–3 B, C, D (group 2) and 35 patients with COPD 2–3 B, C, D (group 3). The control group (CG) consisted of 30 practically healthy persons. The state of carbohydrate metabolism was determined by performing the glucose tolerance test using the glucose oxidase method, fasting insulin (DRG System) by the enzyme-linked immunosorbent assay (ELISA). The degree of insulin resistance (IR) was determined by the body mass index, waist circumference/hip circumference; the HOMA-IR index was calculated using the HOMA Calculator Version 2.2 Diabetes Trials Unit University of Oxford (United Kingdom). Blood lipid spectrum was studied by total lipid content (TL), total cholesterol (TC), triacylglycerols (TG), and high-density lipoprotein (HDL) and low-density (LDL) using diagnostic standard sets of "Simko Ltd" (Ukraine). Hormonal regulation of lipid metabolism was determined by blood leptin, adiponectin (DRG System) by ELISA.
Results: The fasting glycemia index in patients of the 1st and 2nd groups were slightly increased by 10.9% and 14.3% ($p_{1-2} < 0.05$) compared to the CG. Analysis of the postprandial glycemia in patients of the 1st and 2nd groups showed a significant increase glucose level by 18.6% and 34.4% respectively ($p_{1-2} < 0.05$) in comparison to data CG. In patients with an isolated course of COPD improbable changes ($p_3 > 0.05$) were observed. The fasting insulin study revealed probable hyperinsulinemia and HOMA IR index increases which were 2.4 and 2.9 times higher in patients of the 1st and 2nd groups comparing to CG ($p_{1-2} < 0.05$). In patients of the 3rd group insulin content and HOMA-IR index were higher than the score in CG by 1.6 times ($p_3 > 0.05$). Blood total lipid concentration in the 3 groups were higher by 29.5%, 39.8% and 14.9% ($p_{1-3} < 0.05$) respectively and blood content of TC increases by 36.3%, 45.7% and 14.9% ($p_{1-3} < 0.05$) respectively in comparison to CG. A probable increase the TG blood concentration (1.9 and 2.2 times respectively, $p_{1-2} < 0.05$) was registered in the 1st and 2nd groups, while in the 3rd group in 1.6 times increase ($p_3 < 0.05$). A significant increase in the atherogenic index was established in patients of the 1st group by 2.3 times, but in the 2nd group the indicator was lower than in CG by 1.2 times ($p_{1-2} < 0.05$), in patients of the 3rd group-changes were not improbable ($p_3 > 0.05$). Serum leptin level in the 1st group exceeded the scale of CG by 4.7 times, and in the 2nd group-by 5.4 times ($p_{1-2} < 0.05$). Plasma adiponectin level of patients of the 1st and 2nd groups were 1.7 and 2.4 times lower than the indicator of CG ($p_{1-2} < 0.05$). In the 3rd group there were no probable changes in indicators ($p_3 < 0.05$).
Conclusion: The metabolic prerequisites to the progression of NASH in comorbidities with obesity are deepened under the conditions of COPD, which is an additional powerful inducing factor of the lipid distress syndrome and carbohydrate disorders with a likely higher increase in the blood of TG, TC, LDL-C, HDL-C level, atherogenicity index, the degree of IR accompanied by hyperleptinemia, adiponectin deficiency.

SAT-491

The role of M2BPGi for screening of advanced hepatic fibrosis in elderly patients

Hoon Gil Jo[1], Dae Won JUN[2], Eileen Yoon[2], Mimi Kim[2], Hye-Lin Kim[3], Eun Young Cho[1], Se Young Jang[4], Young Youn Cho[5], Ki Tae yoon[6], Yang-Hyun Baek[7], Sang Yi Moon[7], Aejeong Jo[2]. [1]*Wonkwang University College of Medicine and Hospital, Korea, Rep. of South;* [2]*Hanyang University, College of Medicine, Korea, Rep. of South;* [3]*Sahmyook University, College of Pharmacy, Korea, Rep. of South;* [4]*Kyungpook National University, Kyungpook National University Hospital, Daegu, South Korea, Korea, Rep. of South;* [5]*Chung-Ang University Hospital, Seoul, Korea, Korea, Rep. of South;* [6]*Pusan National University, Korea, Rep. of South;* [7]*Department of Internal Medicine, Dong-A University College of Medicine, Busan, South Korea, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: Non-invasive fibrosis markers such as Fibrosis-4 (FIB-4) or NAFLD Fibrosis Score (NFS) are simple and powerful tools to rule out progressive fibrosis in middle age. However, it is known that FIB-4 and NFS showed very low specificity in the elderly. The purpose of this study is to determine if Mac-2 binding protein glycan isomer (M2BPGi) and non-invasive test (NIT) and their combination could be helpful in diagnosing advanced liver fibrosis in elderly patients aged ≥65 years.
Method: Of the 2,177 patients who visited the gastroenterology department of six tertiary general hospitals and performed M2BPGi and transient elastography test (TE), 521 elderly patients aged 65 years or older were finally analyzed. FIB-4 and NFS were calculated for all subjects. Progressive fibrosis was defined as a TE ≥8.0 kPa.
Results: A total of 521 elderly patients were included, with an average age of 74.1 ± 5.3 years. Based on the FIB-4 cut-off 2.0, the sensitivity and specificity for screening advanced hepatic fibrosis were 90.4% and 45.2%. When the M2BPGi cut-off was set as 0.8, the sensitivity and specificity in the elderly patients were 83.9% and 38.8%, respectively. The sequential combination of FIB-4 and M2BPGi showed 77.1%, 62.1%, 54.0%, and 82.5% of sensitivity, specificity, positive predictive value, and negative predictive value, respectively. In the case of using the sequential combination of FIB-4 and M2BPGi, the unnecessary referral rate for transient elastography examination in elderly patients was reduced by 24.7% compared to the case of using FIB-4 alone.
Conclusion: The sequential combination of FIB-4 followed by M2BPGi may reduce unnecessary referral rates and decrease consequently further investigations in elderly patients with mild fibrosis.

SAT-492

Development of a novel non-invasive test for prediction of liver fibrosis in patients with clinically severe obesity defined by a BMI over 50 kg/m²

Maximilian Joseph Brol[1], Uta Drebber[2], Xiaojie Yu[2], Robert Schierwagen[1], Sabine Klein[1], Andreas Plamper[3], Margarete Odenthal[2], Wenyi Gu[1], Frank Erhard Uschner[1], Karl-Peter Rheinwalt[3], Jonel Trebicka[1,4]. [1]*University Hospital Münster, Department of Internal Medicine B, Münster, Germany;* [2]*University Hospital of Cologne, Department of Pathology, Cologne, Germany;* [3]*St. Franziskus-Hospital, Department of Bariatric, Metabolic, and Plastic Surgery, Cologne, Germany;* [4]*European Foundation for the Study of Chronic Liver Failure-EF Clif, Barcelona, Spain*
Email: maximilian.brol@ukmuenster.de

Background and aims: Liver fibrosis is the major driver in chronic liver disease progression. Especially in non-alcoholic fatty liver disease (NAFLD) awareness of liver fibrosis is key for patient stratification and follow-up planning. Non-invasive tests (NIT) for liver fibrosis perform poor in patients with obesity and to date no NIT was validated in the rapidly growing cohort of patients with clinically severe obesity, namely a body mass index (BMI) over 50 kg/m².

Method: This prospective, single-center cohort study included 95 patients who were referred to bariatric surgery. Liver biopsies were acquired during surgery. Liver fibrosis was histopathologically determined according to Kleiner. AST-to-platelet ratio index (APRI), Fibrosis-4 score (FIB-4), NAFLD fibrosis score (NFS) and BMI, AST/ALT-ratio and diabetes score (BARD) with classic and optimized thresholds, determined by maximal Youden-Index were performed. Accuracy, sensitivity, specificity, negative predictive value (NPV) and positive predictive value (PPV) were calculated for each NIT. Multiple regression analysis of clinical variables were used to identify predictive factors in our cohort.
Results: Commonly used NITs showed poor prediction of liver fibrosis in our cohort, with maximum AUROC of.70. Multiple linear regression and ANOVA analyses identified five variables (presence of dyslipidemia, presence of diabetes, serum levels of ALT, AST and creatinine) significantly predicting fibrosis. This resulted in the Severely-Obese-Score (SOS) with an AUROC of.79. Sensitivity was 0.4 for APRI, 0.49 for FIB-4, 0.73 for NFS, 0.64 for BARD and 0.74 for SOS. Specificity was 0.93 for APRI, 0.71 for FIB-4, 0.57 for NFS, 0.43 for BARD and 0.79 for SOS. Accuracy in predicting fibrosis for commonly used NITs ranged between 48–71%. Our score had the best accuracy (75% correctly classified patients) and best NPV for prediction of any degree of fibrosis.

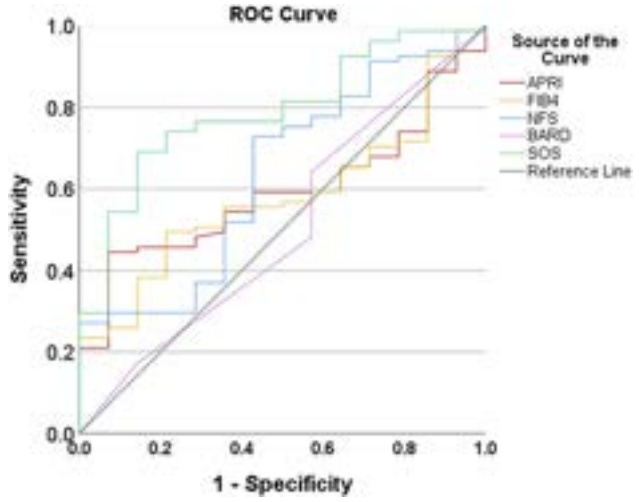

Figure:

Conclusion: Performance of established NITs is weak in patients with clinically severe obesity and a BMI over 50 kg/m². The here presented score is a useful tool this setting. Prospective evaluation of our score should be performed in further studies.

SAT-493

Detecting early improvements in a NAFLD patient population during diet-induced weight loss

Pietro Torre[1], Luigi Schiavo[1], Mario Masarone[1], Benedetta Maria Motta[1], Federica Belladonna[1], Marco Aquino[1], Marcello Persico[1]. [1]*University of Salerno, Department of Medicine, Surgery and Dentistry, "Scuola Medica Salernitana", Italy*
Email: pietrotorre90@gmail.com

Background and aims: Weight loss is the cornerstone in the treatment of NAFLD and was found associated with a histological improvement proportional to its extent. However, it is a difficult goal to achieve and maintain. Moreover, the precise link between weight changes and NAFLD is not fully understood. The aim of this study is to describe the possible positive influences of a nutritionist-guided low-glycemic index diet on anthropometric parameters, Transient Elastography (TE), Controlled Attenuation Parameter (CAP, with the *SmartExam* software), and blood chemistry in overweight or obese NAFLD patients. The genetic correlation with TE/CAP measurements was also taken into account.
Method: 69/106 patients who were attending our Hepatology Unit, with NAFLD, aged ≥18, and with a BMI ≥25 accepted to start the nutritionist-guided diet. Baseline anthropometric data, TE/CAP, and blood test results were recorded. Single nucleotide polymorphisms in NAFLD risk genes were analyzed and genetic risk score (GRS) was calculated. Control visits were scheduled after 1 and 3 months. TE/CAP was performed during each visit, and after 3 months blood tests were repeated.
Results: 57/69 patients (82.61%) attended at least one of the control visits. A significant difference from baseline was observed at both 1-month and 3-month visit in weight (−4.26 kg [−4.78%] p <0.0001, and −7.67 kg [−8.43%] p < 0.0001), BMI (−1.55 Kg/m^2, p < 0.0001, and −2.75 Kg/m^2, p < 0.0001), and CAP (−27.67 dB/m, p = 0.0062, and −42 dB/m, p = 0.0182). Changes in CAP were proportional to the extent of weight loss, whereas mean liver stiffness remained almost unchanged. Baseline CAP was proportional to GRS; high GRS patients presented a higher decrease in TE/CAP values after 3 months of diet. After 3 months of diet, significant differences in glycemia and triglycerides were observed; AST, ALT, total cholesterol and HDL cholesterol also improved.

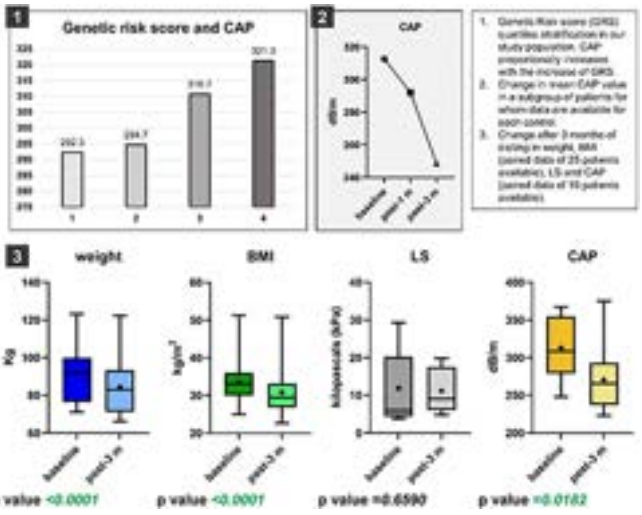

Figure:

Conclusion: In our NAFLD population, after diet-induced weight loss, an improvement in metabolic parameters was observed. The early reduction of CAP could increase patient awareness of the ongoing improvements. Genetics could influence the reduction of steatosis during weight loss.

SAT-494

Echocardiography-based markers for subclinical cardiac dysfunction in patients with non-alcoholic fatty liver disease and significant fibrosis with preserved ejection fraction: preliminary data from a prospective monocentric Italian cohort

Angelo Armandi[1,2], Daphne D'Amato[1], Alessandro Andreis[3], Matteo Bellettini[3], Gian Paolo Caviglia[1], Gabriele Castelnuovo[1], Irene Poggiolini[1], Chiara Rosso[1], Nuria Pérez Diaz del Campo[1], Amina Abdulle[1], Kamela Gjini[1], Davide Ribaldone[1], Gaetano De Ferrari[3], Giorgio Maria Saracco[1], Davide Castagno[3], Elisabetta Bugianesi[1]. Cardiovascular and Thoracic Department, Città della Salute e della Scienza di Torino Hospital, Department of Medical Sciences, University of Turin, Italy
Email: daphne.damato@gmail.com

Background and aims: Individuals with Non-Alcoholic Fatty Liver Disease (NAFLD) have abnormal myocardial energy metabolism and reduced coronary functional capacity, even in the absence of risk factors for cardiovascular disease (CVD), potentially associated with cardiac fibrosis and heart failure (HF). We aimed to evaluate diastolic and systolic function in NAFLD patients and significant fibrosis with preserved ejection fraction (EF).
Method: We prospectively included patients with ultrasound-diagnosed NAFLD undergoing screening echocardiography *per protocol*, in the absence of overt CVD or HF. Echocardiography was performed according to European Society of Cardiovascular Imaging guidelines, including speckle tracking analysis with left ventricular global longitudinal strain (GLS) measurement for accurate quantification of systolic function (Philips, Andover, US). Diastolic dysfunction with increased filling pressures was defined as a mitral E/E′ ratio >9. Liver fibrosis was assessed by non-invasive tests and transient elastography (TE, Fibroscan F530); significant liver fibrosis (SLF) was defined by either FIB-4 score >1.3 or liver stiffness (LS) >7 kPa. Clinical and biochemical parameters, as well as TE and echocardiography, were collected within one month from NAFLD diagnosis.
Results: A total of 95 patients were included. Median age was 53.0 [IQR 44.5–62.5] years and 44.6% was male. Type 2 diabetes mellitus (T2DM) and obesity were present in 21,1% and 43,3% of the cohort, while 46,2% had arterial hypertension. Median FIB-4 was 0.97 [IQR 0.67–1.24]. SLF, diastolic and systolic dysfunction were found in 20%, 17% and 18.3% of the total. Higher FIB-4 levels were found in both diastolic and systolic dysfunction (p = 0.003 and p = 0.001). SLF was associated with diastolic dysfunction (OR 6.8 [95%CI 1.8–25.5], p = 0.004), showing an Area Under the Curve of 0.76 (Se 76.9%, Sp 72.2%, PPV 33.3%, NPV 94.5%) (Figure 1). In a multiple stepwise logistic regression model including T2D, obesity, arterial hypertension, dyslipidemia, male sex and SLF, both SLF and T2D were significantly and independently associated with diastolic dysfunction (aOR of SLF 6.2 [95%CI 1.5–25.1, p = 0.011). In the same regression model for systolic dysfunction, only T2D showed a significant association (aOR 4.6 [95%CI 1.3–16.8], p = 0.021).

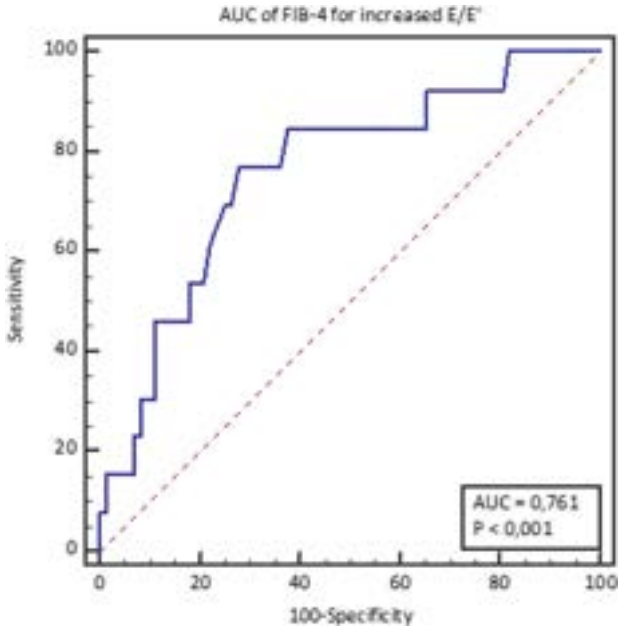

Figure: Discriminative capacity of liver fibrosis for diastolic dysfunction, area under the curve (sensitivity 76.6%, specificity 72.2%, positive predictive value 33.3%, negative predictive value 94.5%).

Conclusion: In NAFLD patients with preserved EF, significant liver fibrosis by FIB-4 and TE correlate with markers of diastolic dysfunction and lower GLS systolic values. T2DM is the strongest factor associated with diastolic dysfunction in this population. Screening echocardiography may be recommended in this population. The research has been supported by the Italian Ministry for Education, University and Research (MIUR) under the programme "Dipartimenti di Eccellenza 2018–2022" Project code D15D18000410001.

SAT-495

Comparison of performance of non-invasive indices in assessing degree of steatosis in non-alcoholic fatty liver disease

En Ying Tan[1], Sin Hui Melissa Chua[1], Eunice Tan[1], Daniel Huang[1], Jonathan Lee[1], Margaret Teng[1], Nur Halisah Binte Jumat[1], Yock Young Dan[1], Mark Muthiah[1]. *[1]National University Hospital (NUH)-Singapore, Department of Gastroenterology and Hepatology, Singapore, Singapore*
Email: tanenying@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent chronic liver disease worldwide, of which the earliest manifestation is simple hepatic steatosis. Most of the patients with NAFLD have hepatic steatosis, without the presence of steatohepatitis or fibrosis. Liver biopsy is the gold standard for assessment of steatosis, but is associated with significant cost, risks and limited availability, and is not feasible in a disease for which identification in large swathes of the population is key. To identify NAFLD in population cohorts, it is essential to evaluate non-invasive tests (NITs) that are easily performed in primary care. We aim to evaluate the performance of various NITs in predicting presence and severity of hepatic steatosis, comparing to histology as the reference standard.
Method: Patients with biopsy-proven NAFLD were enrolled from National University Health System, Singapore to undergo various non-invasive tests. Patients who also had other causes for liver disease were excluded. Hepatic steatosis index (HSI), visceral adiposity index (VAI), NAFLD liver fat score (NLFS), triglyceride-glucose index (TGI), fatty liver index (FLI) and FibroScan Controlled Attenuation Parameter (CAP) were evaluated for performance in assessment for steatosis.
Results: 399 multi-ethnic Asian patients with biopsy-proven NAFLD were recruited from 2014 to 2021. AUC values for identifying steatosis (S1–3) for HIS, FLI, NLFS, TGI, VAI and FibroScan CAP were 0.792, 0.720, 0.905, 0.714, 0.823 and 0.957 respectively. Optimal cut offs for diagnosis of hepatic steatosis were HSI 38.2, FLI 124.8, NLFS –0.818, TGI 8.45, VAI 1.33 and CAP 254 kPa.
Respective AUC values for identifying S2–3 steatosis for the above-mentioned tests were 0.647, 0.592, 0.736, 0.664, 0.671 and 0.677. Respective AUC values for identifying S3 steatosis were 0.581, 0.585, 0.703, 0.613, 0.668 and 0.616. All indices performed better at identifying steatosis than at distinguishing severity of steatosis. In particular, Fibroscan CAP was excellent in identifying steatosis. NLFS had significantly better performance than several other composite scores, especially in diagnosing steatosis.
Conclusion: Our findings suggest NLFS to be a potential NIT for identifying steatosis in population cohorts, given its favourable performance as well as cost and accessibility. As with other NITs, it may be less robust in distinguishing severity of steatosis. FibroScan CAP remains a good option, particularly in places with access to them at the primary care level.

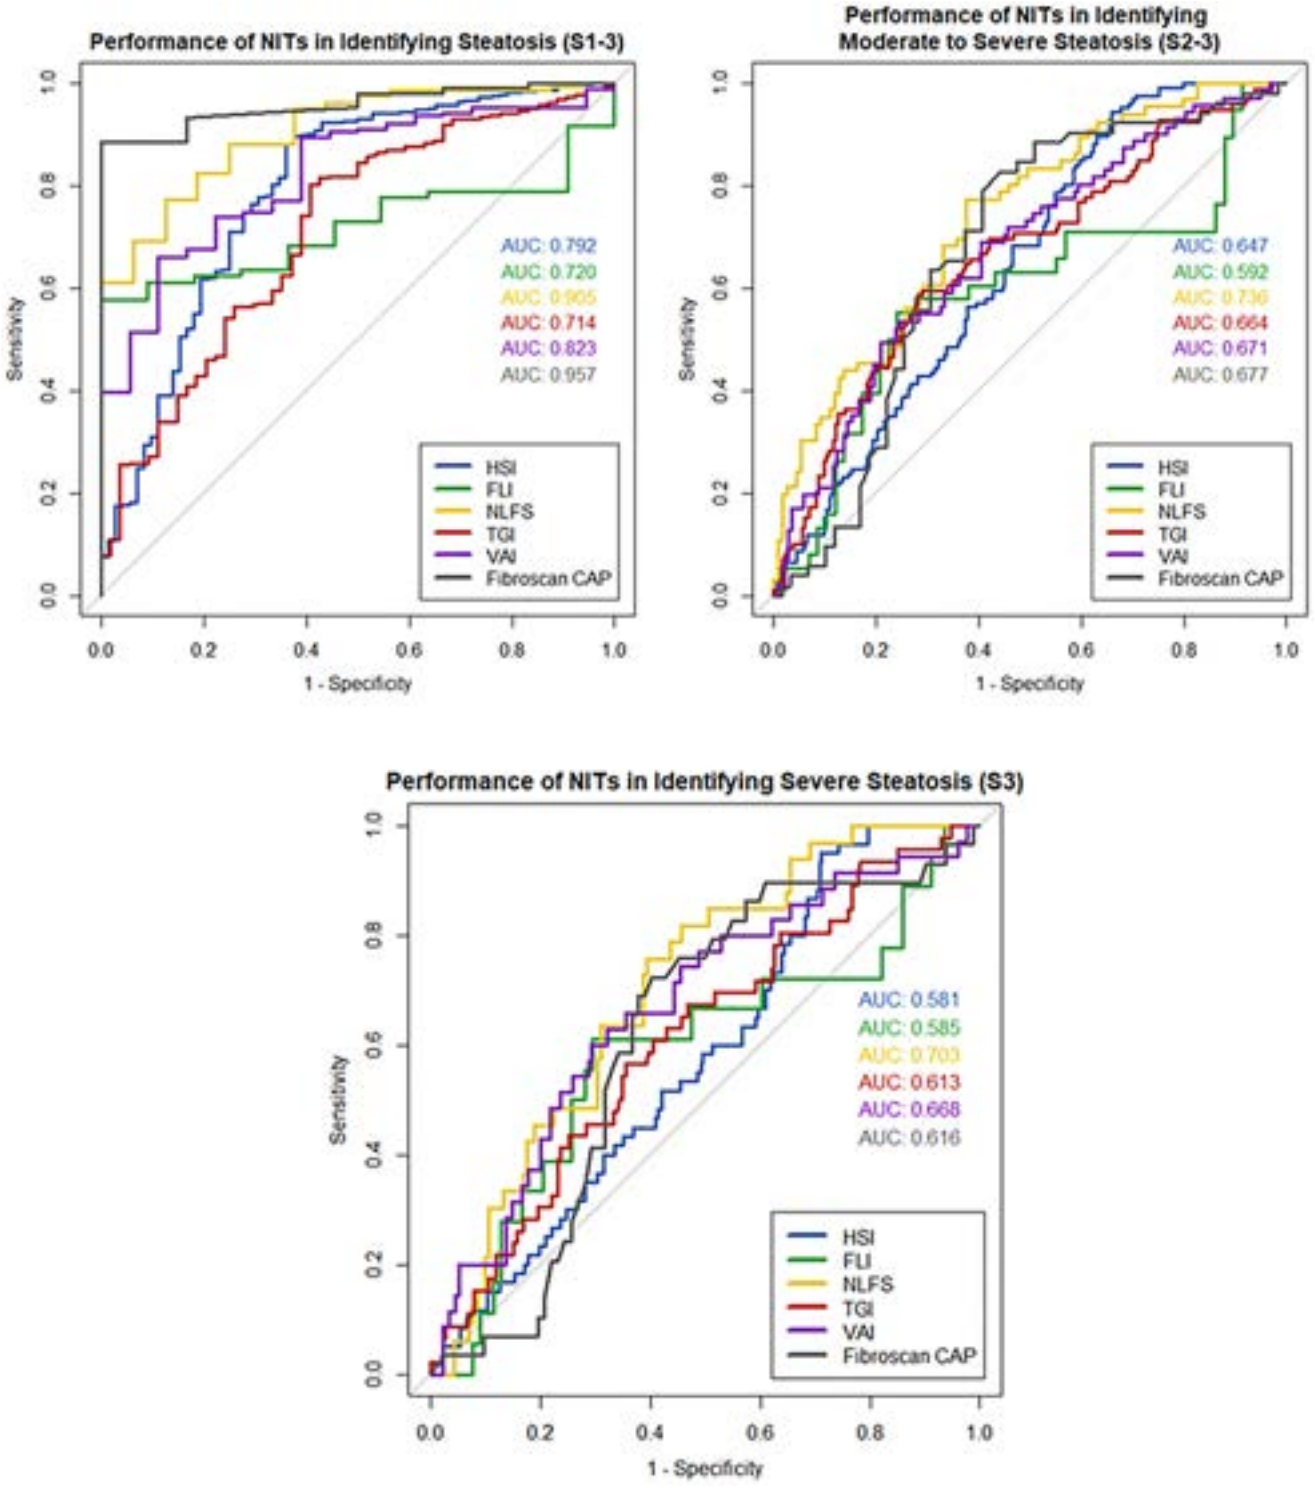

Figure: (abstract: SAT-495).

SAT-496

Evaluation of the performance of a novel single-nuclei digital pathology method for the continuous quantification of steatosis and inflammation in liver biopsies and its correlation with NASH-CRN scores in patients with NASH

Email: mathieu.petitjean@pharmanest.com

Background and aims: The quantification of HandE liver biopsy with Digital Pathology methods based on annotation provided by pathologists (steatosis, inflammation) result in continuous scores of

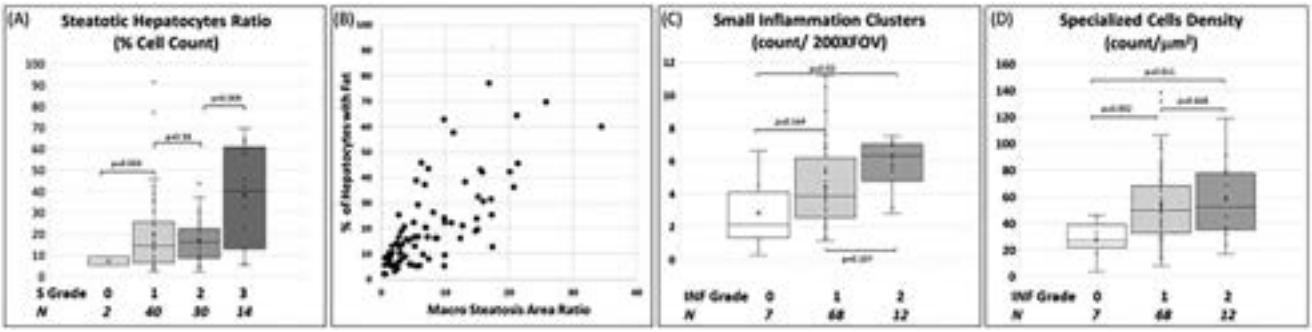

Figure: (abstract: SAT-496).

moderate performances. Here, we report results of a new AI-assisted single-nuclei quantification approach that benefits from (a) training received from pathologists on highly consensual features (cell types) and (b) generates mathematically defined outcomes. This approach address limitations of current histological current nomenclatures and methods (doi:10.1002/hep.32475)

Method: This retrospective cohort included 87 patients with NASH diagnosed by histologic assessment of liver biopsy with lobular inflammation grades of 0 (N = 7), 1 (68), and 2 (12), and steatosis grades of 0 (N = 2), 1 (40), 2 (30) and 3 (14). Quantitative image analysis of 20X Digital pathology images of HandE stained sections was performed to identify cell nuclei (~ 20 k per biopsy) and quantify their morphometric and local surroundings in 86 parameters. A subset of 13 images (~260 K nuclei) was used to develop a machine learning (ML) model using 3.0 K annotations (respectively 3.0 K, 3.3 K, 3.7 K, 1.7 K, 3.0 K) for steatotic hepatocytes, normal hepatocytes, inflammatory cells (all kinds), liver specialized cells (all kinds), and "debris" (cells in apoptosis or distorted). Once classified, a cell tissue panel was calculated to account for cell densities (count/mm2) and relative cell count %. Macro-steatosis Area Ratio was calculated. Clusters of inflammatory cells were identified using "closest neighbor" method and the morphometric features of these clusters was used to classify them into small (<5000 μm^2), medium and large clusters which are then quantified by several continuous and normalized parameters (biopsy area ratio, count per mm2 or 200XFOV).

Results: The cell classification accuracy (error) of the ML model ranged from 14.6% (24.3%) for specialized cells to 77.7% (26.9%) for inflammatory cells. The steatotic hepatocytes count ratio (Fig. A, 0.008<p values<0.38) exhibited similar trends reported previously using ML from pathologists' annotations and correlates well with Area Ratio (Fig. B, R2 = 0.5226). The count of small inflammation clusters (Fig. C, 0.107<p values<0.034) moderately corresponds to the histological grades, which is attributed to the histological definition of inflammatory clusters and their assessment. The inflammatory cell density detects the presence of inflammation with good performance (Fig. D).

Conclusion: Quantitative digital pathology can automatically generate tissues panels from HandE stained sections. While the scores extracted from these tissues panels moderately correspond to NASH-CRN histological stages, they present the benefit of being quantitative and translational, and not sensitive to liver tissue variation due to swelling, fat invasion, or various artifacts.

SAT-497

Development of ultra-sensitivity enzyme linked immunosorbent assay for hepatitis delta virus antibody detection

Nomin Ariungerel[1,2], Ulziigerel Yanjinlkham[1], Saruul Enkhjargal[1,2], Naranjargal Dashdorj[2], Odgerel Oidovsambuu[3]. [1]*School of engineering and applied sciences, Department of chemical and biological engineering, Ulaanbaatar, Mongolia;* [2]*Liver center, Ulaanbaatar, Mongolia;* [3]*National University of Mongolia, Department of Chemical and Biological Engineering, Ulaanbaatar, Mongolia*
Email: a.nomin@onomfoundation.org

Background and aims: The prevalence of hepatitis delta virus (HDV) is unequally distributed in the world. In most countries, the infection rate is very low, but some countries, especially Mongolia has a disproportionally high prevalence of HDV infection. Therefore, the introduction of sophisticated diagnostic assays for detection of HDV infection is less attractive for most companies, and diversity of commercially available kits are very limited. Also, we have found that most ELISA diagnostic kits for anti-HDV IgG detection have single origin in China and their quality issues should be accounted. In this study, we have developed an ultra-sensitive ELISA assay using self-assembled monolayer method, which applies covalent attachment of sHDAg on the plate surface in more organized manner that produces much better results than the conventional physical absorption method in terms of sensitivity and specificity.

Method: Recombinant His-tagged sHDAg protein (23 kDa) was produced in E. Coli and purified by Ni-NTA metal-affinity chromatography. First, the surface of the polystyrene plate was functionalized by treating with 1% sodium hydroxide for binding of 2% 3-(aminopropyl)triethoxysilane (APTES). Then 10 ug/ml HDV-Ag proteins were cross-linked with N-ethyl-N'-3-dimethylaminopropyl) carbodiimide/N-hydroxysuccinimide (EDC/NHS) agents. Then 100 ul of activated proteins were immobilized on the functionalized surface via the crosslinking agents in a self-assembled monolayer. Finally, 100 ul of 5% BSA (bovine serum albumin), healthy human serum and 3% skim milk were used by blocking plates and prevent unspecific binding. For the analysis of sensitivity and specificity, 2 groups (positive and negative) of a total of 131 samples were used. The positive group consisted of samples from 46 patients, who were previously identified as HDV-RNA positive and HBsAg positive. The negative group consisted of samples from 85 people, who were previously identified as healthy by showing HBsAg negative and anti-HCV negative. The optimal conditions for the new ELISA tests were established using checkerboard dilutions of the secondary antibody and serum. Main parameters of the optimal ELISA assay were found as follows: Serum dilution scale 1:100, Secondary Ab dilution scale 1:80000, incubation time 15 min at 370C, color development time 3 min, and total test duration 30 min. For comparison analysis of sensitivity, the commercially available Wantai anti-HDV IgG kit was used.

Results: Our results showed that our in-house developed ELISA assay has a specificity of 98.8%, a sensitivity of 100%, and an agreement of

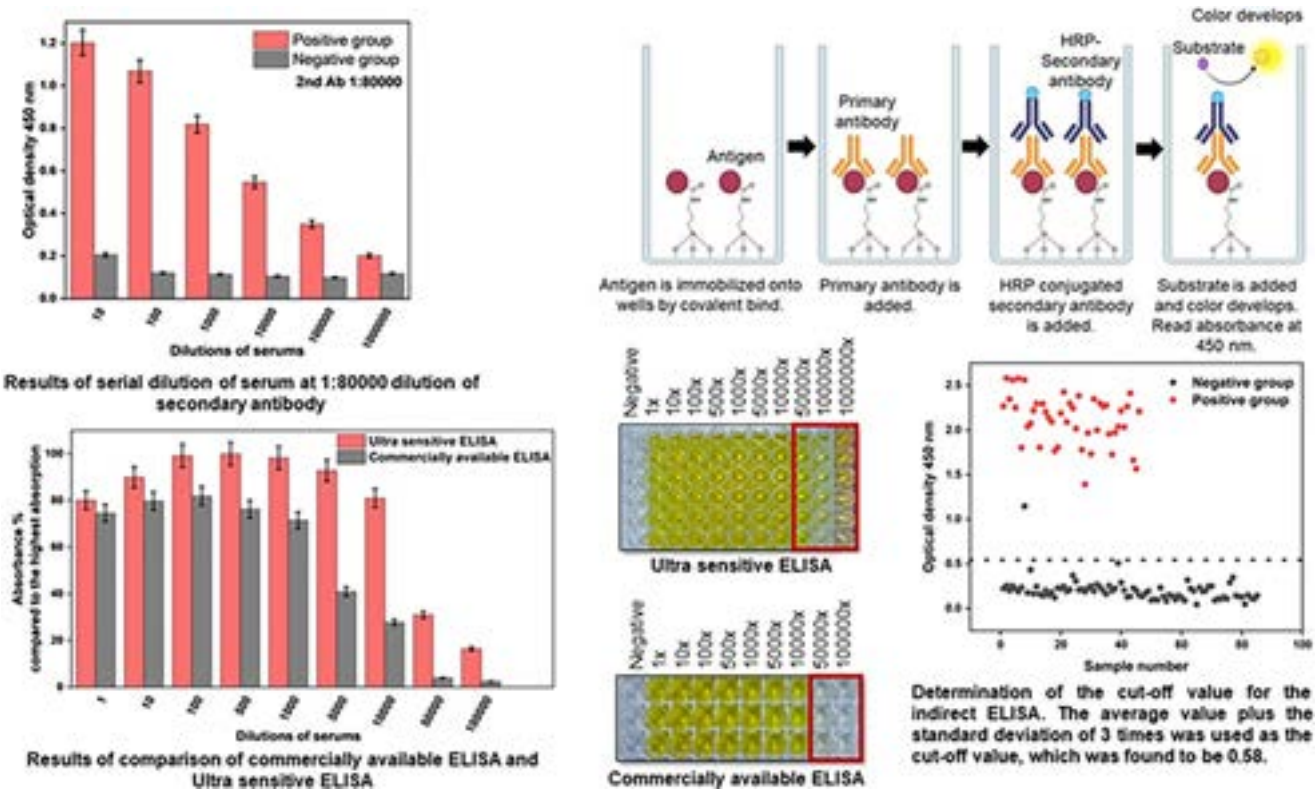

Figure: (abstract: SAT-497).

99.2% respectively. Ultra-sensitivity of the assay was confirmed by the detection of 1:1000000 times diluted serum while the commercially available kit was only able to detect up to 1:50 000 times diluted serum. The total testing process could be done in 30 min, which is 3 times shorter than the commercial testing kit. All these superior results indicate that the self-assembled monolayer method has principally advantageous in terms of design and method.
Conclusion: The ELISA assay developed by self-assembled monolayer method has very high sensitivity and this technology should be introduced to the HDV-diagnostic field.

SAT-498

Biomarkers of hepatocyte basement membrane turnover reflect disease activity in patients with early-stage non-alcoholic fatty liver disease

Ida Lønsmann[1,2], Jane I. Grove[3,4,5], Asma Haider[6], Philip Kaye[6], Morten Karsdal[2], Diana Leeming[2], Guruprasad Aithal[3,4,5]. *[1]University of Southern Denmark, Department of Clinical Research, Odense, Denmark; [2]Nordic Bioscience, Hepatic Research, Herlev, Denmark; [3]University of Nottingham, MRC/EPSRC Nottingham Molecular Pathology Node, Nottingham, United Kingdom; [4]Nottingham University Hospitals NHS trust and University of Nottingham, NIHR Nottingham Biomedical Research Centre, Nottingham, United Kingdom; [5]University of Nottingham, Nottingham Digestive Diseases Centre, Translational Medical Sciences, School of Medicine, Nottingham, United Kingdom; [6]Nottingham University Hospitals NHS Trust, Department of Pathology, Nottingham, United Kingdom*
Email: Ilc@nordicbio.com

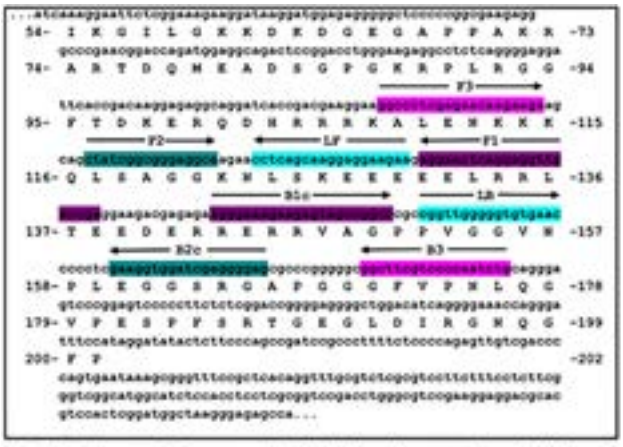
Background and aims: Halting progressive liver disease necessitate novel non-invasive methods to identify and monitor patients in need of early intervention. Investigating the pathophysiology of early liver injury might help to identify unique biomarkers. Early liver injury is characterized by recomposition of the hepatocyte basement membrane (BM) of the extracellular matrix. Thus, we quantified biomarkers targeting two distinct neo-epitopes of the major BM collagen, type IV collagen (PRO-C4 and C4M), in patients spanning the non-alcoholic fatty liver disease (NAFLD) spectrum.
Method: We evaluated BM biomarkers in a cross-sectional study with 97 patients with NAFLD confirmed on histology. Serological levels of PRO-C4 and C4M were quantified using validated competitive enzyme-linked immunosorbent assays (ELISAs). Using the fatty liver inhibition of progression (FLIP) algorithm, we stratified data into two groups: non-alcoholic fatty liver (NAFL) and non-alcoholic steatohepatitis (NASH). Biomarker levels in the two groups were stratified by the NAFLD activity score (NAS). In both groups, biomarker measurements were analyzed in relation to histological scorings of steatosis, inflammation, ballooning, and fibrosis.
Results: The included patients had a body mass index (BMI) of 30.9 ± 5.6 kg/m^2, age of 53 ± 13 years and a NAS range of 1–8. Upon stratification by FLIP, the NASH patients had higher platelets, ALT, and AST levels than the NAFL group. Both PRO-C4 ($p = 0.0125$) and C4M ($p = 0.003$) increased with increasing NAS solely within the NAFL group. Furthermore, both markers were significantly associated with lobular inflammation ($p = 0.020$ and $p = 0.048$) and steatosis ($p = 0.004$ and $p = 0.015$) in patients with NAFL.
Conclusion: This study found that BM turnover is associated with liver injury in patients with NAFL but not those with NASH. These findings support BM turnover as a clinical feature in early disease development.

SAT-499

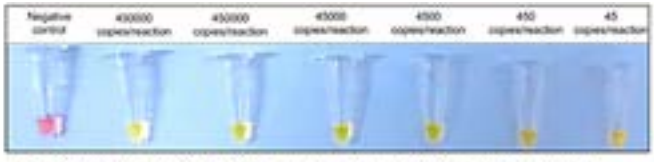
Development of loop-mediated isothermal amplification assay for detection of hepatitis delta virus

Saruul Enkhjargal[1], Nomin Ariungerel[1], Naranjargal Dashdorj[2], Naranbaatar Dashdorj[3], Odgerel Oidovsambuu[4]. [1]*National university of Mongolia, Department of Chemical and Biological Engineering, School of Engineering and Applied Sciences, Ulaanbaatar, Mongolia;* [2]*Liver center, Ulaanbaatar, Mongolia;* [3]*Onom foundation, Ulaanbaatar, Mongolia;* [4]*National University of Mongolia, Department of Chemical and Biological Engineering, Ulaanbaatar, Mongolia*
Email: srl@onomfoundation.org

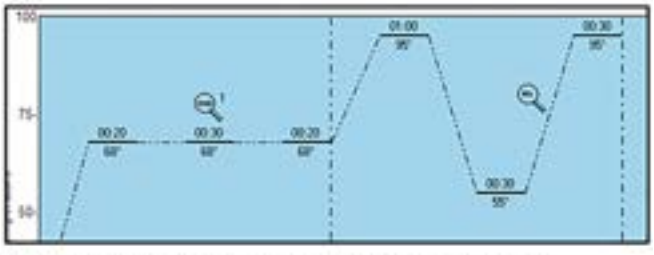
Background and aims: Infection of hepatitis delta virus (HDV) is one of the leading factors for liver disease-related mortality in some countries. For these countries, it is crucial to implement a suitable strategy to eliminate the endemicity of HDV using of sophisticated technologies. Correct diagnostic approaches and management, which enable early detection of HDV infection play a key role in effective elimination. However, HDV-infected people know their infection at a very late time when cirrhosis already developed to a serious stage. Therefore, some countries including Mongolia have initiated a mass screening campaign for the detection of hepatitis viral infection in the entire population, and currently, some apparent improvements were observed in the national viral hepatitis status. Loop-mediated isothermal amplification (LAMP) could be one of the possible options for the detection of active HDV infection in Mongolia, especially since this method might be very useful outside of big cities. LAMP-PCR does not require special equipment like an expensive real-time PCR cycler, and its simple, fast-processing characteristic is very attractive. The aim of this study was to develop and characterize a LAMP-PCR assay for the detection of HDV-RNA (HDV-LAMP assay).
Method: Different primer sets were designed using NEB-online tools on a high homology region of HDV genomic sequence. In this study, commercially available WarmStart Colorimetric and Fluorescent LAMP 2X Master Mix (DNA and RNA) kits from NEB were used. For RNA extraction, Viral RNA isolation kit from Bioactiva Diagnostica was used. Serum samples from 13 HDV-infected patients and 15 healthy people (a total of 28 people) were used for this study. Serially diluted recombinant construct containing HDV genomic sequence were used for the analysis of the limit of detection (LOD). Both colorimetric and fluorescent assays were done for all 23 samples in different protocols to adjust the optimal condition. The amplified products were confirmed by gel electrophoresis and dissociation curve analysis. The overall HDV-LAMP assay was characterized by its sensitivity, specificity, optimal reaction temperature, and time-point of detection.
Results: We tested 5 different primer sets and the best primer set was identified by judging the rate of false positive results. The optimal reaction temperature for the best setting was found as 68°C. Our result indicated that LOD of HDV-LAMP assay is 4.5 copies/reaction, which can be considered a very sensitive assay. The optimal time-point of detection was 50–60 min for colorimetric and 40–50 min for fluorescent assays. Exceeded incubation time increases the probability of false positive results. Our pilot results showed that HDV-LAMP assay has a sensitivity of 100% and a specificity of 94.4%.
Conclusion: Our study concludes that the currently developed HDV-LAMP assay is a rapid, easy-to-use, and highly sensitive diagnostic assay for detecting HDV-RNA in blood samples. The assay can be



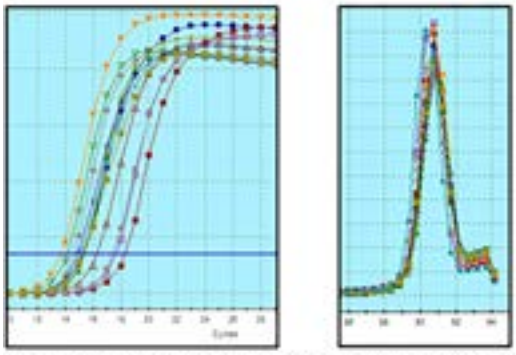
A. Best primer set shown on the high homology region of HDV genomic sequence



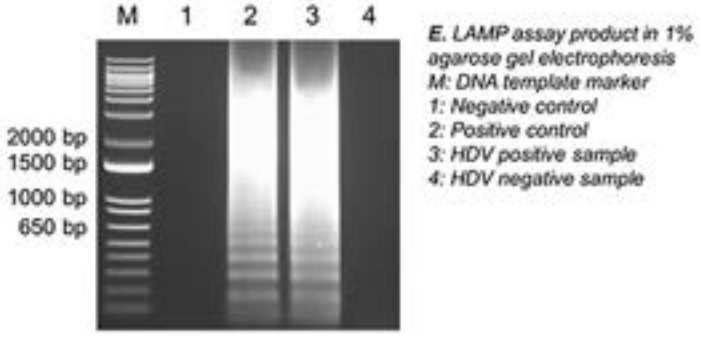
B. Colorimetric HDV-LAMP assay results of HDV standard serial dilution; pink indicates no infection, yellow indicates HDV infection



C. Suitable thermal settings of fluorescent HDV-LAMP assay



D. The amplification curve and dissociation curve of the fluorescent HDV-LAMP assay



E. LAMP assay product in 1% agarose gel electrophoresis
M: DNA template marker
1: Negative control
2: Positive control
3: HDV positive sample
4: HDV negative sample

Figure: (abstract: SAT-499).

broadly utilized in places without real-time PCR equipment and the testing cost will be cheaper. In further, analytical sensitivity and specificity should be determined using a bigger number of patient samples.

SAT-500

Incorporating artificial intelligence in portable infrared thermal imaging for the diagnosis and staging of non-alcoholic fatty liver disease

Yana Davidov[1], Rafael Brzezinski[2], Monika Kaufmann[3], Mariya Likhter[1], Oranit Cohen-ezra[1], Yair Zimmer[4], Orit Pappo[3], Jonathan Leor[5,6], Ziv Ben-Ari[1,2], Oshrit Hoffer[4]. *[1]Sheba Medical Center, Liver Diseases Center, Israel; [2]Tel Aviv University, Sackler School of Medicine, Israel; [3]Sheba Medical Center, Institute of Pathology, Israel; [4]School of Electrical Engineering, Afeka Tel Aviv Academic College of Engineering, Tel Aviv, Israel, Israel; [5]Sheba Medical Center, Tamman Cardiovascular Research Institute, Leviev Heart Center, Israel; [6]Tel Aviv University, Neufeld Cardiac Research Institute, Israel*
Email: y.davidov@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent chronic liver disease worldwide. NAFLD comprises a spectrum of progressive liver pathologies, ranging from simple steatosis to non-alcoholic steatohepatitis (NASH). NASH can progress to advanced liver fibrosis stage, liver failure and liver cancer. Liver biopsy is currently the gold standard for staging NAFLD. In our NAFLD mouse model, thermal imaging combined with advanced image processing and machine learning analysis, the derived algorithm demonstrated a 100% detection rate and classified all mice correctly according to their disease status.
Method: This is a prospective study of 46 patients; all underwent a liver biopsy. Liver thermal imaging using a commercially available portable infrared camera was obtained on the same day the liver biopsy was scheduled. We developed an image processing algorithm that measures relative spatial thermal variation across the skin covering the liver. Thermal parameters including temperature variance, homogeneity levels and other textural features were fed as input to a t-SNE dimensionality reduction algorithm followed by k-means clustering. Patients were diagnosed with NAFLD and stratified according to the NAFLD activity score (NAS) and the fibrosis stage using the Metavir score).
Results: Twenty-one out of 46 patients (median age 54 years (ranges, 19–75); 61% males) were diagnosed with NAFLD, of them NAS >4 was detected in 7 (33%). Using thermal imaging processing, the accuracy to detect patients with NAS >4 was AUC = 0.74, (specificity and sensitivity 56% and 81%). For differentiating advanced fibrosis (F3–4) from early fibrosis stage F0-F2, thermal imaging accuracy was AUC 0.87, with specificity and sensitivity 77% and 88%, respectively.
Conclusion: Non-invasive thermal advanced imaging combined with machine learning-based analysis may improve our ability to diagnose and classify patients with NAFLD.

SAT-501

Metabolic profile reflects stages of fibrosis in patients with non-alcoholic fatty liver disease

Roberta Forlano[1], Nila Jambulingam[1], Benjamin Preston[1], Benjamin H. Mullish[1], Greta Portone[1], Yama Baheer[1], Michael Yee[2], Robert D. Goldin[3], Mark Thursz[1], Pinelopi Manousou[1]. *[1]Imperial college london, Liver unit/Division of Digestive Diseases, Department of Metabolism, Digestion and Reproduction, United Kingdom; [2]Imperial college NHS Trust, Section of Endocrinology and Metabolic Medicine, United Kingdom; [3]Imperial college london, Department of Cellular Pathology, United Kingdom*
Email: r.forlano@imperial.ac.uk

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a leading cause of chronic liver disease worldwide, with fibrosis stage being the main predictor for clinical outcomes. Here, we present the metabolic profile of NAFLD patients with regards to fibrosis progression.
Method: We included all consecutive new referrals for NAFLD services between 2011 and 2019. Demographic, anthropometric, clinical features and non-invasive markers of fibrosis were recorded at baseline and at follow-up. Significant and advanced fibrosis were defined using Liver Stiffness Measurement (LSM) as LSM ≥8.1 kPa and LSM ≥12.1 kPa respectively. Cirrhosis was diagnosed either histologically or clinically. Fast progressors of fibrosis were defined as those with delta stiffness ≥1.03 kPa/year (25% upper quartile of delta stiffness distribution). Targeted and untargeted metabolic profiles were analysed on fasting serum samples using Proton nuclear magnetic resonance (1H NMR).

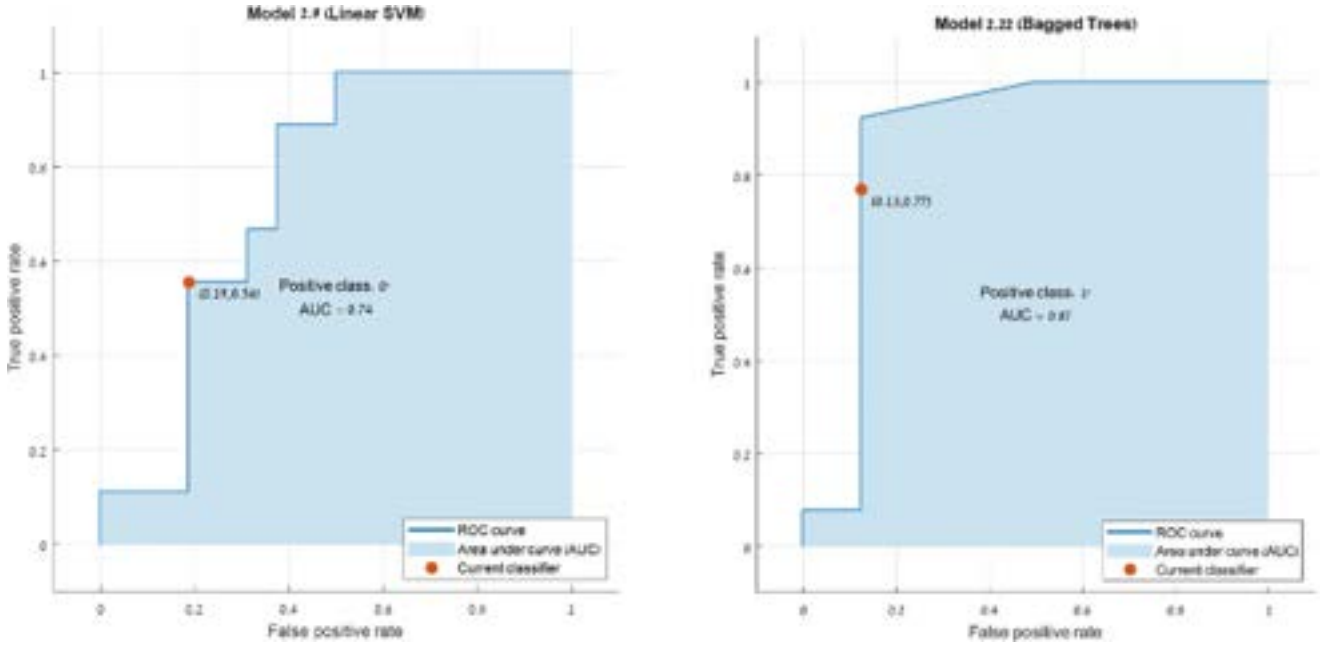


Figure: (abstract: SAT-500).

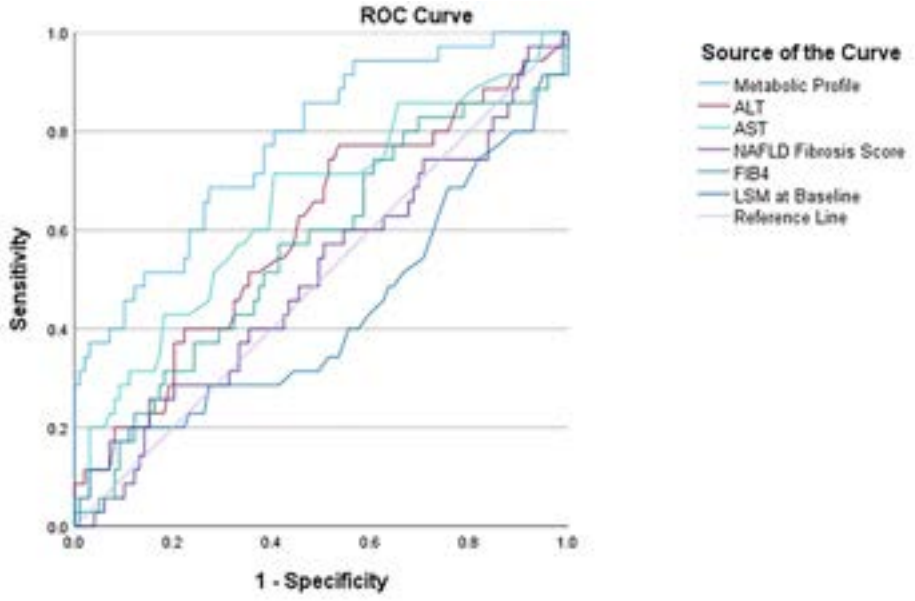

Metabolic profile formula: $30.485 * H2TG\ (mg/dl) + 0.706 * H4A1\ (mg/dl) + 1.586 * H4PL\ (mg/dl) + 1.989 * H4A2\ (m\,g/d\,l) + 0.063 * V4FC\ (m\,g/d\,l) + 0.719 * IDTG\ (m\,g/d\,l) + 12.94 * VLFC\ (m\,g/d\,l) + 0.103 * V3CH\ (m\,g/d\,l) + 42.376 * Proline\ (mmo\,l/l) + 3.18 * IDAB\ (m\,g/d\,l) + 0.284 * VLAB\ (m\,g/d\,l) + 44.243 * V3PL\ (m\,g/d\,l) + 0.532 * VLPL\ (m\,g/d\,l) + 0.319 * H2A2\ (m\,g/d\,l) + 0.339$

Figure 1: Diagnostic performance of metabolic profile for predicting fibrosis progression compared to ALT, AST, NAFLD fibrosis score, FIB-4 and LSM.
Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; LSM: liver stiffness measurement

Figure: (abstract: SAT-501).

Results: 189 patients were included in the study, 111 (58.7%) underwent liver biopsy. Overall, 11.1% patients were diagnosed with cirrhosis, while 23.8% were classified as fast progressors. A combination of metabolites and lipoproteins (formula in Figure 1) could identify the fast fibrosis progressors (AUROC 0.788, 95% CI: 0.703–0.874, p < 0.001) and performed better than non-invasive markers: ALT (AUROC 0.59, 95%CI: 0.48–0.71, p = 0.08), AST (AUROC 0.65, 95% CI: 0.52–0.76, p = 0.006), FIB-4 (AUROC 0.5, 95%CI: 0.39–0.61, p = 0.9), NAFLD fibrosis score (AUROC 0.56, 95%CI: 0.44–0.67, p = 0.26) and LSM at baseline (AUROC 0.43, 95% CI: 0.31–0.55, p = 0.2) (Figure 1).
Conclusion: Specific metabolic profile predicts fibrosis progression in patients with non-alcoholic fatty liver disease. Algorithms combining metabolites and lipids could be integrated in the risk-stratification of these patients.

SAT-502

Diagnostic performance of magnetic resonance imaging, vibration-controlled transient elastography and controlled attenuation parameter in predicting steatohepatitis in NAFLD patients

Sun Young Yim[1], Hyung Sun Yim[1], Jong Su Kim[1], Yeon Seok Seo[1].
[1]*Korea University Hospital, Korea, Rep. of South*
Email: drseo@korea.ac.kr

Background and aims: Non-alcoholic fatty liver disease (NAFLD) ranges from benign non-alcoholic fatty liver to non-alcoholic steatohepatitis (NASH) where NASH includes progressive fibrosis. Liver biopsy is the gold standard method for the diagnosis of NASH and although there are no reliable non-invasive means of differentiating NAFLD from NASH, non-invasive models that correlate with individual histologic parameters have been developed. The aim of the current study was to examine the diagnostic accuracy of magnetic resonance imaging (MRI) and transient elastography (TE) in classifying fibrosis while MRI-derived proton density fat fraction (PDFF) and controlled attenuation parameter (CAP) in classifying degree of steatosis.
Method: We retrospectively reviewed database of 213 patients who had undergone liver MRI and TE from November 2018 to February 2022 and cross-sectional analysis was performed in 113 patients who had underwent both imaging study and liver biopsy. A systematic NAFLD activity score (NAS) was scored using NASH Clinical Research Network. The Area Under the Receiver Operating Characteristics (AUROCs), sensitivity, and specificity of MRI and TE were analyzed according to degree of steatosis and fibrosis. Further analysis was performed to observe if combination of imaging analysis could detect presence of NASH using linear regression analysis.
Results: Out of 113 patients, 78 patients (69%) were male and mean body mass index was 29.3 ± 4.8 kg/m^2. The proportion of patients with probable NASH (NAS 3, 4) and definite NASH (NAS ≥5) were 40.7% and 23%, respectively. The correlation between MRI-PDFF and CAP was moderate (r = 0.57, P < 0.001). The AUROCs of MRI-PDFF and CAP were 0.905 (CI 0.856–0.964, P < 0.001) and 0.739 (CI 0.644–0.835, P < 0.001), respectively in detecting advanced steatosis (score≥3, steatosis>33%). MRI-PDFF provided significantly more reliable fat content measurement than did CAP for every degree of steatosis. The AUROC values for MRI-PDFF and TE were 0.936 vs 0.563 for steatosis grade ≥1 and 0.922 vs 0.92 for steatosis grade ≥2 (p = 0.005 and P < 0.001, respectively). In predicting degree of liver fibrosis, the correlation between MRE and TE was also moderate (r

= 0.631, P < 0.001). The predictive efficacy between MRE and TE did not differ in predicting any degree of liver fibrosis. Since there is no imaging modality that can exactly predict degree of NASH, next we analyzed whether the diagnostic ability of combined modalities improved. The predictive efficacy significantly increased when MRI-PDFF was added to MRE alone (AUROC; 0.869 vs 0.619, P < 0.001) in identifying both definite NASH (NAS ≥5) and probable NASH (NAS 3–4) (AUROC; 0.823 vs 0.602, P < 0.001) but not for the combination of TE and CAP. In multivariate analysis, there was significant correlation between MRE and degree of hepatocyte ballooning in addition to degree of fibrosis (both, P < 0.001).

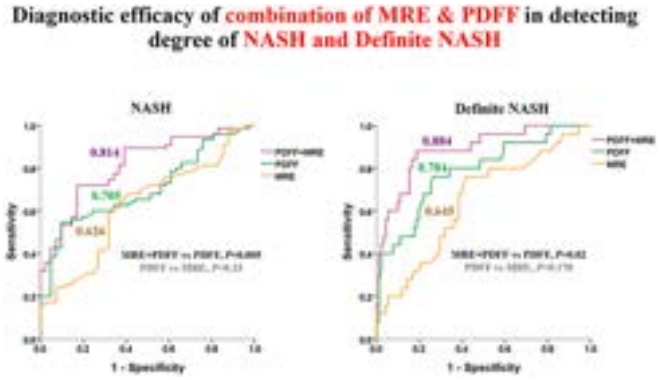

Figure:

Conclusion: MRI-PDFF have higher diagnostic performance in non-invasive detection of liver steatosis than TE but no significant difference was observed in identifying degree of liver fibrosis. Combination of MRE and MRI-PDFF enabled detection of NASH in NAFLD patients with high diagnostic efficacy. Our result presents the possibility of non-invasive method in predicting NASH and could possibly reduce the need for liver biopsy following further validation in a larger cohort.

SAT-503

SAFE score yielded a better performance than FIB-4 and NFS in predicting significant fibrosis among Asian NAFLD patients

Pimsiri Sripongpun[1,2], Sombat Treeprasertsuk[3], Phunchai Charatcharoenwitthaya[4], Apichat Kaewdech[1], Naichaya Chamroonkul[1], Wah-Kheong Chan[5], Cheng Han Ng[6], Mark Muthiah[6], Yock-Young Dan[6], W. Ray Kim[2]. *[1]Prince of Songkla University, Internal Medicine, Thailand; [2]Stanford University School of Medicine, Gastroenterology and Hepatology, United States; [3]Chulalongkorn University, Thailand; [4]Siriraj Hospital Mahidol University, Thailand; [5]University of Malaya, Malaysia; [6]National University of Singapore, Singapore*
Email: pim072@hotmail.com

Background and aims: In patients with non-alcoholic fatty liver disease (NAFLD), having fibrosis stage 2 or higher (significant fibrosis; SF) is independently associated with an increased overall mortality. Recently, the Steatosis-Associated Fibrosis Estimator (SAFE) score has been developed as a non-invasive tool to screen for SF among NAFLD patients in primary care (Hepatology 2022, DOI: 10.1002/hep.32545). We aimed to externally validate and compare SAFE with FIB-4 and NFS in Asian population with NAFLD.

Method: Biopsy-proven NAFLD patients' data from 6 centres in 3 Southeast Asian countries (Thailand, Malaysia, and Singapore) were collected (N = 889). Using liver biopsy as the gold standard, liver fibrosis stage was graded using NASH CRN criteria. Patients with incomplete data on variables used to calculate SAFE, FIB-4, and NFS were excluded. The performance of SAFE, FIB-4, and NFS were evaluated using areas under the receiver operating characteristics curve (AUROC), sensitivities (Sn) and specificities (Sp) in diagnosing F≥2.

Results: A total of 640 patients were included in the analysis, SF was presented in 176 patients (27.5%). As expected, the median age, aspartate and alanine aminotransferase, alkaline phosphatase, serum globulin levels were higher in patients with SF than in those without SF, whereas the serum albumin and platelet levels were lower. Among 3 non-invasive biomarkers, SAFE, FIB-4, and NFS yielded AUROCs (95%CI) of 0.744 (0.700–0.788), 0.731 (0.687–0.775), 0.658 (0.612–0.704), respectively (p = 0.31 for SAFE vs FIB-4, and p < 0.001 for SAFE vs NFS). At the given low cutoffs for detecting SF (SAFE<0, FIB-4 < 0.81, NFS<-2.45), SAFE showed the highest Sn of 89.77%, significantly better than FIB-4 (Sn 80.11%, p < 0.001) and NFS (Sn 80.11%, p = 0.001). At the high cutoffs (SAFE≥100, FIB-4≥1.81, NFS≥0.03), the Sp of SAFE, FIB-4, and NFS for detecting SF were 71.77%, 89.22%, and 89.44%, respectively. The proportion of patients categorized by low and high cutoffs of each score are shown in the Figure.

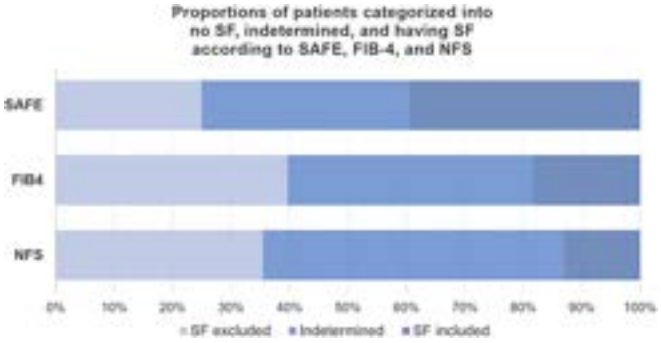

Figure:

Conclusion: SAFE showed the highest AUROC compared to FIB-4 and NFS in the diagnosis of SF in NAFLD patients. SAFE also had a better sensitivity in detecting SF than FIB-4 and NFS. Based on these data, we should emphasize the utility of SAFE score as a non-invasive screening tool for identifying NAFLD patients at a low risk for SF in primary care setting.

SAT-504

A descriptive analysis of transient elastography results and metabolic co-morbidities in people living with HIV mono-infection in an urban clinic in the UK

Claire Mullender[1,2], Rhiannon Owen[1], Manik Kohli[1,2], Irfaan Maan[3], Laura Jane Waters[2], Sarah Pett[1,2,4], Alejandro Arenas-Pinto[1,4], Indrajit Ghosh[2], Stuart Flanagan[2], Richard Gilson[1,2]. *[1]Institute for Global Health, University College London, London, United Kingdom; [2]Central and North West London NHS Foundation Trust, Department of Sexual Health and HIV, United Kingdom; [3]Institute for Global Health, University College London, Faculty of Population Health Sciences, London, United Kingdom; [4]University College London, Medical Research Council Clinical Trials Unit, Institute of Clinical Trials and Methodology, United Kingdom*
Email: r.gilson@ucl.ac.uk

Background and aims: Liver-related morbidity remains high among people living with HIV (PLWH) despite advances in the management of viral hepatitides. Fatty liver disease (FLD) will likely become the leading cause of liver disease in PLWH, who are impacted disproportionately by comorbidities that contribute to the metabolic syndrome (MetS)-obesity, dyslipidaemia, hypertension and insulin resistance. The utility of transient elastography (TE) in PLWH with viral hepatitis co-infection is established, but its use in assessing FLD in PLWH is not well described. To better understand the burden of FLD in PLWH we reviewed results of TE with Controlled Attenuation Parameter (CAP) scores in PLWH with unexplained transaminitis.

Method: We undertook a retrospective review of all PLWH mono-infection with unexplained transaminitis (alanine transaminase (ALT) above 35 IU/l for men and 25 IU/L for women) who had a TE/CAP (by FibroScan®) at our central London clinic between 1/2017–3/

2022. FLD and fibrosis were defined as a CAP score >238 dB/m and a liver stiffness measurement of >7.1kPa respectively. Logistic regression analyses and χ^2 test for trends were performed to assess factors associated with FLD including demographics, HIV-specific variables (antiretroviral medications, CD4+ T-cell count, HIV viral load (VL)), alcohol use, and MetS comorbidities. The definition for MetS included use of diagnostic parameters collected as part of routine care for PLWH (HBA1c, lipids, blood pressure, Body Mass Index (BMI)); or medication history for treatment for any of the above.

Results: 408 PLWH were included: median age 51 years (IQR 45–57), 87% male, 68% of White ethnicity, 99% on ART, 93% undetectable HIV VL and median CD4+ T-cell count 610 cells/mm^3. 70% (263/379) had a BMI >25 Kg/m^2 and 45% had ≥2 metabolic comorbidities. Median ALT was 54 IU/L (IQR 37–75). A valid CAP score was available for 385/408 (94%). 65% (249/385) had FLD, of whom 80% (201/249) were moderate-to-severe (S2/S3, CAp >260 dB/m). Fibrosis was identified in 14% (57/408). There was no association between HIV-specific variables and FLD. Male gender, dyslipidaemia, type 2 diabetes mellitus and BMI were significantly associated with FLD (all $p < 0.05$). An increasing number of metabolic comorbidities was associated with increasing odds of FLD ($p < 0.001$) and fibrosis ($p < 0.001$) compared with individuals with no MetS comorbidities. In a multivariable model including age, gender and significant MetS comorbidities, BMI >25 Kg/m^2 (aOR 6.2 95% CI 3.6–10.6) and dyslipidaemia (aOR 2.4 95% CI 1.4–4.2) remained significantly associated with FLD.

Conclusion: We identified a high prevalence of FLD in our cohort of PLWH with well controlled HIV and low grade transaminitis using TE with CAP. TE/CAP should be more widely applied in screening guidelines to identify FLD in PWLH, especially those with markers of metabolic syndrome and identified as overweight or obese.

SAT-505

Liver stiffness measurements with a new point-of-care device, hepatoscope, using two-dimensional transient elastography showed both very good reproducibility and correlation to fibroscan

Victor de Lédinghen[1,2], Dan Dutartre[3], Françoise Manon[2], Joëlle Abiven[2], Anne-Laure de Araujo[2], Rhizlane Houmadi[2], Julie Dupuy[2], Juliette Foucher[2], Joel Gay[4], Claude Cohen-Bacrie[4]. [1]*INSERM U1312, BRIC, Bordeaux University, Bordeaux, France;* [2]*Bordeaux University Hospital, Hepatology unit, Pessac, France;* [3]*Inria Bordeaux Sud-Ouest, Bordeaux, France;* [4]*E-Scopics, Saint-Cannat, France*
Email: joel.gay@e-scopics.com

Background and aims: Liver stiffness measurement (LSM) by ultrasound-based transient elastography (TE) is recommended in risk stratification algorithms for patients with or at risk of non-alcoholic fatty liver disease (NAFLD). Fibroscan® (FS) is widely used today in hepatology practice and provides a 1D-measurement of shear wave speed. Large-scale screening of NAFLD-NASH could benefit from an available and affordable tool in primary care that would provide point-of-care reproducible and reliable LSM. Our goal was to assess the reproducibility of LSM on a new ultrasound point-of-care device, Hepatoscope™, with TE using 2D-measurements of shear wave speed (2DTE) under ultrasound guidance, and to compare 2DTE LSM with FS and blood tests.

Method: 96 adult patients referred to routine outpatient hepatology consultation for CLD, including LSM with FS, were enrolled in this prospective single centre study (NCT04782050). Four Hepatoscope liver exams were performed by 1 expert and 1 novice operator, to assess the intra-operator and inter-operator reproducibility of LSM. Stiffness values were computed in real time within a region of interest positioned within the liver image. Each exam consisted of a prospective record of 15 consecutive stiffness values with their quality indicator (QI) above 85%. Operators were blinded to any median value for each series of 15 values. LSM was estimated using the median of an incremented number of several stiffness values selected using different QI thresholds. Data were analysed with R to determine the Hepatoscope LSM, reproducibility intraclass correlation coefficients (ICC), and the r² correlation of LSM by experts with other non-invasive tests.

Results: Intra-operator reproducibility of the median of 15 values (LSM_{Med15}) was very good (ICC = 0.85; 95%CI [0.77–0.89]), excellent for experts (ICC = 0.90; 95%CI [0.85–0.93]), and good for novices (ICC = 0.76; 95%CI [0.66–0.83]). Inter-operator reproducibility was very good (ICC = 0.83; 95%CI [0.78–0.88]). With stiffness values having a QI ≥90%, very good intra- and inter-operator reproducibility could be achieved from only 4 values (LSM_{Med4}) (ICC = 0.86; 95%CI [0.78–0.9] and ICC = 0.85; 95%CI [0.80–0.89], respectively). Intra-operator reproducibility for experts and novices was very good (ICC = 0.89; 95%CI [0.85–0.93] and ICC = 0.81; 95%CI [0.73–0.87], respectively). When considering Hepatoscope LSM exams with an IQR/Median <30% (similar to FS routine use), the correlation between LSM performed with Hepatoscope and FS devices was good: r² = 0.79 with LSM_{Med4}, r² = 0.79 with LSM_{Med15}. Correlation coefficients (r²) between LSM from Hepatoscope and FS to conventional liver fibrosis blood tests is presented in Table 1.

Table 1:

r^2 coef.	FIB-4	APRI	NAFLD Fibrosis Score
FS LSM	0.12	0.27	0.16
LSM_{Med4}	0.19	0.63	0.05
LSM_{Med15}	0.22	0.61	0.08

Conclusion: LSM can be performed with the new point-of-care device Hepatoscope and 2DTE modality by experts and novices. Using a QI of at least 90%, Hepatoscope LSM could be defined as the median of only 4 values, possibly leading to exam time savings. LSM measured with Hepatoscope showed good correlation with FS. These results are very encouraging regarding the use of Hepatoscope 2DTE and LSM at the point of care for large scale screening purposes. Future comparative studies against liver histopathology should allow the validation of existing LSM cutoff values for a specific screening and triage of patients at risk of fibrotic NASH.

SAT-506

Are non-invasive tests of fibrosis effective in patients with metabolic associated fatty liver disease? Comparative study between liver biopsy and non-invasive scores or fibroscan

Email: annalisa.cespiati@unimi.it

Background and aims: Metabolic dysfunction-associated fatty liver disease (MAFLD) is characterized by liver steatosis and at least one metabolic comorbidity. Due to limitations of liver biopsy, non-invasive tests of fibrosis (NITs) (FIB4 and NFS) and liver stiffness measurement (LSM) by Fibroscan are used to diagnose fibrosis. Aims 1) to evaluate the diagnostic accuracy of NITs and LSM in MAFLD 2) to evaluate their performance specifically in diabetic and obese subjects 3) to identify new thresholds for scores NITs and LSM in MAFLD.

Method: We enrolled 164 biopsy-proven MAFLD (mean age 56 ± 12 ys, 62% males) in Milan and Lisbon. Clinical, laboratory and Fibroscan data were collected within 6 months from biopsy. FIB-4 < 1.3, NFS<-

1.455 and LSM<8 kPa ruled out advanced fibrosis (≥F3), FIB-4 > 3.25, NFS>0.675 and LSM≥8 kPa suggested advanced fibrosis.
Results: Prevalence of fibrosis ≥F3 was 24% at histology. FIB4 and NFS ruled out advanced fibrosis in 49% and 44% of cases, diagnosed it in 7% and 8% and had indeterminate values in 43% and 49% of cases, respectively. LSM ≥8 kPa in 62% of subjects. All NITs showed a lower accuracy for both identification (AUROCs FIB-4 0.62; NFS 0.57; LSM 0.72) and exclusion (AUROCs FIB-4 0.65; NFS 0.68; LSM 0.72) of advanced fibrosis at biopsy compared to those for non-alcoholic fatty liver disease (NAFLD). The 59% of the cohort was obese, 47% diabetic. For ruling-in advanced fibrosis, FIB-4 and LSM performed worst in diabetic vs non-diabetic (AUROCs FIB-4 0.58 vs 0.69 p < 0.001; LSM 0.66 vs 0.71 p < 0.001) and in obese vs non-obese MAFLD (AUROCs FIB-4 0.59 vs 0.65 p < 0.001; LSM 0.68 vs 0.75 p < 0.001). NFS accuracy did not significantly differ between diabetic and non-diabetic (AUROCs 0.58 vs 0.50 p = 0.06), whereas it seemed to perform better in obese vs non-obese (AUROCs 0.58 vs 0.55 p = 0.01). For the exclusion of fibrosis, all NITs and LSM performed worst in diabetic vs non-diabetic (AUROCs FIB-4 0.59 vs 0.67 p = 0.001; NFS 0.58 vs 0.63 p = 0.003; LSM 0.68 vs 0.69 p = 0.06) and in obese vs non-obese (AUROCs FIB-4 0.66 vs 0.69 p = 0.002; NFS 0.65 vs 0.70 p = 0.003; LSM 0.68 vs 0.74 p < 0.001). The Youden indexes of current cut-offs for FIB4 and NFS were <0.5 for both ruling in and ruling out advanced fibrosis, whereas new thresholds as FIB-4 > 1.63/NFS>-1.09 and FIB-4 < 1.22/NFS<-1.23 had the best Youden indexes. As for Fibroscan, LSM>10.4 kPa seemed to better identify MAFLD patients with advanced fibrosis, whereas a cut-off of 8.4 kPa to exclude it.
Conclusion: In MAFLD, both FIB4 and NFS and Fibroscan performed worse compared to NAFLD, with the latter having the higher accuracy. The presence of diabetes and obesity impairs the performance of score and LSM. In MAFLD lower cut-off of both FIB-4 and NFS are warranted, whereas no change seems to be needed for LSM. Nevertheless, more accurate NITs should be developed specifically for MAFLD.

SAT-507

A biomarker of fibrosis resolution, CTX-III, increases after bariatric surgery in early NAFLD patients with histological liver improvements

Ida Lønsmann[1,2], Julie Steen Pedersen[3], Morten Karsdal[1], Judith Ertle[4], Corinna Schoelch[5], Diana Leeming[1], Flemming Bendtsen[3]. *[1]Nordic Bioscience, Hepatic Research, Herlev, Denmark; [2]University of Southern Denmark, Department of Clinical Research, Odense, Denmark; [3]Hvidovre Hospital, Gastrounit, Hvidovre, Denmark; [4]Boehringer Ingelheim International GmbH, Ingelheim am Rhein, Germany; [5]Boehringer Ingelheim Pharma GmbH and Co. KG, Biberach, Germany*
Email: Ilc@nordicbio.com

Background and aims: The formation of fibrotic bands is characterized by an increase in extracellular matrix components such as collagens. Over time, collagens become inter- and intramolecularly cross-linked. Thus, serological detection of cross-linked collagens resulting from collagen degradation may non-invasively detect fibrosis resolution. Here, we investigated a neo-epitope marker of cross-linked type III collagen resolution (CTX-III) mediated by matrix metalloproteinases. We aimed to investigate whether changes could be observed in CTX-III levels in patients with early-stage non-alcoholic fatty liver disease (NAFLD) with observed improvements in liver histology induced by weight loss after bariatric surgery.
Method: Blood samples and liver biopsies were collected from 70 patients on the day of bariatric surgery. Additional blood samples were taken at three, six, and twelve months past surgery and forty patients had an additional liver biopsy at twelve months follow-up. CTX-III was measured using a fully validated sandwich chemiluminescence immunoassay and levels were analyzed using a linear mixed-effect analysis on log-transformed data.
Results: 61% of the included 70 patients were females and mean age and mean BMI were 44 years and 42 kg/m^2, respectively. Patients had a median NAFLD activity score of 3 and mild-to-moderate fibrosis F0 (3%), F1 (86%), and F2 (11%). In general, CTX-III increased in patients after bariatric surgery (p < 0.0001). The most significant rise was observed from baseline to three-months follow-up (p < 0.001).

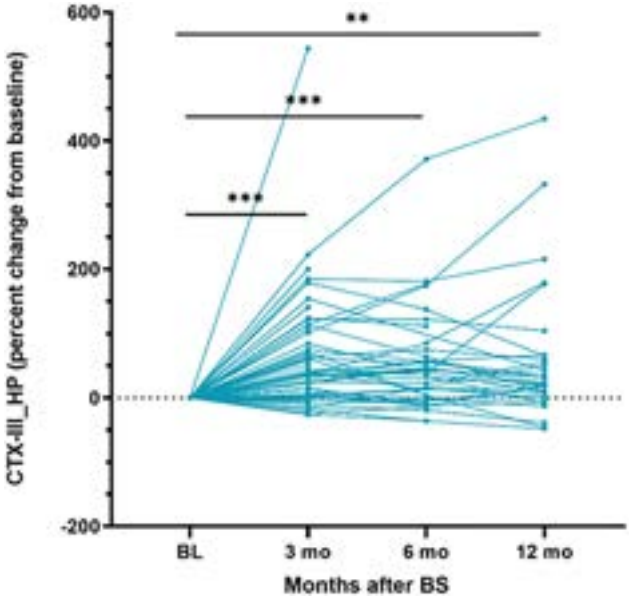

Figure:

Conclusion: This study indicates that CTX-III may be a biomarker of fibrosis resolution in patients with NAFLD undergoing bariatric surgery.

SAT-508

Free light chains: novel serum biomarkers for NASH stratification, an update

Antonio Liguori[1,2], Umberto Basile[1,3], Francesca D'Ambrosio[1,3], Cecilia Napodano[1,3], Lidia Tomasello[1,2], Fabrizio Mancuso[1,2], Giuseppe Marrone[2], Marco Biolato[1,2], Gianludovico Rapaccini[1], Antonio Gasbarrini[1,2], Antonio Grieco[1,2], Luca Miele[1,2]. *[1]Università Cattolica del Sacro Cuore, Italy; [2]Policlinico Universitario A. Gemelli, scienze mediche e chirurgiche, Italy; [3]Policlinico Universitario A. Gemelli, Scienze di laboratorio e infettivologiche, Italy*
Email: luca.miele@policlinicogemelli.it

Background and aims: NAFLD is the most common chronic liver disease with a worldwide prevalence of 25%. It encompasses a wide spectrum of diseases, including non-alcoholic steatohepatitis (NASH) characterized by hepatocyte ballooning, lobular inflammation and progressive fibrosis. For these reasons, one of the most important NASH features is the overexpression of pro-inflammatory biomarkers (IL1-beta, IL6, TNF-alfa). Polyclonal free light chains (FLCs) λ and κ reflect B cell activation and high serum levels of FLCs are observed in a variety of inflammatory conditions. The aim of this study is to evaluate the potential role of FLC as biomarker of inflammation and fibrosis in NAFLD/NASH patients.
Method: We enrolled 254 patients with metabolic liver disease at Liver Outpatient clinic at Policlinico A. Gemelli: 89 with NAFLD, 88 with NASH and 77 with compensated liver cirrhosis. Diagnosis of NASH was histologically assessed. Medical and pharmacological anamnesis, anthropometric measurements and laboratory tests (included FLCλ and κ) were obtained for all patients.
Results: Both serum κ and λFLCs were significantly higher in patients with cirrhosis than in patients with NAFLD or NASH (113.45 vs 31.76 mg/L p < 0.01). No significant difference in λ and κ FLCs levels were observed between NASH and NAFLD patients (respectively

31.423 vs 32.134 mg/L p = 0.2). Among patients who undergone biopsy, λFLCs tended to increase gradually with lobular inflammation severity (p = 0.03). Both k and λFLCs increased proportionally with fibrosis stages (p < 0.01). Finally, total FLCs were significantly higher in patients with a diagnosis of compensated cirrhosis compared with patients with advanced fibrosis (F3-F4) and no fibrosis (p < 0.01).
Conclusion: We assessed that FLCs serum levels are significantly higher in patients with advanced fibrosis and cirrhosis being strictly related to the severity of the inflammatory process. FLCs might be considered useful tools in monitoring the inflammatory status of patients with NAFLD.

Non-alcoholic fatty liver disease made easy for diabetologists: the automated fibrosis-4 index

Mona Ismail[1,2], Lameya Alsheekh[2], Murtaga Makki[2], Jaber Alelyani[2], Zahra Hassan[2], Zahra Alhadhiah[3], Hind Al-Faddagh[2], Nazih Alkhatam[3], Reem Alarqan[1,3], Yasir Elamin[1,3], Alanoud Alanazi[1,3]. *[1]Imam Abdulrahman Bin Faisal University, College of Medicine, Dammam, Saudi Arabia; [2]King Fahad Hospital of the University, Division of Gastroentrology, Department of Internal Medicine, Al Khobar, Saudi Arabia; [3]King Fahad University Hospital, Endocrinology Division, Internal Medicine, Al Khobar, Saudi Arabia*
Email: monai4@hotmail.com

Background and aim: Non-alcoholic fatty liver disease (NAFLD) commonly causes chronic liver disease (CLD), has a global prevalence of 24%, and can progress to cirrhosis and hepatocellular carcinoma. Patients with type 2 diabetes mellitus have a high prevalence of NAFLD (55%), and diabetes is a strong predictor for developing non-alcoholic steatohepatitis (NASH), the severe form of NAFLD, and progressing to bridging fibrosis and cirrhosis in these patients. Recently, the American Diabetes Association recommended screening patients with type 2 diabetes for NASH and advanced fibrosis. Thus, this study aims to evaluate the role of automated Fibrosis-4 (FIB-4) Index calculations in electronic medical records (EMR) in assisting diabetologists in identifying advanced fibrosis in diabetic patients.
Method: In this prospective study, patients with type 2 diabetes attending the diabetes clinic at a tertiary university hospital and unaware of having NAFLD were recruited. We incorporated automated FIB-4 calculations into the EMRs (QuadraMed®, TX, USA). Clinical and demographical data collected were age, sex, body mass index, complete blood count, liver and renal function, body mass index, insulin resistance, presence of comorbidities, dyslipidemia, ischemic heart disease, and medications used. We used logistic regression to identify predictors of advanced fibrosis. Patients with a high FIB-4 index of ≥1.3 and ≤65 years or ≥2.0 and ≥65 years were considered advanced fibrosis and referred to the Hepatology clinic. Patients with a FIB-4 index of <1.3 and <65 years or <2 and <65 years will continue to follow-up with their diabetologist and have a repeat Fib-4 calculation after 3–5 years.
Results: A total of 318 patients were included, and advanced fibrosis was seen in 9.7% of patients with type 2 diabetes. The mean age was 54.8 ± 13.3 years. The majority were females (54.7%), Saudi nationals (89.9%), obese (57.2%), and with HbA1C ≥7 (67.6%). On univariate analysis, advanced fibrosis by FIB-4 index was significantly associated with older age (OR = 1.07, 95% CI 1.02–1.11, p = 0.002), elevated bilirubin (OR = 3.19, 95% CI 1.62–6.30, p = 0.001), elevated GGT (OR = 2.48, 95% CI 1.60–3.84, p < 0.001), and elevated INR (OR = 9.43, 95% CI 1.76–50.39, p = 0.009).
Conclusion: Advanced fibrosis is a significant health issue in diabetic patients with NAFLD. Advanced fibrosis diagnosed by FIB-4 is associated with older age and a worse laboratory profile. Incorporating automated FIB-4 calculation into EMRs created an easy-to-follow clinical care pathway for diabetologists to quickly identify patients with advanced fibrosis as recommended by the American Diabetes Association and facilitate their early referral to specialists for further management.

SAT-510

Establishment and validation of a diagnostic model for liver inflammation in chronic hepatitis B (CHB) patients concurrent with non-alcoholic fatty liver disease (NAFLD) based on machine learning (ML)

Jie Li[1], Qi Xue[2], Fajuan Rui[1], Xiaorong Tian[3], Yayun Xu[4], Qi Zheng[5], Qing-Lei Zeng[6], Zebao He[7], Jian Wang[1], Weimao Ding[8], Chuanwu Zhu[9], Yuanwang Qiu[10], Yunliang Chen[3], Junqing Fan[3], Junping Shi[11], Chao Wu[1]. *[1]Department of Infectious Diseases, Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, China; [2]Department of Infectious Disease, Shandong Provincial Hospital Affiliated to Shandong Frist Medical University, China; [3]School of Computer Science, China University of Geosciences, China; [4]Shandong Provincial Hospital, Shandong University, China; [5]Hepatology Research Institute, the First Affiliated Hospital of Fujian Medical University, China; [6]The First Affiliated Hospital of Zhengzhou University, China; [7]Department of Infectious Diseases, Taizhou Hospital of Zhejiang Province affiliated to Wenzhou Medical University, China; [8]Department of Hepatology, Huai'an No. 4 People's Hospital, China; [9]Department of Infectious Diseases, The Affiliated Infectious Diseases Hospital of Soochow University, China; [10]Department of Infectious Diseases, The Fifth People's Hospital of Wuxi, China; [11]Department of Infectious Diseases, The Affiliated Hospital of Hangzhou Normal University, China*
Email: lijier@sina.com

Background and aims: Chronic hepatitis B (CHB) patients concurrent with non-alcoholic fatty liver disease (NAFLD) are common, but there are still lack of non-invasive models to evaluate liver inflammation. We aimed to build a diagnosis model for liver inflammation in those patients.
Method: This study consecutive enrolled CHB patients concurrent with NAFLD underwent liver biopsy and laboratory examination from eight medical centers of China between April 2004 and October 2020 as training cohort and patients from Tianjin Municipal Infectious Disease Hospital between January 2016 and September 2021 as independent external validation cohort. Inflammation grade 3–4 were predicted using ML models (logistic regression (LR), random forest (RF), decision tree classifier (DCT), gaussian naive bayes (GNB), and K nearest neighbor (KNN)). Features with Pearson correlation coefficients >0.2 were included in the diagnostic model. To avoid overfitting, 5-fold cross validations were used in the ML models building process.
Results: A total of 1340 CHB patients with NAFLD underwent liver biopsy included in the final analysis, with an average age of 38 (32–47) years (1032 males and 308 females). 216 cases (16.12%) were inflammation grade 3–4. Prothrombin time (PT), Aspartate transaminase (AST), alanine transaminase (ALT) were positively associated with inflammation grade 3–4, and albumin (ALB), platelet (PLT) were negatively associated with inflammation grade 3–4. LR model had the best performance, and its AUC for the diagnosis of inflammation grade 3–4 were 0.863 (0.810–0.916) in training cohort, and 0.890 (0.864–0.917) in validation cohort.
Conclusion: LR model performed the best overall performance in predicting inflammation. ML could be an effective tool for identifying clinically liver inflammation in CHB patients concurrent with NAFLD.

Economic modelling of clinical management options of unexplained hyperferritinaemia in the adult general population: a proposed new model of care

John Olynyk[1,2,3], Mukesh Nasa[1], Khurshid Alam[4]. [1]*Fiona Stanley Hospital, Murdoch, Australia;* [2]*Edith Cowan University Joondalup Campus, Joondalup, Australia;* [3]*Curtin University, Medicine, Bentley, Australia;* [4]*Murdoch University, Murdoch, Australia*
Email: john.olynyk@health.wa.gov.au

Background and aims: Unexplained hyperferritinaemia in the absence of iron overload or HFE haemochromatosis is common, especially in association with non-alcoholic fatty liver disease, and of no direct clinical significance. We modelled the discharge of unexplained hyperferritinaemia individuals from care either following diagnosis or after magnetic resonance FerriSmart (MR) measurement of hepatic iron concentration to exclude iron overload (Intervention MR model) compared to the standard of care, involving varying degrees of clinician review, ferritin testing and phlebotomy therapy which all become more likely as ferritin levels rise (comparator model). We hypothesise that the intervention model is more cost-efficient than the comparator model.
Method: A cost-minimization analysis was undertaken from the Australian health system perspective using Medicare and industry-provided costs. Costs of the intervention and comparator models were determined over a 5-year period for unexplained hyperferritinaemia individuals with elevated serum ferritin levels of 620–999 ug/L or ≥1000 ug/L.
Results: For the intervention model, the year 1 and 5-year average costs per individual for the 620–999 ug/L and ≥1000 ug/L groups were AU$464.83 and AU$92.97 and AU$784.70 and AU$156.94, respectively. For the comparator model, the year 1 and 5-year average costs per individual for the 620–999 ug/L and ≥1000 ug/L groups were AU$298.74 and AU$312.38 and AU$745.84 and AU$560.89, respectively. The intervention model was most cost-efficient after the first year.

Figure: Cost comparisons (per patient per year) of the group receiving MR intervention followed by discharge from care for no proven clinically significant iron overload compared with standard of care (SOC) in which there is continued management of UH individuals.

	Intervention MR Model		Comparator SOC Model	
Ferritin group (mg/L)	620–999	≥1000	620–999	≥1000
Cost ($/patient/year)				
Year 1	464.83	784.70	307.99	745.84
Year 2	0	0	367.30	598.60
Year 3	0	0	330.57	538.74
Year 4	0	0	297.51	484.87
Year 5	0	0	267.76	436.38
Average over 5 years	92.97	156.94	314.23	560.89

Modelling based on algorithms described in methods and assuming a 10% loss each year for follow-up in years 2–5 in the SOC group.

Conclusion: It is more cost-efficient to discharge unexplained hyperferritinaemia individuals, with or without MR measurement, compared with the standard of care.

SAT-512

A systematic review and meta-analysis of the prevalence and cross-sectional severity of South Asian patients with non-alcoholic fatty liver disease

Michael James[1], Naheeda Rahman[1], Melanie Smuk[1], Georgia Black[2], William Alazawi[1]. [1]*Blizard Institute, Centre for Immunobiology, United Kingdom;* [2]*Wolfson Institute of Population Health, United Kingdom*
Email: mikejames5289@gmail.com

Background and aims: Patients of South Asian (SA) ethnicity represent a distinct cohort in non-alcoholic fatty liver disease (NAFLD), with an aggressive phenotype, embodying a growing proportion of the patients referred to hepatology services. We performed a systematic review and meta-analysis to assess overall prevalence and cross-sectional severity of NAFLD in SA patients.
Method: PubMed, Embase, Ovid and Cochrane databases were searched from January 2002-November 2022. We included observational/cross-sectional studies and clinical trials, in English, involving adults (age >18 years) of SA ethnicity (defined as Indian, Pakistani, Bangladeshi, Sri Lankan). All contained data on prevalence of NAFLD in the general or diabetic population, diagnosed by ultrasound (US) or biopsy. Data on severity were collected, measured by AST:ALT ratio, fibrosis score F0-F4 on biopsy or steatosis grade S1-S3 on US. Abstracts were screened for relevance and then full-text review undertaken by two reviewers. Random effects meta-analyses were performed. Quality of included studies was assessed using The National Institutes of Health quality assessment tool.
Results: We identified 3175 articles from the literature search and included 43 eligible studies with a total of 24419 individuals, average mean age of 47 (95% confidence interval (CI) 43.9–50.1). 32 studies were based on Indian populations, 6 Sri Lankan, 3 Pakistani and 2 Bangladeshi. 33 studies had data on prevalence of NAFLD in general and in diabetic populations, with 22 using US as the sole method of diagnosis. AST:ALT ratio, FIB4 and vibration-controlled transient elastography were utilized in 4 studies. The pooled prevalence of NAFLD in the general population was 47% (CI 34–60%). In people with diabetes, this increased to 66% (CI 55–77%). 34 studies reported on severity, 17 with biopsy, with 12 having a breakdown of fibrosis scores. Of these, 216/1278 had clinically significant fibrosis (≥F3). The pooled proportion of patients who had ≥F3 on biopsy was 12.67% (CI 6.74–18.6) (figure). In terms of risk stratification, only 8/17 liver histology studies reported non-invasive assessment prior to biopsy (all US) and none reported on the use of a formal diagnostic assessment pathway. The proportion of patients biopsied with clinically significant fibrosis is higher than reports from multiethnic cohorts in Britain (7.7%, 1) and in the United States (4.28%, 2).

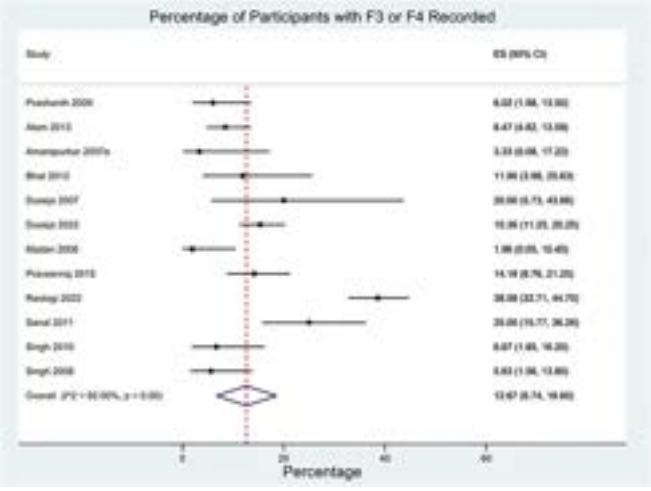

Figure:

Conclusion: The pooled prevalence of NAFLD in general and diabetic South Asian populations is higher than reported in previous systematic reviews. More work is needed to understand the epidemiology and natural history of NAFLD and the mechanisms that underlie the more aggressive disease phenotype in South Asian populations.

Serum glycochenodeoxycholic acid-3-sulfate can discriminate non-alcoholic steatohepatitis from steatosis

Barbora Nováková[1,2], Kateřina Žížalová[2], Vaclav Smid[1], Karel Dvorak[3,4], Aleš Kuběna[2], Libor Vitek[2,3], Martin Lenicek[5], Radan Bruha[3]. *[1]First Faculty of Medicine, Charles University and General University Hospital in Prague, 4th Department of Internal Medicine-Department of Hepatogastroenterology, Prague 2, Czech Republic; [2]First Faculty of Medicine, Charles University and General University Hospital in Prague, Institute of Medical Biochemistry and Laboratory Diagnostics, Prague 2, Czech Republic; [3]First Faculty of Medicine, Charles University and General University Hospital in Prague, 4th Department of Internal Medicine-Department of Hepatogastroenterology, Prague 2, Czech Republic; [4]Regional Hospital Liberec, Liberec, Czech Republic; [5]First Faculty of Medicine, Charles University and General University Hospital in Prague, Institute of Medical Biochemistry and Laboratory Diagnostics, Prague 2, Czech Republic*
Email: cizkova.barbora@gmail.com

Background and aims: Currently, liver biopsy is the only way to differentiate between non-alcoholic steatohepatitis (NASH) and steatosis (NAFL). Although the role of bile acids (BA) as a potential surrogate marker of NASH has already been investigated, the role of sulfated BA has not been tested yet. Therefore, our objective was to determine whether BA, including their 3-sulfates, can distinguish NASH from NAFL.

Method: We compared fasting serum concentrations of 22 individual BA and 23 BA 3-sulfates between the groups in an exploratory patient cohort (NASH n = 24, NAFL n = 18, healthy controls (CTRL) n = 15). The Kruskal-Wallis ANOVA with the appropriate post hoc test was used to compare BA concentrations between the groups. Two potential markers, glycochenodeoxycholic acid-3-sulfate (GCDCA-3S) and glycoursodeoxycholic acid-3-sulfate (GUDCA-3S) were further analysed in the biopsy-proven validation cohort (NASH n = 43, NAFL n = 21). Furthermore, we tested their ability to discriminate NASH using the ROC curve and a general linear model that contained potential confounders (liver fibrosis or cirrhosis, age, sex, BMI).

Results: Patients with NASH had significantly higher concentrations of GCDCA-3S compared to NAFL and CTRL (medians [μmol/L]: exploratory cohort NASH 0.306, NAFL 0.127, CTRL 0.105, p (NASH×NAFL) = 0.030, p (NASH×CTRL) = 0.008; validation cohort NASH 0.200, NAFL 0.049, p <0.0001). Furthermore, in the validation cohort, GCDCA-3S could distinguish NASH with 90% specificity and 60% sensitivity (AUROC = 0.785). The ability of GCDCA-3S to

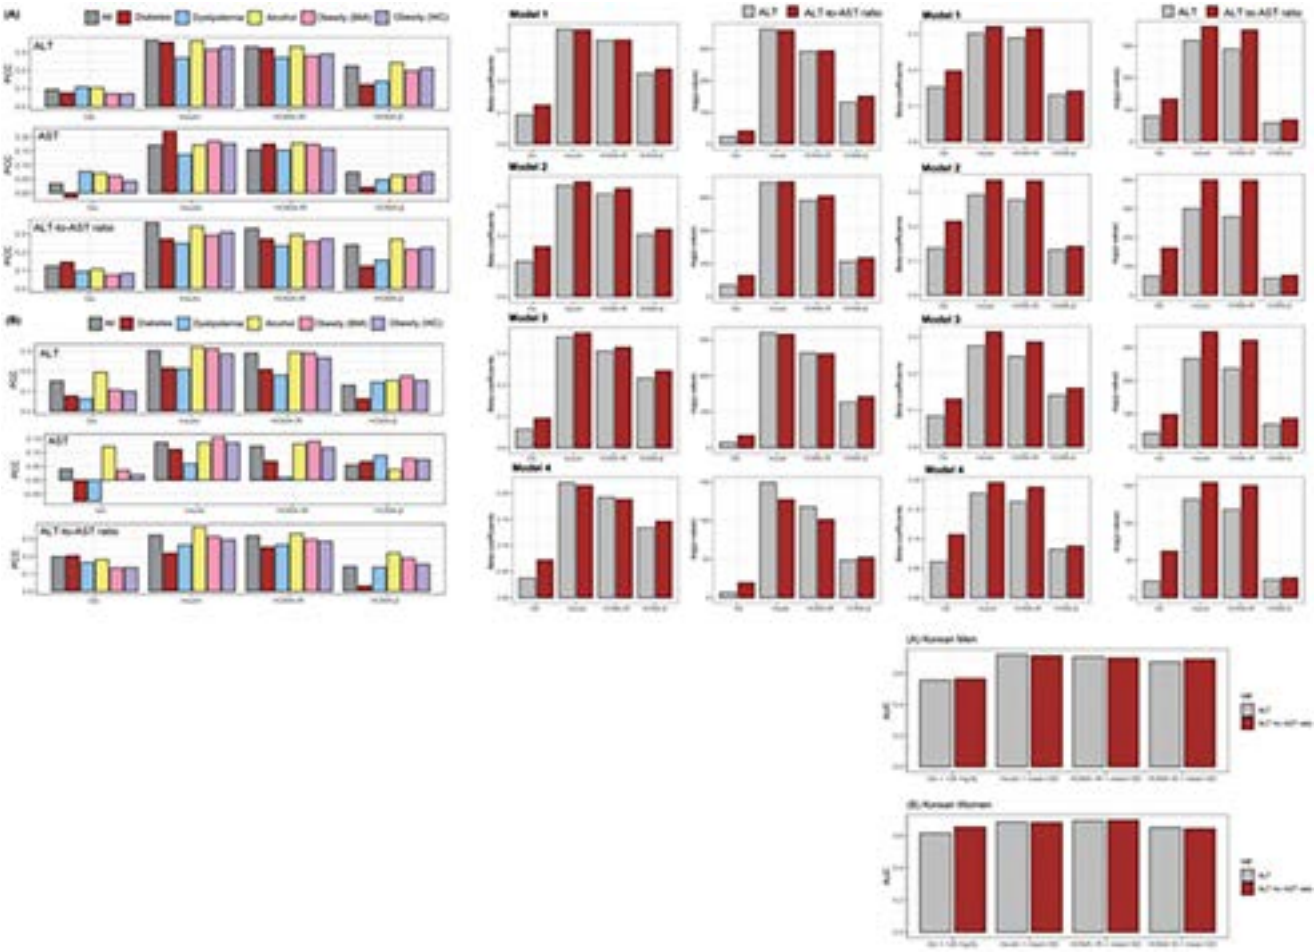

Figure: (abstract: SAT-514).

discriminate between NASH/NAFL remained significant in the linear model that contained the presence of moderate to severe fibrosis or cirrhosis (p = 0.006). Fibrosis/cirrhosis was the only significant confounder in the model (p = 0.028). Concentrations of another candidate, GUDCA-3S, were significantly elevated in NASH in the exploratory cohort; however, this was not confirmed in the validation cohort.

Conclusion: Serum GCDCA-3S concentration appears to distinguish NASH from NAFL.

SAT-514

ALT/AST ratio: the useful predictive marker for insulin resistance

Han Seul Ki[1,2], Moon Young Kim[1,2], Taesic Lee[3,4]. *[1]Yonsei University Wonju College of Medicine, Department of Internal Medicine, Division of Gastroenterology and Hepatology, Wonju-si, Korea, Rep. of South; [2]Wonju Severance Christian Hospital, Regenerative Medicine Research Center, Wonju-si, Korea, Rep. of South; [3]Yonsei University Wonju College of Medicine, Division of Data Mining and Computational Biology, Wonju-si, Korea, Rep. of South; [4]Yonsei University Wonju College of Medicine, Department of Family medicine, Wonju-si, Korea, Rep. of South*
Email: drkimmy@yonsei.ac.kr

Background and aims: Insulin resistance (IR) is common pathophysiology in type 2 diabetes mellitus, cardiovascular disease, and non-alcoholic fatty liver disease. As increased to the prevalence of these diseases, screening the risk for IR becomes important to prevent disease progression. To predict insulin resistance in the general population, regardless of comorbidity, we analyzed the health examination data using ALT/AST ratio for analysis.

Method: 2015, 2019, and 2020 Korea National Health and Nutrition Examination Survey (KNHANES) were analyzed to validate our hypothesis. For the evaluation of insulin resistance, the following four indices were implemented: fasting serum glucose (Glc) and insulin; Homeostatic Model Assessment for Insulin Resistance (HOMA- IR) and β cell function (HOMA- β). Pearson correlation coefficient (PCC) was implemented to evaluate the degree of association of liver profiles with indices for IR. Linear or logistic regression (LiR or LR) was implemented to identify the association of liver profiles with IR value or status, respectively. Classification performance was evaluated based on the area under curve of Receiver Operating Characteristic (AUC).

Results: Based on PCC, serum ALT in Korean men and women was positively related to four IR indices, including Glc, insulin, HOMA-IR (Homeostatic Model Assessment for Insulin Resistance), and HOMA-β. These positive relationships remained after selecting subjects diagnosed with diabetes or dyslipidemia, alcohol consumption, or subjects having general obesity or abdominal obesity. ALT/AST ratio was also robustly correlated with the four IR indices. In the multivariate LiR, when comparing ALT levels, ALT/AST ratio in Korean men exhibited better predictive performance for Glc and HOMA-β, besides, that in Korean women provided improved outcomes for all IR indices. Based on the prediction for the binary form of IR status, the ALT/AST ratio in Korean men and women could well predict HOMA-β and HOMA-IR, compared to the sole ALT level, respectively.

Conclusion: In the analysis that includes a large community-based population, ALT/AST ratio is a useful predictive marker compared with HOMA-IR. A simple, precise marker that is represented to ALT/AST could be a practical method to screen insulin resistance in the general population regardless of DM, alcohol intake, and gender.

SAT-515

Validation of Baveno VII criteria in NAFLD patients according to body mass index

María Del Barrio Azaceta[1], Carmen Lara Romero[2], Paula Iruzubieta[1], Andrea Cornejo[2], Maria del Carmen Rico[2], María Teresa Arias Loste[1], Javier Crespo[1], Manuel Romero Gomez[2,3]. *[1]Gastroenterology and Hepatology Department, Clinical and Translational Research in Digestive Diseases, Valdecilla Research Institute (IDIVAL), Marqués de Valdecilla University Hospital, Santander, Spain; [2]Digestive Diseases Unit, Hospital Universitario Virgen del Rocío, SeLiver Group, Institute of Biomedicine of Sevilla (HUVR/CSIC/US), Department of Medicine, University of Seville, Seville, Spain, Spain; [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Madrid, Spain*
Email: mromerogomez@us.es

Background and aims: In Baveno VII consensus, new criteria have been defined to try to identify the presence of clinically significant portal hypertension (CSPH). "The rule of 5 (R5)" establishes liver stiffness values in combination with the platelet count, to predict the presence of CSPH. However, in obese patients with Metabolic associated fatty liver disease (MAFLD) these criteria have not been validated.

Method: Bicentric cross-sectional study of 131 patients with MAFLD diagnosed by biopsy (n = 41;31.3%) or clinical criteria (n = 90; 68.7%) and who had a transient elastography (TE) with significant fibrosis (≥8kPa). CSPH was defined as the presence of esophageal varices or gastropathy, hepatic decompensation, collaterals, or ascites. The R5 Baveno VII inclusion criteria were used: A) ET≥25 kPa; B) 20 kPa>ET<25 kPa and <150,000 platelets; C) 15 kPa>ET<20 kPa and <110,000 platelets; exclusion criteria: ET<10 kPa or 10 kPa>ET<20kPa and >150,000 platelets.

Results: Ninety-one patients had obesity (BMI>30). In patients with MAFLD, the R5 had an overall sensitivity (Sen) of 68.08%, specificity (Spe) 51.19%, PPV 58.18% and NPV 90.38%. Sensitivity and PPV were lower in obese MAFLD patients (BMI>30 kg/m^2): (S: 63.3% E: 55.7%; PPV 51.4%; NPV: 90.38%), compared to those with BMI ≤30 (S: 76.5%; E: 56.52% and PPV: 72.2%; NPV: 86.7%); p < 0.05. The probability of classification in the grey area was 17/91 (18.7%) in obese patients compared to 7/40 (17.5%) in BMI<30 kg/m^2 (p = ns); presenting CSPH 10/24 (41.6%) and being absent in 14/24 (58.83%). Figure. In the univariate and multivariate (LR) analysis, the only independent predictor variable to predict the failure was age with Exp = 5.050–0.76 × Age (year).

Figure:

Conclusion: Predictive criteria proposed by Baveno VII for CSPH are less accurate in obese patients with MAFLD and should be corrected for age.

A real world experience utilising the FAST score to identify patients with NASH fibrosis

Gres Karim[1], Dewan Giri[1], Brooke Wyatt[2], Ilan Weisberg[3], Amreen Dinani[2,4]. [1]*Mount Sinai Beth Israel, United States;* [2]*Icahn School of Medicine at Mount Sinai, United States;* [3]*New York Presbyterian-Brooklyn Methodist Hospital, United States;* [4]*Duke Health, Gastroenterology and Hepatology, United States*
Email: gres.karim@mountsinai.org

Background and aims: The need to develop simple and non-invasive methods to diagnose non-alcoholic steatohepatitis (NASH) and fibrosis is one of the tasks the NAFLD community recognizes as important and necessary. Several non-invasive tests (NITs) have been studied and validated with moderate predictive capability to accurately rule out advanced fibrosis. The FibroScan-AST (FAST) score is a NIT that uses a combination of the liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) from vibration controlled transient elastography (VCTE), and aspartate aminotransferase (AST) to identify patients with 'fibrotic NASH', defined as NASH with significant liver fibrosis (stage 2 fibrosis or higher [>F2]). The aim of this study was to test the performance of the FAST score to accurately identify NASH + >F2 in a cohort of patients with a histological diagnosis of NASH, using a cutoff of >0.35 as a rule in factor. The cut off of 0.65 was not tested in this study as it has been proposed to identify those with >F3 fibrosis (advanced fibrosis). We compared the performance of the FAST score to LSM >8kPa and Fibrosis-4 Index (FIB-4) >1.3 (both cut-off for >F2) and attempted to identify risk factors to develop a model for improving diagnostic accuracy.
Method: Patients with a histological diagnosis of NASH were identified from 2020 to 2021. Demographic information, laboratory data, and VCTE data was collected. FAST score and FIB-4 were calculated. Univariate and backwards entry multivariate logistic regression analysis were performed to identify additional risk factors to diagnose NASH + >F2. Discrimination and overall accuracy (c-statistic) was assessed using area under receiver operating characteristic (AUROC) curves.
Results: Using a rule in cutoff of >0.35, the FAST score performed with a sensitivity, specificity, NPV, and PPV of 96.4%, 36.8%, 77.7%, 81.8%, respectively. Independent logistic regressions within this sample showed age (OR = 0.05, CI:1.0–1.07, p = 0.05) and a FAST >0.35 (OR = 15.75, CI:2.9–85.48, p = 0.001) to be associated with correctly identifying NASH + >F2 based on histological evidence. Although the FAST score >0.35 performed with the highest accuracy (81.3%), it performed with the lowest c-statistic (0.70, CI: 0.55–0.84) when compared to LSM >8kPa (0.72, CI:0.59–0.85) and FIB-4 >1.3 (0.73, CI:0.59–0.87). Our proposed FAST + Age model outperformed the others with a sensitivity of 94.6%, specificity of 42.1%, PPV of 82.7%, NPV of 96.4% and c-statistic of 0.78 (CI: 0.64–0.92).

NASH diagnostic Criteria/tests	Sensitivity	Specificity	PPV	NPV	Overall Accuracy	C statistic	C statistic Confidence Interval
FAST ≥0.35	96.4%	36.8%	81.8%	77.7%	81.3%	0.70	(0.55, 0.84)
FIB-4 ≥1.3	64.3%	68.4%	86%	40%	65.0%	0.73	(0.59, 0.87)
LSM ≥8kPa	75%	52.6%	82.4%	41.6%	69.0%	0.72	(0.59, 0.85)
FAST ≥0.35 + Age	94.6%	42.1%	82.7%	96.4%	81.3%	0.78	(0.64, 0.92)

Conclusion: A FAST score with a cutoff of >0.35 as a rule in factor performed reasonably well (AUROC: 0.70, and 0.78 when age was incorporated into the model) in detecting NASH + >F2 fibrosis in the real world. The FAST score + Age performed superiorly to LSM and FIB-4 in detecting individuals with NASH + >F2.

SAT-517

The sequential use of liver stiffness measurement and direct biomarkers of fibrosis is able to identify patients with severe non-alcoholic steatohepatitis

Filippo Gabrielli[1,2], Simonetta Lugari[3], Alessia Cavicchioli[3], Amedeo Lonardo[3], Cristina Felicani[3], Antonia Rudilosso[3], Chiara Pacchioni[4], Carla Greco[4], Chiara Valenti[4], Luigi Valerio[4], Mario Bondi[4], Daniele Santi[4], Giorgia Spaggiari[5], Stefano Ballestri[6], Tommaso Trenti[5], Valentina Pecoraro[5], Manuela Simoni[4], Pietro Andreone[2], Fabio Nascimbeni[3]. [1]*Università degli studi di Bologna, Medical and surgical sciences, Bologna, Italy;* [2]*University of Modena and Reggio Emilia, Department of Medical and Surgical Sciences Maternal-Childish and Adult, Modena, Italy;* [3]*Azienda Ospedaliero-Universitaria di Modena, Internal Medicine, Modena, Italy;* [4]*Azienda Ospedaliero-Universitaria di Modena, Endocrinology, modena, Italy;* [5]*Azienda Ospedaliero-Universitaria di Modena, Corelab, modena, Italy;* [6]*Pavullo Hospital, Internal Medicine, Pavullo Nel Frignano, Italy*
Email: judeslash1@gmail.com

Background and aims: The identification of patients with severe non-alcoholic steatohepatitis (NASH), who are at greater risk of progression to cirrhosis, and who most deserve targeted interventions and recruitment in clinical trials, is a major priority. Several non-invasive tests (NITs) have been developed to detect patients at risk of severe NASH and to reduce the use of liver biopsy. We conducted a prospective single-centre study aimed at evaluating the diagnostic performance of different NITs in the identification of biopsy-confirmed severe NASH. Moreover, we explored if the sequential use of NITs was able to improve their diagnostic accuracy.
Method: 56 consecutive patients (73.2% men; age 52 [22–69] years) performed liver biopsy for the suspicion of severe NASH, defined as the presence of NASH, NAFLD activity score ≥4 and fibrosis stage ≥F3. Simple wet NITs [aspartate aminotransferase (AST), alanine aminotransferase (ALT), albumin, platelet count, AST/ALT ratio (AAR) and AST to platelet ratio index (APRI)], complex wet NITs, [BARD score, Fibrosis-4 index (FIB-4), NAFLD fibrosis score (NFS), Forns Index and Hepamet fibrosis score (HFS)], direct biomarkers of fibrosis [collagen IV (CIV), laminin (LM), cholylglycine (CG), hyaluronic acid (HA) and procollagen type III amino-terminal peptide (PIIIP)], measurement of liver stiffness (LS) with Fibroscan®, and AGILE 3+ and AGILE 4 scores, were all evaluated at the time of liver biopsy. The area under the receiver operating characteristic curve (AUROC) for the identification of severe NASH of each single NIT was calculated. Finally, we evaluated the diagnostic accuracy of the sequential use of the NITs yielding the best diagnostic performance at AUROC analysis.
Results: Severe NASH was present in 12 (21.4%) patients. Simple wet NITs were not able to significantly detect severe NASH (AUROCs ranging from 0.46, p = 0.68 for albumin to 0.67, p = 0.08 for GOT, platelet and AAR). Among complex wet NITs, only BARD was able to significantly detect severe NASH (AUROC 0.77, p = 0.004), while FIB-4, NFS, Forns Index and HFS were not (AUROCs ranging from 0.45, p = 0.71 for Forns Index to 0.65, p = 0.12 for NFS). All direct biomarkers of fibrosis significantly detected severe NASH, with PIIIP (AUROC 0.81, p = 0.001) and CIV (AUROC 0.80, p = 0.002) showing the best diagnostic performance. NITs based on LS with Fibroscan® also significantly detected severe NASH, however AGILE 3+ (AUROC 0.71, p = 0.03) and AGILE 4 (AUROC 0.70, p = 0.04) scores did not improve the diagnostic performance of LS alone (AUROC 0.76, p = 0.007). The sequential use of LS (cut-off 8.5 kPa) and PIIIP (cut-off 22 ng/ml) or CIV (cut-off 16.5 ng/ml) had a diagnostic accuracy of 85.7% and 91.1%, respectively.
Conclusion: The sequential use of LS and direct biomarkers of fibrosis, such as PIIIP and CIV, may be a promising approach to non-invasively identify patients with severe NASH.

SAT-518

The clinical significance of transient elastografy and cap in the diagnosis and surveillance of non-alcoholic fatty liver disease

Eleni Gigi[1], Despoina Vasileiou[1], Theodoros Michailidis[1]. [1]*Aristotle's University of Thessaloniki, Hepatology Dep of 2nd Internal Medicine, Greece*
Email: elengigi@auth.gr

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is characterized nowadays as the most common liver disease with a prevalence of 25–30% in the general population. While in most cases it has a benign course, a significant percentage of patients progress to non-alcoholic steatohepatitis (NASH), which is characterized by inflammation of the hepatocytes, and then a percentage of them end up with cirrhosis, with an increased risk of developing HCC. The gold standard method for the diagnosis of NAFLD is liver biopsy, but due to the fact that it is an invasive method accompanied by complications, there has been an attempt in recent years to use new non-invasive diagnostic methods such as transient elastography. The purpose of this thesis is to clarify whether transient elastography is a reliable method for the diagnosis and monitoring of NAFLD.
Method: In this context, a cross sectional study was carried out at the Hepatology Department of General Hospital of Thessaloniki "Ippokratio." 81 participants with different liver diseases underwent transient elastography, upper abdomen ultrasound and laboratory blood tests.
Results: The results of the study showed that the participants had an average CAP value of 254 dB/m, which corresponds to stage 1 steatosis, but 18, 52% showed a high risk of disease progression based on the FAST score. In addition, it was shown that the results of the transient elastography were strongly related to the results of the ultrasound with a Spearman rank correlation coefficient = 0.589 and a p value <0.001. It was also found that BMI, SGPT, fasting glucose, uric acid and triglycerides were significantly associated with CAP with p values <0.001, 0.004 and 0.002, 0.036 and 0.041 respectively. Regarding severe NAFLD only BMI appeared to have a strong correlation with a p value = 0.006. However, in the multivariate analysis only the first three variables showed a significant correlation and so they were used to form a multivariate model: CAP_{new} = 27, 249 + 4, 723xBMI + 0, 26x SGPT + 0, 536xFasting glucose.
Conclusion: Transient elastography is a reliable diagnostic tool for the management of NAFLD, however, it has weaknesses in terms of confounding factors that affect its results and reduce its diagnostic accuracy.

NAFLD Experimental and pathophysiology

Caspase 8 reverses progression of NASH after hepatocyte-specific JNK deletion

Ines Volkert[1], Julia Piche[1], Christian Trautwein[1]. [1]*RWTH Aachen University hospital, Medical department III, Aachen, Germany*
Email: ivolkert@ukaachen.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disorder in the Western world. Despite intensive research the mechanisms that may lead to progression towards end-stage cirrhosis and hepatocellular carcinoma (HCC) remain unclear. c-Jun N-terminal kinases (JNKs) are known to play a significant role in liver physiology and disease pathogenesis. In the present study, we aimed to investigate the mechanisms of liver damage after hepatocyte-specific Jnk1 and Jnk2 deletion in an experimental NASH model.
Method: NASH was induced by feeding animals a Western-style diet (WSD) to compare disease development between wild-type (WT) and mice with a hepatocyte-specific deletion of Jnk1 and Jnk2 (JNK1/$2^{\Delta hepa}$). After pathway analysis, JNK1/$2^{\Delta hepa}$/caspase$8^{\Delta hepa}$ animals were generated.
Results: WSD of JNK1/$2^{\Delta hepa}$ mice caused significantly increased transaminases, enhanced fibrogenesis and strongly increased inflammation, as evidenced by infiltration of immune cells and liver cytokines and chemokines, compared to WT mice. A gene set pathway analysis revealed distinct pathways, which are activated among WSD in JNK1/$2^{\Delta hepa}$ livers. Besides inflammatory signals, we specially found a strong increase of apoptotic pathways, which was further confirmed by TUNEL and Cleaved Caspase 3 staining. Hence, JNK1/$2^{\Delta hepa}$/caspase$8^{\Delta hepa}$ animals were fed with a WSD. Triple ko animals showed significantly decreased liver transaminases and inflammation. Moreover, fibrogenesis and cell death were completely rescued. Interestingly, pathway analysis showed that most genes that were upregulated in JNK1/$2^{\Delta hepa}$ mice, were reversed after additional caspase 8 knockdown. Thus, an additional knockout of Caspase 8 achieved a complete reversal of the severe phenotype.
Conclusion: Our results demonstrate that hepatocyte-specific deletion of Jnk1 and Jnk2 triggers a strong oxidative stress response leading to increased NASH progression associated with apoptotic cell death. Interestingly additional hepatocyte-specific caspase 8 deletion completely rescued the phenotype. Hence, caspase 8 seems a promising hepatocyte-specific therapeutic target during NASH progression.

TOP-086

Novel role of macrophage Foxo1-mediated YAP-Notch axis in NASH progression

Dongwei Xu[1,2], Xiaoye Qu[1,2], Tao Yang[1], Xiao Wang[1], Michael Ke[1], Jun Li[3], Longfeng Jiang[3], Qiang Xia[2], Douglas Farmer[1], Bibo Ke[1]. [1]*The Dumont-UCLA Transplant Center, Division of Liver and Pancreas Transplantation, Surgery, Los Angeles, United States,* [2]*Renji Hospital, Shanghai Jiaotong University School of Medicine, Liver Surgery, Shanghai, China,* [3]*The First Affiliated Hospital, Nanjing Medical University, Infectious Diseases, Nanjing, China*
Email: bke@mednet.ucla.edu

Background and aims: Innate immune activation is critical in initiating and amplifying hepatic inflammation in NASH progression. However, the mechanisms of immunoregulatory molecules in recognizing lipogenic, fibrotic, and inflammatory signals remain unclear.
Method: A mouse model of a high-fat diet (HFD)-induced NASH was used in the myeloid-specific Foxo1, YAP, or Notch1 knockout or double knockout mice. Liver injury, lipid accumulation, fibrogenic genes, and immune regulatory molecules were assessed *in vivo* and *in vitro*.
Results: HFD-induced oxidative stress activates Foxo1, YAP, and Notch1 signaling in hepatic macrophages. Macrophage Foxo1 deficiency (Foxo1$^{M\text{-}KO}$) ameliorates hepatic inflammation, steatosis, and fibrosis in HFD-challenged livers, accompanied by reduced STING, TBK1, and NF-κB activation in HFD-challenged livers. However, disruption of Foxo1 and YAP double knockout (Foxo1/YAP$^{M\text{-}DKO}$) or Foxo1 and Notch1 double knockout (Foxo1/Notch1$^{M\text{-}DKO}$) enhances STING function and exacerbates HFD-induced liver injury. Interestingly, Foxo1$^{M\text{-}KO}$ markedly reduces TGF-β1 release from palmitic acid (PA)-stimulated Kupffer cells, and decreases Col1α1, CCL2, and Timp1 but increases MMP1 expression in primary hepatic stellate cells (HSCs) after co-culture with Kupffer cells. Notably, the PA challenge in Kupffer cells augments LIMD1 and LATS1 co-localization and interaction, which induces YAP nuclear translocation. Foxo1$^{M\text{-}KO}$ activates PGC-1α and enhances nuclear YAP activity. Disruption of YAP in Foxo1$^{M\text{-}KO}$ macrophages increases ROS

production in hepatocytes after co-culture exposed to PA challenge. Moreover, YAP deletion in Foxo1$^{M\text{-}KO}$ macrophages reduces mitochondrial transcription factor A (TFAM) and mitochondrial DNA (mtDNA) expression but augments intracellular lipid levels in PA-stimulated hepatocytes after co-culture. Using chromatin immunoprecipitation (ChIP) coupled with massively parallel sequencing (ChIP-Seq) and *in situ* RNA hybridization approaches, we find that NICD co-localizes with YAP and targets *Mb21d1* (cGAS) and modulates STING function leading to impeding NASH development.
Conclusion: Macrophage Foxo1-mediated YAP-Notch1 axis controls NASH progression via regulating cGAS-STING immune activation and mitochondrial biogenesis. YAP is a novel coactivator of NICD, and the YAP-NICD interaction is crucial for inhibiting STING function in NASH progression.

NAFLD is a night-time disease driven by nocturnal hepatic, adipose, and skeletal muscle insulin resistance

Thomas Marjot[1,2,3], Sarah White[1,3], Elspeth Johnson[1], Felix Westcott[1], Kate Gralton[1], Riccardo Pofi[1], David Dearlove[1], David Ray[1,3], Leanne Hodson[1,3], Jeremy Tomlinson[1,3]. *[1]Oxford Centre for Diabetes, Endocrinology and Metabolism, Churchill Hospital, University of Oxford, Oxford, United Kingdom, [2]Oxford Liver Unit, Translational Gastroenterology Unit, Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom, [3]NIHR Oxford Biomedical Research Centre, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom*
Email: thomas.marjot@ndm.ox.ac.uk

Background and aims: Rodent models show that hepatic lipid and glucose metabolism are under tight circadian control yet there are no clinical studies exploring diurnal patterns in functional processes governing intrahepatic lipid accumulation. We have characterised these metabolic pathways during day and night in patients with NAFLD before and after weight loss as well as matched controls.
Method: 11 NAFLD patients and 11 controls underwent detailed metabolic phenotyping during the day (07:00 AM-13:00 PM) and at night (19:00 PM-01:00 AM) under standardised fasting conditions. Investigations included a 2-step hyperinsulinaemic euglycaemic clamp, stable isotope assessments of glucose utilization, and paired biopsies of adipose and skeletal muscle tissue. Identical day and night-time investigations were performed in patients with NAFLD after a 12-week weight loss program.

Results: In NAFLD patients, glucose utilization (M/I value) was lower at night compared to day during both low- (12.1 ± 4.8 vs. 23.2 ± 3.7 mg/kg/min per uU/ml; p = 0.046) and high-dose insulin infusions (13.5 ± 2.3 vs. 20.6 ± 3.6 mg/kg/min per uU/ml; p = 0.042) indicative of night-time hepatic and skeletal muscle insulin resistance respectively (Fig. 1A). Isotopically measured glucose disposal (Gd) was also lower at night compared to day (18.6 ± 2.0 vs. 27.3 ± 2.7 μmol/kg/min; p < 0.001) (Fig. 1B) as was total body glucose oxidation assessed by $^{13}CO_2$ detection in breath (1.57 ± 0.1 vs. 1.72 ± 0.1 mmol/min/kg; p = 0.03). In contrast, control participants had no diurnal differences in M/I values, glucose disposal, or glucose oxidation. Patients with NAFLD also had markedly elevated plasma non-esterified fatty acids (NEFA) at night compared to day during basal (384 ± 58 vs. 299 ± 461 mmol/L; p = 0.001) and low-dose insulin phases of the clamp (234 ± 74 vs. 173 ± 49 mmol/L; p = 0.006) (Fig. 1C). These data are consistent with night-time adipose insulin resistance which positively correlated with degree of hepatic steatosis measured by controlled attenuation parameter (CAP) (r = 0.806; p = 0.005). Self-reported food diaries demonstrated that NAFLD patients consumed 48% of their mean daily calories during a single evening meal which may compound their night-time metabolic dysfunction. 9/11 (81%) NAFLD patients completed the lifestyle intervention achieving 6% weight loss and a 19% CAP reduction. Whilst there were global improvements in insulin sensitivity and adipose function, diurnal differences in M/I values (p = 0.02) and circulating NEFA levels (p = 0.008) persisted with continued metabolic dysfunction at night. Across all groups, there were no significant differences in calory intake, physical activity, and sleep quality in the week preceding day and night-time investigations suggesting that observed metabolic changes were related to time-of-day rather than external lifestyle factors. Proteomic analysis of adipose and skeletal muscle tissue will now help establish a mechanistic basis for this diurnal variability in metabolic phenotype.
Conclusion: Night-time metabolic dysfunction may represent a unique risk factor for NAFLD with multiple contributory pathogenic pathways augmented at night compared to day. These findings will help establish the optimal window for energy intake in patients with NAFLD and guide the best time-of-day to deliver medications currently in development.

Single-cell RNA sequencing in DIAMOND mice reveals differentially regulated pathways specifically associated with the transition from simple steatosis towards NASH

Rocío Gallego-Durán[1,2], Douglas Maya[1,2], Ignacio Benedicto[3], José María Herranz[2,4], Lucía López-Bermudo[5,6], Elena Vázquez-Ogando[7], Rocío Montero-Vallejo[1,2], Mª José Robles-Frias[8], Blanca Escudero-López[5,6], Antonio Cárdenas-García[5,6], Ana Quintas[9], Elena Blázquez-López[2,7], Francisco Javier Cubero[2,3], Javier Vaquero[2,7], Yulia Nevzorova[3], Maite G Fernandez-Barrena[2,4], Matías A Avila[2,4], Jordi Gracia-Sancho[2], Rafael Bañares[2,7], Franz Martin-Bermudo[5,6], Manuel Romero Gomez[1,2], Javier Ampuero[1,2]. *[1]UCM Digestive Diseases, Hospital Universitario Virgen del Rocío; SeLiver Group, Instituto de Biomedicina de Sevilla (HUVR/CSIC/US), Departamento de Medicina Universidad de Sevilla, Sevilla, Spain, [2]CIBEREHD- Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas, Spain, [3]Departamento de Inmunología, Oftalmología y ORL, Facultad de Medicina, Universidad Complutense de Madrid, Madrid, Spain, [4]Program of Hepatology, Centre of Applied Medical Research (CIMA), University of Navarra, Spain, [5]Centro Andaluz de Biología Molecular y Medicina Regenerativa-CABIMER, Universidad Pablo de Olavide, Universidad de Sevilla, Consejo Superior de Investigaciones Científicas (CSIC), Spain, [6]CIBERDEM- Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas, Spain, [7]HepatoGastro Lab, Servicio de Ap. Digestivo del HGU Gregorio Marañón, Instituto de Investigación Sanitaria Gregorio Marañón, Spain, [8]Pathology Department, Hospital Universitario Virgen del Rocío, Spain, [9]Centro Nacional de Investigaciones Cardiovasculares (CNIC), Spain*
Email: jampuero-ibis@us.es

Background and aims: DIAMOND™ mice have been validated as preclinical model mirroring the metabolic and histological features of human NASH without significant fibrosis. The main aim was to employ single-cell RNAseq (scRNAseq) technology in this preclinical model to unveil the differential changes specifically associated with the progression from simple steatosis to NASH.

Method: We performed scRNAseq on parenchymal and non-parenchymal cells (NPCs) isolated from 8 DIAMOND™ mice fed high-fat high-fructose diet (HF-HFD) *vs*. controls at 19 and 32 weeks. For cell isolation purposes, livers were perfused and divided into two different fractions, one for hepatocytes and the other for the evaluation of NPCs. Briefly, hepatic tissue was dissociated, centrifugated, purified, sorted by FACS and prepared to single-cell sequencing analysis using 10x Genomics. Several ingenuity pathway analyses (IPA) tools were used to find altered pathways, upstream regulators and toxic molecules specifically associated to NASH transition ($\Delta_{33w\text{-}19w}$ activation z-score >|2|). Mitochondrial gene presence filtering was tested with several cut-offs selecting the most appropriate one for the experiment and validating its effect in clustering and differential expression. Clustering was carried out using the Seurat package in R with different resolutions to find the most adequate one for the experiment and validating the biological existence of the cluster using published markers and human protein atlas. Cell type annotation was generated using celldex package and validated using published and human protein atlas cell type markers to rename liver specific populations. The similarity with human NASH progression was measured using a robust NASH signature from previously published data. Mice livers were stained for haematoxylin-eosin and Masson's trichrome, SAF Score and fibrosis were calculated by a pathologist blinded to the provenance of samples.

Results: Histopathological analysis following SAF Score showed NASH exclusively at 32 w despite significant inflammation at 19w of diet. Mild fibrosis was observed in all animals fed HF-HFD. We obtained a total of 70637 hepatocytes and 151132 NPCs, and identified six clusters of hepatocytes at week 19 and five at week 32 (see figure). NPCs clustering identified 21 clusters at week 19 and 24 at week 32, and 12 out of 21 and 10 out of 24 were assigned as known cell types respectively. Preliminary IPA analysis on hepatocytes reinforced the idea that the presence of NASH is associated with mitochondrial disfunction (Mitochondrial dysfunction $\Delta_{z\text{-score}} = 3.78$; Oxidative phosphorylation $\Delta_{z\text{-score}} = -5$; Sirtuin signalling pathway $\Delta_{z\text{-score}} = 5.74$). Interestingly, we observed a significant downregulation of several pathways linked to caspase-dependent apoptosis (Apoptosis of hepatocytes $\Delta_{z\text{-score}} = -2.178$; Cell death of hepatocytes $\Delta_{z\text{-score}} = -2.662$) despite a much higher presence of ballooned hepatocytes in NASH tissue together with an activation of a pathway related to caspase-independent apoptosis (Granzyme A signalling $\Delta_{z\text{-score}} = 3.74$).

Conclusion: A single-cell model to analyse the transition towards NASH independently of fibrosis stage using DIAMOND™ mice has been established. Preliminary results link mitochondrial dysfunction in hepatocytes to NASH and ballooning, and highlight some noteworthy deregulations in pathways mediating apoptosis.

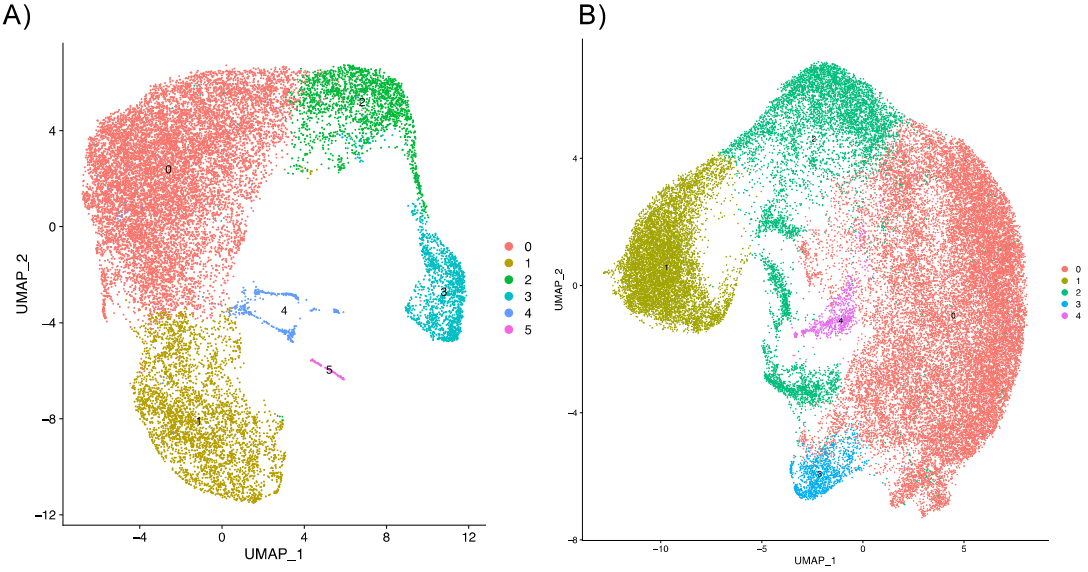

Figure: (abstract: TOP-090): UMAP results from parenchymal cells isolated from livers at 19w (a) and 32w (b) of diet.

A functional interaction between hepatic estrogen receptor-α and PNPLA3 p.I148M inherited variant drives fatty liver disease susceptibility in women

Alessandro Cherubini[1], Mahnoosh Ostadreza[1], Oveis Jamialahmadi[2], Serena Pelusi[1], Eniada Rrapaj[1], Elia Casirati[3], Giulia Passignani[1], Guido Alessandro Baselli[1], Luisa Ronzoni[1], Sara Della Torre[4], Paola Dongiovanni[5], Daniele Prati[1], Stefano Romeo[6], Luca Valenti[1,7]. *[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Transfusion Medicine, Milano, Italy, [2]Gothenburg University, Department of Molecular and Clinical Medicine, Gothenburg, Sweden, [3]University of Milan, Pathophysiology and Transplantation, Milano, Italy, [4]University of Milan, Department of Pharmaceutical Sciences, Italy, [5]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, General Medicine and Metabolic Diseases, Milano, Italy, [6]University of Gothenburg, Department of Molecular and Clinical Medicine, Sweden, [7]University of Milan, Pathophysiology and Transplantation, Italy*
Email: alessandro.cherubini@policlinico.mi.it

Background and aims: Fatty liver disease (FLD) related to metabolic dysfunction and excessive alcohol affects almost one third of the global population and is a leading cause of liver related mortality. The *PNPLA3* p.I148M variant accounts for the largest fraction of FLD heritability. Although women are protected during the reproductive age, especially after menopause some are susceptible to FLD, but this sexual dimorphism is neglected in clinical studies. Aim was to examine the *PNPLA3* p.I148M*female sex interaction in FLD development, and to investigate the underlying mechanism.
Method: The female sex**PNPLA3* p.I148M interaction on FLD was tested in the Liver Biopsy (n = 1861), severe FLD case-control (n = 4374), Liver-Bible-2021 (n = 817) and UK Biobank (n = 347,127) cohorts. PNPLA3 expression was determined in transcriptomic cohort (n = 107). HepG2 cells were used for estrogen receptor (ER) modulation and fatty acid treatment, and to generate PNPLA3-ER element (ERE) knock-out clones.
Results: In all cohorts we observed an interaction between female sex and *PNPLA3* p.I148M, but not other FLD genetic risk variants, in determining FLD development and progression, with a larger effect in postmenopausal women ($p < 0.05$). Higher hepatic PNPLA3 mRNA expression was independently associated with the p.I148M variant and female sex ($p = 0.002$ and $p = 0.007$, respectively). At chromatin immunoprecipitation, ERα agonists induced the ER binding to a specific ERE at a *PNPLA3* enhancer site, enhancing its transcriptional activity at luciferase assays. PNPLA3 mRNA and protein expression was upregulated via direct Erα agonists, leading to intracellular fat accumulation in p.I148M homozygous HepG2 cells, but not in wild-type hepatocytes. Genetic deletion of the PNPLA3-ERE by Crispr/Cas9 editing in HepG2 abolished the ERα-induced PNPLA3 and intracellular lipid accumulation in response to fatty acids.
Conclusion: We identified a driver of FLD acceleration occurring in a subset of women with metabolic dysfunction at menopause, highlighting at the same time a therapeutic target of particular relevance.

WED-395

Brain-derived neurotrophic factor knock-out mice develop non-alcoholic steatohepatitis

Mayuko Shimizu[1], Masami Kojima[2,3], Shingo Suzuki[4], Misaki Miyata[2], Toshiyuki Mizui[3], Koichi Tsuneyama[1]. *[1]Tokushima University, Pathology and Laboratory Medicine, Japan, [2]Kanazawa Institute of Technology, Applied Bioscience, Japan, [3]National Institute of Advanced Industrial Science and Technology, Biomedical Research Inst, Japan, [4]Kagawa University, Anatomy and Neurobiology, Japan*
Email: masamikojima@neptune.kanazawa-it.ac.jp

Background and aims: Brain-derived neurotrophic factor (BDNF), which is originally discovered as a growth factor that promotes neuronal survival, differentiation, and synaptic plasticity in the brain, is associated with the development of brain diseases. The aim of the present study was to investigate the role of BDNF in peripheral disease in life stages from adulthood to advanced age.
Method: Male BDNF knock-out mice ($BDNF^{\pm}$) and controls ($BDNF^{+/+}$) were fed with a normal diet in group housing. At 10 months of age, whole body organs were histopathologically analysed. Histological findings from the liver were scored using the non-alcoholic steatohepatitis (NASH) Clinical Research Network Scoring System. RNA-seq and gene ontology analysis were performed on the liver of animals. In addition, to ensure the implication of reduced BDNF expression, the histological study was performed in the liver of proBDNF knock-in ($BDNF^{+/pro}$) mice, genetically engineered mouse line in which precursor BDNF is inefficiently converted into the matured form of BDNF.
Results: $BDNF^{\pm}$ mice developed symptoms of NASH: zone 3 steatosis, lobular inflammation, ballooning hepatocytes, and fibrosis, while no histological lesions were seen in the heart, kidney, intestine, lung, pancreas and spleen. Obesity and higher serum levels of glucose and insulin—major pathologic features in human NASH—were dramatic. Dying adipocytes were surrounded by macrophages in visceral fat, suggesting that chronic inflammation occurred in adipose tissue. RNA-seq studies of the liver revealed that the most significantly enriched term includes the fatty acid metabolic process and modulation of neutrophils aggregation, pathologies that well characterize NASH. The results of gene ontology analysis were experimentally verified using the liver tissues of $BDNF^{\pm}$ mice and immunostaining with myeloperoxidase, a marker for activated neutrophils, indicating the infiltration of neutrophils in the liver of mutant animals. Gene expression analysis by RNA-seq also suggests that the $BDNF^{\pm}$ mice are under oxidative stress, as indicated by alterations in the expression of cytochrome P450 family and reduction of glutathione S-transferase p, an antioxidant enzyme (Figure). Lastly, histopathologic phenotypes of NASH were observed in $BDNF^{+/pro}$ mice as well.

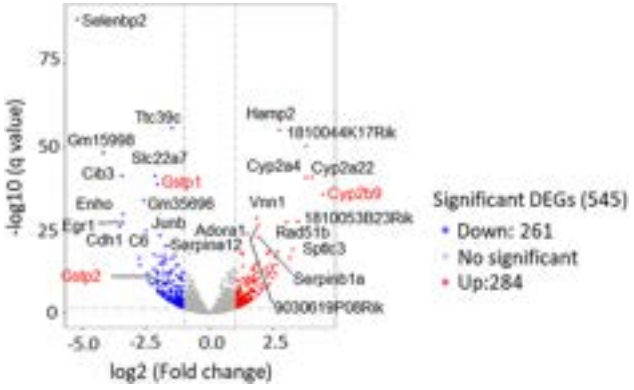

Figure:

Conclusion: This is the first report demonstrating that reduced BDNF expression induces the critical pathogenic mechanism leading to the development of the full spectrum of NASH. Our study thus describes a new model animal of the brain-liver connection.

WED-396

The PNPLA3 p.I148M risk variant was fixed in Neanderthals and segregates neutrally in humans

Andreas Geier[1], Jonas Trost[1], Ke Wang[2], Marcin Krawczyk[3], Stephan Schiffels[4]. *[1]University Hospital Würzburg, Division of*

Hepatology, Department of Internal Medicine II, Würzburg, Germany, [2]Max Planck Institute of Geoanthropology, Department of Archaeogenetics, Jena, Germany, [3]Saarland University Hospital, Department of Medicine II, Homburg/Saar, Germany, [4]Max-Planck-Institute for Evolutionary Anthropology, Department for Archaeogenetics, Leipzig, Germany
Email: geier_a2@ukw.de

Background and aims: The liver is the central organ in the human body responsible for carboyhdrate and lipid metabolism and plays a key role in fat storage under conditions of overnutrition. Fat deposition is modulated by environmental factors and genetic predisposition. GWAS studies identified PNPLA3 p.I148M as a common variant that increases risk of developing non-alcoholic fatty liver. The association of this variant to harmful phenotypes including end-stage liver disease suggests a potential effect on fitness and hence a potential role of natural selection. To understand its past trajectory throughout human evolution, we turn to archaeoegenetic data spanning the last 50,000 years.
Method: 6444 published ancient (modern humans, Neanderthal, Denisovan) and 3943 published present-day genomes were used for analysis after extracting genotype calls for PNPLA3 p.I148M (rs738409). The deeper evolutionary context was explored using reference genome sequences of current primates. To quantify changes through time, two regression analyses were performed: logistic regression based on presence/absence of the risk allele in ancient and modern individuals from different continents; linear regression based on allele frequencies by grouping individuals according to geography and age. To compare these changes with expected changes due to neutral factors such as genetic drift, we compiled a reference dataset of 1000 randomly selected SNPs for genome wide analysis, and performed the exact same logistic and linear regressions.
Results: The ancestral (reference) allele is fixed among all great apes (Chimpanzee, Bonobo, Gorilla, Orangutan). In contrast, on the human lineage, all available Neanderthal (n = 5) and Denisovan individuals (n = 3 including a Neanderthal/Denisovan hybrid) exclusively carry the risk (derived) allele, suggesting fixation of the allele in the ancestor of all archaic humans (Figure). In contrast, present-day humans exhibit a wide range of minor allele frequency ranging from 8% in Kenya up to 72% in Peru. Over the last 15,000 years, distributions of ancestral and derived alleles roughly match the present day distribution, including a high frequency in the Americas even in the earliest samples from 10,000BP. On all continents, the observed frequency change of PNPLA3 variant were within the expected distribution as estimated from the neutral reference SNP set. Similarly, in a logistic regression along latitude again compared to the randomly selected reference SNP set, and finally a multivariate logistic regression against both time and latitude, the observed changes were within the expected variation, consistent with absence of natural selection.

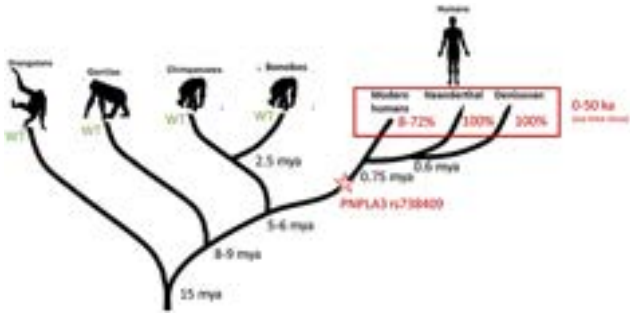

Figure: Presence of PNPLA3 rs738409 ancetral (Wildtype; WT) and derived alleles in the great ape lineage family tree.

Conclusion: Archaic human individuals exclusively carried a fixed PNPLA3 risk allele, whereas allele frequencies in modern human populations range from very low in Africa to more than 50% in Mesoamerica. Our observation might underscore the advantage of fat storage in cold climate and particularly for Neanderthal under ice age conditions. The negative genome-wide analysis without signals of natural selection during modern human history does not support the thrifty gene hypothesis in case of PNPLA3 p.I148M polymorphism where other mechanisms like gene drift may contribute to present day allele distribution.

Email: adlsimao@ff.ulisboa.pt

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is characterized by intracellular lipid accumulation in the liver and associates with pathogenic changes in additional metabolic tissues, particularly the adipose tissue (AT). In parallel, increasing evidence supports a functional role for extracellular vesicles (EVs) in inter-organ crosstalk during NAFLD progression. Finally, activation of Takeda G-protein coupled bile acid receptor 5 (TGR5) ameliorates NAFLD in experimental mouse models. Here, we aimed to elucidate whether modulation of TGR5 activity in adipocytes affects the content of its secreted EVs and in turn alters hepatocyte function, in vitro. In parallel, we evaluated the role of AT TGR5 in a mouse model of NAFLD.
Method: AT-derived EVs were isolated from adipocytes exposed to LPS and then incubated with unstimulated hepatocytes. Alternatively, EVs were isolated from adipocytes after silencing of TGR5 or upon exposure to different TGR5 agonists and then incubated with hepatocytes stimulated with LPS. AT-derived EVs were isolated by polymer-based precipitation and characterized by nanoparticle tracking analysis. AT-specific TGR5 KO mice and respective littermate controls were fed a high-fat diet (HFD) for 14 weeks. Gene and protein expression levels were analyzed by qRT-PCR and immunoblotting, respectively.
Results: Results showed that AT TGR5 plays a key role in the metabolic response of mice to high-calorie intake. In particular, AT-specific TGR5 KO mice fed an HFD displayed significantly increased body weight, compared to littermate controls, starting at 9 weeks of feeding. EVs released from LPS-stimulated adipocytes triggered an inflammatory response in hepatocytes, as seen by the increased mRNA expression of different pro-inflammatory cytokines, resulting in enhanced cell death. Interestingly, incubation of unstimulated hepatocytes with EVs from TGR5-silenced adipocytes similarly increased the expression of pro-inflammatory cytokines, while also promoting lipogenesis. Compared to unstimulated cells, incubation of adipocytes with different TGR5 agonists activated critical intracellular signalling mediators and led to decreased EV release. Of note,

EVs released from TGR5-activated adipocytes reduced the inflammatory response of hepatocytes stimulated with LPS.
Conclusion: Overall, our results suggest that EVs from TGR5-activated adipocytes contain anti-inflammatory molecules capable of exerting a functional role within hepatocytes, with in vivo data underscoring the role of TGR5 in ameliorating obesity and inter-organ lipid accumulation. A better characterization of TGR5-dependent fat-to-liver signalling will unravel the prospective therapeutic potential of TGR5 agonists for metabolic diseases (HR17-00601, Fat2LiverTGR5; PTDC/MED-PAT/31882/2017, EXPL/MED-OUT/1317/2021 and SNSF 31003A_125487).

WED-398
Hepatic lipid flux, and not lipid amount, damages the liver during starvation-induced steatosis
Macarena Pozo-Morales[1], Ansa Cobham[2], Cielo Centola[2], Nicolas Rohner[2], Sumeet Singh[1]. *[1]UNIVERSITÉ LIBRE DE BRUXELLES (ULB), IRIBHM, Anderlecht, Belgium, [2]Stowers Institute for Medical Research, United States*
Email: sumeet.pal.singh@ulb.be

Background and aims: During starvation, animals utilize the liver as lipid storage organ. For instance, patients suffering from anorexia nervosa, overnight fasted mice and starved zebrafish larvae have been reported to develop fatty liver. Like other cases of non-alcoholic fatty liver diseases (NAFLD), starvation-induced hepatic steatosis is related to liver damage. But it is not clear if the organ damage is due to the accumulation of lipid droplets in hepatocytes or their utilization as an energy source. Also, it remains unknown if the resolution of lipid droplets is beneficial to the animal. Here, we use the zebrafish model system to investigate the impact of lipid amount and lipid flux on liver damage. Further, we study how cavefish, a model of starvation resistance, protects its liver from atrophy during starvation.
Method: Our previous work in the zebrafish model system had shown that starvation-induced hepatic steatosis is regulated by calcium signaling (Pozo-Morales et al, *Hepatology*, 2022; doi: 10.1002/hep.32663). In line with our findings, in this study we manipulated lipid droplet flux by altering calcium flux. We increased calcium oscillations in the liver by mobilization of endo-lysosomal calcium stores, using TPC2 agonist. In contrast, we utilized a genetically encoded calcium chelator to reduce the turnover of lipid droplets.
Further, to understand how animals with enhanced starvation resistance deal with hepatic steatosis and liver damage, we investigated the starvation response in Mexican cavefish, *Astyanax mexicanus*. Here, we labeled hepatic lipid droplets using Nile Red staining and performed comparative analysis between surface and cavefish.
Results: In zebrafish, increase of calcium flux using TPC2 agonist efficiently reduced lipid droplets in the liver. However, the resolution of steatosis enhanced macrophage infiltration, hepatocyte phagocytosis and starvation-induced mortality. Thus, suggesting that fatty liver helps with starvation resistance.
On the other hand, buffering cytoplasmic calcium reduced the turnover of lipid droplets, increasing hepatic steatosis in later stages of starvation. The reduced lipid turnover led to reduced liver inflammation and increased the lifespan of starved animals, thereby suggesting that hepatic lipid flux damages the liver.
In the cavefish model, we found that, surprisingly, cavefish do not accumulate lipid droplets in the liver upon starvation and are protected from liver damage. In contrast, surface fish accumulate lipid droplets in the liver during starvation and display liver atrophy. Using transcriptome analysis, we identify the long-chain fatty acid importer, SLC27A2, as one of the gene responsible for hepatic steatosis during starvation. Zebrafish and surface fish, but not cavefish, upregulate the expression of slc27a2a in the liver upon starvation. Pharmacological inhibition of SLC27A2 inhibits lipid accumulation in the starved zebrafish liver.

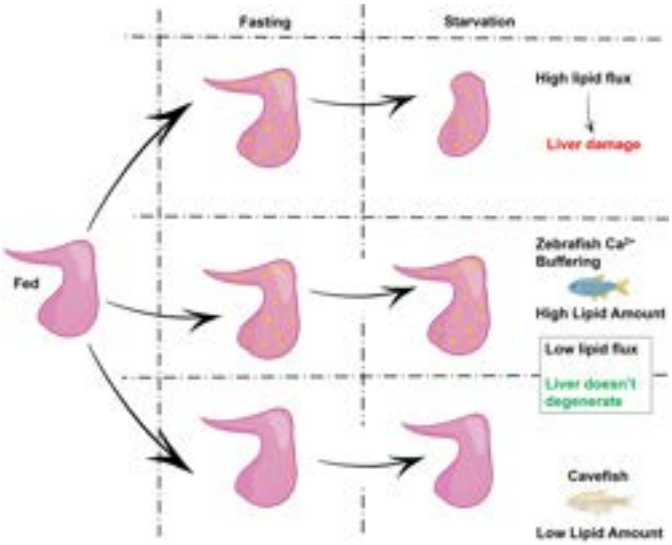

Figure:

Conclusion: Our study demonstrates that the turnover of lipid droplets in hepatocytes during starvation is detrimental to liver health and identifies a protective mechanism in cavefish against liver atrophy.

WED-399
Targeting Apolipoprotein J restores autophagy and improves metabolic-associated fatty liver disease and diabetic nephropathy
Wang Hsin-Tzu[1], Duan Shuangdi[2], Qin Nong[2], Pi Jiayi[2], Sun Pei[2], Sun Hung-Yu[1]. *[1]National Cheng Kung University, Taiwan, [2]Hunan University, China*
Email: s5893149@gmail.com

Background and aims: Metabolic disorders affect 20–25% of adult population globally and have become a heavy burden on society. Targeting hepatic lipid deposition represents a therapeutic strategy against metabolic syndromes. In this investigation, Apolipoprotein J (ApoJ) was identified as a potential target of aberrant lipid accumulation to relieve metabolic-associated fatty liver disease (MAFLD) and diabetic nephropathy (DN).
Method: The diet-induced MAFLD, streptozotocin-induced type-II diabetes (T2DM), and genetically diabetic db/db mice were administered intravenously with ApoJ antagonist peptide (10 mg/kg/3 days) or intraperitoneally with liraglutide (200 μg/kg/day) for 8 weeks. The tissue pathology was examined by histochemical staining. The glucose and insulin tolerance test was performed to address insulin sensitivity.
Results: We first demonstrated that targeting ApoJ reactivates autophagy and lysosomal activity and prevents intracellular lipid deposition. Next, a peptide with a Kd of 2.54 μM was applied to antagonize ApoJ and restore mTOR-FWB7 E3 ligase interaction to promote proteasomal degradation of mTOR. Administration of ApoJ antagonist peptide improved hepatic pathology, serum lipid and glucose homeostasis, and insulin sensitivity in mice with MAFLD or T2DM. In addition, the peptide reactivated TFEB, restored autophagy, and prevented accumulation of lipid and reactive oxygen species of renal tubular, thus reversed renal injury and fibrosis in mouse models of DN.
Conclusion: The findings demonstrated ApoJ would be a therapeutic target for intracellular lipid deposition and a proof-of-concept ApoJ antagonist peptide was proposed as a novel strategy against metabolic syndromes.

mTORC1 response to glucose via dihydroxyacetone phosphate is regulated by MAT1A. Role in NAFLD

María de los Reyes Luque Urbano[1,2], Jon Bilbao[1], David Fernández Ramos[1,3], Fernando Lopitz Otsoa[1], Virginia Gutiérrez de Juan[1], Ganeko Bernardo-Seisdedos[1,4], Luis Manuel Cervera Seco[5], Urko M Marigorta[5], Lucía Barbier Torres[6], Shelly C. Lu[6], Oscar Millet[1,3,4], José M. Mato[1,3]. *[1]CIC bioGUNE-Centro de Investigación Cooperativa en Biociencias, Precision Medicine and Metabolism Laboratory, Derio, Spain, [2]Atlas Molecular Pharma, Spain, [3]CIBERehd, Instituto de Salud Carlos III, Spain, [4]Atlas Molecular Pharma, Spain, [5]CIC bioGUNE-Centro de Investigación Cooperativa en Biociencias, Integrative Genomics Laboratory, Derio, Spain, [6]Karsh Division of Gastroenterology and Hepatology, Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA., United States*
Email: director@cicbiogune.es

Background and aims: Deletion in mice of MAT1A, the main enzyme responsible for the hepatic synthesis of S-adenosylmethionine (SAMe), leads to the spontaneous development of liver steatosis and its progression to NASH, fibrosis, and hepatocellular carcinoma. Because it is not yet fully understood how MAT1A loss induces hepatic fat accumulation, we studied how MAT1A-deficient mouse hepatocytes respond to glucose challenge.

Method: Murine primary hepatocytes were isolated by liver perfusion from wild-type (WT) and MAT1A knockout (-KO) mice. After plating, hepatocytes were serum starved overnight and incubated with ^{13}C- glucose (25 mM, 3 hours). Protein and mRNA expression of glycolysis, pentose phosphate pathway (PPP), AMPK and mTOR pathways were studied by western blot and qPCR. Metabolites content was measured by NMR.

Results: Here we show that glucose sensing by mTORC1 is impaired in MAT1A-KO hepatocytes exposed to high glucose, as evidenced by inhibition of phosphorylation of mTORC1 and its downstream substrate S6K1, leading to reduced synthesis of phosphatidylcholine via the CDP-choline pathway, impaired VLDL export, and accumulation of intracellular lipids. We found that the concentration of dihydroxyacetone phosphate (DHAP), a glycolytic intermediate and activator of mTORC1, is reduced 8-fold in MAT1A-KO hepatocytes exposed to 25 mM glucose compared with WT hepatocytes. We also found that mRNA content of aldolase B (ALDOB), the enzyme that catalyzes the reversible conversion of fructose 1, 6-bisphosphate to DHAP and glyceraldehyde 3-phosphate (G3P), was reduced in MAT1A-KO hepatocytes. To neutralize this reduction in glucose flux between the upper and lower glycolysis, MAT1A-KO hepatocytes increased the expression of glucose-6-phosphate dehydrogenase (G6PD), the rate-limiting step of the PPP, and transketolase (TKT), the enzyme that channels excess sugar phosphates in the PPP to lower glycolysis at the G3P level. These alterations were prevented by the addition of SAMe to the culture medium. Consistent with the redirection of glucose flux through the PPP, we found that at high glucose AMPK and its target enzyme acetyl-CoA carboxylase 1, the rate limiting step in fatty acid synthesis, were hypophosphorylated in MAT1A-KO hepatocytes leading to increased lipogenesis.

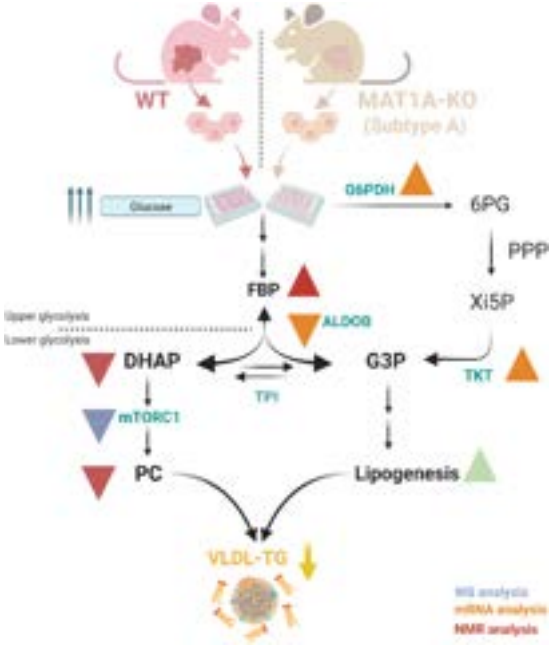

Figure:

Conclusion: The present findings, together with the observation that MAT1A expression is often reduced in NASH patients and our

previous finding demonstrating that NAFLD patients displaying a serum lipidomic signature similar to MAT1A-KO mice (subtype A) have lower VLDL secretion rate and serum VLDL levels than patients with a different lipidomic profile, suggest that DHAP-mediated mTORC1 response to glucose is impaired in NAFLD patients with subtype A. These results suggest that increasing hepatic DHAP content may be a therapeutic target in NAFLD patients with subtype A.

WED-401

Development of a target engagement biomarker for HSD17B13: preclinical pharmacodynamic studies of small molecule inhibition of HSD17B13 by INI-822

Cindy McReynolds[1], Michael Carleton[1], Chuhan Chung[1], Heather Hsu[1]. [1]*Inipharm, RandD, Bellevue, United States*
Email: hhsu@inipharm.com

Background and aims: Polymorphisms rendering the lipid droplet-located protein HSD17B13 enzymatically inactive protect against NASH, cirrhosis, and liver cancer. Analysis of human liver tissue demonstrated increased hepatic phosphatidylcholines in individuals with inactive HSD17B13 (Luukkonen 2020 JCI). INI-822, a selective small molecule inhibitor of HSD17B13, was used to test for lipidomic changes consistent with humans carrying the inactive HSD17B13 gene.
Method: INI-822 was dosed orally once daily in multiple rat models of liver injury including Zucker rats (3 weeks dosing, n = 4/group) on an atherogenic diet and CDAA-HFD and Sprague-Dawley rats (2 weeks dosing, n = 8/group). Changes in liver transaminase levels, circulating and hepatic phospholipids (GC/MS, LC/MS) and hydroxylated lipid substrates (LC/MS) were measured. Statistical significance was evaluated by ANOVA followed by a Bonferroni multiple comparison test. All parameters presented have a $p < 0.05$. The ED50 was calculated by a nonlinear 4 parameter fit.
Results: INI-822 treatment of Zucker obese rats led to a decrease in ALT in all models. INI-822 treatment in Zucker rats led to increased hepatic phosphatidylcholines seen in both diets but to a greater degree in rats on the CDAA-HFD. In contrast, plasma levels of phosphatidylcholines were decreased in animals treated with INI-822 on the CDAA-HFD. There was an increase in plasma levels of esterified hydroxy-lipid HSD17B13 substrates while these same substrates were decreased in free fatty acid form. This was seen on both diets but was more pronounced on the atherogenic diet. There was a dose-dependent increase in a panel of hydroxy-lipid HSD17B13 substrates with a mean ED50 of 5.6 ± 2.4 mg/kg. The change in these endogenous hydroxy-lipids was as great as 5.9-fold for 15-HETE under these conditions. There was also a dose-dependent decrease in the keto-lipid HSD17B13 product, 9-oxoODE, with an ED50 also of 5.6 mg/kg ($r^2 = 0.5215$).

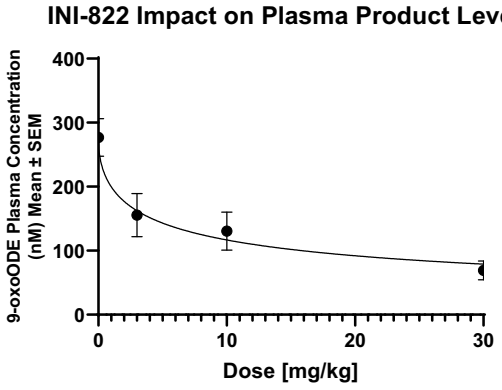

Figure:

Conclusion: HSD17B13 inhibition with INI-822 decreased liver transaminases and led to increased hepatic phosphatidylcholine content in multiple preclinical models. Inhibition of HSD17B13 resulted in increases in plasma levels of hydroxy-lipid HSD17B13 substrates, particularly in the esterified form. These changes in hydroxy-lipid substrates indicate their use as potential target engagement biomarkers and suggest that INI-822 phenocopies the human protective allele of HSD17B13.

WED-402

Modelling the biological mechanisms of a PNPLA3 polymorphism in a 3D human liver spheroid for NASH progression and drug efficacy

Francisco Verdeguer[1], Radina Kostadinova[1], Philipp Vonschallen[1], Jesus Glaus[1], Thomas Hofstetter[1], Simon Ströbel[1]. [1]*InSphero, Liver Discovery, Switzerland*
Email: francisco.verdeguer@insphero.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is a progressive severe disease characterized by lipid accumulation, inflammation and fibrosis in the liver. Single nucleotide polymorphisms (SNPs) at specific loci have revealed differential propensity to develop NASH. Among them, "GG" rs738409 located in PNPLA3 results in the I148M amino acid change. PNPLA3 is a triacylglycerol lipase localized in lipid droplets but its function in the context of NASH is not fully understood and yet represents an interesting therapeutic target. The aim of this study was to investigate the effect of PNPLA3 (I148M) mutant on the development of NASH hallmarks in a 3D human liver *in-vitro* culture model.
Method: We generated a human in-vitro liver spheroid model by co-culturing primary human hepatocytes, Kupffer cells, endothelial cells and hepatic stellate cells obtained from human donors. Hepatocytes were obtained from either the major allele for PNPLA3 or PNPLA3 (I148M) variant. Spheroids were incubated with either physiological or steatotic and proinflammatory media conditions to assess the influence of PNPLA3 in NASH hallmarks by performing biochemical, imaging and transcriptomics analysis.
Results: We show that steatotic and proinflammatory conditions lead to increased intracellular triglycerides levels and secretion of inflammatory markers IL-6, MIP-1α, TNF-α, IL-10, MCP-1 and IL-8 and increased secretion of procollagen peptides I and III. These results show a recapitulation of the hallmarks of NASH. PNPLA3 (I148M) genotype in liver spheroids resulted in an increased levels of steatosis and fibrosis measured by triglyceride content and collagen secretion compared to the major allele. In line with these results, transcriptomics analysis show that both de-novo lipogenesis and fibrotic pathways are elevated in the PNPLA3 (I148) donors compared to major allele.These results are in agreement with the expected phenotypic propensity to develop NASH in the human population carrying the PNPLA3 (I148M) variant.
Finally, small molecules Firsocostat, Selonsertib and ALK5i lead to a decrease levels of triglycerides and inflammatory markers and collage secretion compared to NASH, and the response was exacerbated in PNPLA3 (I148M) variants.
Conclusion: In summary we show a spheroid model that recapitulates NASH hallmarks and differential drug responses to specific SNPs relevant for NASH.

WED-403

Perivascular macrophages contribute to adipose tissue angiogenesis in patients with advanced non-alcoholic fatty liver disease

Celia Martinez-Sanchez[1,2], Octavi Bassegoda[3], Hilmar Berger[4], Xènia Almodovar[1], Laia Aguilar[3], Yilliam Fundora[3], Ainitze Ibarzábal[3], Ana de Hollanda[3], Pep Vidal[3], Anna Soria[3], Irina Luzko[3], Alex Guillamon[1], Frank Tacke[4], Pau Sancho-Bru[1], Pere Ginès[1,2,3], Isabel Graupera[1,3], Mar Coll[1]. [3]Hospital Clínic de Barcelona, Spain, [4]Charité Universitätsmedizin Berlin, Germany
Email: cmartinezs@recerca.clinic.cat

Background and aims: In non-alcoholic fatty liver disease (NAFLD) macrophages infiltrating the adipose (ATMs) acquire a pro-inflammatory phenotype and contribute to liver damage. However the heterogeneity of ATM populations and its relationship along disease progressions is still unknown. The aim of the present study is to unveil the main ATMs' subsets with a significant role in NAFLD patients.
Method: Single cell RNA sequencing from sorted myeloid cells (CD14+) was performed from the adipose tissue of obese patients without NAFLD (n = 2); NAFLD patients with mild hepatic fibrosis (n = 2) and NAFLD patients with advanced fibrosis (n = 2). We integrated our single cell data with those of previously reported single cell data from obese adipose tissue (Hildreth et al. 2021). Validation of *scRNAseq* findings by gene expression and immunohistological analysis was performed in adipose tissue of a larger cohort of NAFLD patients without fibrosis (n = 24) and with advanced fibrosis (n = 12). Moreover, we performed an adipose tissue clearing technique to have a 3D volumetric image of the entire tissue. Finally we isolated ATMs and collected their secretome to evaluate the secretion of angiokines by *ELIS*A.
Results: *ScRNAseq* analysis of myeloid cells clustered into 10 different sub-types according to their transcriptome signature. Interestingly perivascular macrophages (PVMs) subset was found significantly enriched in patients with advanced fibrosis. The increase of PVMs was confirmed by gene expression of several key PVMs markers including *RNASE1, LYVE1; MAF; CSF1R* and by IHC using the surface marker FOLR2 (p = 0.006) in the adipose tissue of the NAFLD cohort. The functional analysis revealed, among others, the role of PVMs on local endothelial cell proliferation. Moreover integration of our ATMs' scRNA seq with adipose tissue *scRNAseq* confirmed the interaction between PVMs and adipose tissue endothelial cells in the VEGF signaling pathway. By assessing the gene expression of the angiogenic markers: *NRP1; EGFL7* and *CXCL12* (p = 0.004; p = 0.037 and p = 0.04, respectively) and protein expression of CD31 and VWF (p = 0.023 and p = 0.001), we confirmed the presence of increased angiogenesis in the adipose tissue in patients with advanced fibrosis. Furthermore, we found a positive correlation between angiogenesis and PVMs (r = 0.51, p = 0.04). Finally, using the clearing technique we found that the angiokine EGFL7 co-localize with PVMs. Moreover, we found that PVMs from patients with advanced fibrosis had higher EGFL7 secretion compared to PVMs from patients without hepatic fibrosis (p = 0.042).
Conclusion: We report an increased abundance of PVMs' subset in the adipose tissue at advanced stages of NAFLD which might contribute to local angiogenesis. The correlation between PVMs and adipose tissue angiogenesis in advanced NAFLD suggests that this subset of ATM could promote liver disease progression.

WED-404

The E2F2-miR34a-5p axis is involved in the biliary metabolism dysregulation in NASH

Email: patricia.aspichueta@ehu.eus

Background and aims: Accumulation of toxic bile acids together with lipotoxic lipids promote non-alcoholic steatohepatitis (NASH) progression. E2F2 transcription factor is upregulated in metabolic associated fatty liver disease (MAFLD). A connection between E2F2 and miRNAs has been described in several pathologies but not in liver disease. Our aims were 1) to identify if liver E2F2 regulates biliary metabolism in NASH-progression 2) to investigate the implication of liver E2F2 in bile acid induced liver damage.
Method: Progressive NASH was induced in *E2f2*$^{-/-}$ and WT mice by injection of diethylnitrosamine (DEN) and feeding a high-fat diet (HFD) for 6 months or by a Choline-deficient HFD (ChD-HFD) for 6 months. Chow diet-fed (CD) 3 month-old mice were also used. E2F2 was overexpressed in liver using adeno-associated viruses serotype 8 (AAV8). Biliary duct ligation (BDL) was included as a cholestasis model. miRNA sequencing was performed in mouse livers. Metabolic fluxes, lipid content, transcriptome analysis and gene expression were analyzed.
Results: *E2f2*$^{-/-}$ mice were protected from NASH in DEN-HFD and ChD-HFD models. The expression of *Chpt1*, involved in phosphatidylcholine (PC) synthesis, A*bcg5* and *Abcg8*, regulators of cholesterol (CL) secretion in bile, and *Cyp7a1* and *Bsep*, involved in bile acid metabolism, was increased in DEN-HFD *E2f2*$^{-/-}$ and ChD-HFD *E2f2*$^{-/-}$ compared with corresponding WTs. Analysis of metabolic fluxes showed that in DEN-HFD *E2f2*$^{-/-}$ mice the increased synthesis of PC and CL did not induce their storage in liver, suggesting an increased efflux into bile. Moreover, hepatic bile acid content was lower in ChD-HFD *E2f2*$^{-/-}$ mice when compared with their controls. miRNA sequencing and validation by qPCR showed that in DEN-HFD *E2f2*$^{-/-}$ mice, resistant to MAFLD-progression, miR34a-5p, miR155-5p and miR146a-5p were downregulated. miR34a-5p was the only miRNA found decreased in CD-fed *E2f2*$^{-/-}$ mice, and increased when E2F2 was overexpressed in liver. The same profile was observed in *E2f2*$^{-/-}$ ChD-HFD mice, showing lower miR34a-5p levels when compared with corresponding WTs. A crosschecked analysis between upregulated genes in DEN-HFD *E2f2*$^{-/-}$ mice and miR34a-5p predicted targets, according to miRWalk software, showed that analyzed genes involved in synthesis and secretion of bile and biliary lipid genes were among them. *E2f2*$^{-/-}$ mice were also protected from BDL-induced cholestasis, a model in which E2F2 and miR34a-5p are upregulated. This protection was lost when primary hepatocytes of *E2f2*$^{-/-}$ mice were treated with bile acids and miR34a-5p mimic.
Conclusion: E2F2 regulates miR34a-5p expression in liver disease. Its deficiency promotes the generation and efflux of bile acids and biliary lipids, protecting the liver against their accumulation in NASH and cholestasis.

Email: michael.trauner@meduniwien.ac.at

Background and aims: Progressive non-alcoholic fatty liver disease is increasingly becoming a global health problem associated with underlying genetic polymorphism, the rs738409; C > G in patatin-like phospholipase domain-containing protein 3 (PNPLA3). Inflammation is the main driver for advanced liver injury, and we previously established that PNPLA3 I148M (148M^{oe}) macrophage is pro-inflammatory. Since the metabolic state of macrophage determines its pro-inflammatory phenotype, we were interested in whether the PNPLA3 I148M affects mitochondrial function and thereby alters metabolic function.

Method: To explore mitochondrial and metabolic function in a macrophage cell line, we established a THP-1 stable cell line overexpressing the PNPLA3 wildtype and I148M isoforms. Gel-shift, gene expression analysis, metabolomics, and extracellular flux analysis were conducted. Reactive oxygen species (ROS) was measured by flow cytometry using MitoSOX assay.

Results: In 148M^{oe} M1 macrophages, glycolytic genes like *GLUT1*, *HK1*, *LDHA*, and *HIF-alpha* were significantly increased compared to the WT^{oe}. The 148M^{oe} M1 macrophage had reduced basal (−29%) and maximum (−48%) mitochondrial respiration, as well as downregulation of *CPT1-alpha* (−63%), compared to the WT^{oe}. In agreement, the metabolic fluxes like Itaconate, succinate, fumarate, FAD, and NAD were reduced significantly in the I148M^{oe} macrophage, suggesting reduced oxidative phosphorylation. In line with the extracellular flux analysis, the I148M^{oe}, compared to the WT^{oe}, has reduced mitochondrial ROS-positive cells (−15%). Significantly downregulated *MCU* and *IP3R* suggest that impaired Ca^{2+} signaling may, at least in part, be responsible for the reduced ROS in 148M^{oe} macrophages. Despite high ROS levels in the WT^{oe}, their mitochondrial function remained intact, suggesting that potential protective mechanisms are in place. The expression levels of *SOD2*, *SOD3*, and *TXNRD1*, *TXNRD2* were significantly upregulated in the WT^{oe} compared to 148M^{oe}. In addition, glutathione biosynthesis and metabolism were reduced in the I148M^{oe} compared to the WT^{oe}. In line, genes associated with mitochondrial function like *PGC1-alpha*, *NRF1/2*, *mt-ND1*, *16sRNA*,

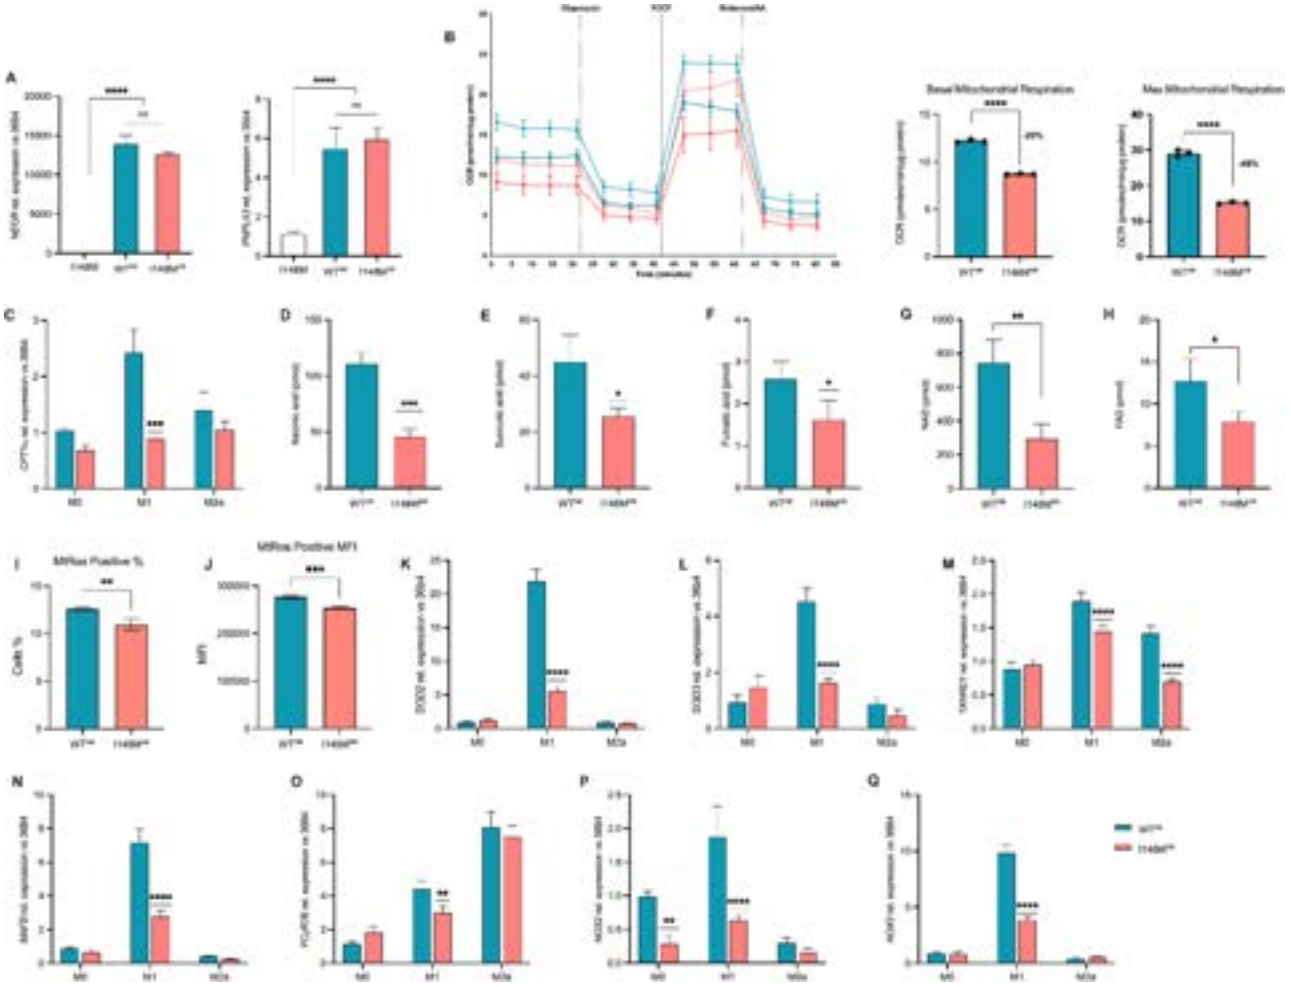

Figure: (abstract: WED-405).

LC3A, and *LC3B* were markedly reduced in the 148M^{oe}. WT^{oe} macrophages had a higher number of mitochondria, as reflected by significantly upregulated *mt-ND1* and *16sRNA* compared to the I148M^{oe}. Interestingly, *MAFB* (−57%), which controls phagocytosis through the opsonic phagocytic receptor, FCγR2B (−30%), was significantly reduced in the 148M^{oe} macrophage. Likewise, *NOS2* and *NOX2*, the two components of the phagolysosome, were reduced, respectively, by 61% and 55% in the I148M^{oe} macrophages. In addition, Itaconate, a macrophage-induced metabolite that acts as an antimicrobial effector, was reduced by 59% in 148M^{oe} macrophage.
Conclusion: Our findings show that the PNPLA3 148Moe reprograms macrophage metabolism away from mitochondrial respiration. Reduction of mitochondrial ROS, *NOS2, NOX2, MAFB* and *FCγR2B* coupled with reduction of itaconate in the 148Moe may lower their phagocytotic and antimicrobial activities.

WED-406

Toll-like receptor 5 signalling mediates pro-inflammatory and fibrogenic responses in non-alcoholic steatohepatitis (NASH)

Wenhao Li[1], Patricia Garrido[1], Iris Gines Mir[1], Kathryn Waller[1], Anja Versteeg-de Jong[1], James Hallimond Brindley[1], Waleed Khan[1], Gillian Hood[1], James Boot[2], Chaz Mein[2], Kalpana Devalia[3], John Loy[3], William Alazawi[1]. [1]*Barts Liver Centre, Blizard Institute, London, United Kingdom,* [2]*Genome Centre, Queen Mary University of London, London, United Kingdom,* [3]*Homerton University Hospital NHS Foundation Trust, United Kingdom*
Email: wenhao.li@doctors.org.uk

Background and aims: Non-alcoholic steatohepatitis (NASH) is a common, progressive inflammatory liver condition with no approved therapies. Hepatocyte lipotoxicity results in inflammation, immune (T cell) infiltration and stellate cell activation leading to fibrosis. Hepatic Toll-like receptors (TLR) sense gut-derived inflammatory signals such as lipopolysaccharide (via TLR4) and flagellin (TLR5) and may represent therapeutic targets in NASH. Flagellin and TLR5 have been implicated in murine NASH models and here we test the hypothesis that this pathway plays a pathogenic role in human disease.
Method: Plasma TLR5 binding capacity and flagellin, stool *Flic* gene load (shotgun metagenomics sequencing) and hepatic *TLR5* gene expression were measured in samples from 139 patients and 24 controls recruited from outpatient clinics and elective bariatric surgery. Lipotoxicity was modelled in vitro using oleic (1 mM) and palmitic (0.5 mM) acid in human hepatocyte-like (HepG2) and stellate (LX2) cells.
Results: Compared to controls, plasma TLR5-binding capacity was increased in advanced NASH fibrosis but not earlier stages of disease (TLR4-binding increased at all disease stages) as was flagellin concentration (538.3v 745.8 pg/ml, $p = 0.004$) which normalised in samples taken median 83 days following bariatric surgery ($n = 20$, $p = 0.005$). Stool *Flic* gene expression and hepatic *TLR5* (but not *TLR2* or *TLR4*) expression were increased in NASH, along with markers of intestinal permeability (FABP2, D-lactate). In vitro, TLR5 inhibition attenuated toxic lipid-mediated IL8 protein expression (all $p < 0.001$, vs control) in HepG2. TLR5 inhibition also attenuated both flagellin- and toxic lipid-induced IL8 production in LX2 cells by 1.9-fold ($p = 0.019$) and 2.1-fold ($p = 0.032$) respectively. Although neither flagellin nor toxic lipids directly induced pro-collagen 1a1 production in LX2 cells, lipid-injured HepG2-conditioned media induced 3.2-fold increase in pro-collagen 1a1 production compared to control ($p = 0.0015$). TLR5 inhibition in HepG2 cells prior to media transfer led to a reduction in LX2 pro-collagen 1a1 production ($p = 0.030$). Similarly, lipid-injured HepG2-conditioned media induced Th1 differentiation of naïve T cells from healthy donors in a TLR5-dependent manner ($p < 0.001$).
Conclusion: TLR5 signalling is activated in human NASH, reverses following bariatric surgery and is associated with mechanisms of lipid-mediated inflammation and stellate cell activation. This pathway has potential as a novel therapeutic target in NASH.

WED-407

Characterization of extracellular vesicles derived from human precision-cut liver slices in non-alcoholic fatty liver disease

Yana Geng[1], Ke Luo[1], Janine Stam[1,2], Dorenda Oosterhui[1], Alan Gorter[1], Marius van den Heuvel[3], Rossella Crescitelli[4], Vincent de Meijer[5], Justina Wolters[1], Peter Olinga[1]. [1]*Univerisity of Groningen, Department of Pharmaceutical Technology and Biopharmacy, Netherlands,* [2]*University of Groningen, Department of Analytical Biochemistry, Netherlands,* [3]*University Medical Center Groningen, Department of Pathology and Medical Biology, Netherlands,* [4]*University of Gothenburg, Sahlgrenska Center for Cancer Research and Wallenberg Centre for Molecular and Translational Medicine, Sweden,* [5]*University Medical Center Groningen, Department of Surgery, Netherlands*
Email: p.olinga@rug.nl

Background and aims: Extracellular vesicles (EVs) are membranous and cell-derived vesicles that contain multiple biomolecules which reflect the cellular state. In non-alcoholic fatty liver disease (NAFLD), EVs show great potential in helping understand the pathogenesis of the disease and be used as biomarkers. However, so far, there is no information available on liver tissue-derived EVs in the context of NAFLD. Therefore, in this study, we aim to characterize tissue-derived EVs from an *ex vivo* model of human precision-cut liver slices (PCLS).
Method: EVs were isolated from human PCLS, prepared from either healthy livers (patients undergoing partial hepatectomy or organ donation) or non-alcoholic steatohepatitis (NASH) cirrhotic livers (liver explants from transplantations). PCLS were incubated for 48 hours in a normal medium (WEGG: Williams' Medium E with GlutaMAX medium supplemented with 11 mM glucose and 10 μg/ml gentamycin) or a modified medium to mimic the pathophysiological condition of NAFLD (GFIPO: WEGG supplemented with 25 mM glucose, 5 mM fructose, 1 nM insulin, 0.24 mM palmitic acid, 0.48 mM oleic acid). The PCLS-derived EVs were isolated by differential ultracentrifugation and further characterized by transmission electron microscopy (TEM), western-blot, nanoparticle tracking analysis and mass spectrometry.
Results: The transmission electron microscopy pictures showed the presence of particles with typical EV elements, with sizes between 50 and 250 nm. We confirmed by western blot typical markers of EVs: CD81, CD9 and Rab7 and the absence of cytochrome-c indicating high purity of the EV pellet. NASH PCLS produced a higher amount of EVs compared to healthy PCLS ($p < 0.05$), although there was no significant difference regarding the size of EVs. Using mass spectrometry we identified 2636 proteins both in NASH PCLS-derived EVs and healthy PCLS-derived EVs. There are 151 proteins significantly up-regulated, and 142 proteins significantly down-regulated in EVs derived from NASH PCLS compared to EVs derived from healthy PCLS (FDR < 0.05). GO molecular function analysis showed that those significantly changed proteins were largely enriched for protein/lipid binding functions. By employing the EV proteins as ligands and using a manually curated ligand-receptor database-Cellinker, we found 150 cognate-binding partners that were significantly different in NASH PCLS-derived EVs. The up-regulated cognate-binding partners showed potential in modulating metabolic status (via inhibin βE (INHBE)), promoting fibrosis (via latent transforming growth factor β binding protein 1 (LTBP1), integrin subunit β5 (ITGB5)) and inducing inflammation (via C-X-C motif chemokine 12 (CXCL12)). Furthermore, we found that epithelial cell adhesion molecule (EPCAM) and integrin subunit α3 (ITGA3) enriched in our EVs are positively and increasingly associated with the progression of NAFLD, which showed the potential of liver-derived EVs as biomarkers for NAFLD.
Conclusion: In this study, we characterized the EVs derived from healthy and NASH human PCLS with the characterization of their protein compositions. The different protein cargos in EVs from NASH

versus healthy PCLS may assist future studies on identifying liver-specific EVs, understanding the pathogenesis of NAFLD and NAFLD-associated complications, as well as in finding specific EV biomarkers for NAFLD.

Email: patricia.aspichueta@ehu.eus

Background and aims: Lipotoxicity is associated to non-alcoholic steatohepatitis (NASH) and generates stress and toxic species that activate the DNA damage response (DDR). This response is associated with the progression of the disease, characterized by the over-expression of the E2F transcription factors. The aims here were to: 1) Identify the role of DNA damage in the metabolic dysregulation of NASH; 2) Investigate the involvement of E2F2.
Method: A cohort of obese patients with liver biopsy classified as NASH or no-NASH was used to analyze hepatic levels of pH2AX (DNA damage marker) and E2F2, hepatic and serum parameters and the activity of hepatic mitochondrial complexes. E2f2 knockout mice (E2f2-/-) and their controls, injected with diethylnitrosamine (DEN) (DNA damage-inducing agent) and fed a high-fat diet (DEN-HFD) for 10 weeks or a choline-deficient diet HFD (CD-HFD) for 6 months were used to induce progressive liver disease. Primary cultures of hepatocytes were used to induce DNA damage by DEN or palmitic acid (PA).
Results: NASH patients showed higher levels of pH2AX than no-NASH patients, which correlated positively with parameters of worse metabolic status. In addition, those NASH patients with higher DNA damage had increased hepatic triglyceride (TG) and diglyceride (DG) levels, and higher mitochondrial complex IV activity, without showing higher levels of ketone bodies, suggesting higher ROS-generating activity but inefficient fatty acid oxidation (FAO). These results were reproduced in mouse models of NASH, suggesting that DNA damage participates in the metabolic rewiring inhibiting FAO in a condition of lipid-overload. Precisely, levels of the FAO regulator E2F2 correlated positively with pH2AX just in NASH patients. Furthermore, E2f2-/- mice were protected from the DNA damage induced by DEN and lipotoxic diets. The in-vitro studies corroborated that E2f2-/- hepatocytes were protected from PA-induced DNA damage and the associated rewiring in lipid metabolism. In concordance, overexpressing E2f2 in hepatocytes led to increased DNA damage when treated with PA or DEN. When classifying NASH patients in a subset of high E2F2 and high pH2AX-hepatic protein levels, these patients showed increased alteration of glucose metabolism, liver accumulation of lipids, markers of atherogenesis and FGF21 secretion compared to NASH patients with lower levels of both proteins. This subset of NASH patients with high E2F2 and high pH2AX levels were younger, suggesting that this subpopulation has an accelerated disease progression.
Conclusion: DNA damage dysregulates lipid metabolism affecting the progression of NASH in an E2F2-dependent mechanism. Lack of E2F2 protects against lipotoxicity-induced DNA damage, while its overexpression exacerbates it. Thus, targeting E2F2 might be valuable to reduce the DDR associated to NASH and its metabolic complications.

WED-409

Uncovering a novel potential target in non-alcoholic fatty liver disease

Stine Marie Praestholm[1], Jorge Correia[1], Jorge Ruas[1]. [1]*Karolinska Institutet, Physiology and pharmacology, Stockholm, Sweden*
Email: jorge.ruas@ki.se

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease in the world affecting 25% of the adult population. The global prevalence of NAFLD is expected to increase in consistence with the increase in type 2 diabetes and obesity, which are well-known risk factors for NAFLD. We have identified a zinc finger protein of previously unknown function (TRAIN) and discovered that it operates as a regulator of inflammation, extracellular matrix remodeling, and fibrogenesis. In this project we investigate the function of TRAIN in NAFLD/non-alcoholic steatohepatitis (NASH) and evaluate its potential as a novel therapeutic target.
Method: We are using genetic and viral approaches to modulate TRAIN expression in mice and in cell cultures in combination with NAFLD/NASH/liver injury inducing treatments to investigate the role of TRAIN in liver disease. Specifically, we have generated whole-body and hepatocyte-specific TRAIN knockout (KO) mice and are using adenovirus (Ad) and adeno-associated virus (AAV) delivery systems to acutely induce, repress or KO TRAIN expression. These mice are then challenged in different models of NAFLD/NASH/liver injury including feeding mice on a western diet, methionine-choline deficient (MCD) diet or through CCl4 injections. Hepatocyte and hepatic stellate cell lines as well as mouse and human primary hepatocytes are treated with NAFLD-associated stimuli to investigate the NAFLD-driven pathways regulating TRAIN expression. Lastly, we are using GST pull-down followed by mass spectrometry to investigate the molecular function of TRAIN.
Results: TRAIN expression is elevated in liver disease in both human patients and in various mouse models. Importantly, we have found that increasing liver TRAIN expression, within pathophysiological levels, is sufficient to drive NASH-like metabolic, morphological, histological, and hepatic transcriptional characteristics. This includes TRAIN-induced expression of a panel of genes associated with immune response, extracellular tissue remodeling and fibrosis. Interestingly, TRAIN gene ablation in hepatocytes ameliorates glucose homeostasis and energy expenditure in NASH-diet fed mice. In cell cultures, NAFLD-associated conditions including oxidative stress, lipid accumulation as well as TGFb1, IL-6 and IFNg activated pathways drive TRAIN expression in both hepatocytes and in hepatic stellate cells. Moreover, we have found that TRAIN associates with RNA binding proteins and binds a specific set of RNAs.
Conclusion: TRAIN is a novel regulator of inflammation involved in some of the key molecular and cellular events of NAFLD/NASH development and progression. Research in this project could form the foundation for finding a new class of pharmacological therapies for NAFLD/NASH and potentially other liver inflammatory diseases, such as alcoholic hepatitis.

WED-410

mir-22 inhibition as glp1 agonist orthogonal mechanism for nafl and nash treatment

Riccardo Panella[1], Sakari Kauppinen[1], Simone Tomasini[1], Henrik B. Hansen[2], Michael Feigh[2]. *[1]Aalborg University, Center for RNA Medicine, Clinical Medicine, Copenhagen SV, Denmark, [2]Gubra, Hørsholm, Denmark*
Email: riccardop@dcm.aau.dk

Background and aims: MicroRNA-22 (miR-22) orchestrates multiple pro-lipogenic and adipogenesis programs through both direct and indirect signaling mechanisms. Genetic ablation of miR-22 has been demonstrated to suppress these programs resulting in stimulated energy expenditure and brown adipose tissue activation. Collectively, this supports the relevance of miR-22 inhibition in the treatment of obesity and associated disease complications, notably non-alcoholic steatohepatitis (NASH). The present study aimed to characterize locked nucleic acid (LNA) oligonucleotide-based therapy targeting miR-22 in preclinical models of obesity and NASH.
Method: The LNA-based anti-miR-22 oligo was designed using a mix-mer strategy targeting the seed region of hsa-miR-22-3p, evolutionary conserved between mouse and human. Female C57BL/6 mice were made diet-induced obese by feeding a high-fat diet (60 kcal% fat) for 24 weeks (DIO mice). DIO mice (n = 5–8 per group) received (SC) vehicle, scrambled LNA (10 mg/kg) or LNA anti-miR-22 (10 mg/kg) once weekly throughout the feeding period. Other female C57BL/6 mice were fed the Gubra-Amylin-NASH (GAN) diet high in fat, fructose and cholesterol for 38 weeks prior to study start (GAN DIO-NASH mice). Only GAN DIO-NASH mice with liver biopsy-confirmed NASH (NAFLD Activity Score, NAS ≥ 5) and fibrosis (stage ≥1) were included and stratified into treatment groups based on quantitative fibrosis histology. GAN DIO-NASH mice (n = 14–16 per group) were administered (SC) vehicle, scrambled LNA (SCR, 10 mg/kg) or LNA anti-miR-22 (10 mg/kg) once weekly for 24 weeks. Vehicle-dosed chow-fed mice (n = 10) served as normal controls. Histopathological pre-to-post individual assessment of NAS and fibrosis stage was performed in GAN DIO-NASH mice. In both studies, terminal end points included body weight and quantitative liver histology.
Results: Vehicle and SCR-dosed DIO mice showed similar robust and progressive weight gain over the course of the study. In contrast, LNA anti-miR-22 treatment completely prevented development of obesity and steatosis in DIO mice. Food intake in DIO mice was unaffected by treatments. LNA anti-miR-22 reduced body weight in GAN DIO-NASH mice while also reducing NAS, driven by significant improvements in steatosis and lobular inflammation scores. The benefits on liver histology in GAN DIO-NASH mice were further supported by reduced quantitative histological markers of steatosis (% area of lipids, % lipid-laden hepatocytes) and inflammation (galectin-3.
Conclusion: We have developed a locked nucleic acid (LNA) oligonucleotide efficiently inhibiting miR-22 function. LNA anti-miR-22 treatment effectively prevents development of obesity and improves liver disease hallmarks in clinical translational mouse models of obesity and NASH without affecting food consumption, supporting further development of LNA anti-miR-22 for obesity and obesity-related liver complications.

WED-411

Biomarkers identifying hepatic inflammation in non-alcoholic fatty liver disease (NAFLD)

Mikkel Werge[1], Annabelle Hoegl[2], Marie Louise Therkelsen[2], Mads Grønborg[2], Gianluca Mazzoni[2], Lea Mørch Harder[2], Henning Hvid[2], Elias Rashu[1], Mira Thing[1], Liv Hetland[1], Anders Junker[1], Reza Serizawa[3], Mogens Vyberg[3,4], Elisabeth Galsgaard[2], Lise Lotte Gluud[1,5]. *[1]Copenhagen University Hospital Hvidovre, Gastro Unit, Hvidovre, Denmark, [2]Novo Nordisk A/S, Research and Early Development, Maaloev, Denmark, [3]Copenhagen University Hospital Hvidovre, Pathology, Hvidovre, Denmark, [4]Aalborg University Copenhagen, Center for RNA Medicine, Copenhagen SV, Denmark, [5]University of Copenhagen, Clinical Medicine, Copenhagen N, Denmark*
Email: edg@novonordisk.com

Background and aims: Hallmarks of non-alcoholic steatohepatitis (NASH) are steatosis, lobular inflammation and hepatocyte ballooning driving fibrosis and progression to cirrhosis, end-stage liver disease and hepatocellular carcinoma. The aim of the study was to identify plasma proteins as non-invasive biomarkers of hepatic inflammation in NAFLD patients.
Method: LC-SM based plasma proteomics was conducted on 77 healthy controls and 198 NAFLD patients (F0 = 42, F1 = 55, F2 = 45, F3 = 26, F4 = 30) in the Fatty Liver Disease in Nordic Countries (FLINC) cohort. A combination of differential expression analyses and machine learning (SVM) was used to identify novel biomarker candidates. Immunohistochemistry of pan-leucocyte marker CD45 in formalin-fixed paraffin-embedded (FFPE) liver biopsies determined overall hepatic inflammatory. CD45 proportionate area for 148 NAFLD and 14 controls were calculated by digital image analysis. Gene expression of candidate biomarkers was assessed from bulk transcriptomics in the same FFPE liver biopsies from 118 NAFLD patients and 12 controls.
Results: Analysis of the LC-MS dataset identified a 4-protein panel that were able to identify NAFLD patients and controls in 93% and 93% of cases, respectively: Aldolase B (ALDOB), paraoxonase 3 (PON3), a disintegrin and metalloproteinase with thrombospondin motifs like 2 (ADAMTSL2), and cathepsin D (CSTD). CD45 proportionate area was 2.08% and 3.11% (median) in controls and NAFLD patients, respectively. Differential expression analysis of plasma proteomics identified 6 upregulated proteins in non-cirrhotic NAFLD patients with

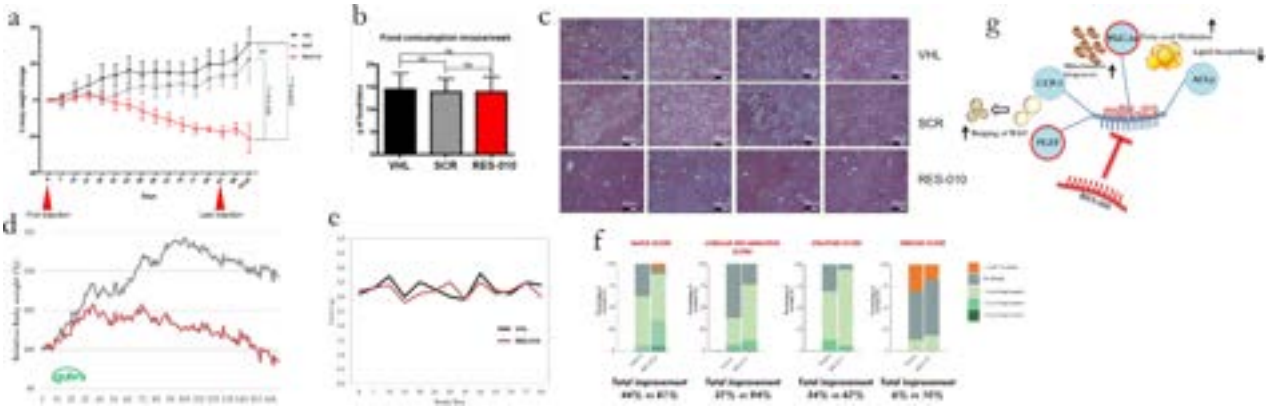

Figure: (abstract: WED-410).

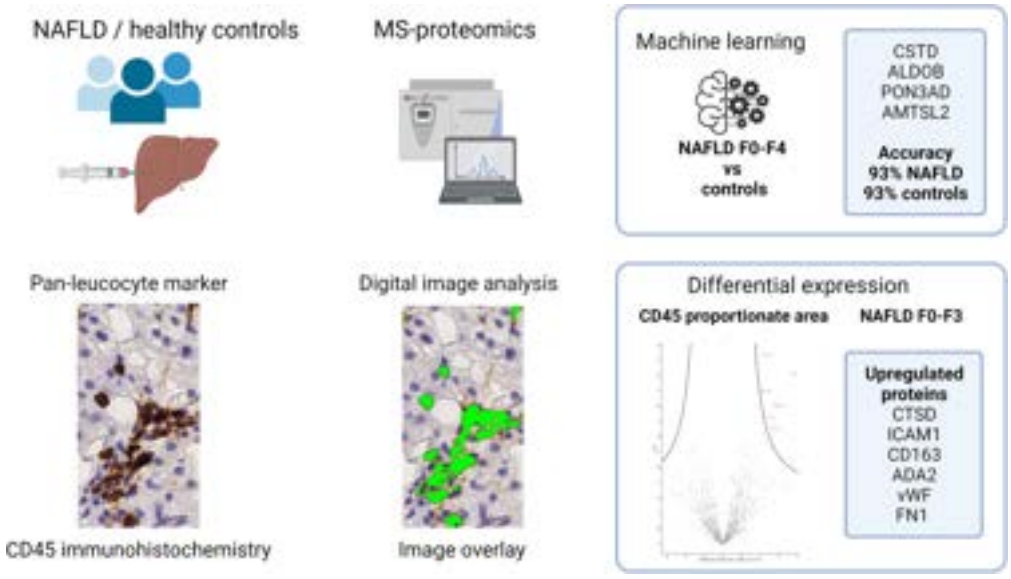

Figure: (abstract: WED-411).

increased hepatic CD45 proportionate area [High >3.5 (n = 60) % vs Low <2.5% (n = 49)]: Intracellular adhesion molecule 1 (ICAM1) mediating leukocyte endothelial transmigration), adenosine deaminase 1 (ADA2) expressed predominantly in macrophages), CD163 marker of monocyte/macrophage lineage, von Willebrand factor (vWF) increased with adverse changes to the endothelium, fibronectin 1 (FN1) a fibroblast-derived glycoprotein present both in plasma and extracellular matrix, and cathepsin D (CSTD) an endolysosomal protease linked to deregulated metabolism and inflammation in NAFLD. Interestingly, only CTSD was upregulated in non-cirrhotic NAFLD patients with biopsy-confirmed lobular inflammation. Hepatic gene expression of ICAM1, ADA2, CD163, and vWF was, moreover, positively associated with CD45 proportionate area when assessed by bulk transcriptomics ($p = 0.0002$, $p = 1.06^{*}10\text{-}7$, $p = 0.0008$, and $p = 0.001$, respectively). In contrast, hepatic CTSD and FN1 gene expression did not correlate with CD45 area fraction. Increased plasma levels of CTSD, ICAM1, ADA2, CD163, and vWF, but not FN1, were associated with fibrosis.

Conclusion: We identified 6 plasma proteins as potential biomarkers of overall hepatic inflammation in non-cirrhotic NAFLD patients. High levels of hepatic inflammation were associated with fibrosis and characterized by endothelial activation and increased monocyte/macrophage cell infiltration.

WED-412

Peroxisome proliferator-activated receptor alpha and estrogen related receptor alpha ligand combinations ameliorate non-alcoholic fatty liver disease

Milton Antwi[1,2,3,4], Sander Lefere[2,4], Lisa Koorneef[1], Anneleen Heldens[2,4], Louis Onghena[2,4], Anja Geerts[2,4], Lindsey Devisscher[2,3], Karolien De Bosscher[1]. [1]*Translational Nuclear Receptor Research lab, VIB-UGent Center for Medical Biotechnology, UGent Department of Biomolecular Medicine, Gent, Belgium,* [2]*Liver Research Center Ghent, Ghent University, Ghent University Hospital, Gent, Belgium,* [3]*Gut-Liver Immunopharmacology unit, Ghent University, Department for Basic and Applied Medical Sciences, Gent, Belgium,* [4]*Hepatology Research Unit, Department Internal Medicine and Pediatrics, Liver Research Center, Ghent University, Gent, Belgium*
Email: milton.antwi@vib-ugent.be

Background and aims: As a result of the increasing prevalence of obesity, non-alcoholic fatty liver disease (NAFLD) has become the most common liver disease worldwide. Left untreated, NAFLD can progress to non-alcoholic steatohepatitis (NASH), cirrhosis and primary liver cancer. There is currently no approved pharmacotherapy available for NAFLD. Two nuclear receptor candidates, peroxisome proliferator-activated receptor (PPAR) alpha and estrogen-related receptor (ERR) alpha independent findings have been linked as a therapeutic target against NALFD. Additionally, literature findings support a close functional interconnection between both receptors. We therefore studied whether pharmacological modulation of PPARalpha and ERRalpha in tandem can inhibit NAFLD progression.

Method: The *in situ* protein expression and localization of PPARalpha and ERRalpha in healthy control, NAFLD, and NASH patients from Ghent University Hospital were studied by confocal microscopy. To evaluate a potential nuclear receptor crosstalk, serum-starved human hepatoma (HEPG2) cells were treated with PPARalpha agonist Pemafibrate (5 μM) and ERRalpha inverse agonist compound C29 (5 μM). Using a diabetic background streptozotocin (STZ)-western diet (WD) mouse model, male mice were fed a western diet from 4 to 12 weeks of age, and treated with Pemafibrate (0.1 mg/kg) and C29 (10 mg/kg) from weeks 6 to 12 via daily oral gavage. Clinical features, blood parameters, histology and gene expression of the liver were evaluated.

Results: Total PPARalpha protein expression decreased in NAFLD patients and further diminished in NASH patients ($p = 0.042$). Conversely, ERRalpha protein expression was not significantly affected in both NAFLD and NASH patients. PPARalpha protein expression outside the nucleus of the hepatocytes decreased in NASH patients ($p = 0.0293$). ERRalpha protein expression was localized more outside the nucleus similarly in healthy, NAFLD and NASH patients. Both nuclear receptors overlapped to a greater extent in healthy controls compared to NASH patients ($p = 0.046$). In vitro, PPARalpha and ERRalpha ligand combination increased the expression of genes involved in lipid metabolism. In vivo, mice treated with the ligand combination showed improved steatosis, inflammation, NAFLD activity score ($p < 0, 0001$) and fibrosis ($p = 0.042$), and fewer and smaller liver tumours compared to untreated or single treated mice. The ligand combination decreased blood serum triglyceride level ($p = 0, 0042$), and improved gene expression of markers involved in glucose and lipid metabolism.

Conclusion: These findings support that dual nuclear receptor targeting by increasing PPARalpha and diminishing ERRalpha activity may represent a viable novel strategy against NAFLD.

WED-413

PNPLA3, MBOAT7 and TM6SF2 modify mitochondrial dynamics in NAFLD patients: dissecting the role of cell-free circulating mtDNA and copy number

Miriam Longo[1], Erika Paolini[1], Marica Meroni[1], Michela Ripolone[1], Laura Napoli[1], Giada Tria[1], Marco Maggioni[1], Maurizio Moggio[1], Anna Ludovica Fracanzani[1], Paola Dongiovanni[1]. [1]*Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy, Italy*
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: Mitochondrial (mt) dysfunction is a hallmark of progressive NAFLD. MtDNA copy number (mtDNA-CN) and cell-free circulating mtDNA (ccf-mtDNA), which reflect mt-mass and mt-dysfunction, respectively, are gaining attention for NAFLD non-invasive assessment. We demonstrated that *PNPLA3*, *MBOAT7* and *TM6SF2* deficiency in HepG2 cells increased mt-mass, mtDNA-CN and ccf-mtDNA. To assess the genetic contribution on mt-dynamics, mtDNA-CN and ccf-mtDNA in 1) primary mouse hepatocytes silenced for *PNPLA3*|*MBOAT7*/*TM6SF2* genes; 2) Discovery (n = 28) and Validation (n = 773) cohorts, including biopsied NAFLD patients, stratified according to number of risk variants (NRV = 3).
Method: Mt-morphology was assessed by TEM. mtDNA-CN was measured in the entire Validation cohort (n = 773), while ccf-mtDNA in a subgroup (n = 300) with available serum samples. mtDNA-CN and mt-related genes were evaluated in liver biopsies.
Results: Primary mouse hepatocytes challenged with fat overload or *PNPLA3*/*TM6SF2*|*MBOAT7* co-silencing lowered mt-fusion paralleled by higher mt-fission and ccf-mtDNA release, suggesting that lipid accumulation and genetics may independently unbalance mt-dynamics. In the Discovery cohort, NRV = 3 patients showed the highest mtDNA-CN compared to those with 1–2 or no variants. At TEM, NRV = 3 carriers increased mt-mass and presented an elevated pattern of mt-morphological alterations (swollen shapes, double membranes rupture). In the Validation cohort, mtDNA-CN associated with the NAFLD histological spectrum and NRV = 3 at multivariate analyses, supporting that both NAFLD severity and genetics may modulate mt-dynamics. In liver biopsies, mtDNA-CN was higher in NRV = 3 patients together with reduction of mt-fusion and activation of mt-fission, resembling what observed in hepatocytes. Ccf-mtDNA was augmented in NRV = 3 patients with low-moderate/severe NAFLD, thereby sustaining that this effect was amenable to the 3 at-risk polymorphisms. ROC curves showed that mtDNA-CN discriminated NAFLD subjects *vs* controls (AUC: 0.71), while ccf-mtDNA was highly predictive of NAFLD-HCC vs NALFD (AUC: 0.79).
Conclusion: mtDNA-CN and ccf-mtDNA may have pathological and predictive significance in NAFLD patients at high-risk, especially in those genetically-predisposed.

WED-414

NAT10-mediated N4-acetylcytidine of hepatic lipogenesis-associated mRNA contributes to maternal high-fat diet-induced non-alcoholic fatty liver disease in juvenile offspring

Qianren Zhang[1], Tianyi Ren[1], Jiangao Fan[1]. [1]*Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, China*
Email: fanjiangao@xinhuamed.com.cn

Background and aims: Growing evidence have shown that early life exposure to maternal high fat diet (HFD) during pregnancy and lactation increases the risk of non-alcoholic fatty liver disease (NAFLD) in juvenile offspring, which is regulated by epigenetic machinery. As a novel epi-transcriptomic modification, N4-acetylcytidine (ac4C) could enhance the expression of target gene by increasing mRNA stability and translation efficiency. The aim of this study was to explore the involvement of ac4C and its writer protein N-acetyltransferase 10 (NAT10) in maternal HFD-induced NAFLD.
Method: 6-week-old female C57BL/6J mice were fed either chow diet or HFD for 6 weeks before fertilization and kept on the same diet throughout gestation and lactation. At weaning, morphological and biochemical indicators of pups were analyzed. Hepatic NAT10 expression and ac4C abundance were also assessed. Hepatocyte-specific *Nat*10 knockout (*Nat10*^{HKO}) mice were generated by intercrossing *Nat10*$^{fl/fl}$ mice with Alb-Cre mice. Chow-fed male *Nat10*^{HKO} mice were mated with chow-fed or HFD-fed (6-week feeding before fertilization, maintained respective diets during gestation and lactation) female *Nat10*$^{fl/fl}$ mice to generate *Nat10*^{HKO} and *Nat10*$^{fl/fl}$ littermates which could be subdivided into 4 groups: chow *Nat10*$^{fl/fl}$, chow *Nat10*^{HKO}, HFD *Nat10*$^{fl/fl}$ and HFD *Nat10*^{HKO}. All pups were sacrificed at weaning to assess body weight, liver histopathology and lipid metabolism. Transcriptomic-wide mapping of ac4C modification was performed on mRNA samples isolated from primary hepatocytes of pups, with the aid of RNA-seq and acetylated RNA immunoprecipitation sequencing (acRIP-seq).
Results: C57BL/6J offspring of HFD dams weighed more at weaning, exhibited higher hepatic triglyceride levels, had more hepatic lipid accumulation, expressed significantly higher NAT10, and presented markedly improved ac4C abundance in hepatocyte mRNAs, when compared with pups of chow C57BL/6J dams. Similarly, pups of the HFD *Nat10*$^{fl/fl}$ group exhibited more lipid droplets and triglyceride contents in livers than offspring from the chow *Nat10*$^{fl/fl}$ group. However, genetic ablation of *Nat10* in offspring hepatocytes markedly ameliorated hepatic steatosis induced by maternal HFD. Moreover, expression of lipogenesis-associated proteins, including SREBP-1c, phosphorylated ACC and FASN were also inhibited in HFD *Nat10*^{HKO} pups when compared with HFD *Nat10*$^{fl/fl}$ pups. RNA-seq and acRIP-seq results showed that *Nat10* deletion led to significantly reduced ac4C abundance in Srebp1c, Acc and Fasn, which was in line with suppressed transcriptional expressions and reduced half-lives of these mRNAs.

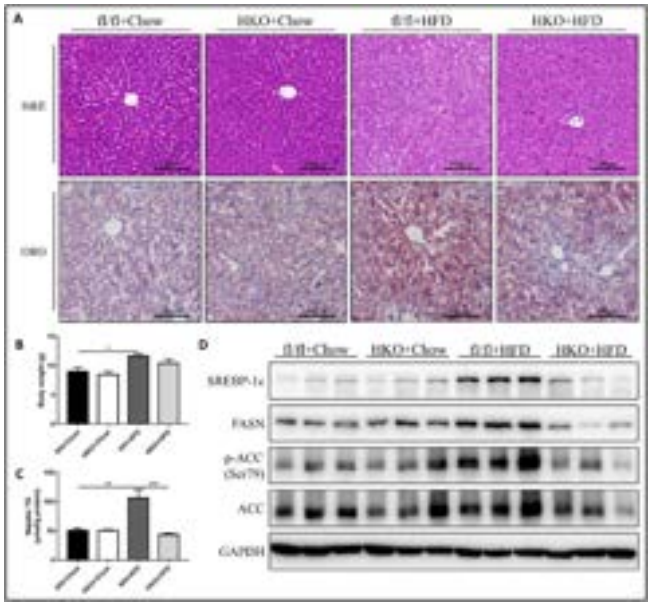

Figure:

Conclusion: NAT10-mediated ac4C modification on mRNAs of lipogenic genes played an important in maternal HFD induced offspring NAFLD, which serves as a potential therapeutic target.

WED-415

Type I NKT cells are involved in exacerbation of steatohepatitis in aged mice

Kazuyoshi Kon[1], Kumiko Arai[1], Akira Uchiyama[1], Hiroo Fukada[1], Toshifumi Sato[1], Shunhei Yamashina[1], Kenichi Ikejima[1]. [1]*Juntendo University School of Medicine, Department of Gastroenterology, Japan*
Email: kazukon@juntendo.ac.jp

Background and aims: The pathogenesis of non-alcoholic steatohepatitis (NASH) is still unclear. Aging is an independent risk factor for

exacerbation of NASH; however, the underlying mechanism is not well understood. NKT cells are classified into type I (iNKT cells) and type II NKT cells, and exhibit different interrelationships depending on disease. Therefore, our aim in this study was to investigate the role of type I and type II NKT cells in age-related exacerbation of steatohepatitis using aged mice and NKT knockout (KO) mice.
Method: Wild-type C57Bl/6 mice, type I NKT cell KO mice (Vα14KO), and type I + type II NKT cell KO mice (CD1dKO) aged 8 weeks (young) and 55 weeks (elder) mice were fed a high-fat/high-cholesterol diet (HFHC) or a control diet for 8 weeks. Expression of mRNA in liver tissue was quantified by RT-PCR. Liver fibrosis was visualized with Sirius Red staining.
Results: Whereas HFHC-fed wild young mice developed only trivial hepatic steatosis with slight elevation of serum ALT levels to 54 ± 11 IU/L, HFHC-fed wild elder mice showed severe macrovesicular steatohepatitis and the serum ALT level reached to 406 ± 46 IU/L. Serum ALT levels in young mice were unchanged in Vα14KO and significantly decreased to 41 ± 5 IU/L in CD1dKO compared to wild mice. In contrast, serum ALT levels of both Vα14KO and CD1dKO mice significantly decreased compared to the elder wild mice to 268 ± 45 IU/L and 159 ± 23 IU/L, respectively. HFHC increased the expression of TNFα/TLR4 mRNA in the liver tissue, and the expression was approximately twice as high in HFHC-fed elder mice as in HFHC-young mice. HFHC-induced upregulation of TNFα and TLR4 was significantly suppressed by Vα14KO/CD1dKO in both young and elder mice. Although the expression of PPARα mRNA in elder mice was not significantly changed by HFHC in wild mice, it was significantly enhanced in both Vα14KO/CD1dKO mice fed HFHC. Sirius Red staining showed pericentral fibrosis in HFHC-aged mice, while Vα14KO/CD1dKO did not induce fibrosis. Expression of TGFβ mRNA was enhanced only in HFHC-fed elder mice, and was significantly suppressed in both Vα14KO/CD1dKO.
Conclusion: These findings demonstrated that the type I NKT cells became more dominant for the induction of inflammatory cytokines in elder mice and causes the exacerbation of steatohepatitis and development of fibrosis. It was concluded that the activation of type I NKT cells plays an key role in the exacerbation of steatohepatitis with aging.

WED-416

Single-cell transcriptomics depicts metabolism reprogramming and immune landscape of bariatric surgery intervened non-alcoholic fatty liver

Shuai Chen[1], Xiurong Cai[2], Liming Tang[1], Adrien Guillot[3], Frank Tacke[3], Hanyang Liu[1,3]. [1]*Nanjing medical university, Changzhou medical center, China,* [2]*Charité Universitätsmedizin Berlin, Department of hematology, oncology and tumor immunology (CVK), Germany,* [3]*Charité Universitätsmedizin Berlin, Department of hepatology and gastroenterology (CVK), Germany*
Email: hanyang.liu@charite.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is one of the most common chronic liver diseases worldwide, composed of metabolic dysfunction, steatosis, inflammation and fibrosis. Importantly, non-alcoholic fatty liver (NAFL) caused by the elevated hepatic lipid deposition acts as not only the consequence of obesity, but also the early stage of the NAFLD. It has been reported that morbidly obese patients represent more than 90% of patients with NAFLD. Till now, no effective resolutions have been approved to effectively prevent the disease progression. Current evidence suggests that the weight loss has been considered as a potential treatment for NAFLD by remising hepatic steatosis, inflammation and fibrosis. Weight loss approaches include lifestyle alterations (mainly diet management), metabolic medicine and bariatric surgery (BS). Recently, BS is considered as a novel disease-modifying therapy for NAFLD, according to clinical studies. Despite physiological alterations, underlying mechanisms of cellular crosstalk and microenvironment remain indeterminate.
Method: In this study, we gathered open bulk RNA-seq datasets from patient's cohorts. Gene alterations of metabolism, inflammation and carcinogenesis were compared according to liver-derived transcriptomic data from post-surgery and diet managed patients. Furthermore, we established mouse BS models (including sleeve gastrectomy and by-pass surgery). As the ongoing work, we perform the single-cell transcriptomic analysis on liver tissues from mouse models [healthy, high-fat diet (HFD) + regression, HFD + sham surgery and HFD + BS mice). Furthermore, we will identify metabolism reprograming and immune landscape according to cell clustering, cellular interactions and functional enrichment analysis. To reveal the metabolism-related immune modulation, the metabolism-immune association and key factor will be demonstrated.
Results: We demonstrated that the post-BS livers show more improvements of metabolism-, inflammation- and carcinogenesis-related markers, compared to the diet management. In addition, differences were disclosed in immune cell infiltration (especially macrophage populations) in post-BS patients' livers. Accordingly, we speculate that the immune modulation in post-surgery livers might contribute to metabolic improvement, exerting superior effectiveness than the diet management. On this basis, we will be able to reveal the metabolism reprograming and immune modulation, aiming to characterize metabolism-inflammation interactions and key molecules in BS intervened NAFLs.

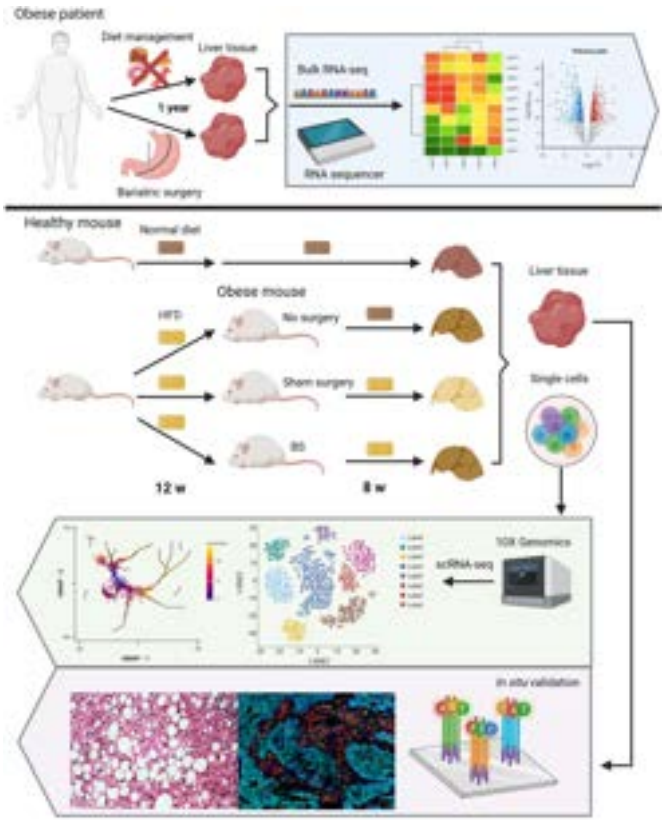

Figure:

Conclusion: This study determined superior functions of BS on metabolism improvement and NAFL attenuation, compared to the diet management. Furthermore, this study will disclose novel mechanisms and clinical potentials of the BS intervenes non-alcoholic fatty liver.

WED-417

Efficacy and reproducibility of AI-assisted Gubra Histopathological Objective Scoring Technique (GHOST) in preclinical rodent models of NASH

Susanne Pors[1], Jacob Nøhr-Meldgaard[1], Denise Oró[1], Casper G Salinas[1], Henrik B. Hansen[1], Michael Feigh[1]. [1]*Gubra, Hørsholm, Denmark*
Email: sup@gubra.dk

Background and aims: Drug efficacy studies in animal models of non-alcoholic steatohepatitis (NASH) typically include histopathological end points. While the clinical-derived NAFLD Activity Scoring (NAS) and Fibrosis Staging system, outlined by Kleiner et al., is largely reproducible in preclinical models of NASH, manual histopathological scoring systems are prone to inter- and intra-observer variability which can influence robustness and reproducibility of study results. To enable objective and unbiased histopathological assessment in liver biopsies from mouse models of NASH, we developed Gubra Histopathological Objective Scoring Technique (GHOST), an automated deep learning-based digital imaging analysis pipeline for the NAS and fibrosis staging system.
Method: Liver biopsies were obtained from two rodent models of NASH, i.e. the GAN diet-induced obese (GAN DIO-NASH) mouse and choline-deficient L-amino acid defined high fat diet (CDAA-HFD) rat model, respectively. Age-matched chow-fed mice and rats served as normal controls. Automated GHOST deep learning computational analysis of NAS and fibrosis scores was performed on hematoxylin-eosin (HE) and picrosirius red (PSR) stained sections, respectively. Also, the GHOST module was extended to enable automated analysis of fibrosis severity in CDAA-HFD rats using the Ishak scoring system. All GHOST data were validated against manual scoring by an expert histopathologist. Quantitative morphometrics were derived from the scoring variables, expressed as density of hepatocytes with lipid droplets, number of inflammatory foci, as well as fractional area of fibrosis.
Results: GHOST accurately and reproducibly detected central veins and portal areas in liver biopsy sections from GAN DIO-NASH mice and CDAA-HFD rats, enabling segmentation of zones relevant for clinical histopathological scoring. In HE stained sections, hepatocytes, inflammatory cells, and ballooned hepatocytes were identified. Inflammatory foci were considered as clusters of ≥4 inflammatory cells. NAS was computed and validated using a test set of 338 mouse liver biopsies with a Cohen's Kappa value of 0.72 between the AI and manual scoring of NAS. PSR-stained collagen fibers were localized in the sinusoidal and periportal space by GHOST, reproducibly identifying collagen forming bridges and branch points. From these segmentations, Kleiner fibrosis stage was computed and validated using a test set of 537 mouse liver biopsies, achieving a Cohen's Kappa value of 0.84 between AI and manual scores. For Ishak fibrosis scores, PSR stained sections were divided into smaller images that was classified using convolutional neural network (CNN) analysis. The output of the CNN model was used in a machine learning algoritm (random forest) to predict fibrosis stage and a Cohen's Kappa value of 0.82 was achieved with a test-set of n = 86 liver biopsies from CDAA-HFD rats.
Conclusion: In conclusion, we confirm high concordance between GHOST-automated and expert histopathologist manual scores in industry-standard rodent models of NASH, including the GAN DIO-NASH mouse and CDAA-HFD rat. Using GHOST for automated assessment of NAS and fibrosis scores provides fast, accurate and reproducible histopathological scoring, thus being instrumental for the assessment of test drug effects in preclinical models of NASH.

WED-418

The PNPLA3 I148M variant aggravates inflammation through dysfunctional LXR and PPAR gamma signalling in macrophages

Emmanuel Dauda Dixon[1], Thierry Claudel[1], Jakob-Wendelin Genger[2], Ci Zhu[3], Erika Paolini[4], Alexander D Nardo[1], Sarah Stadlmayr[5], Veronika Mlitz[1], Claudia Fuchs[1], Christine Radtke[5], Andreas Bergthaler[6], Paola Dongiovanni[4], Wilfried Ellmeier[3], Michael Trauner[1]. [1]*Medical University of Vienna, Hans Popper Laboratory of Molecular Hepatolog, Division of Gastroenterology and Hepatology, Internal Medicine III, Wien, Austria,* [2]*Medical University of Vienna, Austria; Center for Pathophysiology, Infectiology and Immunology, Wien, Austria,* [3]*Medical University of Vienna, Institute of Immunology, Vienna, Austria,* [4]*Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico; Department of Pharmacological and Biomolecular Sciences, Università degli Studi di Milano, Italy,* [5]*Medical University of Vienna, Department of Plastic, Reconstructive and Aesthetic Surgery, Vienna, Austria,* [6]*CeMM Forschungszentrum für Molekulare Medizin GmbH, Center for Pathophysiology, Infectiology and Immunology, Wien, Austria*
Email: michael.trauner@meduniwien.ac.at

Background and aims: Several studies have associated the single nucleotide polymorphism (rs738409; C > G) in patatin-like phospholipase domain-containing protein 3 (PNPLA3) with the development and progression of non-alcoholic fatty liver disease. Most functional studies focused on the role of PNPLA3 I148M in hepatocytes and hepatic stellate cells, but its role in inflammation has not yet been addressed. Here, we explored the impact of the PNPLA3 I148M variant on macrophage immunometabolism.
Method: We isolated monocytes from the human peripheral blood of volunteers carrying the PNPLA3 I148M variant and conducted flow cytometry analysis. We established a THP-1 stable cell line overexpressing the PNPLA3 wildtype and I148M isoforms to enable mechanistic dissection. Gel-shift, gene expression analysis, cytokine array analysis, lipidomic, and cholesterol efflux assay were conducted.
Results: Unstimulated monocytes from PNPLA3 I148M patients showed increased levels of CD16 marker and expressed higher *CCL2, IL-8, TNFα,* and *IL-1β* compared to the WT patients. To unravel the molecular mechanisms, we generated stable THP-1 cells overexpressing the PNPLA3 WT and I148M. The transfected cells, THP-1 WT^{oe} (+387%) and $I148M^{oe}$ (+428%) showed significantly increased levels of the *PNPLA3* mRNA transcript compared to the untransfected cells. In M0 and M1 macrophage, the proinflammatory cytokines *IL-1β* (M0, +481%; M1, +446%), *IL-6* (M1, +24%) and the LPS receptor *TLR4* (M0, +86%; M1, +24.5%) were significantly induced in the $I148M^{oe}$ compared to WT^{oe}. Conversely, in M2 macrophages, the anti-inflammatory cytokine *IL-10* was reduced (-83.7%) in the $148M^{oe}$ compared to the WT^{oe}. Accordingly, $I148M^{oe}$ conditioned medium inhibited SGBS adipocyte differentiation because *PPAR gamma, FABP4*, and *GLUT4* were significantly reduced while inducing adipocyte inflammation. Gel-shift analysis revealed reduced LXR binding activity. LXR-alpha gene expression in the $148M^{oe}$ M1 macrophages was reduced significantly, leading to the downregulation of cholesterol efflux machinery, *ABCA1* (−36.7%), and *ABCG1* (−32%). Furthermore, LXR agonist T0901317 treatment in the $148M^{oe}$ M1 macrophages restored LXR signalling and cholesterol efflux at the gene level and improved inflammation (*IL-6*, −25%), indicating impaired LXR signalling in macrophages carrying the PNPLA3 I148M variant. Similarly, the PNPLA3 $148M^{oe}$ showed impaired PPAR gamma and GR alpha signalling due to abnormal phosphorylation mediated by CDK5.
Conclusion: Our results suggest that the PNPLA3 I148M variant aggravates inflammation in macrophages, at least in part, due to impaired LXR and PPAR gamma signalling. These findings could enhance our understanding of the metabolic role of PNPLA3 in immunometabolism, which may lead to the development of novel therapeutic strategies.

The disturbance of intracellular chloride induces the development and progression of non-alcoholic fatty liver disease

Jiaxing Zhu[1], Hai Jin[1], Xingyue Yang[1], Li Zhang[1], Liming Zheng[1], Hui Wang[1], Shun Yao[1], Yanxia Hu[1], Guorong Wen[1], Jiaxing An[1], Xuemei Liu[1], Biguang Tuo[1]. [1]*Affiliated Hospital of Zunyi Medical University, Gastroenterology, China*
Email: tuobiguang@aliyun.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become the most common chronic liver disease worldwide. The advanced stage of NAFLD, non-alcoholic steatohepatitis (NASH), has been recognized as a leading cause of end-stage liver diseases. Although many clinical and experimental studies have been performed, the mechanisms of NAFLD remain to be elucidated. Chloride is a physiologically important anion. Changes in intracellular chloride concentration affect diverse cellular functions. Here we demonstrate that the disturbance of intracellular chloride induces the development and progression of NAFLD.

Method: Hepatocyte-specific transgene mice for chloride channels, ANO1, CLIC1, CLCN2, and SLC26A6, were generated by Cyagen Biosciences Inc. High-fat diet (HFD)-induced simple NAFLD and high-fat high-cholesterol (HFHC) diet-induced NASH models in mice were established. Intracellular chloride was measured with chloride assay kit. Intracellular lipid deposition was examined with oil red O staining assay and triglyceride level measurement.

Results: The hepatocyte-specific ANO1, CLIC1, CLCN2, and SLC26A6 overexpression mice all spontaneously developed liver steatosis at the age of 6 months and marked features of NASH, liver steatosis, ballooning, and inflammation accompanied by liver fibrosis at the age of 12 months, whereas the wild type control mice had no liver steatosis and NASH at the same age. These transgene mice also displayed higher fasting blood glucose, insulin, HOMA-IR (homeostasis model assessment of insulin resistance) levels, less glucose tolerant and insulin sensitive at the age of 6 and 12 months compared to control littermates. The results from intracellular chloride assay in the liver tissues revealed that the intracellular chloride content in ANO1, CLIC1, and SLC26A6 overexpression mice was higher than that in control mice, but intracellular chloride content in CLCN3 overexpression mice was lower than that in control mice. In primary hepatocytes, LO2 cells and HepG2 cell, low chloride (58 mM) and high chloride (158 mM) mediums, which induced the decrease and increase of intracellular chloride respectively, markedly enhanced palmitate-induced intracellular lipid deposition in comparison with normal chloride (118 mM) medium. Further studies showed that 4, 4′-diisothiocyano-2, 2′-stilbenedisulfonic acid disodium salt, a chloride channel blocker, markedly inhibited the incidence of HFD-induced simple NALFD and HFHC diet-induced NASH and attenuated HFD-induced simple NALFD and HFHC diet-induced NASH in mice.

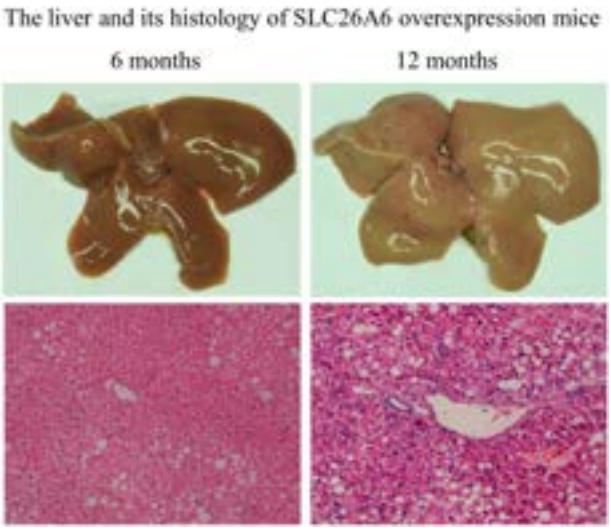

Figure:

Conclusion: These data demonstrated that the disturbance of intracellular chloride plays a key role in the pathogenesis of NALFD and targeting chloride disturbance may be a promising therapeutic target for the treatment of NAFLD and NASH. But the detailed mechanisms of chloride action need further investigation.

WED-420

Mice lacking Cyclophilin B, but not Cyclophilin A, are significantly protected from the development of major features of NAFLD/NASH in a diet and chemical-induced model

Winston Stauffer[1], Daren Ure[2], Robert Foster[2], Philippe Gallay[1].
[1]*Scripps Research, United States,* [2]*Hepion Pharmaceuticals, Canada*
Email: wstauffer@scripps.edu

Background and aims: The large percentage of the population affected by NAFLD/NASH is in need of new effective treatments developed from drugs previously shown to be effective in animal models that replicate human disease. In mice, repeated administration of the potent hepatotoxin carbon tetrachloride (CCl_4), together with the "western diet" (WD) of high-fat, high-sugar, and high-cholesterol chow and high-sugar solution, reproduces many prominent features of human NAFLD/NASH, including high NAFLD Activity Scores and liver fibrosis. We previously reported that the pan-cyclophilin inhibitor drug CRV431 (reconfilstat) decreased NASH in mice under the western-diet/CCl_4 model. Reconfilstat inhibits several cyclophilin isoforms, among which cyclophilin A (CypA) and B (CypB) are most abundant. Here, we report evidence that *Ppib-/-* mice lacking CypB, an endoplasmic reticulum (ER) chaperone, develop significantly reduced features of NASH in this model, relative both to wild-type (WT) mice, and to other knockout mice lacking CypA.
Method: 10-week-old male *Ppib-/-* mice, together with *Ppia-/-* and WT C57/BL/6J control mice, were administered 0.2 uL/g CCl_4 intraperitoneally twice weekly. While some groups continued on normal chow and water, other groups received *ad libitum* WD chow containing 21.1% fat, 41% sucrose, and 1.25% cholesterol by weight, together with high-sugar solution (23.1 g/L fructose and 18.9 g/L glucose) instead of water. After 20 weeks, mice (n = 10 per group) were sacrificed at 30 weeks old. Body and liver weight were recorded and livers were fixed for histological analysis. Sections of livers stained with HandE were assigned NAFLD Activity Scores (NAS) based on inflammation, steatosis, and hepatocyte ballooning. Liver sections were also stained with Sirius Red for examination of collagen fibrosis. Unpaired Student's t-tests were conducted with GraphPad Prism.
Results: Naïve *Ppib-/-* mice were smaller than WT but neither exhibited liver fibrosis or steatosis. In both CCl_4-only and CCl_4+WD conditions, *Ppib-/-* mice exhibited liver fibrosis that was reduced by more than 40% and 72%, respectively, compared to WT counterparts, ($p < 0.001$). Additionally, in the CCl_4+WD condition, WT livers exhibited a NAS over 7, indicative of NASH, while *Ppib-/-* livers were not significantly changed ($p > 0.05$) from naïve conditions. *Ppia-/-* mice under CCl_4-only and CCl_4+WD conditions did not significantly differ from their respective WT controls in either liver fibrosis or NAS.
Conclusion: Cyclophilin inhibition is a promising and novel avenue of treatment for diet-induced NAFLD/NASH. In this study, mice without CypB, but not mice without CypA, were significantly protected from the development of the characteristic features of NASH. Further investigation is necessary to determine whether the specific role of CypB in the ER secretory pathway is of significance to its effect on NASH development.

WED-421

Growth differentiation factor 15 in plasma and liver is associated with hepatic oxidative stress in non-alcoholic fatty liver disease

Mikkel Werge[1], Josephine Grandt[1], Mira Thing[1], Liv Hetland[1], Elias Rashu[1], Anne-Sofie Houlberg Jensen[1], Anders Junker[1], Martin Richter[1], Søren Møller[2], Flemming Bendtsen[1], Lea Mørch Harder[3], Gianluca Mazzoni[3], Birgitte Viuff[4], Henning Hvid[4], Sebastian Jørgensen[5], Kristian Bendtsen[6], Jonas Kildegaard[6], Mogens Vyberg[7], Reza Serizawa[7], Elisabeth Galsgaard[6], Nicolai J Wewer Albrechtsen[8], Lise Lotte Gluud[1].

Email: mikkel.parsberg.werge@regionh.dk

Background and aims: Growth Differentiation Factor 15 (GDF15) is a stress-inducible protein with known centrally mediated effects, including regulation of food intake and food preference, weight loss, emesis and delayed gastric emptying. We investigated the association of GDF15 with non-alcoholic fatty liver disease (NAFLD) based on a discovery (n = 30; healthy controls, NAFLD and cirrhosis (F4 fibrosis)) and a validation cohort (n = 276; healthy controls and NAFLD with F0 to F4 fibrosis).
Method: Plasma GDF15 was measured by enzyme-linked immunosorbent assays (ELISA) and a proteomics platform (SomaScan). Hepatic GDF15 mRNA expression was determined by in-situ hybridisation in liver samples from 33 patients with NAFLD and by bulk RNA-sequencing in samples from 12 healthy controls and 118 NAFLD patients with F0 to F4 fibrosis. Liver sections were immunostained for p62 as a marker of oxidative stress, and the percentage of positive p62 staining (area fraction) was calculated by digital image analysis.
Results: Plasma GDF15 was increased in patients with NAFLD and in patients with cirrhosis ($p < 0.0001$) compared to controls and was associated with increasing fibrosis stage ($p < 0.0001$) but not steatosis ($p = 0.67$). Patients with advanced fibrosis (F2–F4) had the highest levels of GDF15; the area under the ROC curve for diagnosing advanced fibrosis (F2–F4) was 0.83 (95% CI: 0.76–0.91). The association of advanced fibrosis with plasma GDF15 remained after adjustment for age, sex, BMI and type 2 diabetes in multivariate logistic regression.
GDF15 plasma levels were obtained at 1-year and 2-year follow-up for 71 NAFLD patients and showed an increase (14%, 95% CI: 3–27, p = 0.01) at 2-year follow-up. However, those patients treated with a glucagon like peptide-1 receptor agonist (GLP-1-RA) at baseline had an estimated treatment effect on GDF15 levels of –28% ($p = 0.01$).
Hepatic GDF15 mRNA was observed to be mainly expressed in a subset of hepatocytes throughout the parenchymal area in the liver, including steatotic hepatocytes. Expression was also observed in

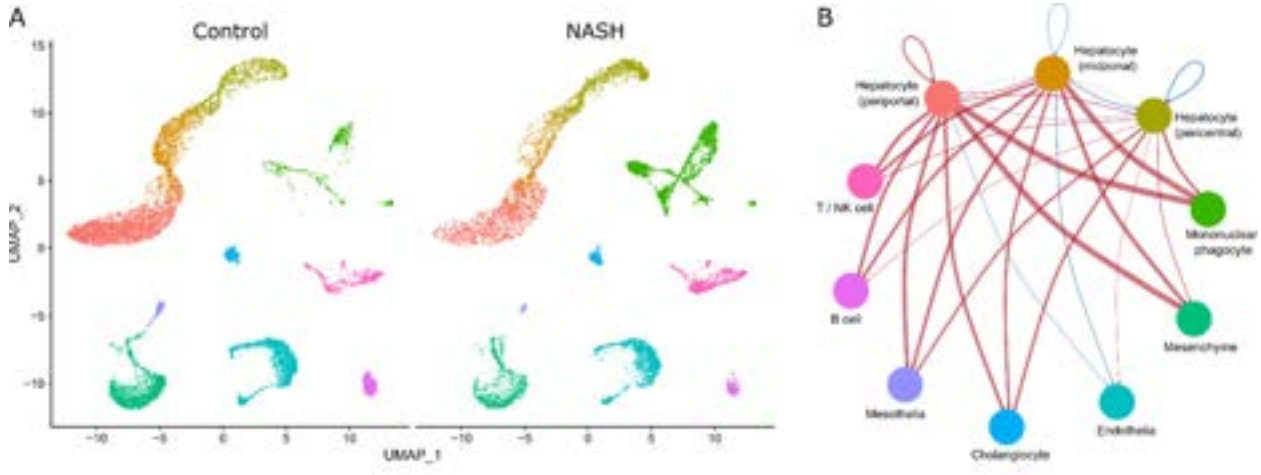
some cholangiocytes and in a small subset of non-parenchymal cells, with high expression in fibrotic areas.
Hepatic GDF15 was increased in NAFLD patients (p = 0.007) compared to controls, but there was no association with liver fibrosis (p = 0.93). Among NAFLD patients, GDF15 expression was highest in patients with non-alcoholic steatohepatitis (NASH, p = 0.01).
GDF15 levels in plasma and liver were found to be correlated to the p62 area fraction (β = 0.12, p = 0.006; β = 0.49, p < 0.0001, respectively).
Conclusion: Plasma GDF15 was highest in patients with advanced fibrosis, while the hepatic expression of GDF15 mRNA was highest in patients with NASH. Both plasma and hepatic GDF15 are associated with the degree of oxidative stress in the liver. Further research is necessary to understand the molecular connection between GDF15 expression and oxidative stress in the NASH liver.

WED-422
Decoding hepatocyte transcriptional responses in murine non-alcoholic steatohepatitis using single-nucleus RNA-sequencing
Juliet Luft[1], Mulugeta Seneshaw[2], Faridoddin Mirshahi[2], Eleni Papachristoforou[1], Huiping Zhou[3,4], Arun Sanyal[2], Prakash Ramachandran[1]. *[1]University of Edinburgh, Centre for Inflammation Research, United Kingdom, [2]Virginia Commonwealth University, Department of Internal Medicine, United States, [3]Virginia Commonwealth University, Department of Microbiology and Immunology, United States, [4]Central Virginia VA Health Care System, United States*
Email: jluft@ed.ac.uk

Background and aims: Single cell transcriptomics has transformed our understanding of liver non-parenchymal cell (NPC) heterogeneity in non-alcoholic steatohepatitis (NASH). Despite hepatocytes being the primary target of NASH-related injury, it remains unknown how NASH impacts the hepatocyte transcriptome at single-cell resolution, how these effects differ across the zones of the liver lobule and how hepatocyte injury regulates NPC activation to drive the fibroinflammatory cascade. Consequently, we utilised single-nucleus RNA-seq (snRNAseq) to interrogate changes in hepatocyte transcription in the diet-induced animal model of non-alcoholic fatty liver disease (DIAMOND) model of murine NASH.
Method: NASH was induced in B6/129 mice by treatment Western diet for 40 weeks (DIAMOND model). Age matched mice fed with standard chow were used as controls. SnRNAseq was performed on liver nuclei of NASH (n = 2) or healthy controls (n = 2) using the 10X Genomics Chromium platform. A total of 17,511 single nuclei passed quality control. Computational analysis was performed in R.
Results: DIAMOND mice developed NASH with advanced bridging fibrosis. Unsupervised clustering and annotation enabled atlassing of all major liver cell lineages (Figure A), identifying subpopulations of NASH-associated *Trem2+Cd9+* macrophages and *Pdgfra+Col1a1+* myofibroblasts, key NPC populations which regulate liver inflammation and fibrosis. Focusing on hepatocytes, NASH resulted in global transcriptional changes with significant increases in genes associated with cytokine signaling and apoptosis. Trajectory inference was performed using Slingshot to reconstruct the spatially defined periportal-pericentral axis of hepatocyte zonation, defining zone-specific NASH responses. Ligand-receptor analysis using CellChat, showed that NASH resulted in an increase in both the number and strength of predicted cell-cell interactions between hepatocytes and NPCs (Figure B). Specifically, hepatocytes from NASH livers signaled to mesenchymal, endothelial and immune cells via families of ligands including Angiopoietin-Like Proteins, Platelet derived Growth Factors, Complement and Ephrins. Ligand expression also varied zonally across the liver lobule, with Neuregulins and Junctional Adhesion Molecules upregulated in the periportal hepatocytes of NASH livers, and Fibroblast Growth Factors in the pericentral.
Conclusion: Using snRNAseq in a tractable pre-clinical model, we have defined the transcriptional responses of hepatocytes in NASH, identifying zone-specific injury responses and modelling cross-talk between injured hepatocytes and NPCs which drive liver inflammation and fibrosis. This work provides a molecular framework for future interventional studies aimed at targeting hepatocyte-NPC interactions as a therapeutic strategy for NASH.

WED-423
Hepatic inactivation of the epigenetic regulators Suv420h1-h2 mitigates NAFLD development and progression in mice
Alessia Pagani[1], Valeria Furiosi[1], Mariateresa Pettinato[1], Letizia Bavuso Volpe[1], Sandro Altamura[2], Antonella Nai[1,3], Davide Gabellini[4], Simona Pedrotti[4], Laura Silvestri[1,3]. *[1]IRCCS Ospedale San Raffaele, Regulation of Iron Metabolism Unit- Division of Genetics and Cell Biology, Milan, Italy, [2]University of Heidelberg and Molecular Medicine Partnership Unit (MMPU), Department of Pediatric Hematology, Oncology and Immunology, Heidelberg, Germany, [3]Università Vita-Salute San Raffaele, Milan, Italy, [4]IRCCS Ospedale San Raffaele, Gene Expression and Muscular Distrophy Unit, Division of Genetics and Cell Biology, Milan, Italy*
Email: pagani.alessia@hsr.it

Background and aims: The molecular mechanisms involved in the development and progression of NAFLD to NASH are still under investigation, and their identification represent an unmet clinical



(A): UMAP of cell lineages, coloured as in B. **(B)**: Differential strength of outgoing hepatocyte ligand-receptor interactions. Red = increase, blue = decrease.

Figure: (abstract: WED-422).

need. Several factors contribute to NAFLD development, including deregulated iron metabolism. Notably, a genomic region encompassing the histone methyltransferase *Suv420h* has been associated to iron-dependent liver steatosis in mice. Thus we hypothesize that liver *Suv420h*, by modulating the crosstalk between lipid- and iron metabolism, may play a role in NAFLD-NASH.
Method: we generated mice lacking both *Suv420h1* in the liver and Suv420h2 in whole body (dKO). Eight week-old male mice were fed a NAFLD-NASH-inducing diet (FPC diet) or a normal diet for 16 weeks. Body weight was monitored weekly. At termination, histological, biochemical and gene expression analysis was performed for phenotypic characterization.
Results: dKO mice showed no developmental defects and perinatal lethality, and their body weight was comparable to control mice. FPC diet induced mild obesity and hepatomegaly in control mice, whereas dKO animals were protected. Inactivation of *Suv420h* in hepatocytes counteracted hepatocyte ballooning, reduced lipid droplet formation, monocyte recruitment and inflammation, and collagen deposition. Hypertrophy of subcutaneous and visceral adipose tissues was mitigated by *Suv420h* deletion, and decreased lipid droplet numbers and size were observed in brown adipose tissues. RNAseq was performed on total liver: dKO mice showed enrichment of PPARa-dependent genes and reduced SMAD3-dependent genes, suggesting a protective gene signature. Since deregulated iron metabolism contributes to NAFLD-NASH, we analyzed iron-related genes in control and dKO mice. In normal diet, expression of *Tfr1*, *ferroportin*, *Bmp6*, BMP-SMAD target genes and the iron-regulatory hormone *hepcidin* were comparable between genotypes. However, in FPC-treated control mice *hepcidin* was downregulated in a BMP-SMAD independent way, and *Tfr1* upregulated, suggesting liver iron deficiency. On the contrary, in FPC-treated dKO mice *hepcidin* and *Tfr1* expression remained unchanged.
Conclusion: *Suv420h1/h2* deletion in hepatocyte counteracts NAFLD-NASH in mice. *Hepcidin* expression, decreased by FPC in control mice, remains unchanged in dKO animals, suggesting a protective effect in counteracting body iron accumulation. Further studies are needed to dissect the signaling pathway modulated by Suv420h1/h2 in hepatocytes. However, these methyltransferases can be considered a promising therapeutic target for NAFLD treatment and NASH prevention.

WED-424
Peculiar monocyte bioenergetic profile in non-alcoholic steatohepatitis (NASH)

Moris Sangineto[1], Martina Ciarnelli[1], Antonino Romano[1], Rosanna Villani[1], Gaetano Serviddio[1]. [1]*University of Foggia, Department of Medical and Surgical Sciences-Liver Unit, Italy*
Email: moris.sangineto@unifg.it

Background and aims: In Non-alcoholic steatohepatitis (NASH), several pathogenetic mechanisms have been described, although treatment options remain elusive. Beyond the "multiple hit hypothesis" it seems that different triggers converge to the activation of innate immunity, which in turn orchestrates inflammation in NASH. Kupffer cells are activated by pathogen- and damage-associated molecular patterns (PAMPs and DAMPs), with the consequent recruitment of circulating monocyte-derived macrophages which perpetuate inflammation. Recent studies shed light on the promising field of immunometabolism, although very little is known about immunometabolic alterations in chronic diseases such as NASH. This is relevant as the modulation of immune cell bioenergetics may extinguish inflammatory processes, suggesting immune cell metabolism as a potential therapeutic target. Here we aimed to investigate the immunometabolic alterations in patient monocytes in the NASH.
Method: Circulating monocytes from 20 NASH patients (histologically determined) and 10 healthy controls were isolated in order to dissect cellular bioenergetics by using a Seahorse analyser (Agilent). To do this, glycolysis and mitochondrial respiration were studied by quantifying extracellular acidification rate (ECAR) and oxygen consumption rate (OCR), respectively. In a second step, Wild-type (C57BL/6) mice were fed with high-fat and high-cholesterol diet (HF-HC) for 6 weeks in order to induce steatohepatitis. During the last 3 weeks mice were intraperitoneally treated with Dimethyl malonate (DMM) (160 mg/kg) every second day, while vehicle (PBS) injection served as control. DMM is a succinate dehydrogenase (SDH) inhibitor with demonstrated immunomodulating effects in macrophages. Biochemical and histological alterations were assessed.
Results: Interestingly, the examination of bioenergetic profile of NASH monocytes, showed a considerable increase of both glycolysis and mitochondrial respiration (MR) compared to controls. In particular, MR in NASH patients was characterized by increase of

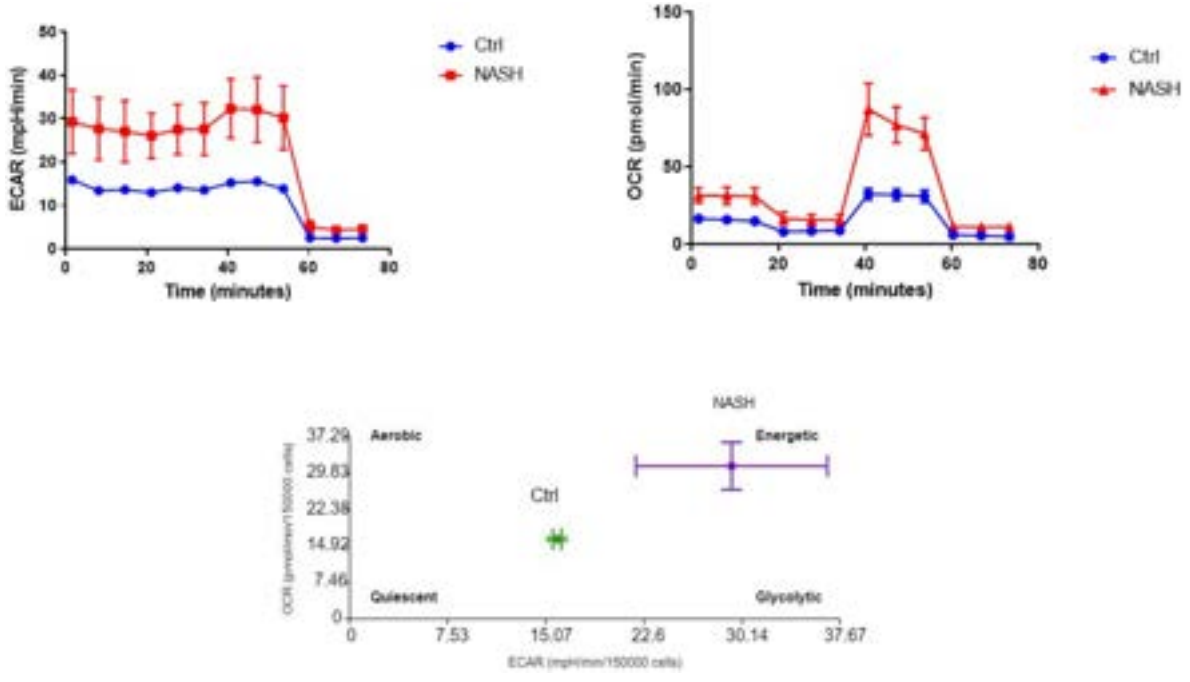


Figure: (abstract: WED-424).

basal and maximal respiration, although a part of this respiration was dissipated by proton leak and not finalized to the ATP production. Moreover, we found that NASH monocytes presented a higher respiratory chain (RC) complex I enzymatic activity and higher mRNA expression of several RC subunits and mitochondrial biogenesis markers such as TFAM and PGC-1α. Taken together these results underline that monocytes in NASH exhibit an aberrant bioenergetic profile characterized by high glycolysis and high MR levels with mitochondrial dysfunction. Therefore, in order to analyse the potential effects of targeting immunometabolism, HFHC-fed mice were treated with DMM. In fact, DMM is a malonate derivative and a known immunometabolic modulator in macrophages. Interestingly, DMM treated mice improved in terms of liver injury, steatosis and inflammation as indicated by serum ALT levels, hepatic fat, number of inflammatory foci and expression of inflammatory cytokines (e.g., IFN-γ and IL-1β).

Conclusion: Immunometabolism candidates as a novel therapeutic target in NASH.

WED-425

Co-stimulatory signals mediated by inducible T-cell co-stimulator (ICOS) influence the hepatic expansion auto-aggressive CD8+T-cells in non-alcoholic steatohepatitis (NASH)

Cristina Vecchio[1], Alessia Provera[1], Laila lavanya Gadipudi[1], Ramavath Naresh Naik[1,2], Renzo Boldorini[1], Nausicaa Clemente[1], Luca C. Gigliotti[1], Elena Boggio[1], Umberto Dianzani[1], Emanuele Albano[1], Salvatore Sutti[1]. [1]*University of East Piedmont, Dept. of Health Sciences, Italy,* [2]*Washington University in St. Louis, Dept. of pediatrics, endocrinology and diabetes, United States*
Email: cristina.vecchio@uniupo.it

Background and aims: Recent evidence indicated that cytotoxic $CD8^+$ T-lymphocytes play important role in the progression of non-alcoholic steatohepatitis (NASH) toward fibrosis. The Inducible T-cell Co-Stimulator (ICOS) present on T lymphocytes and its ligand ICOSL (B7h) expressed on myeloid cells are member of the B7/CD28 family and play multiple roles in immunity by regulating T-cell activation/survival. From the observation that ICOS-expressing $CD8^+$ T-cells are important in driving liver healing following acute injury, we have here investigated the possible involvement of ICOS-ICOSL dyad in modulating T-cells functions during NASH evolution.

Method: ICOS and ICOSL were investigated in experimental model of NASH based on mice feeding with choline/methionine deficient (MCD) or a cholesterol-enriched Western (WD) diets.

Results: Liver $CD8^+$ T cells expressing ICOS expanded in animal models of NASH in parallel with an up-regulation of ICOSL in $CD11b^{high}$/F4-80^+ monocytes/macrophages (MoMFs). Mice deficient for ICOS receiving the MCD diet for 6 weeks had milder steatohepatitis. This effect was confirmed in mice fed with the WD diet for 24 weeks that also showed reduced hepatic fibrosis. The characterization of $ICOS^+$/$CD8^+$ T-cells in WD-fed mice showed that they featured C-X-C motif chemokine receptor 6 (CXCR6) and programmed cell death protein-1 (PD-1) previously associated with the capacity of killing hepatocytes. Conversely, $ICOSL^+$ MoMFs expressed CD9, and the triggering receptor expressed on myeloid cells-2 (TREM-2) that characterize NASH-associated macrophages (NAMs). ICOS deficiency strongly reduced $CD8^+$ T-cell expansion and prevented PD-1 upregulation. Such effect also associated with a lowering in the expression of CD122, the β-chain component of both IL-2 and IL-15 receptors responsible for $CD8^+$ T-cell proliferation and survival.

Conclusion: Altogether these data indicate that ICOS signals are critical for the expansion auto-aggressive $CD8^+$ T cells in NASH and suggest a possible interaction between these lymphocytes and NAMs, thus indicating ICOS/ICOSL dyad as a possible target for therapeutic interventions.

WED-426

Uncovering the role of ISOC1 in non-alcoholic fatty liver disease

Fabrice Marger[1], Etienne Delangre[1], Tifany Schaer[1], Francesco Negro[1,2], Sophie Clément-Leboube[2], Michelangelo Foti[1], Nicolas Goossens[1,2]. [1]*University of Geneva, Geneva, Switzerland,* [2]*Hôpitaux Universitaires de Genève (HUG), Genève, Switzerland*
Email: nicolas.goossens@hcuge.ch

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a complex disease with heterogeneous hepatic molecular pathways and gene expression alterations. Innovative strategies to identify novel molecular targets of NAFLD are urgently needed to help drive therapeutic discovery. Using a large scale computational approach we identified Isochorismatase Domain Containing 1 (ISOC1) gene deregulation as a novel molecular target in NAFLD and we aimed to validate its role *in vitro* and in an animal model of NAFLD.

Method: We generated a consensus human NAFLD liver gene expression signature (NAFLD-sig) using whole-genome meta-analysis of multiple available datasets. Comparison of NAFLD-sig with over one million perturbagen gene signatures in the CMap database resulted in the identification of ISOC1 downregulation as the most closely associated signature with human NAFLD in both early and late stages. Knockdown (KD) of ISOC1 was performed through siRNA-mediated KD and CRISPR/Cas9-mediated knockout in human hepatocyte (Huh7) and hepatic stellate (LX2) cell lines. The effects of ISOC1 KD were also evaluated in a mouse model using hepatotropic AAV8 encoding for shRNA directed against ISOC1 in C57BL/6 mice following a 19-day Methionine/Choline Deficient (MCD) diet.

Results: To identify the NAFLD-sig we identified 14 publicly available datasets comparing 300 subjects at different stages of NAFLD. We combined these datasets using gene expression meta-analysis and found that the ISOC1 downregulation gene expression signature most closely approximated the NAFLD-sig at all stages of NAFLD. We next proceeded to validate the association between ISOC1 deregulation and NAFLD in vitro. CRISPR/Cas9-mediated knockout of ISOC1 in Huh7 cells was associated with a significant increase in lipid droplet size, number and total area. Expression of key genes involved in lipid metabolism and transport were deregulated (CPT1A, ACAT2, MTTP, all $p < 0.05$). In hepatic stellate cells, ISOC1 knockout and KD was associated with increase of fibrogenic genes (COL1A1, MMP2, TGFBR1, all $p < 0.05$) expression. Microarray analysis of ISOC1 KD in LX2 cells showed induction of pathways associated with hepatic stellate cell activation and collagen deposition. In the murine model of NAFLD, a 19-day MCD diet was associated with a reduction of the hepatic gene expression of ISOC1 and development of steatosis but no fibrosis due to the relatively short duration. Preliminary analysis showed that ISOC1 KD was associated with increased serum ALT levels and increased hepatic lobular inflammation.

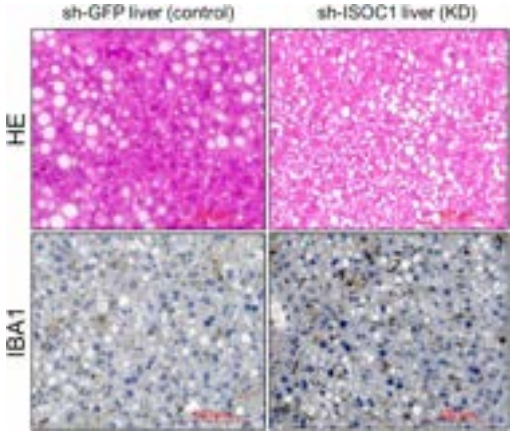

Figure: ISOC1 KD in MCD mice is associated with increased inflammatory infiltrates characterized by increased infiltration of IBA1 positive macrophages.

Conclusion: Our study provides novel insights into the role of the ISOC1 gene in the development of NAFLD. Using a large-scale computational approach, we identified ISOC1 downregulation as the most closely associated gene expression signature with human NAFLD in both early and late stages. Our in vitro and animal model results validate ISOC1 as a novel molecular target in NAFLD however, further studies are necessary to fully understand the mechanisms and potential consequences of ISOC1 modulation in NAFLD.

WED-427

APB-R3, a novel long-acting IL-18 binding protein, inhibits IL-18 activity, and thereby ameliorates NASH progress with reduced liver fibrosis

Eun-Bi Song[1], Jin Joo Park[2], Mi-Hyun Park[2], Young Saeng Jang[3], Kyungsun Lee[2], Jaekyu Han[2], Susan Chi[2], Moo Young Song[2], Seung Goo Kang[2,3], Sang-Hoon Cha[2], Yong-Hyun Han[1]. [1]*Laboratory of Pathology and Physiology, College of Pharmacy, Kangwon National University, Korea, Rep. of South,* [2]*AprilBio Co., Ltd., Korea, Rep. of South,* [3]*Division of Biomedical Convergence, College of Biomedical Science, Kangwon National University, Korea, Rep. of South*
Email: yhhan1015@kangwon.ac.kr

Background and aims: Non-alcoholic steatohepatitis (NASH) is chronic inflammatory diseases in the liver, which leads to progression from simple steatosis to cirrhosis. Despite recent advances in understanding the pathogenesis of NASH, there are no clinically approved drugs to relieve NASH-induced fibrosis. Interestingly, IL-18, one proinflammatory cytokines that belong to IL-1 subfamily, had been known to be a strong inducer of hepatic fibrosis. Knowing that IL-18BP is a negative feedback controller of IL-18 in a physiological condition, we, herein, developed the long-acting IL-18BP, referred to APB-R3, via recombinantly fused to an anti-albumin Fab, and accessed the therapeutical effect of APB-R3 in rodent NASH models.
Method: We employed two experimental NASH models including STAM and fructose, palmitic acid, and cholesterol-containing (FPC) diet. STAM mice were intraperitoneally injected with 10 mg/kg dose of APB-R3 from 6 to 12 weeks of age. For diet-induced NASH model, FPC diet were fed for 19 weeks. To evaluate combination therapy, APB-R3 and Liraglutide (GLP-1R agonist) were administered independently or combinedly from 11 to 19 weeks of feeding period.
Results: APB-R3 significantly lowered NASH injury markers such as plasma ALT and hepatic triglyceride levels in STAM model. In particular, we found that APB-R3 strongly ameliorated STAM-induced hepatic fibrosis. In the FPC diet-fed NASH model, APB-R3 prevented development of NASH and reduced plasma ALT, inflammatory foci and IFNγ. Similarly, fibrotic changes such as collagen deposition and mRNA expression of pro-fibrotic genes were largely attenuated by administration of APB-R3. Importantly, the combination treatment with both APB-R3 and Liraglutide completely inhibited NASH progression.

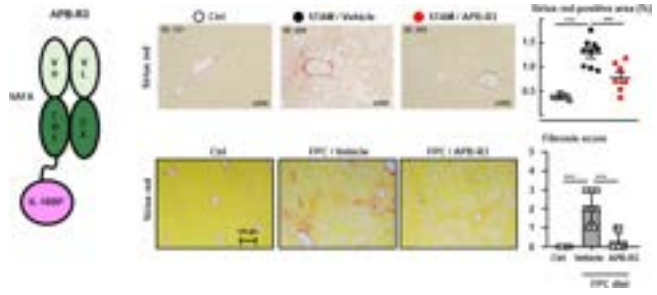

Figure:

Conclusion: APB-R3 treatment exhibits significant reduction of hepatic injury and fibrosis in mice NASH models, and our results emphasize the marked value of APB-R3 as a novel therapeutic arsenal in treating NASH especially when combined with anti-steatotic agents.

WED-428

In vitro investigation of the role of adipocyte-derived exosomes in the development of non-alcoholic steatohepatitis

Robim M Rodrigues[1], Berta Vazquez Olivet[2], Alexandra Gatzios[2], Matthias Rombaut[2], Vera Rogiers[2], Joost Boeckmans[2], Joery De Kock[2], Tamara Vanhaecke[2]. [1]*Faculty of Medicine and Pharmacy-Free University of Brussels (VUB), In vitro Toxicology and Dermato-cosmetology, Brussels, Belgium,* [2]*Faculty of Medicine and Pharmacy-Free University of Brussels (VUB), In vitro Toxicology and Dermato-cosmetology, Belgium*
Email: robim.marcelino.rodrigues@vub.be

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with visceral obesity. Adipocyte atrophy and accompanying inflammation of the adipose tissue (AT) lead to the secretion of a plethora of factors that once taken up by the liver, exacerbate the development of non-alcoholic steatohepatitis (NASH). Yet, the exact mechanisms behind the interplay between AT and the liver is not fully understood. In this study, we investigate the potential steatogenic and inflammatory effects that adipocyte-derived exosomes might have on the liver using multipotent stem cell-based *in vitro* models.
Method: Human adipose-derived stromal cells (hATSc) were isolated from liposuction material after ethical approval and informed consent of the patients. Upon expansion, the cells were differentiated towards adipocyte-like cells (hATSc-adipo). To mimic the micro-environment of AT in NASH patients, these cells were then exposed for 24 h to a cocktail of multiple NASH-specific factors. The latter were identified from transcriptomics datasets of AT samples of patients with histologically proven NASH and also mimic hyperglycemic and hypertriglyceridemic blood levels of obese patients. Upon a recovery wash-out period of 24 h, exosomes were isolated from the cell supernatants of hATSc-adipo cultures. The steatogenic and inflammatory effects of the isolated exosomes were evaluated using human skin-derived precursors (hSKP) differentiated towards hepatic cells (hSKP-HPC).
Results: Compared to control conditions, the expression of proinflammatory leptin (*LEP*, 1.5 fold) was upregulated in hATSc-adipo cells exposed to the NASH cocktail, whereas the expression of anti-inflammatory adiponectin was downregulated (*ADIPOQ*, −4.0 fold). Furthermore, an upregulation of interleukin beta (*IL1B*, 1.5 fold), tumour necrosis factor alfa (*TNFA*, 1.5 fold), interleukin 6 (*IL6*, 62 fold) and the chemokines C-X-C motif chemokine 5 (*CXCL5*, 1510 fold) and C-C motif chemokine ligand 2 (*CCL2*, 243 fold) was observed in the triggered hATSc-adipo cells. These results suggest that hATSc-adipo cells exposed to a NASH-specific cocktail respond in a similar way as inflamed adipose tissue. Of note, the expression of the exosomal marker human exosome component 9 (*EXOSC9*) remained constant. The exosomes isolated from the cell supernatants of the hATSc-adipo cells exposed to the cocktail or vehicle control conditions had a diameter of 101 nm (91% mode) and 117 nm (82% mode), respectively. Exposure of hSKP-HPC to these exosomes released by the triggered hATSc-adipo cells, induced stearoyl-CoA desaturase-1 (*SCD1*, 1.6 fold) and fatty acid synthase (*FASN*, 1.2 fold), which both play a role in *de novo* lipogenesis. Contrarily, perilipin 2 (*PLIN2*), which promotes the formation of lipid droplets and *CD36* that play a role in fatty acids uptake, were 1.5 and 6.3 fold downregulated, respectively. Strikingly, the expression of proinflammatory cytokines *IL6*, *IL1A*, *CCL2* and *CXCL5* was highly upregulated (2.9, 3.7, 3.3 and 46.3 fold, respectively).
Conclusion: Our data show that adipocyte-like cells derived from human hATSc can mimic cellular responses specific to inflamed AT during NASH. The exosomes secreted by these cells induce the expression of steatogenic and inflammatory markers in an established hepatic *in vitro* system. This study shows the value of human-based *in vitro* cell systems in the investigation of complex pathophysiological processes, such as the interplay between AT and the liver during NASH.

A novel HIF2A mutation causes dyslipidemia and promotes hepatic lipid accumulation

Feiqiong Gao[1], Qigu Yao[1], Jiaqi Zhu[1], Wenyi Chen[1], Xudong Feng[1], Bing Feng[1], Jiong Yu[1], Hongcui Cao[1]. [1]*The First Affiliated Hospital, Zhejiang University School of Medicine, China*
Email: hccao@zju.edu.cn

Background and aims: Hypoxia-inducible factor –2α (HIF-2α) is a transcription factor responsible for regulating genes related to angiogenesis and metabolism. Mutations in the oxygen-dependent domain (ODD) of HIF-2α have been reported in association with erythrocytosis and tumors. This study aims to explore the effect of a previously unreported mutation c.C2473T (p.R825S) in the C-terminal transactivation domain (CTAD) of HIF-2α that we detected in tissue of patients with liver disease.
Method: We sequenced liver samples obtained during partial liver resection or liver transplantation performed for clinical indications such as hepatocellular carcinoma and liver failure. In tandem, we constructed cell lines and a transgenic mouse model bearing the corresponding identified mutation in HIF-2α from which we extracted primary hepatocytes. We evaluated lipid accumulation in these cells and liver tissue from the mouse model using Oil Red O staining; serum, intrahepatic, and intracellular lipid levels from the same model were measured by biochemical detection kit. Lipidomics was used to assess the lipid metabolism of mouse liver.
Results: Herein, we found a mutation in the CTAD of HIF-2α (c.C2473T; p.R825S) in 5 of 356 liver samples obtained from patients with hepatopathy and dyslipidemia. We also found that introduction of this mutation into the transgenic mouse model led to an increase in triglyceride levels, lipid droplet accumulation in the liver of the mutant mice and in their extracted primary hepatocytes, and increased transcription of genes related to hepatic fatty acid transport and synthesis in the mutant compared to the control groups. In mutant mice and cells, the protein levels of nuclear HIF-2α and its target gene perilipin-2 (PLIN2) were also elevated. Decreased autophagy was observed in mutant groups.
Conclusion: We identify a mutation in HIF-2α and find that patients with it are more likely to have dyslipidemia. The HIF-2α^{R825S} mutation elevates blood fatty levels and leads to non-alcoholic fatty liver disease (NAFLD). Identification of the subset of patients with HIF-2α ^{R825S} mutation may help to cure patients with surgery and developed targeted personalized therapeutics.

WED-430

Adipose tissue macrophage dysfunction and depletion are associated with a breach of vascular integrity in non-alcoholic steatohepatitis

Markus Boesch[1], Andreas Lindhorst[2], Rita Furtado Feio de Azevedo[1], Paola Brescia[3], Alessandra Silvestri[3], Matthias Lannoo[4], Ellen Deleus[4], Joris Jaekers[4], Halit Topal[4], Baki Topal[4], Marie Wallays[1], Lena Smets[1], Lukas Van Melkebeke[1,4], Tania Roskams[5], Pierre Bedossa[6], Jef Verbeek[1,4], Sven Francque[7,8], Alejandro Sifrim[1], Thierry Voet[1], Maria Rescigno[3,9], Martin Gericke[2], Hannelie Korf[1], Schalk van der Merwe[1,4]. Email: markus.boesch@kuleuven.be

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is reaching epidemic proportions, fueled by the obesity pandemic. In NAFLD, monocytes infiltrate visceral adipose tissue that promote local and hepatic inflammation. It however remains unclear what drives inflammation and how the immune landscape in adipose tissue differs across the NAFLD severity spectrum. We aimed to assimilate the adipose tissue macrophage (ATM) heterogeneity in a NAFLD cohort.

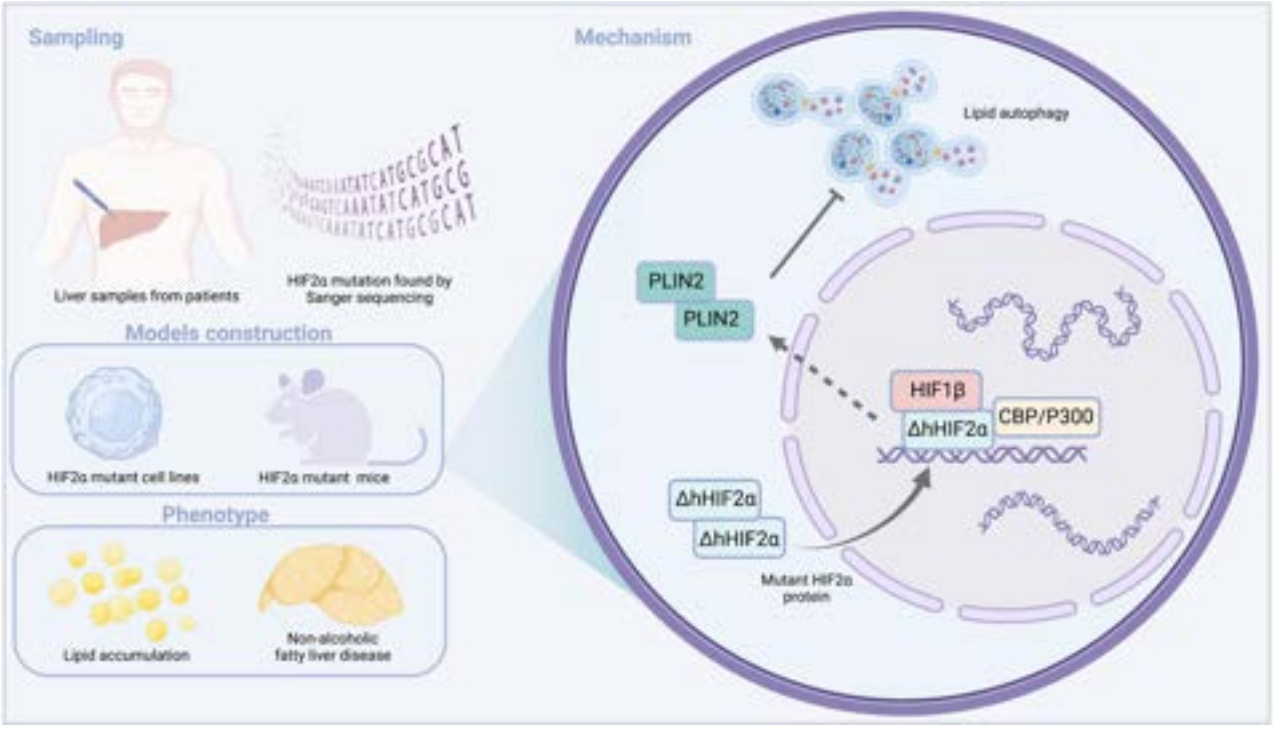

Figure: (abstract: WED-429).

Method: Visceral adipose tissue macrophages from obese patients stratified into NAFLD phenotypes underwent single-cell RNA sequencing. Adipose tissue vascular integrity and breaching was assessed via immunohistological staining on paraffin embedded human adipose tissue sections of plasmalemma vesicle-associated protein 1 (PV1) and albumin, respectively.
Results: We discovered multiple ATM populations, including resident vasculature-associated macrophages (ResVAMs) and distinct metabolically active macrophages (MMacs). Using trajectory analysis, we show that ResVAMs and MMacs replenish from a common transitional macrophage subtype (TransMac) and localize around the vasculature, where they interact with endothelial cells. Across the NAFLD severity spectrum, the adipose tissue MMac subset is progressively depleted and not effectively replenished by TransMac precursors. This coincided with an adipose tissue vasculature breach characterized by albumin extravasation into the perivascular tissue.
Conclusion: NAFLD-related macrophage depletion and dysfunction coincides with a loss of adipose tissue vascular integrity providing a strong plausible mechanism by which tissue inflammation is perpetuated in adipose tissue and downstream in the liver.

WED-431

Circadian sleep-wake rhythms in non-alcoholic fatty liver disease

Sofia Roth[1,2], Andrijana Bogdanovic[1], Talitha Hildebrandt[1], Anne Geng[1], Emilio Flint[3], Michael Strumberger[4], Martin Meyer[5], Markus Heim[1,6], Christian Cajochen[5], Christine Bernsmeier[1,6].
[1]Department of Biomedicine, University of Basel, Switzerland, Switzerland, [2]University Centre for Gastrointestinal and Liver Diseases, Basel, Switzerland, [3]Department of Biomedicine, University of Basel, Switzerland, Basel, Switzerland, [4]Centre for Chronobiology, Psychiatric Hospital of the University of Basel, Basel, Switzerland, [5]Centre for Chronobiology, Psychiatric Hospital of the University of Basel, Switzerland, [6]University Centre for Gastrointestinal and Liver Diseases, Switzerland
Email: sofia.roth@unibas.ch

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has a multifactorial pathogenesis including dietary, environmental and genetic factors. Previous mouse models and data from sleep questionnaires suggested circadian misalignment might influence liver homeostasis and development of NAFLD. In this study, we aimed to objectively assess the sleep-wake rhythm in patients with NAFLD and healthy controls (HC) using actigraphy.

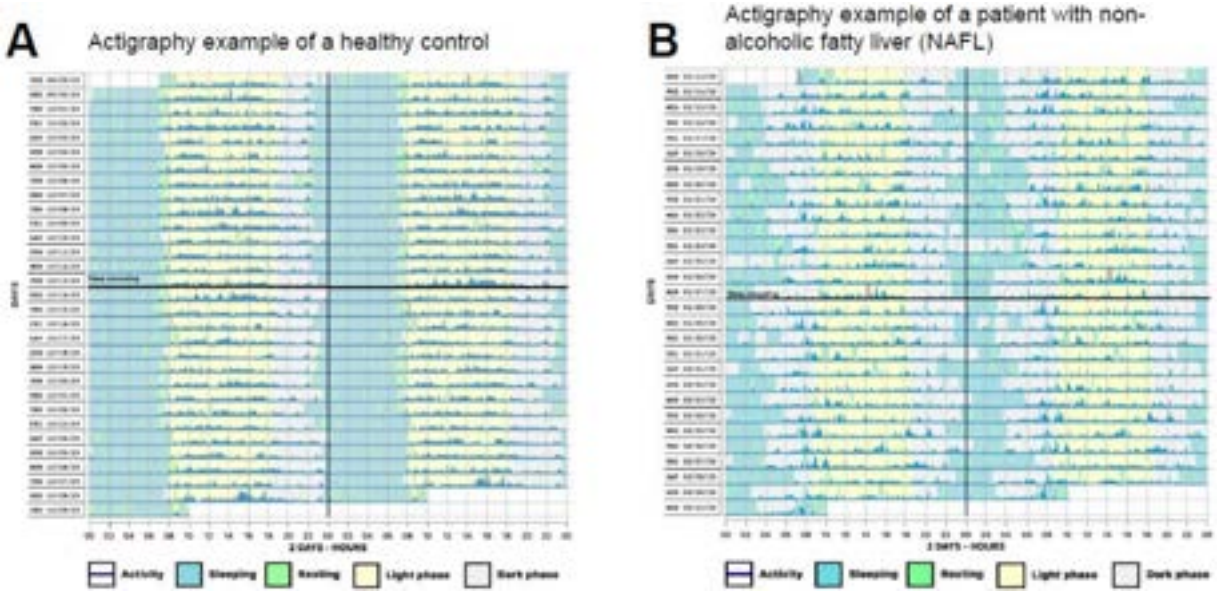

Figure A: (abstract: WED-431).

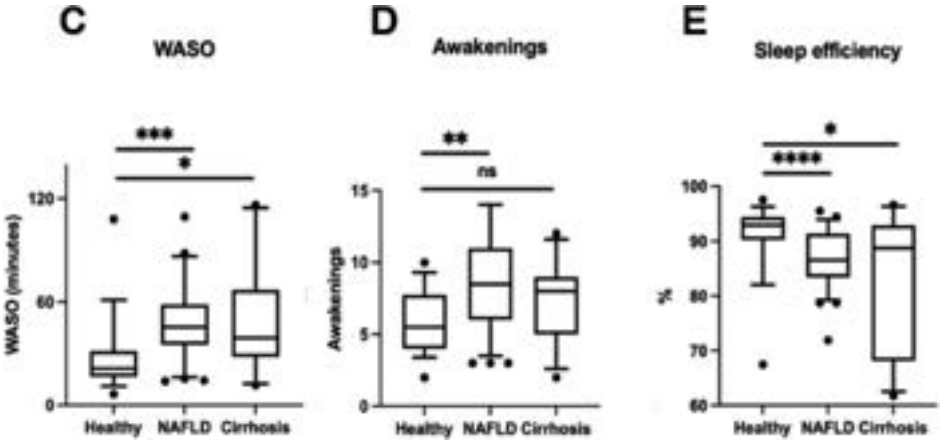

Figure B: (abstract: WED-431).

Method: We included 62 subjects: patients with NAFLD (non-alcoholic fatty liver (NAFL, n = 11), non-alcoholic steatohepatitis (NASH, n = 16), NASH with cirrhosis (n = 8)), patients with cirrhosis of other origin (n = 11) and HC (n = 16). Sleep-wake rhythm was assessed by actigraphy (ActTrust, Condor) 24/7 for 4 weeks. Additionally, metabolic, laboratory data and subjective sleep parameters were assessed at baseline and week 4. After 2 weeks a single standardised sleep hygiene counselling was performed.
Results: Actigraphy analysis revealed NAFLD patients had more fragmented sleep with more nocturnal awakenings per night (NAFLD vs. HC 8.5 vs. 5.5, p = 0.003) and longer wakefulness after sleep onset (WASO; NAFLD vs. HC, 45.4 min vs. 21.3 min, p = 0.0004) compared with HC, while sleep duration was comparable. Sleep efficiency was lower in NAFLD and cirrhosis patients compared with HC (NALFD vs. HC 86.5% vs. 92.8%, p = 0.0008: cirrhosis vs. HC 88.7% vs. 92.8%, p = 0.03). A single session of sleep hygiene counselling did not change sleep and laboratory parameter, nor subjective sleep quality (p > 0.05).
Conclusion: Using an objective method, NAFLD patients had more fragmented nocturnal sleep with increased awakenings and reduced sleep efficiency compared with HC. A single session of sleep hygiene education was not successful in improving objective or subjective sleep parameters.

WED-432

A novel ALK5 inhibitor (TLR-X) attenuates steatosis and fibrosis in non-alcoholic steatohepatitis in vivo

Marit ten Hove[1], Ruchi Bansal[1]. [1]*University of Twente, Enschede, Netherlands*
Email: m.m.tenhove@utwente.nl

Background and aims: Non-alcoholic steatohepatitis (NASH) represents a major health burden worldwide with no FDA-approved therapies available. Transforming growth factor-beta 1 (TGF-β1) is significantly upregulated in human NASH. Through Smad signaling, TGF-β1 promotes NASH by inducing lipid accumulation in hepatocytes and contributing to hepatocyte death, and activating hepatic stellate cells (HSCs). TGF-β receptor I (ALK5) is an attractive target for intervention in canonical TGF-β1 signaling due to its druggability, centrality, and specificity in the pathway. Silencing this pathway is expected to attenuate hepatic steatosis and fibrosis. In this study, we investigated the novel, highly selective, and orally administrable ALK5 inhibitor (TLR-X) for the treatment of NASH.
Method: Based on promising in vitro results, we investigated the effects of orally administered TLR-X in a NASH mouse model. C57BL/6J mice (8-weeks old) were fed western-diet (WD) containing 21.1% fat, 41% sucrose and 1.25% cholesterol by weight supplemented with high sugar solution (23.1 g/L d-fructose and 18.9 g/L d-glucose), combined with increasing low weekly doses (0.05–0.2 ml/kg) of carbon tetrachloride (CCl4) for 12 weeks. In the last three weeks, TLR-X (30 mg/kg) was orally administered twice daily. Blood, liver and different organs were collected for subsequent analysis.
Results: We observed a significant decrease in plasma cholesterol levels in TLR-X-treated WD/CCl4 mice (n = 7) compared to vehicle-treated mice (n = 7). Oil-red-O staining showed a significant decrease in intrahepatic fat accumulation in TLR-X-treated mice. Additionally, the expression of genes involved in de novo synthesis of fatty acids (FASN, SCD1 and ACACA) was significantly decreased in the TLR-X-treated group compared to the vehicle-treated group. We further assessed the effect of TLR-X on fibrosis and observed that total hydroxyproline content, collagen-I immunostaining and profibrotic gene expression (TGFB1, PDGFRB and ACTA2) were significantly decreased in the TLR-X treated group compared to the vehicle group. Overall, these results indicate the attenuation of hepatic steatosis and fibrosis by TLR-X.
Conclusion: Our results demonstrate that inhibition of the canonical TGFβ signaling using TLR-X represents a potential therapeutic approach for the treatment of NASH, by attenuating steatosis and fibrosis, with possible clinical implications.

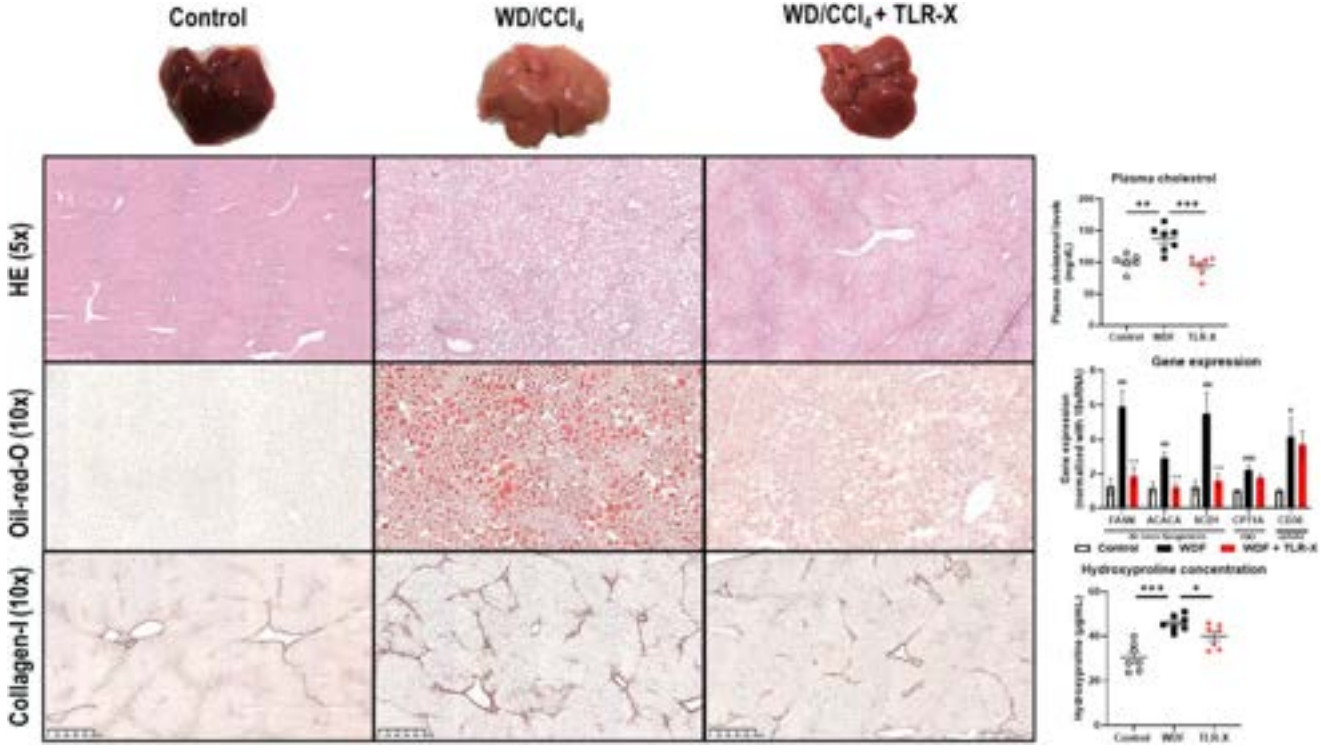

Figure: (abstract: WED-432).

WED-433

Gamma-muricholic acid inhibits steatosis-dependent peroxidative impairment to attenuates non-alcoholic steatohepatitis by activation of FXR/SHP/LXRα/FASN signaling

Yang Xie[1], Rui-Xu Yang[1], Feng Shen[2], Jiangao Fan[1], Qin Pan[1,3]. [1]*Xinhua Hospital Affiliated To Shanghai Jiaotong University School of Medicine, Department of Gastroenterology, Shanghai, China,* [2]*Xinhua Hospital Affiliated To Shanghai Jiaotong University School of Medicine, Endoscopy center, Shanghai,* [3]*Shanghai University of Medicine and Health Sciences Affiliated Zhoupu Hospital, Research center, Shanghai, China*
Email: pan_qin@yeah.net

Background and aims: Non-alcoholic steatohepatitis (NASH) reflects the key step from non-alcoholic fatty liver to hepatic fibrosis/cirrhosis and hepatocellular carcinoma depending on steatosis-induced oxidative stress. γ-muricholic acid (γ-MCA) with effect of lipogenic inactivation by farnesoid X receptor (FXR) agonizing plays potential role against liver steatosis and then peroxidative impairments.
Method: Except for the normal controls, experimental NASH was established in mice by 16-week high-fat high-cholesterol (HFHC) diet, with (NASH+10 mg/kg γ-MCA, NASH+100 mg/kg γ-MCA groups) or without simultaneous γ-MCA exposure (NASH, NASH+vehicle groups). Both oil red O staining and triglyceride (TG) analysis revealed the impact of γ-MCA on hepatic steatosis. Liver concentrations of malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE) exhibited steatosis-dependent lipid peroxidation. Peroxidative injury and related hepatocyte apoptosis were further investigated by transferase levels and terminal deoxynucleotidyl transferase nick end labeling (TUNEL) assay, respectively. NAFLD activity score (NAS) finally exhibited the outcome of γ-MCA treatment. Mechanically, effect of γ-MCA on FXR and downstream signalling of small heterodimer partner (SHP)/liver X receptor α (LXRα)/fatty acid synthase (FASN) was investigated *in vivo* and *in vitro*.
Results: γ-MCA agonized FXR to upregulate the SHP expression of hepatocytes. An increase in SHP attenuated the TG-dominated hepatic steatosis induced *in vivo* by HFHC diet, and *in vitro* by free fatty acids, on the basis of LXRα and FASN inhibition. In contrast, FXR knockdown abrogated the γ-MCA-dependent lipogenic inactivation. When compared to their excessive production in HFHC diet-induced rodent NASH, products of lipid peroxidation (MDA, 4-HNE) exhibited significant reduction upon γ-MCA treatment. Moreover, the decreased levels of serum ALT and AST demonstrated an improvement in peroxidative injury of hepatocytes. By TUNEL assay, injurious amelioration protected the γ-MCA-treated mice against hepatic apoptosis. The abolishment of apoptosis resultantly prevented lobular inflammation, which downregulated the incidence of NASH by lowering NAS (NASH group *vs* NASH+100 mg/kg γ-MCA group: 5.75 ± 0.590 *vs* 1.375 ± 0.420, $p < 0.05$).

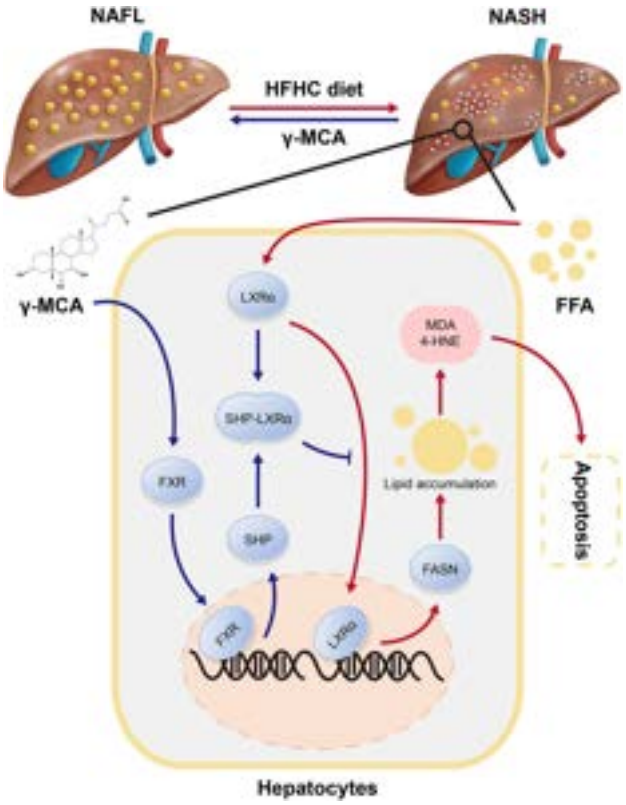

Figure:

Conclusion: γ-MCA inactivates lipogenesis to ameliorate hepatic steatosis by targeting FXR/SHP/LXRα/FASN signalling. Mitigation of steatosis-based peroxidative injury results in the NASH attenuation.

WED-434

Statins regulate PNPLA3 through a mechanism that requires SREBF2 in human liver cells

Osman Ahmed[1,2], Vladimir S Shavva[1], Wanmin Dai[1], Laura Tarnawski[1], Stephen Malin[1], Anders Franco-Cereceda[3], Per Eriksson[1], Hanna Björck[1], Peder Olofsson[1]. [1]*Karolinska institutet and Karolinska University Hospital, Department of Medicine Solna, Stockholm, Sweden,* [2]*University of Khartoum, Department of Biochemistry, Khartoum, Sudan,* [3]*Karolinska institute and Karolinska University Hospital, Department of Molecular Medicine and Surgery, Stockholm, Sweden*
Email: osman.ahmed@ki.se

Background and aims: Genetic variation within the patatin-like phospholipase domain containing 3 (PNPLA3) gene is associated with both susceptibility to NAFLD and response to statin treatment in NAFLD patients. Here, we studied the association between statin treatment and hepatic expression of *PNPLA3* from liver biopsies of patients without any known liver diseases.
Method: Liver biopsies were collected from 261 patients undergoing open-heart surgery. Patients were stratified by 1) Statins versus non-statin users in all cohort 2) by presence of the metabolic syndrome among non-statins users 3) Statins versus non-statins users among patients with metabolic syndrome only. In this cohort, 81 patients were treated with statins and 144 were not while 36 patients did not fulfil the inclusion criteria. Among the 144 non statins users 26 patients fulfilled the criteria of metabolic syndrome defined by the International Diabetes Federation. Liver gene expression and genotypes data in addition to plasma proteomic and lipoprotein profile were analyzed. Using atorvastatin, we validated the data from the human liver cohorts using *in vitro* models of HepG2 and hepatic stellate cells (HSC) LX2.

Results: Among non-statin users, mRNA levels of NAFLD- and lipogenesis-associated genes (*PNPLA3*, *ACACA*, *SCD-1* and *ACLY*) were significantly different between patients that did and did not fulfill criteria for the metabolic syndrome. Moreover, patients with metabolic syndrome and on statin therapy have higher fasting glucose, insulin and HbA1c levels in plasma compared to non-statin-treated metabolic syndrome patients. In addition, the mRNA levels of *PNPLA3*, *ACACA* and *ACLY* in liver were higher in patients with metabolic syndrome and on statin therapy than in non-statin-treated metabolic syndrome patients. Exposure of HepG2 hepatocyte-like cells and LX2 stellate-like cells, respectively, to atorvastatin *in vitro* significantly increased mRNA levels of *SREPF2*, *HMGCR*, *PCSK9*, *LDLR* and *PNPLA3* when compared to vehicle-treated cells. Knock-down of SREBP2 in HepG2 hepatocyte-like cells and LX2 hepatic stellate-like cells, respectively, abolished this effect and significantly reduced levels of these mRNAs both in cultures exposed to vehicle- and to atorvastatin.
Conclusion: Both statin treatment and the metabolic syndrome itself are associated with upregulation of lipogenesis-associated genes and *PNPLA3* mRNA levels in the human liver. SREBP2 is essential for the regulation of *PNPLA3* by atorvastatin in hepatocyte-like cells and hepatic stellate-like cells. Our study suggests that statins exaggerate hyperglycemic features in patients that fulfilled criteria for metabolic syndrome which may be a consequence of transcriptionally induced hepatic lipogenesis.

WED-435
Deletion of mixed lineage kinase domain like pseudokinase aggravate chronic alcohol induced liver injury via increasing apoptosis

Hyo Young Lee[1], Dae Won Jun[2], Eileen Yoon[2], Huiyul Park[3], Sang Bong Ahn[4], Mimi Kim[2], Chul-min Lee[2], Bo-Kyeong Kang[2], Joo Hyun Sohn[2], Jihyun An[2], Hyunwoo Oh[1], Jang Han Jung[5], Joo Hyun Oh[4], Eun Chul Jang[6], Young Eun Chon[7]. *[1]Uijeongbu Eulji Medical Center, Eulji University College of Medicine, Korea, Rep. of South, [2]Hanyang University, College of Medicine, Korea, Rep. of South, [3]Myoungji Hospital, Hanyang University College of Medicine, Korea, Rep. of South, [4]Nowon Eulji Medical Center, Eulji University School of Medicine, Korea, Rep. of South, [5]Dongtan Sacred Heart Hospital of Hallym University Medical Center, Korea, Rep. of South, [6]Soonchunhyang University College of medicine, Korea, Rep. of South, [7]CHA Bundang Medical Center, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: The mixed lineage kinase domain like pseudokinase (MLKL) is known to play a protective role in non-alcoholic fatty liver disease (NAFLD) via inhibition of necroptosis pathway. However, the role of MLKL in alcoholic liver disease (ALD) is not yet clear.
Method: C57BL/6N wild-type (WT) and MLKL-knockout (KO) mice (8–10 weeks old) were randomly divided into eight groups. To establish ALD model of different durations ethanol (EtOH) was fed to WT and MLKL KO for 10 days, 4 weeks and 8 weeks. The control group was fed with Lieber-DeCarli control diet for 8 weeks. Mortality, degree of hepatic inflammation, and steatosis were compared among the groups. Bulk mRNA transcriptome analysis was performed. Abundance of transcript and gene expressions were calculated based on read count or Transcript by Million (TPM) value.
Results: Survival rate of MLKL KO mice compared to WT was similar until 4 weeks, but the survival of MLKL KO mice significantly decreased after 8 weeks in ALD model. There was no difference in degree of inflammation, steatosis, and NAS scores between EtOH fed MLKL KO and EtOH fed WT mice at 10 days. However, at 4 weeks and 8 weeks, the degree of hepatic steatosis, NAS and inflammation were increased in MLKL KO mice. RNA transcriptome data showed that fatty acid synthesis, and lipogenesis, mitochondria, and apoptosis related pathways were upregulated in EtOH fed MLKL KO mice compared to EtOH fed WT mice. Although hepatocyte apoptosis (BAX/BCL2 ratio, caspase-3, and TUNEL staining) increased after EtOH intake; however, apoptosis was more significantly increased in EtOH fed MLKL KO mice compared to the WT group. At the same time, hepatic cFLIP was decreased in EtOH fed MLKL KO mice compared to the WT group.
Conclusion: MLKL deletion did not prevent chronic alcohol-induced liver damage independently of necroptosis and exacerbated hepatic steatosis by increasing hepatocyte apoptosis.

WED-436
Validation and utility of artificial intelligence-based zonal annotations as an additional assessment tool for the histopathologic review of fibrosis in non-alcoholic steatohepatitis patients

Gwyneth Soon[1], Aileen Wee[2], Wei Qiang Leow[3], Elaine Chng[4], Dean Tai[4], Yayun Ren[4], Feng Liu[5], Lai Wei[6], Arun Sanyal[7]. *[1]National University Hospital, Department of Pathology, Singapore, [2]Yong Loo Lin School of Medicine, National University of Singapore, Department of Pathology, Singapore, [3]Singapore General Hospital, Singapore and Duke-NUS Medical School, Department of Anatomical Pathology, Singapore, [4]HistoIndex Pte Ltd, Singapore, [5]Peking University Hepatology Institute, Peking University People's Hospital, China, [6]Hepatopancreatobiliary Center, Beijing Tsinghua Changgung Hospital, China, [7]Stravitz-Sanyal Institute of Liver Disease and Metabolic Health, VCU School of Medicine, United States*
Email: gwyneth_st_soon@nuhs.edu.sg

Background and aims: Inter-observer variability for categorical scores of liver fibrosis among pathologists ranges from fair to moderate weighted kappa. Artificial intelligence (AI) and advances in digitised whole-slide imaging (WSI) have facilitated the use of AI-assistive tools in pathology to improve histopathologic interpretation. Second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy with qFibrosis staging and continuous values as AI- assistive tools has been shown to help standardize pathologist assessment, contributing to higher overall intra- and inter-rater agreements. With the additional provision of AI-based zonal annotations, we aim to explore whether there will be further improvements on the overall inter-pathologist agreement on fibrosis assessment.
Method: Unstained sections of liver biopsies from 50 untreated NASH patients (F0-F4) were evaluated. Fibrosis was quantitated using SHG/TPEF microscopy (qFibrosis). Unassisted reads comprised digitized HandE and Masson trichrome-stained images uploaded to a WSI platform. Level I assisted reads included additional SHG images with qFibrosis outputs. Level II assisted reads further included zonal annotations. The zonal annotations serve to highlight the portal tract (PT), central vein (CV), peri-PT, peri-CV and perisinusoidal regions. To evaluate performance for assisted and unassisted reads, three pathologists with 5 to 40 years' experience interpreted images in 2 sessions: a) Unassisted versus Assisted level I, b) Unassisted versus Assisted level II. Each session consisted of 4 reads, starting with the unassisted read followed by sample randomization before proceeding to the assisted read. This was repeated after a 3–4-week washout period.
Results: When assisted by the level I AI tool, the concordance rate between pathologists improved to near-perfect agreement, with 0.82 linear weighted kappa, as compared to 0.72 for the unassisted review. Mean overall percentage agreement (PA) between pathologists improved from 89.38% to 92.93% ($p = 0.032$). Mean linear weighted kappa for intra-observer agreement was also higher, achieving 0.91 kappa compared to 0.79 for unassisted reads. When compared with the assistive level I tool, the concordance between pathologists with assistive level II tools showed marginal improvement from 0.82 to 0.84. The overall PA increased slightly from 92.9% to 93.8% ($p = 0.473$).

Zonal annotations and the impact of AI-assistive tools on intra- and inter-rater agreements.

		Unassisted	Assisted Level I	Assisted Level II
inter-observer	Mean percentage agreement	89.4%	92.9%	93.8%
	Mean weighted kappa (Linear)	0.72	0.82	0.84
intra-observer	Mean percentage agreement	92.1%	96.5%	95.63%
	Mean weighted kappa (Linear)	0.79	0.91	0.88

Figure:

Conclusion: qFibrosis as an AI-assistive tool can improve inter-pathologist weighted kappa to near-perfect (close to 93%) agreement. Additional AI-based zonal annotations provide negligible improvement in inter-pathologist weighted kappa.

WED-437

Anti-inflammatory and anti-fibrotic effects by simultaneous activation of glucagon, GIP, and GLP-1 of efocipegtrutide (HM15211) in thioacetamide-induced mouse model of liver injury and fibrosis

Jung Kuk Kim[1], Yohan Kim[1], Jong Suk Lee[1], Hyunjoo Kwon[1], Eun Jin Park[1], Jeong A Kim[1], Sung Min Bae[1], Dae Jin Kim[1], Sang Hyun Lee[1], In Young Choi[1]. [1]*Hanmi Pharm.Co., Ltd., Korea, Rep. of South*
Email: iychoi@hanmi.co.kr

Background and aims: Despite of increase in number of fibrosis due to NASH which becomes a major cause of liver-related outcomes, no approved drug is available. Recently, potential benefit of incretins such as glucagon (GCG), GIP and GLP-1 beyond metabolism has been proposed especially in inflammation and fibrosis. Thus, to optimally implement these incretins, efocipegtrutide, a long-acting GCG/GIP/GLP-1 triple agonist, was developed. Here, we evaluated and compared the therapeutic effects of efocipegtrutide with available incretin drugs in TAA (thioacetamide)-induced liver injury and fibrosis mouse.

Method: TAA was intraperitoneally injected to mouse for 12 weeks to induce liver injury and fibrosis, and efocipegtrutide was administered during last 10 weeks, and semaglutide as well as tirzepatide were included as comparative controls. At end of treatment, hepatic hydroxyproline content was measured and the liver tissues were subjected to HandE and Sirius red staining followed by histological grading. qPCR and ELISA were performed to evaluate relevant hepatic and blood bio-markers.

Results: Efocipegtrutide treatment was associated with significant reduction of hepatic hydroxyproline content (231.9 nmol/g vs. 350.4 nmol/g for TAA, vehicle; $p < 0.001$) while that of semaglutide (322.5 nmol/g) or tirzepatide (322.1 nmol/g) had minor effects. Similarly, treatment of efocipegtrutide (0.83%, $p < 0.001$), significantly reduced Sirius red positive area (vs. 5.75% for TAA, vehicle), unlike neither semaglutide (4.93%) nor tirzepatide (3.61%). To further confirm the potential benefit of efocipegtrutide, histological grading was conducted by using Sirius red and HandE staining, in which efocipegtrutide (1.29, 1.00 vs. 3.00, 3.00 for TAA, vehicle) exhibited greater reduction effects on both fibrosis and portal inflammation score compared to semaglutide (2.14, 2.71) or tirzepatide (2.00, 2.57). Consistent with such histologic analysis, expression of hepatic marker genes for fibrosis and inflammation were significantly/numerically reduced only in efocipegtrutide group. Significant reduction in blood TIMP-1 level was also observed.

Conclusion: Efocipegtrutide effectively improved liver inflammation and fibrosis in TAA mice. Notably, greater improvement effect over semaglutide and tirzepatide highlights the potential benefit of simultaneous use of GCG, GIP, and GLP-1. Thus, efocipegtrutide could be a novel therapeutic option for fibrosis due to NASH. Human study is ongoing to assess the clinical relevance of these findings.

Collagen co-localized with macrovesicular steatosis better differentiates fibrosis progression in non-alcoholic fatty liver disease mouse models

XiaoXiao Wang[1], Rui Jin[1], Xiaohe Li[1], Qiang Yang[2], Xiao Teng[3], Fangfang Liu[4], Nan Wu[1], Huiying Rao[1], Feng Liu[1]. *[1]Peking University People's Hospital, Peking University Hepatology Institute, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis, Beijing, China, [2]Hangzhou Choutu Technology Co, China, [3]HistoIndex Pte Ltd, Singapore, [4]Peking University People's Hospital, China*

Email: liu1116m@sina.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a global commonly occurring liver disease. However, its exact pathogenesis is not fully understood. The purpose of this study was to quantitatively evaluate the progression of steatosis and fibrosis by examining their distribution, morphology, and co-localization in NAFLD animal models.

Method: Six mouse NAFLD groups were established: (1) western diet (WD) group; (2) WD with fructose in drinking water (WDF) group; (3) WDF + carbon tetrachloride (CCl4) group, WDF plus intraperitoneal injection of CCl4; (4) high-fat diet (HFD) group, (5) HFD with fructose (HFDF) group; and (6) HFDF + CCl4 group, HFDF plus intraperitoneal injection of CCl4. Liver tissue specimens from NAFLD model mice were collected at different time points. All the tissues were serially sectioned for histological staining and Second-harmonic generation (SHG)/two-photon excitation fluorescence imaging

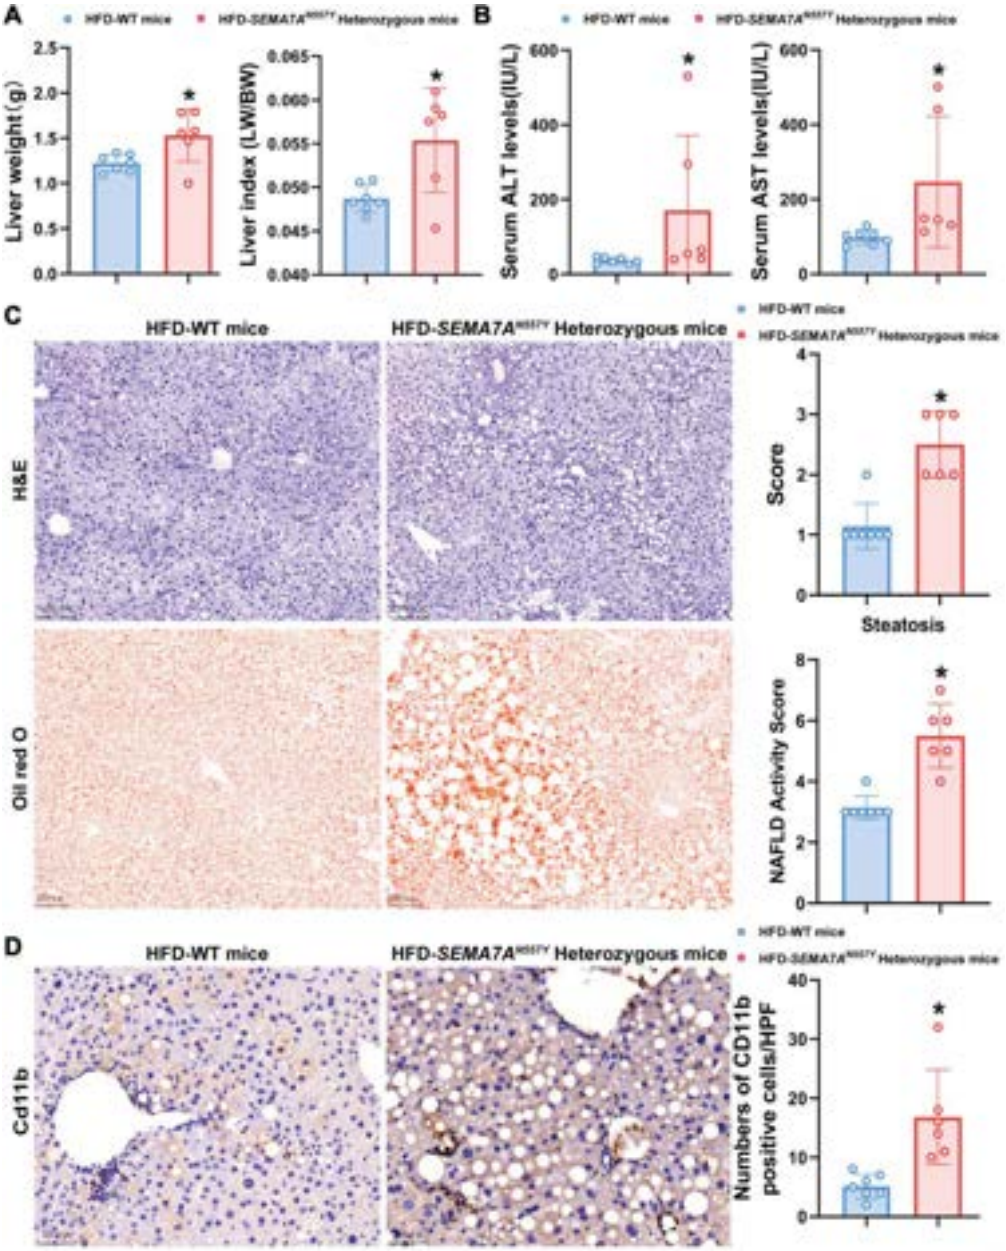

Figure: (abstract: WED-439) The *Sema7a*^{N557Y} heterozygous mutation aggravates liver injury, steatosis and inflammation in NAFLD induced by high-fat diet in mice. Liver weights and the liver/body weight ratios. HFD-WT (n = 7), HFD-*Sema7a*^{N557Y} (n = 6). (B) Serum ALT and AST levels. (C) HandE and oil red O-stained liver histology. Scale bar, 100 μm. NAFLD activity score is shown. (D) Representative images of IHC staining of Cd11b and their quantitative assessments of randomly selected microscopic fields. Scale bar, 50 μm. Data are presented as mean ± SD. *$p < 0.05$ versus the HFD-WT mice. The data were analyzed with Student's t test.

(TPEF) imaging. The progression of steatosis and fibrosis was analyzed using SHG/TPEF quantitative parameters with respect to the NASH CRN scoring system.
Results: qSteatosis showed a good correlation with steatosis grade (R: 0.823–0.953, $P < 0.05$) and demonstrated high performance (AUC: 0.617-1) in six mouse models. Based on their high correlation with histological scoring, qFibrosis containing four shared parameters (#LongStrPS, #ThinStrPS, #ThinStrPSAgg, and #LongStrPSDis) were selected to create a linear model that could accurately identify differences among fibrosis stages (AUC: 0.725-1). qFibrosis co-localized with macrosteatosis generally correlated better with histological scoring and had a higher AUC in six animal models (AUC: 0.846-1).
Conclusion: Quantitative assessment using SHG/TPEF technology can be used to monitor different types of steatoses and fibrosis progression in NAFLD models. The collagen co-localized with macrosteatosis could better differentiate fibrosis progression and might aid in developing a more reliable and translatable fibrosis evaluation tool for animal models of NAFLD.

A heterozygous N559Y mutation in Semaphorin 7A promotes non-alcoholic fatty liver disease progression through induction of hepatic ROS production and inflammation

Yao Tong[1], Xiaoxun Zhang[1], Nan Zhao[1], Jin Chai[1]. [1]*the First Affiliated Hospital (Southwest Hospital) of Third Military Medical University (Army Medical University), China*
Email: jin.chai@cldcsw.org

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a serious liver disease of worldwide concern, which can lead to cirrhosis and hepatocellular cancer. Notably, genetic factors play an important role in the pathogenesis of NAFLD. Semaphorin 7A (SEMA7A), as a membrane-bound protein, contributes to axon growth, T cell activation, and other biological processes. In this study, we examined mechanism of *SEMA7A*^{N559Y} heterozygous mutation aggravating non-alcoholic fatty liver disease.
Method: We generated *Sema7a*^{N557Y} (equal to human *SEMA7A*^{N559Y}) heterozygous mutated mice to investigate the role of *SEMA7A*^{N559Y} mutation in the progression of NAFLD. 8-week-old wild type mice and *Sema7a*^{N557Y} heterozygous mutated mice were fed with high-fat diet (HFD) for 8 weeks. All mice were sacrificed and their serum and liver tissue were collected and analyzed. HandE staining, Oil Red O staining, and immunohistochemistry (IHC) of Cd11b protein were performed to evaluate liver steatosis and inflammation. Western blot analysis was used to measure the expression of lipid metabolism and cell pyroptosis-related proteins. NOX, CAT, and MDA content were measured as oxidative stress markers in liver tissue. Expression of Il-1beta, Il-18, Il-6, Tnf-alpha, Ccl2 and Cd11b was determined in total liver by real-time qPCR.
Results: In our previous study, *SEMA7A*^{N559Y} heterozygous mutation was identified in NAFLD patients. HFD-*Sema7a*^{N557Y} mice had higher liver weight, liver index, serum ALT and AST levels than that of HFD-WT mice. Liver histologic analyses revealed that the *Sema7a*^{N557Y} variant markedly increased liver steatosis and inflammation. Further studies indicated that *Sema7a*^{N557Y} mutation can significantly increased the proteins expression of lipid metabolism and ROS levels by enhancing PI3 K/AKT signaling. In addition, *Sema7a*^{N557Y} mutation markedly activate the ROS/NLRP3 pathway and cause liver inflammatory response.
Conclusion: In conclusion, our research demonstrates that *SEMA7A*^{N559Y} heterozygous variant may be a new genetic determinant of NAFLD and promotes liver injury by inducing hepatocytes pyroptosis and liver inflammation.

WED-440
Endothelial and platelet-derived microvesicles as a biomarker of cardiovascular risk in patients with metabolic dysfunction-associated fatty liver disease (MAFLD)

Sheila Gato Zambrano[1], Rocio Munoz Hernandez[1], Rocío Montero-Vallejo[1], María del Carmen Rico[1], Vanessa García Fernández[1], Angela Rojas Alvarez-Ossorio[1], Antonio Gil-Gomez[1], Javier Gallego[1], Rocío Gallego-Durán[1], Douglas Maya Miles[1], Javier Ampuero[1], Manuel Romero Gomez[1]. [1]*Servicio de Aparato Digestivo, Hospital Universitario Virgen del Rocío; SeLiver Group, Instituto de Biomedicina de Sevilla (HUVR/CSIC/US), Departamento de Medicina Universidad de Sevilla; CIBEREHD, Sevilla., Spain*
Email: mromerogomez@us.es

Background and aims: MAFLD is associated with cardiovascular risk (CVR), but it is not clear if it contributes independently to the development of this disease. Early detection of endothelial dysfunction and CVR reduces premature morbidity and mortality. Endothelial dysfunction is associated with increased plasma levels of endothelial (EMVs) and platelet-derived microvesicles (PMVs). The objective of the study was to evaluate the levels of EMVs and PMVs in MAFLD patients and their relationship with CVR.
Method: 97 MAFLD biopsy-proven patients were included and classified according to the SAF-score as steatosis (SS) or steatohepatitis (NASH). We assessed the presence of subclinical atherosclerosis using the ankle-brachial index (ABI) and the atherosclerotic cardiovascular disease risk index (ASCVD). We quantified PMVs (AV+CD31+CD41+), EMVs (AV+CD31+CD41+) and activated EMVs (AV+CD62e+) in heparin-plasma samples by flow cytometry.
Results: Baseline patients characteristics are represented in Table 1. We did not observe differences in the proportion of patients with pathological ABI and ASCVD between the different MAFLD groups. In contrast, PMVs (AV+ CD41+) are increased in patients with NASH vs. SS ($p = 0.02$) (Fig 1a), although platelet levels are similar. In addition, patients with lobular inflammation present higher levels of PMVs (AV+CD31+CD41+) compare to those without inflammation ($p = 0.029$, Fig1b); on the other hand, there were no differences according to the degree of ballooning. Moreover, levels of activated EMVs (AV+CD62e+) are increased in MAFLD and hypertension (AHT) patients vs. those without AHT ($p = 0.037$) (Fig 1c), in the same way, are increased in patients with ASCVD > 10% ($n = 16$) vs. those with ACSVP < 10% ($n = 17$) (365.7 ± 104.3 vs. 649.7 ± 158.6; $p = 0.045$). Finally, according to the severity of liver disease and the presence of atherosclerosis (depending on ABI and ASCVD), we did not observe differences in the levels of EMVs or PMVs.
Conclusion: PMVs levels are associated with disease and lobular inflammation, suggesting the presence of endothelial damage. Activated EMVs increase in patients with hypertension, suggesting that the impact of MAFLD on endothelial activation and, therefore, on vascular structure, may depend on the coexistence of other CVR factors such as hypertension.

A novel orally available type IV autotaxin inhibitor, IOA-289, ameliorates steatosis and fibrosis in a preclinical model of non-alcoholic steatohepatitis

Marit ten Hove[1], Giusy Di Conza[2], Karolina Niewola[2], Marcel Deken[2], Lars van der Veen[2], Ruchi Bansal[1]. [1]*University of Twente, Netherlands,* [2]*iOnctura SA, Genève, Switzerland*
Email: m.m.tenhove@utwente.nl

Background and aims: Non-alcoholic steatohepatitis (NASH) represents a major health burden worldwide with no FDA-approved therapies available. Lysophosphatidic acid (LPA), produced by autotaxin (ATX), is correlated with the progression of NASH, and regulates lipid homeostasis, and induces liver inflammation and fibrosis. Hepatic ATX knockdown in a high-fat diet mouse model showed protection against NASH by decreasing hepatic steatosis, inflammation, and fibrosis. Recently, we have shown that inhibiting ATX using a type-IV inhibitor (that occupy the tunnel and the pocket of ATX) possess better potential in ameliorating NASH than a type-I inhibitor (that targets the catalytic site and the pocket of ATX). In this study, we aim to further investigate the therapeutic effects of a novel and orally available type IV ATX inhibitor, IOA-289, for the treatment of NASH.
Method: First, we examined the expression of ATX and LPA receptors in different liver pathologies. Thereafter, we tested the efficacy of IOA-289 in vitro employing disease-specific stimulated hepatic cell types to recapitulate different processes of NASH. Based on promising in vitro results, we investigated the effects of orally administered IOA-289 in a NASH mouse model. C57BL/6J mice were fed western-diet (WD) containing 21.1% fat, 41% sucrose and 1.25% cholesterol supplemented with high sugar solution (23.1 g/L d-fructose and 18.9 g/L d-glucose), combined with increasing low weekly doses (0.05–0.2 ml/kg) of carbon tetrachloride (CCl4) for 12 weeks. In the last six weeks, IOA-289 (30 mg/kg) or PF-8380 (a type-I ATX inhibitor, 30 mg/kg) was orally administered twice daily. Blood, liver, and different organs were collected for subsequent analysis.
Results: In our NASH mouse model, Oil-red-O staining showed a significant decrease in intrahepatic fat accumulation in IOA-289-treated mice (n = 7) and PF-8380-treated mice (n = 7) compared to vehicle-treated mice (n = 7). Additionally, the expression of genes involved in de novo synthesis of fatty acids (FASN, SCD1 and ACACA) were significantly decreased in the ATX inhibitor-treated groups compared to the vehicle-treated group. We further assessed the effect of both ATX inhibitors on fibrosis and observed that total hydroxyproline content, collagen-I immunostaining and profibrotic gene expression (TGFB1, PDGFRB and ACTA2) were significantly attenuated only in the IOA-289 treated group, but not in the PF-8380 treated group, compared to the vehicle group. Overall, these results indicate the amelioration of hepatic steatosis and fibrosis by IOA-289.
Conclusion: Our results demonstrate that inhibition of the LPA-ATX pathway, particularly using a type IV inhibitor, represents a potential

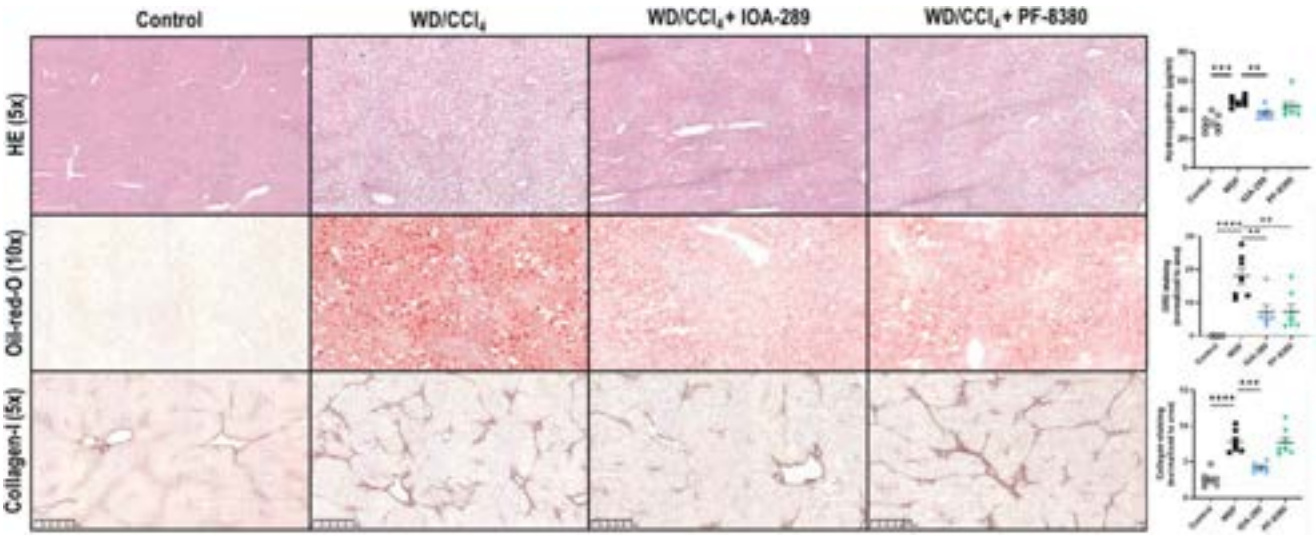

Figure: (abstract: WED-441).

therapeutic target in NASH, by attenuating steatosis and fibrosis, with possible clinical implications.

Cannabidiolic acid (CBDA) regulates energy homeostasis and protects against non-alcoholic fatty liver disease (NAFLD) in mice

Albert Giralt[1], Battsetseg Batchuluun[2,3], Robin Willows[1], Steve Lassueur[1], Christian Chabert[1], Dongdong Wang[2,3], Emily Day[2,3], Marisa Morrow[2,3], Evelyn Tsakiridis[2,3], Russta Fayazi[2,3], Sonia Rehal[2,3], James Lally[2,3], Eris Desjardins[2,3], Jaya Gautam[2,3], Carles Canto[1], Olivier Ciclet[1], Martine Naranjo Pinta[1], Denis Barron[1], Philippe Delerive[4], Gregory Steinberg[2,3,5], Marine Kraus[1], Matthew Sanders[1]. *[1]Nestlé Institute of Health Sciences, Nestlé Research, Société des Produits Nestlé S.A., Lausanne, Switzerland, [2]Centre for Metabolism, Obesity and Diabetes Research, McMaster University, Hamilton, Canada, [3]Division of Endocrinology and Metabolism, Department of Medicine, McMaster University, Hamilton, Canada, [4]Nestlé Health Sciences, Société des Produits Nestlé S.A, Switzerland, [5]Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, Canada*
Email: albert.giralt@rd.nestle.com

Background and aims: There has been growing interest in the potential health benefits of cannabinoids found in Cannabis Sativa for several years, however, their therapeutic potential for non-alcoholic fatty liver disease (NAFLD) remains largely unexplored. The aim of this study was to evaluate whether the main cannabinoid found in Cannabis Sativa, cannabidiolic acid (CBDA), could improve NAFLD in a mouse model.

Method: We examined the effect of CBDA on de novo lipogenesis (DNL) in mouse primary hepatocytes and in mice after a 4-day treatment with CBDA (10 mg/kg or 30 mg/kg, oral gavage). NAFLD was induced in C57BL/6J male mice by placing them at thermoneutrality (29°C) and feeding them a NASH diet (40% fat, 20% fructose, 0.02% cholesterol) for 16 weeks. After the onset of obesity and NAFLD, mice were treated daily with either CBDA (10 mg/kg or 30 mg/kg, oral gavage) or a vehicle for an additional 9 weeks. Insulin tolerance and glucose tolerance tests were performed at week 7 and 8 after the beginning of treatment, respectively. The impact of CBDA on liver triglycerides and lipid droplet area were quantified. NASH status was assessed by a blinded pathologist (NAFLD activity score) and liver fibrosis was quantified by pico-Sirius red staining area. Liver gene expression was assessed by RNA-seq. Primary human hepatic stellate cells (hHSC) were pre-treated with CBDA (1 h) and stimulated with TGBβ (48 h) and alpha-SMA1 levels and pro-collagen secretion in the media were measured. The effects of CBDA on cellular respiration in cells were evaluated using the Seahorse analyzer (Agilent) and the effects of CBDA on mitochondrial respiration in isolated mouse liver mitochondria were evaluated using the Oroboros (Oroboros Instruments).

Results: CBDA inhibited hepatic DNL in mouse primary hepatocytes and in vivo. CBDA treatment in a NAFLD mouse model successfully improved glucose tolerance and insulin sensitivity without significant changes in body weight. CBDA stimulated whole-body fat oxidation and significantly reduced hepatic steatosis. CBDA promoted NASH resolution and significantly decreased liver fibrosis. Liver gene expression analyses revealed a stimulation of pathways linked to lipid oxidation and a decrease in pathways associated with inflammation and fibrosis in response to CBDA treatment. In agreement, CBDA blunted TGFβ-induced activation of primary human HSCs and procollagen secretion, which was associated with DNL inhibition. Mechanistically, CBDA activates AMP-activated protein kinase (AMPK) in vitro and acutely stimulates cellular and mitochondrial respiration. These effects extended to several cannabinoid acid derivatives and were not observed in their respective neutral derivatives (e.g., cannabidiol, CBD).

Conclusion: This study demonstrates that CBDA inhibits hepatic DNL and improves several features of NAFLD, concomitantly with an improvement in glucose tolerance and insulin sensitivity. Additionally, for the first time, we show that CBDA and other cannabinoid acids increase mitochondrial respiration. These data provide evidence for a novel mechanism of action for the cannabinoid acids that could be exploited for the treatment of NAFLD and other metabolic diseases.

WED-443

Quantification of vessel and bile duct parameters using Second Harmonic Generation in patients with NAFLD across fibrosis stages

Jörn Schattenberg[1], Yayun Ren[2], Dean Tai[2], Elaine Chng[2], Maurice Michel[3], Christian Labenz[3], Beate Straub[4]. *[1]Metabolic Liver Research Center, University Medical Center of the Johannes Gutenberg-University, Germany, [2]HistoIndex Pte Ltd, Singapore, [3]University Medical Center of the Johannes Gutenberg-University, Department of Medicine, Germany, [4]University Medical Center of the Johannes Gutenberg-University, Department of Pathology, Germany*
Email: joern.schattenberg@unimedizin-mainz.de

Background and aims: Liver histology defines the pathophysiological alterations occurring in patients with NAFLD while they

develop progressive (especially perisinusoidal) fibrosis and progress to liver cirrhosis. Fibrosis and cirrhosis are defined by changes in the vascularisation as well as bile ducts, but they have not been systematically assessed in patients with NAFLD so far. The aim of this exploratory analysis was done to identify features of the hepatic vasculature and bile ducts using second harmonic generation imaging (SHG) and to correlate them with the histological fibrosis scores.

Method: Unstained sections from 132 patient with NAFLD that underwent liver biopsy between 2016 and 2018 for suspected NASH were included. Fibrosis staging was done based on the NASH CRN fibrosis score on Gomöri and evG stained liver biopsies. Second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy was done using unstained liver sections.

Results: Among the 132 patients, 52.7% were male with a mean age of 54 years [43.0–60.0] and a mean BMI of 32.2 kg/m2 [28.7–37.0]. Laboratory findings included ALT (U/l) 73.0 [50.0–115.7], AST 50 [38–67], gGT 109 [60.7–115.7], A1c 6.0 [5.4–6.9]. Mean transient elastography was 8.2 kPa [5.7–13.2]. Comorbidities included Type 2 Diabetes (41.2%), arterial hypertension (72.5%), hypertriglyceridemia (32.8%) and obesity (BMI > 30; 54.2%). Advanced fibrosis was present in 34.4% of liver biopsies. The histological fibrosis stages were distributed, according to Kleiner, as follows F0 (3.1%), F1a-c (27.5%), F2 (35.1%), F3 (23.7%) and F4 (10.7%).

SHG was used to quantify histological characteristics of the intrahepatic vasculature. A total of 50 pathological changes, including those of central veins, portal veins, arteries, as well as bile ducts and their respective morphological features were identified and quantified. The correlation of these features with fibrosis stages are shown as a heat map in the figure attached. A pattern that followed fibrosis stages was seen in portal tracts. The total area of portal tracts (Rho = 0.477), as well as the small (Rho = 0.316) and medium-sized portal vein (Rho = 0.344) branches increased progressively across fibrosis stages. In addition, features of arteries were relatively stable between disease stages from F0 to F3 but a sudden drop in correlations with arteries was observed at F4.

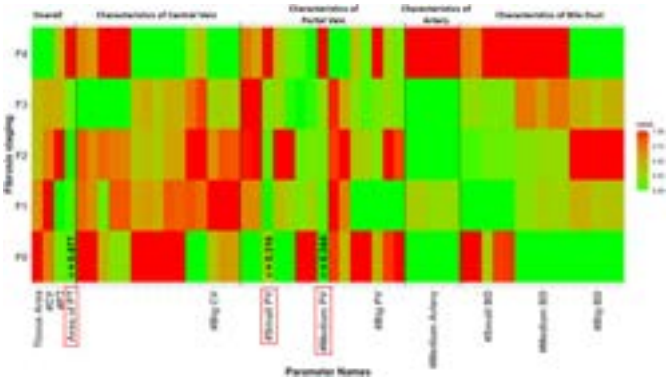

Figure: Heatmap indicated the correlation of histological characteristics with fibrosis stages. The range of characteristics was normalized to 0–1. Three features with largest coefficients were highlighted, including the total area of portal tract (Area of PT), number of small portal vein (#Small PV) and number of medium portal vein (#Medium PV). The correlation coefficient was calculated by Spearman's correlation method.

Conclusion: In patients with histologically defined NAFLD, alterations of the central veins, portal veins, as well as of bile ducts in the liver are correlated with increasing fibrosis stages with the exception of arteries. With onset of cirrhosis, changes are dramatically altered. Additional work is in progress to correlate this vasculature information to clinical data and other non-invasive tests results.

Liver-associated dysmetabolism is related to brain structure and perfusion changes in obesity: the BARICO study

Florine Seidel[1,2], Debby Vreeken[1,3], Emma Custers[1,3], Maximilian Wiesmann[1], Serdar Özsezen[4], Wim van Duyvenvoorde[2], Martien P. M. Caspers[4], Martine C. Morrison[2], Lars Verschuren[4], Marco Duering[5,6], Eric J. Hazebroek[3,7], Amanda Kiliaan[1], Robert Kleemann[2]. *[1]Radboud University Medical Center, Medical Imaging (Anatomy), Netherlands, [2]the Netherlands Organisation for Applied Scientific Research (TNO), Metabolic Health Research, Netherlands, [3]Vitalys, part of Rijnstate hospital, Bariatric surgery, Netherlands, [4]the Netherlands Organisation for Applied Scientific Research (TNO), Microbiology and Systems Biology, Netherlands, [5]University Hospital LMU Munich, Institute for Stroke and Dementia Research (ISD), Germany, [6]University of Basel, Medical Imaging Analysis Center (MIAC) and Department of Biomedical Engineering, Switzerland, [7]Wageningen University, Human Nutrition and Health, Netherlands*
Email: florine.seidel@tno.nl

Background and aims: Despite numerous studies showing negative associations between obesity and brain health, the molecular understanding of this relationship is very limited. Dysmetabolism-defined as derangement of metabolic homeostasis-is a hallmark of obesity and its comorbidities including non-alcoholic fatty liver disease (NAFLD). This exploratory study aims to molecularly characterize liver-associated dysmetabolism in obese persons to gain insight into relationships between liver and brain health.

Method: Liver biopsies and plasma samples from 76 mid-age obese subjects (BARICO study) were analyzed. Participants underwent MRI to investigate brain structure and perfusion. We investigated relationships between brain MRI readouts and liver lipids and gene expression, and plasma fatty acids and bile acid concentrations.

Results: Participants differed considerably in intrahepatic lipid load and plasma profiles indicating substantial heterogeneity in metabolic states. Concentration of intrahepatic lipids positively correlated with cerebral blood flow in the cortex of the temporal lobe and with putamen volume. Hepatic gene expression strongly correlated with these MRI readouts and distinct canonical pathways, among which 'oxidative phosphorylation' and 'mitochondrial dysfunction', were enriched with the correlating gene transcripts. Correlating genes also included genes implicated in lipid and bile acid metabolism. Consistently concentration of many plasma fatty acids (e.g. trans-fatty acids) and bile acids were inversely correlated with brain MRI readouts.

Conclusion: This exploratory study supports the view that general loss of metabolic homeostasis, rather than a specific metabolite, is critical for brain health already in mid-life.

WED-445

Combination therapy of TERN-501, a selective agonist of thyroid hormone receptor (THR) beta with TERN-101, a farnesoid X receptor (FXR) agonist improves non-alcoholic steatohepatitis (NASH) in a GAN diet-induced and biopsy-confirmed mouse model

Christopher Jones[1], Malte H. Nielsen[2], Denise Oró[2], Michael Feigh[2], Xiao Teng[3], Anthony Lie[3], Gideon Ho[3], Jeffrey Jasper[1]. *[1]Terns Pharmaceuticals, Foster City, United States, [2]Gubra, Hørsholm, Denmark, [3]HistoIndex Pte Ltd, Singapore, Singapore*
Email: cjones@ternspharma.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is a serious disease of the liver that will likely require a combination therapy to achieve maximal therapeutic response. TERN-501, a potent and selective agonist of thyroid hormone receptor (THR) beta, and TERN-101, a non-steroidal agonist of farnesoid X receptor (FXR), were tested alone and in combination in a Gubra-Amylin NASH (GAN) diet-induced obese mouse model of NASH (DIO-NASH).

Method: TERN-101 (10 mg/kg, PO) and TERN-501 (0.3 [Low], 2 [Med], and 10 [High] mg/kg, PO) were administered once daily as

single agents or in combination in biopsy-confirmed GAN DIO-NASH mice (n = 16/group) for 12 weeks. Histological analyses were performed at baseline and end of treatment to assess steatosis, inflammation, and fibrosis on stained biopsies. Liver biopsies were also assessed by stain-free artificial intelligence (AI)-based digital pathology (HistoIndex®) using second harmonic generation and two photon emission.

Results: The NAFLD Activity Score (NAS) was improved to a greater extent by combination treatment with 19%, 25%, and 43% of mice showing ≥2-pt NAS improvement from baseline in the Low, Med, and High combination arms, respectively. Quantitative liver histomorphometry on stained biopsies showed the combination treatment had greater anti-steatotic activity, including reduced liver lipids, fewer hepatocytes containing lipid droplets, and reduced lipid droplet size. Analyses by HistoIndex indicated that the combination treatment significantly lowered fibrosis colocalized with macrosteatotic vesicles and reduced the progression of fibrosis colocalized with microsteatotic vesicles. The perisinusoidal area showed significant reduction of fibrosis in the Med and High combination arms.

Conclusion: Treatment with the THR-beta agonist TERN-501 in combination with the FXR agonist TERN-101 led to greater NAS and fibrosis improvements from baseline compared with single agent treatments, likely driven by increased anti-steatotic activity. These data suggest that combining the robust anti-steatotic effects of a selective THR-beta agonist with an FXR agonist may provide a superior therapeutic benefit for NASH over either agent alone. The use of AI-digital pathology can provide granularity in NASH drug development during the preclinical phase, which may be translated to current use in NASH clinical trials.

WED-446

Unravelling the role of iron-catalysed ferroptotic cell death in non-alcoholic steatohepatitis

Cédric Peleman[1,2], Ine Koeken[3], Geraldine Veeckmans[3], Astrid Van den Branden[3], Emily Van San[3,4,5], Behrouz Hassannia[3,4,5], Luc Van Nassauw[6], Els Goeman[6], Ann Driessen[7,8], Lieve Vits[1], Annelies Van Eyck[1,9], Wilhelmus Kwanten[1,2], Luisa Vonghia[1,2], Joris De Man[1], Benedicte De Winter[1,2], Christophe Van Steenkiste[1,2], Tom Vanden Berghe[3,4,5], Sven Francque[1,2]. *[1]University of Antwerp, Laboratory of Experimental Medicine and Pediatrics, Infla-Med Centre of Excellence, Belgium, [2]Antwerp University Hospital, Department of Gastroenterology and Hepatology, Belgium, [3]University of Antwerp, Laboratory of Pathophysiology, Belgium, [4]Ghent University, Department of Biomedical Molecular Biology, Belgium, [5]VIB-UGent Center for Inflammation Research, Belgium, [6]University of Antwerp, Department of ASTARC, Faculty of Medicine and Health Sciences, Belgium, [7]Antwerp University Hospital, Department of Pathology, Belgium, [8]University of Antwerp, Centre for Oncological Research, Belgium, [9]Antwerp University Hospital, Department of Pediatrics, Belgium*
Email: cedric.peleman@uantwerpen.be

Background and aims: Hepatocyte cell damage and cell death are hallmarks of non-alcoholic steatohepatitis (NASH). Cell death inhibition might constitute a therapeutic option for NASH, but the dominant subtype of hepatocyte cell death in NASH remains to be elucidated. Accumulating evidence points towards ferroptosis as an important driver in NASH pathogenesis. Ferroptosis is a type of regulated necrotic cell death executed by iron-catalysed peroxidation of polyunsaturated fatty acids (PUFA) in membrane phospholipids. In the present study we examined the determinants of increased ferroptosis sensitivity of hepatocytes in vitro and the effects of ferroptosis inhibition on NASH in vivo in a murine dietary model.

Method: In vitro, we studied the sensitivity of HepG2 cell line to undergo ferroptosis after exposure to a NASH environment, i.e. oleic and palmitic acid (non-PUFA), hyperglycemia, hyperinsulinemia and cytokines. Finally, lipidomics assessed membrane phospholipid composition of HepG2 cells to elucidate determinants of ferroptosis sensitivity. In vivo, in C57BL/6J mice fed the choline-deficient L-amino acid defined high-fat diet (CDAHFD) for 4 weeks, the ferroptosis markers malondialdehyde (MDA) and 4-hydroxynonenal (4HNE) were assessed. The effect of ferroptosis inhibition by the third-generation ferrostatin analogue UAMC-3203 was tested in mice fed CDAHFD or standard diet (SD) on serum liver enzymes, hepatomegaly, liver fat and histology.

Results: In vitro, steatotic HepG2 cells displayed higher sensitivity towards ferroptosis inducer ML162, as evidenced by lower EC50 values for cell death with Sytox Green assay. Mechanistically, excess non-PUFA fatty acids increased PUFA incorporation in membrane phosphatidylglycerol in HepG2 cells, making them more vulnerable towards ferroptosis. In vivo, murine livers displayed NASH with increased hepatic MDA levels and panlobularly increased 4HNE staining on immunohistochemistry, compared to controls displaying normal liver histology. Simultaneous (preventive) treatment with UAMC-3203 for 4 weeks reduced hepatic MDA ($p < 0.01$ treatment effect, Fig 1A), hepatomegaly ($p < 0.001$, Fig 1B) and alanine transaminase levels ($p < 0.01$, Fig 1C) in CDAHFD, compared to vehicle. Likewise, therapeutic administration of UAMC-3203 during the last 2 out of 4 weeks of diet reduced MDA ($p < 0.05$) and alanine transaminase levels ($p < 0.01$), while attenuating macrovesicular steatosis and immune cell infiltration, compared to vehicle.

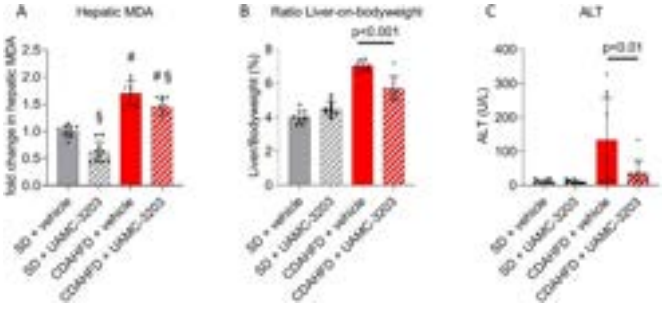

Figure:

Conclusion: Ferroptotic cell death is present in murine NASH livers, while its inhibition reduces systemic liver enzymes and attenuates hepatic lipid accumulation and immune cell infiltration. Mechanistically, non-PUFA fatty acids increased the vulnerability of hepatocytes to ferroptosis. Our findings imply that ferroptosis is a detrimental factor in NASH and thus may constitute a new therapeutic target.

WED-447

Antagonism of C-C motif chemokine receptor 2 (CCR2) using a novel in silico designed peptide attenuates macrophage infiltration and non-alcoholic steatohepatitis in vivo

Eline Geervliet[1,2], Ralf Weiskirchen[2], Ruchi Bansal[1]. *[1]University of Twente, Medical cell biophysics, Enschede, Netherlands, [2]RWTH Aachen, Institute of Molecular Pathobiochemistry, Experimental Gene Therapy and Clinical Chemistry, Aachen, Germany*
Email: ekgeervliet@gmail.com

Background and aims: Non-alcoholic steatohepatitis (NASH) represents a major health burden worldwide. Upon injury, C-C motif chemokine ligand 2 (CCL2) secreted by hepatocytes, hepatic stellate cells, and Kupffer cells trigger the recruitment of C-C motif chemokine receptor 2 (CCR2) expressing circulating monocytes that significantly contribute to the macrophage compartment of the liver and liver inflammation that further progresses to liver fibrosis, cirrhosis and/or hepatocellular carcinoma. CCR2 antagonism by Cenicriviroc (CVC), a small molecule CCR2/CCR5 dual inhibitor, showed reduction in macrophage/monocyte recruitment *in vitro* and *in vivo* in acute and chronic mouse models. Despite promising results in the phase 2b (Centaur) trial, CVC failed in phase 3 (Aurora) trial due to the lack of efficacy possibly because of poor pharmacokinetic profile and lack of specificity. Using *in silico* modelling

approach, we have designed an antagonizing peptide against CCR2 to inhibit monocyte recruitment and liver inflammation. Our previous data has shown that AP2 significantly attenuated CCL2-induced macrophage/monocyte infiltration *in vitro* and *in vivo* in an acute carbon tetrachloride (CCl4)-induced liver injury mouse model. Here, in this study, we investigate the effects of AP2 in a chronic NASH mouse model.

Method: We established a NASH mouse model by feeding mice with western diet (21.1% fat, 41% sucrose and 1.25% cholesterol) supplemented with high sugar solution (23.1 g/L d-fructose and 18.9 g/L d-glucose), combined with low weekly doses of CCl4 for 12 weeks. After 8 weeks, mice were treated intraperitoneally with 1 µmol/kg AP2 or CVC (2x per day) for 4 weeks. To assess intrahepatic monocyte infiltration *in vivo*, liver tissues were mechanically dissociated using Tissue Grinder, and cell population characterized by CD11b and F4/80 expression levels were analyzed using flow cytometry. Effects of AP2 and CVC on disease pathogenesis (steatosis, inflammation and fibrosis) were assessed using immunohistochemistry, RNA-sequencing, and plasma analysis.

Results: Flow cytometric analysis revealed a decrease in intrahepatic monocytes-derived macrophages in AP2 and CVC treated mice. Immunohistochemical analysis evidenced decreased steatosis (oil-red-O), inflammation (F4/80) and fibrosis (Collagen-I) in AP2 (and CVC) treated mice. AP2 and CVC treatment significantly inhibited the total plasma levels of AST, ALT, cholesterol and triglycerides. RNA sequencing analysis showed an improved NASH specific gene expression profiles in AP2 and CVC treated animals. CVC-treated mice showed reduced body weight on treatment and higher mortality compared with AP2.

Conclusion: Our CCR2 antagonizing peptide successfully inhibited intrahepatic monocyte/macrophage infiltration and ameliorated liver disease progression *in vivo*, in a chronic NASH mouse model.

WED-448

Longitudinal ultrasound imaging assessment of murine liver fibrosis in a high fat, fructose, cholesterol (FFC) model and its response to therapy

Heather Holmes[1], Caroline Sussman[1], Qianqian Guo[1], Juan Rojas[2], Ryan Gessner[2], Tomasz Czernuszewicz[2], Matthew Urban[1], Samar Ibrahim[1], Michael Romero[1]. [1]*Mayo Clinic College of Medicine and Science, United States,* [2]*PerkinElmer, Inc., United States*
Email: ryan.gessner@perkinelmer.com

Background and aims: Ultrasound and shear wave elastography (SWE) can be used to non-invasively monitor liver disease phenotypes, such as steatosis and fibrosis, and are clinically widespread. These imaging technologies have recently been adapted for small animal use in a robotic in vivo imaging system capable of automated scanning (Vega®, PerkinElmer). Our goal was to evaluate the feasibility of using this device to monitor response to therapy in the high fat, fructose, and cholesterol (FFC) model, a highly translatable preclinical model of obesity and metabolic disease. Non-invasive imaging of FFC mice is of particular interest (as opposed to invasive/terminal studies) due to intra-group phenotypic variability, extended time required to instantiate the model, and associated costs for these mice. This work represents a feasibility study aimed to use a robotic ultrasound scanner to monitor a cohort of mice over time developing diet-induced fibrosis of the liver, and then attempt to detect differences between un-treated and treated mice responding to a therapy.

Method: Two-month-old male C57Bl6 mice (N = 22) were used for this study and imaged at 32 weeks. Mice were split into four groups: (a) standard chow without treatment, (b) standard chow with treatment, (c) FFC diet without treatment, and (d) FFC diet with treatment. N = 8 mice were placed on standard chow, and N = 14 were

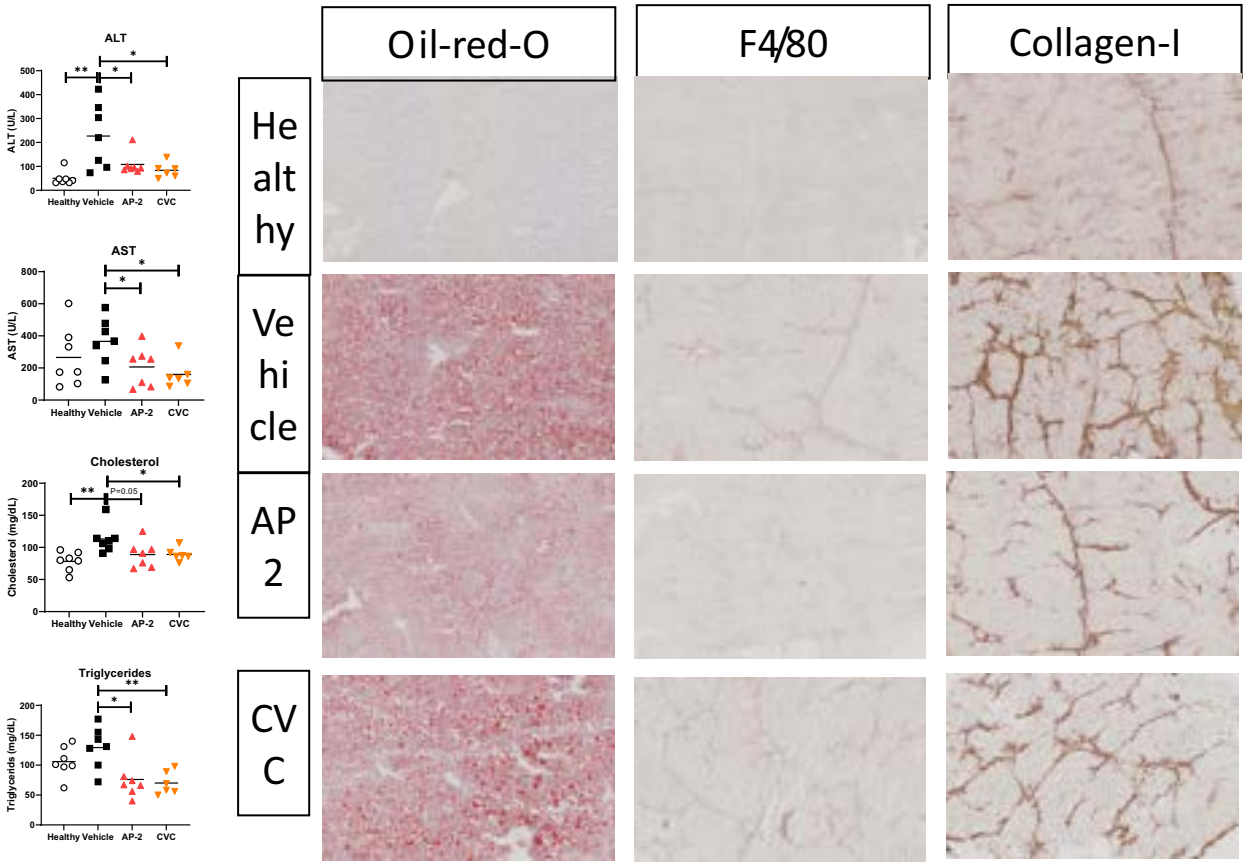

Figure: (abstract: WED-447).

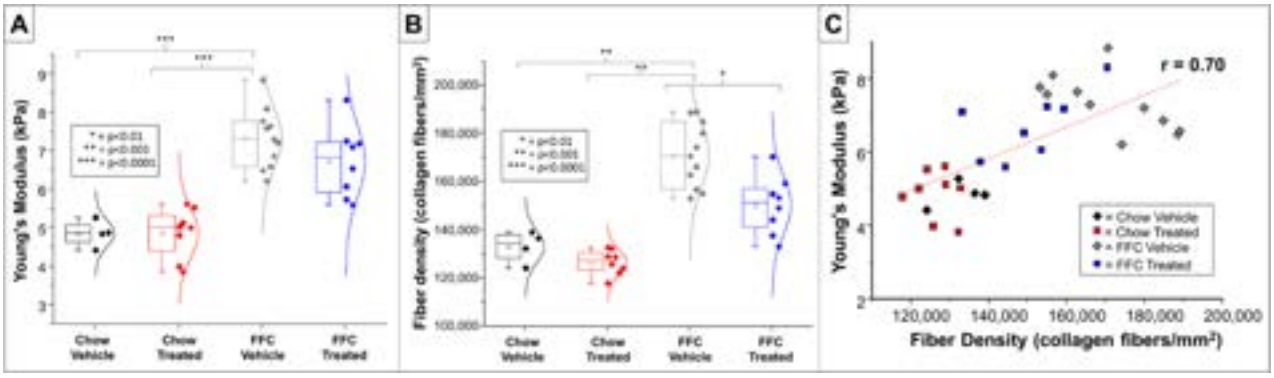

Figure: (abstract: WED-448) **A:** Non-invasive *in vivo* ultrasound SWE measures of tissue stiffness as a biomarker of liver fibrosis. B: *Ex vivo* validation of collagen fiber density after final timepoint via CT-FIRE. C: Correlation between *in vivo* ultrasound and *ex vivo* CT-FIRE measures of liver fibrosis pooled across all groups. Pearson's r correlation was 0.7 between the *in vivo* and *ex vivo* measurement approaches.

placed on FFC diet (AIN-76A, TestDiet, St Louis, MO); both diet groups were split evenly between treated and untreated. The treatment was delivered intraperitoneally at 10 mg/kg body weight/dose, 3 times a week for the last 4 weeks of the study. Imaging consisted of 3D B-mode for liver localization, and targeted SWE captures for liver stiffness measurements. For comparison, collagen fiber density, width, length, and straightness were determined by Sirius red staining and automated fiber detection and quantification using CT-FIRE software.

Results: Young's modulus (YM), a measure of tissue stiffness known to correlate with liver fibrosis, was significantly increased in the FFC diet group when compared to the chow controls ($p < 0.001$). FFC animals in the treatment group exhibited a slight, but nonsignificant, decrease in YM compared to the untreated FFC animals. There was no significant difference in liver stiffness between the treated and untreated mice in the standard chow group. Similarly, fiber density was significantly increased in FFC diet vs chow controls and lower in the FFC treatment group vs FFC vehicle controls ($p < 0.01$). Overall, collagen fiber density positively correlated with YM ($r = 0.70$). Collagen fibers were narrower and longer with FFC diet than chow controls, and with greater fiber curvature in the FFC treatment group vs no treatment.

Conclusion: These studies demonstrate the potential of the automated robotic ultrasound system to provide insights into the progression (and regression) of liver fibrosis in NASH models non-invasively. Future work will investigate improvements to sensitivity and specificity of the technique.

WED-449

Inhibition of CCAT/enhancer-binding protein beta-serpinB3 axis by 1-piperidin propionic acid: a new targeted therapy for non-alcoholic steatohepatitis

Francesca Protopapa[1], Gianmarco Villano[2], Erica Novo[1], Cristian Turato[3], Santina Quarta[2], Mariagrazia Ruvoletto[2], Alessandra Biasiolo[2], Monica Chinellato[2], Andrea Martini[4], Elisabetta Trevellin[2], Marnie Granzotto[2], Stefania Cannito[1], Laura Cendron[2], Maria Guido[2], Maurizio Parola[1], Roberto Vettor[2], Patrizia Pontisso[2]. [1]*University of Torino, Italy,* [2]*University of Padova, Italy,* [3]*University of Pavia, Italy,* [4]*Azienda Ospedaliera Padova, Italy*
Email: erica.novo@unito.it

Background and aims: Non-Alcoholic Fatty Liver Disease (NAFLD) is becoming the major cause of chronic liver disease worldwide, with a 25% prevalence in the general population and a higher prevalence in obese and type II diabetes patients. NAFLD includes a spectrum of liver diseases ranging from simple hepatic steatosis to non-alcoholic steatohepatitis (NASH). The serine protease inhibitor SerpinB3 has been proposed as a novel hepatokine able to modulate liver inflammation, fibrosis as well as insulin resistance during NASH development. In the present study we have tested a specific SerpinB3 inhibitor, 1-Piperidin Propionic Acid (1-PPA), in *in vivo* and *in vitro* models of NASH as a novel targeted therapeutic strategy for NASH.

Method: *In vivo* pre-clinical models: histological parameters and gene expression of pro-fibrotic and pro-inflammatory markers were analyzed in the liver of both SerpinB3-transgenic (TG) fed on either MCD or CDAA diets to induce experimental NASH; in some experiments, SerpinB3 TG mice, starting from the second month, were injected with 1-PPA (70 ng/g). *In vitro* models: expression of pro-fibrotic and pro-inflammatory genes was assessed in THP1 and LX2 cell lines exposed to human recombinant SerpinB3 (hrSB3, 200 ng/ml) alone or with 1-PPA (100 ng/ml). The expression of CCAAT Enhancer Binding Protein Beta (CEBP-beta), a SerpinB3 transcription factor, also involved in metabolic disorders and inflammatory response, was analyzed in the mentioned cell lines with or without 1-PPA as well as in mouse livers in relation to SerpinB3 expression.

Results: Treatment with 1-PPA of TG/SB3 mice fed on CDAA or MCD diet led to a significant reduction of liver fibrosis and inflammatory infiltrate as compared to control mice fed on the same diets, as showed by Sirius Red staining, immunohistochemistry for F4/80 and analysis of transcript levels of major fibrotic and inflammatory mediators. *In vitro* experiments showed that in LX2 cells, pre-treatment with 1-PPA led to a significant reduction of SB3-dependent chemotaxis as well as of transcript levels of Col1A1, alpha-SMA, TGF-beta1. Moreover, 1-PPA treatment also reduced transcript levels of pro-inflammatory mediators, including IL-1beta, CCL-2 and TNF-alpha in THP1 cells exposed to hrSB3. Moreover, the inhibitory mechanism exerted by 1-PPA is likely to also act by affecting a peculiar C/EBP-beta/SerpinB3 axis, in which C/EBP-beta transcription factor was found to up-regulate SB3 but at the same time to be elicited by this serpin.

Conclusion: C/EBP-beta-SerpinB3 axis could have a role in the development of NASH. The SerpinB3 inhibitor 1-PPA is effective in down-regulating inflammatory and fibrogenic responses both *in vitro* and in NASH murine models, suggesting that this molecule has the potential markedly to reduce NASH progression.

WED-450

Senescence sensitizes hepatocytes for fatty acid-induced cytotoxicity by compromising the mitochondrial function

Lilli Rausch[1], Pavitra Kumar[1], Felix Heymann[1], Mohsin Hassan[1], Akosua Boakye Yiadom[1], Fausto Andreola[2], Frank Tacke[1], Cornelius Engelmann[1,2,3]. *[1]Charité—Universitätsmedizin Berlin, Department of Hepatology and Gastroenterology, Berlin, Germany, [2]University College London, Institute for Liver and Digestive Health, London, United Kingdom, [3]Berlin Institute of Health (BIH), Berlin, Germany*
Email: cornelius.engelmann@charite.de

Background and aims: Senescence is an irreversible cell cycle arrest caused by cellular stressors leading to a senescent phenotype that includes elevated p53, p21, and $\gamma H_2A.X$ expression and cytokine release. Steatotic liver has increased hepatocellular senescence and in pre-clinical models, senolysis reduces the senescent phenotype and fat content in the liver. As the molecular link (s) between cellular senescence and fat accumulation remain unclear, in the present study we explore the cause or consequences of hepatocyte steatosis and senescence. We hypothesize that senescent hepatocytes are susceptible to steatosis and lipotoxicity and senolysis could provide therapeutic cues against the free fatty acid (FFA)-induced cytotoxicity.
Method: Primary hepatocytes were isolated from C57BL/6J mice and cultured overnight. Cells were sensitized for 24 hours with pre-optimized dosages of senescence inducers H_2O_2 (250 µM) (*via* oxidative stress) and Nutlin 3a (10 µM) (*via* p53 stabilization) and subsequently incubated with 0.3 mM oleic acid (OA, unsaturated fatty acid), palmitic acid (PA, saturated fatty acid), or their 1:1 mixture (MIX) for further 24 hours. For the rescue experiment, steatotic and senescent cells were treated with senolytics, dasatinib and quercetin D+Q for 24 hours. Neutral lipid accumulation in cells was measured by Oil Red O staining (ORO) and senescence markers (p53, p21 and $\gamma H_2A.X$) were measured by immunofluorescence. Mitochondrial function was assessed by XFe Seahorse analyser with 10 mM glucose, 2 mM pyruvate, and 1 mM glutamine as substrates.
Results: FFA treatment increased lipid accumulation in mice hepatocytes, OA and MIX by 4-fold, and PA by 3-fold ($p < 0.02$). Additionally, 24 h OA treatment resulted in the upregulation of senescent markers (p53, $\gamma H_2A.X$, and p21) whilst MIX caused primarily a p53 and $\gamma H_2A.X$ elevation. PA downregulated senescence makers but acted toxic to the cells. In senescent cells (H_2O_2 or Nutlin 3a-treated), OA further increased lipids accumulation along with increased p53 and $\gamma H_2A.X$ levels (Figure 1A) when compared to non-senescent OA-treated cells and to MIX or PA treated cells. Senescent cells showed lower cellular respiration (glycolysis and oxidative phosphorylation), that was further compromised after fatty acid treatment. Senolysis (D+Q) rescued the cellular respiration (glycolysis and oxidative phosphorylation) significantly in both steatotic and senescent hepatocytes (Figure 1B).
Conclusion: Free fatty acids induce senescent phenotype in murine hepatocytes. Senescent hepatocytes are prone to steatosis. Senolysis could rescue the cytotoxic effects of free fatty acids-induced senescence *via* elevating cellular respiration.

WED-451

Ageing rates and oxidative stress in patients with non-alcoholic fatty liver disease and profound insulin resistance

Olena Kolesnikova[1], Anastasiia Radchenko[1], Vilena Chupina[2]. *[1]L.T. Malaya Therapy National Institute of the National Academy of Medical Sciences of Ukraine, Department of Study of Aging Processes and Prevention of Metabolic-Associated Diseases, Kharkiv, Ukraine, [2]Kharkiv National Medical University, Kharkiv, Ukraine*
Email: anastasha.radchenko@gmail.com

Background and aims: Redox imbalance can be both a cause and a consequence of many metabolic pathologies, including non-alcoholic fatty liver disease (NAFLD) and insulin resistance (IR). Data regarding ageing rates and redox markers in NAFLD patients based on the IR level is limited. The aim of our study was to evaluate the parameters of oxidative stress (OS) and aging rates in patients with NAFLD and IR of various severity.
Method: Our study included 82 patients with NAFLD with a mean age of 48.5 [41.0;57.0] years (62.5% women) and comparison group of 62 patients without NAFLD with a mean age of 49.0 [38.4;54.9] years (64.6% women). Patients were divided into subgroups according to IR index (HOMA-IR): patients without IR (n = 22 and n = 28 with/without NAFLD accordingly), with IR less than 3 times the upper limit of normal (ULN) (n = 32 and n = 34) and with IR 3 times higher than ULN (n = 28, present only in NAFLD group). Markers of OS included content of total hydroperoxides (THP) and total antioxidant activity (TAA), measured using colorimetric method. Ageing rates were estimated based on the difference between biological age calculated

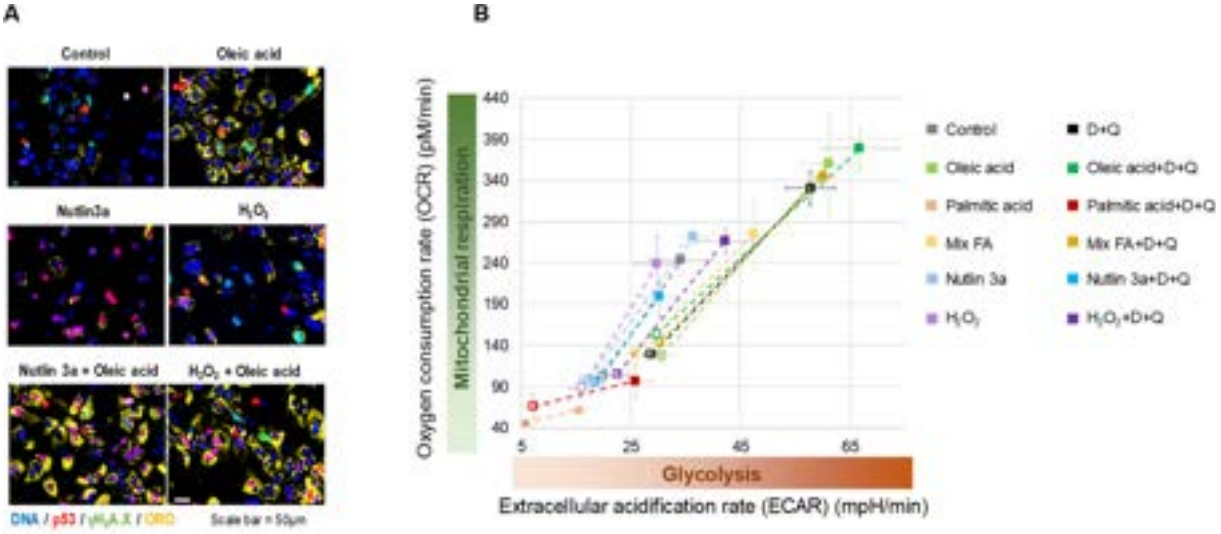

Figure 1. Effect of senescence on free fatty acid-induced cytotoxicity **A)** senescence markers and lipid accumulation **B)** cell energy phenotype measured by XFe Seahorse analyser

Figure: (abstract: WED-450).

according to the M. Levine et al. (2018) and calendar age for each patient.
Results: Analysis of studied parameters in patients with NAFLD and IR 3 times higher UNL revealed significant higher levels of glucose, alkaline phosphatase and THP compared to NAFLD patients with IR less than 3 ULN (p = 0,015, p = 0,014 and p = 0,004) and NAFLD patients without IR (p = 0,004 p = 0,036 and p = 0,046). No such differences were observed between NAFLD patients without IR and with IR less than 3 ULN. In addition, NAFLD patients with IR 3 times higher UNL had higher ageing rates compared with NAFLD patients without IR. Such data indicate the appearance of impaired glucose tolerance, pronounced increase in the activity of oxidative processes and, as a result, noticeable increase in the rate of aging in NAFLD patients with profound IR only. No differences were found between patients without IR with versus without NAFLD, but patients with IR less than 3 times UNL without NAFLD had lower levels of THP than patients with similar IR level without NAFLD (p = 0,010). In patients without NAFLD higher THP levels were observed in the absence of IR (p = 0,027). Available data indicate that insulin suppresses, while elevated glucose levels increase lipid peroxidation. So hyperinsulinemia in patients without NAFLD with mild IR and normal glucose levels may be the reason for lower THP levels. In patients with NAFLD IR is probably not the cause but rather a consequence of redox disturbances, so higher IR levels are accompanied by higher THP levels.
Conclusion: NAFLD patients with IR 3 times UNL had higher ageing rates compared with NAFLD patients with lower IR level or without it, probably due to higher levels of THP. IR emergence in NAFLD patients most likely mediated by the increased OS. The data obtained can be useful for the prevention of accelerated aging rates in patients with NAFLD.

WED-452

The potential role of Omentin-1 in metabolic associated fatty liver disease (MAFLD): evidence from translational studies

Noel Salvoza[1,2,3], Pablo J Giraudi[1], Silvia Gazzin[4], Deborah Bonazza[5], Silvia Palmisano[6], Claudio Tiribelli[1,4], Natalia Rosso[1]. Email: noel.salvoza@fegato.it

Background and aims: Obesity, characterized by excessive visceral adipose tissue (VAT) is tightly associated with MAFLD. The pathogenesis of MAFLD is complex but recent studies reveal that the adipose tissue-liver axis plays a key role in MAFLD development. We investigated the potential role of omentin-1, a novel adipokine expressed by VAT, in MAFLD pathogenesis.
Method: *In silico* analysis of differentially expressed genes in VAT from obese patients with and without MASH, showed that omentin-1 might play a significant role. For *in vivo* clinical validation, omentin-1 mRNA expression and plasma protein levels were measured in lean controls and obese patients with biopsy-proven MAFLD. mRNA and protein levels of omentin-1 in VAT of juvenile mice MAFLD model have also been assessed. For *in vitro* and *ex vivo* studies, we assessed the effects of omentin-1 in the MAFLD-related mechanisms such as steatosis, inflammation, and oxidative stress. Finally, the effects of D-glucose and insulin on VAT omentin-1 were also analyzed *ex vivo*.
Results: The obese groups showed significantly lower VAT mRNA expression and plasma levels of omentin-1 as compared to the lean group (all p values <0.05). Interestingly, within the MASH group, fibrosis does not affect omentin-1 expression. Likewise, VAT of mice fed with high-fat diet, showing histological signs of MASH showed decreased omentin-1 mRNA (p = 0.012) and protein expression (p = 0.038) as compared to their control diet counterpart. *In vitro*, the addition of omentin-1 on fat-loaded (FFA) human hepatocytes showed no effect on steatosis but significantly decreased TNF-alpha levels (mRNA and protein), reduction in ER stress markers (*BiP* and *Chop*), and enhanced superoxide dismutase (SOD) antioxidant activity (all p values <0.05 vs. FFA). The same results were obtained using *ex vivo* VAT explants from obese patients upon omentin-1 supplementation (all p values <0.05 vs. control). In addition, omentin-1 reduced nuclear factor kappa B (*NF-KB*) mRNA expression in both *in vitro* (p value <0.01 vs. FFA) and *ex vivo* (p value <0.01 vs. control) studies. In VAT explants, D-glucose and insulin significantly reduced omentin-1 mRNA expression and protein levels (all p values <0.05 vs. control).

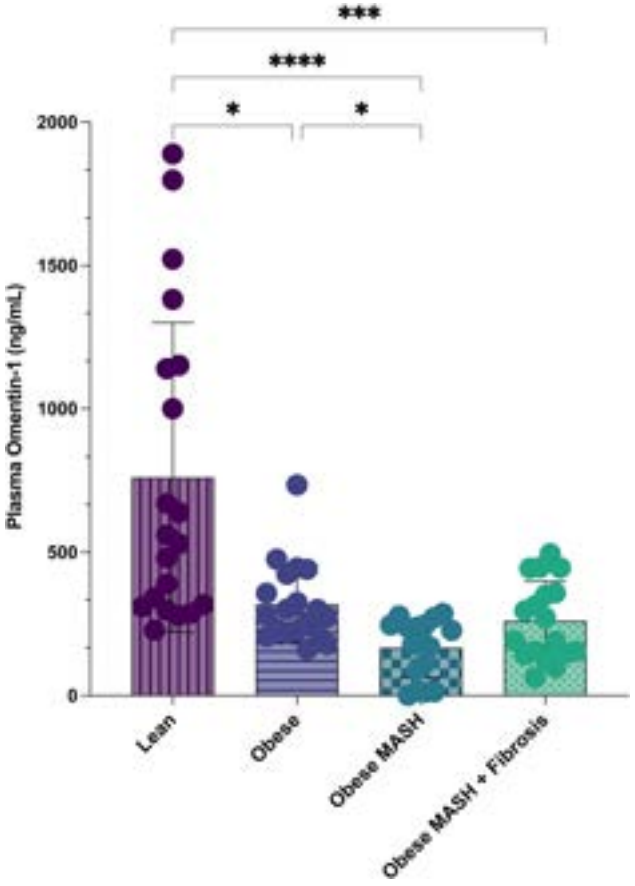

Figure: Human plasma omentin-1 levels in obese groups and lean controls. Values presented in the boxplots are the means ± SD of individual patients. Group comparison by Kruskal-Wallis and post hoc Dunn's test. * p < 0.05, ** p < 0.01, *** p < 0.001, **** p < 0.0001.

Conclusion: Taken together, our findings suggest that reduced levels of omentin-1 contribute to MAFLD development. Omentin-1 supplementation reduces inflammation and oxidative stress probably via inhibiting the *NF-KB* pathway, and might also play a role in the regulation of glucose and insulin. Further studies are needed for omentin-1 to be considered as a therapeutic target and/or biomarker.

WED-453

Two-dimensional versus one-dimensional transient elastography: benefits of ultrasound imaging-based processing for liver stiffness measurements

Adrien Besson[1], Baptiste Hériard-Dubreuil[1], Victor de Lédinghen[2,3], Dan Dutartre[4], Françoise Manon[2], Joëlle Abiven[2], Anne-Laure de Araujo[2], Rhizlane Houmadi[2], Julie Dupuy[2], Juliette Foucher[2], Joel Gay[1], Claude Cohen-Bacrie[1]. [1]*E-Scopics, Saint-Cannat, France,* [2]*Bordeaux University Hospital, Hepatology Unit, Pessac, France,* [3]*INSERM U1312, BRIC, Bordeaux University, Bordeaux, France,* [4]*Inria Bordeaux Sud-Ouest, Bordeaux, France*
Email: adrien.besson@e-scopics.com

Background and aims: Fibroscan® (FS) Transient Elastography (TE) performs liver stiffness measurements (LSM) using a measure of the velocity of a shear wave generated by a 50 Hz single element probe mechanical vibration. It relies on a high pulse repetition frequency capture of the one-dimensional (1D) ultrasound (US) signal of that same probe. A new point of care ultrafast US imaging device (POCUS), Hepatoscope™, has been used to compute maps of shear wave velocities generated by a 50 Hz mechanical vibration of a US imaging probe. That same POCUS device provides conventional US imaging of the liver to help positioning the 2DTE map. We hypothesized that 2D processing of shear wave speed in tissue using 2DTE would somehow overcome an intrinsic limitation of 1D TE, where shear wave propagation speed can only be measured in the direction of the single element piston as opposed to a measurement that follows the direction of the shear wave propagation. The aim of this work was to assess the benefits of 2DTE against 1D TE methods, as available on the FS device, and as processed from US per-channel raw-data collected with Hepatoscope on patients with chronic liver diseases.
Method: 96 adult patients referred to a routine hepatology consultation for chronic liver disease, including a FS exam, were enrolled in this prospective single centre study (NCT04782050). Four Hepatoscope consecutive liver exams were added to routine care, performed by 2 operators (1 expert and 1 novice). US per-channel raw-data corresponding to at least three 2DTE stiffness values by Hepatoscope were recorded for each exam. Hepatoscope LSM computed as the median of 3 stiffness values obtained from both 1D (LSM_{1D}) and 2D (LSM_{2D}) processing of these data were compared to FS LSM. The intra-and inter-operator reproducibility of LSM_{1D} and LSM_{2D} were also assessed.
Results: LSM_{2D} showed a significant improvement over LSM_{1D} of the intra-operator reproducibility for experts (ICC_{2D} = 0.84; 95% CI [0.73, 0.91] vs ICC_{1D} = 0.53; 95% CI [0.33, 0.68]), and of the inter-operator reproducibility (ICC_{2D} = 0.74; 95% CI [0.60, 0.84] vs ICC_{1D} = 0.59; 95% CI [0.43, 0.72]). Figure 1 illustrates the ability of 2DTE to better track the shear wave and measure its speed in its propagation direction, thus eliminating measurement bias.

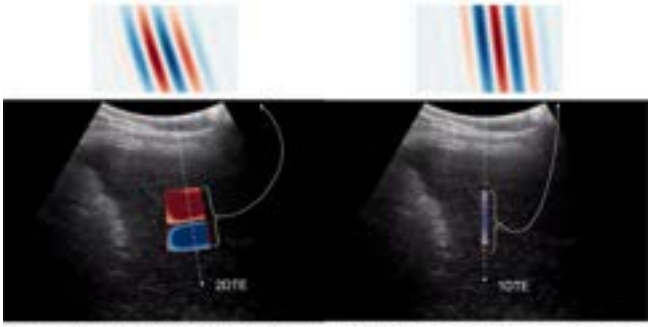

Figure 1: From left to right, Shear-Wave Propagation overlaid on B-Mode image as seen with 2DTE (leftmost image) and 1D TE (rightmost image). As the direction of propagation is not aligned with the analysis direction, 1D TE overestimates the shear-wave velocity.

Figure:
Linear regression analysis between LSM_{1D} and LSM_{2D} obtained by experts showed a slope of 0.95 and an intercept of 2.05 ($p = 10^{-19}$, r = 0.72), demonstrating an overestimation of LSM_{1D} as compared to LSM_{2D} in the range [0 kPa, 40 kPa]. This was confirmed by linear regression analysis between LSM_{1D} (resp. LSM_{2D}) and FS LSM which exhibited a slope of 1.18 (resp. 1.04) and an intercept of 1.97 (resp. 1.39) ($p = 10^{-13}$ (resp. $p = 10^{-20}$), r = 0.63 (resp. r = 0.72)).
Conclusion: 2D processing of US data to measure the shear wave velocity along the direction of shear wave propagation, has demonstrated its ability to eliminate over-estimation bias of LSM. In addition, the estimation of liver stiffness in 2D has led to an increased intra- and inter-operator reproducibility, even considering LSM performed by novices. These results are encouraging as they support a broader use of 2DTE LSM, as available on the Hepatoscope POCUS device, as a less user-dependent method for widespread screening programs of liver fibrosis.

WED-454

Zebrafish larvae as a model system to characterize effects of metabolic, drug and genetic perturbations on liver fat accumulation

Endrina Mujica[1], Hanqing Zhang[1], Anastasia Emmanouilidou[1], Amin Allalou[2], Marcel den Hoed[1]. [1]*The Beijer Laboratory and Department of Immunology, Genetics and Pathology; Uppsala University and SciLifeLab, Uppsala, Sweden,* [2]*Department of Information Technology; Division of visual information and interaction; Uppsala University and SciLifeLab, Uppsala, Sweden*
Email: endrina.mujica@igp.uu.se

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has a complex pathology that includes a spectrum of liver insults. No FDA-approved pharmacological treatment is currently available. The aim of this study is to validate a zebrafish model system for systematic genetic and drug screens for liver fat using CRISPR/Cas9, fluorescence imaging, and deep learning-based image analysis.
Method: To validate the model system, we first compared liver fat in larvae fed 3x more than sibling controls (n = 721). In overfed larvae, we subsequently examined the effect of i) 4% extra dietary cholesterol; and/or ii) 3% glucose added to the water (n = 574). Next, we examined the effect of treating metabolically challenged larvae with 0, 10 or 25μM rosiglitazone (n = 865). Finally, we targeted the zebrafish orthologues of *MTARC1* (n = 383) and *GPAM* (n = 307) using CRISPR/Cas9, in fertilized eggs from parents with transgenically expressed, fluorescently labeled hepatocytes (*Tg (lfabp10a:EGFP)*). Larvae from all experiments were phenotyped at 10 or 11 days post fertilization. Before imaging, lipids were stained by incubation with a fluorescent dye (monodansylpentane) that labels neutral lipids. Next, optical sections of the liver were acquired using fluorescence microscopy. Liver size and the number of lipid droplets in the liver were automatically segmented and quantified using deep learning-based image analysis pipelines.
Results: Overfeeding resulted in more liver fat (beta ± SE 0.49 ± 0.10 SD units, $p = 6.5 \times 10^{-7}$). In overfed larvae, both cholesterol (0.61 ± 0.10) and glucose (1.35 ± 0.10) challenges resulted in more liver fat, in a non-additive manner (−1.29 ± 0.14). In overfed larvae challenged with extra cholesterol and glucose, treatment with 10 or 25 μM rosiglitazone protected from liver fat accumulation (−0.25 ± 0.09, $p = 5.8 \times 10^{-3}$). Finally, mutations in zebrafish orthologues of *MTARC1* and *GPAM* resulted in less liver fat compared with controls (−0.28 ± 0.14 and −0.56 ± 0.24). These findings are directionally consistent with effects of loss-of-function mutations identified in humans and are in line with these genes being the culprits in loci recently identified by genome-wide association studies for NAFLD.
Conclusion: Image-based screens in zebrafish larvae can be used to systematically characterize genes and drugs for a role in the development of NAFLD and prioritize the most promising candidates for further in-depth characterization and drug development.

WED-455

Cyclophilin inhibition with rencofilstat shifts the liver transcriptome and lipidome in preclinical models toward resolution of non-alcoholic steatohepatitis

Daren Ure[1,2], Winston Stauffer[3], Bhavesh Variya[1,2], Lacey Haddon[1,2], Patrick Mayo[1,2], Philippe Gallay[3], Robert Foster[1,2]. [1]*Hepion Pharmaceuticals, United States,* [2]*Hepion Research, Canada,* [3]*Scripps Research Institute, United States*
Email: dure@hepionpharma.com

Background and aims: Cyclophilins are a multi-isoform class of enzymes that regulate the structure and function of proteins across a wide cross-section of the human proteome and have been shown to contribute to many disease processes. Rencofilstat is a potent inhibitor of several cyclophilin isoforms and has demonstrated antifibrotic, anti-inflammatory, and other therapeutic activities in liver disease models, supporting its current evaluation in Phase 2 clinical trials for non-alcoholic steatohepatitis (NASH). The aim of the present investigations was to characterize rencofilstat's effects on the liver transcriptome and lipidome in three liver disease models to better delineate its modes of action.
Method: Three liver disease studies were conducted: 1) DIAMOND mouse model of NASH; 2) western diet plus carbon tetrachloride mouse model of NASH/fibrosis; 3) thioacetamide-induced liver fibrosis in rats (Physiogenex, France). Rencofilstat was administered in all studies. Elafibranor (ELF) and obeticholic acid (OCA) were additionally administered in the DIAMOND mouse study. Liver steatosis, inflammation, and fibrosis were measured histologically. RNA sequencing and mass spectrometry-based lipidome analysis (OWL, Spain) was performed on liver samples from all three studies.
Results: Rencofilstat decreased liver fibrosis in all three experimental models by 50–80% as measured by percentage Sirius red. RNA sequencing showed that rencofilstat altered the expression of 500–1500 genes in diseased livers which was approximately one-third the number of differentially expressed genes (DEGs) from ELF-treated or OCA-treated mice. A range of 74–81% of the rencofilstat DEGs overlapped with ELF or OCA DEGs. KEGG pathway mapping and network hub gene prediction similarly showed extensive overlap among the three drugs. Furthermore, all three treatments significantly attenuated KEGG pathways that were activated in vehicle-treated animals and in human NASH. Lipidomic analyses revealed that rencofilstat altered 4–19% of the liver lipid species across the three models, which was similar to OCA but less than ELF. Rencofilstat effects included reductions in saturated triglycerides, lysophospholipids, and sphingolipids, and especially the shorter-chain species of these lipids. The lipids decreased by rencofilstat were typically increased in vehicle animals and correlated with percentage-area Sirius red staining.
Conclusion: Despite no known mechanisms of transcriptional regulation, rencofilstat positively changed gene expression networks similarly to FXR and PPAR agonists. Rencofilstat also altered liver lipid signatures consistent with attenuation of lipotoxic processes. These findings suggest that cyclophilins contribute to many pathophysiologic processes and blocking their modulatory actions with rencofilstat shifts the liver transcriptome and lipidome towards NASH resolution.

WED-456

Tyrosol reduces steatosis, fibrosis and inflammation in a murine model of NASH by modulating the immune hepatic phenotype

Daniela Gabbia[1], Katia Sayaf[2], Martina Colognesi[1], Ilaria Zanotto[1], Francesco Paolo Russo[2], Sara De Martin[1]. [1]*University of Padova, Dept. of Pharmaceutical and Pharmacological Sciences, Italy,* [2]*University of Padova, Department of Surgery, Oncology and Gastroenterology, Italy*
Email: sara.demartin@unipd.it

Background and aims: Besides its metabolic and detoxifying activity, the liver is an immunological organ where innate and adaptive immune cells are in close contact with blood-borne and gut-derived pathogens. Recent evidence indicates that NASH patients display a dysregulation of the hepatic immune landscape, mainly due to the increased influx of myeloid-derived monocytes and monocyte-derived cells. Such changes fuel uncontrolled inflammation and cooperate with hepatocytes, hepatic stellate cells (HSCs) and liver sinusoidal endothelial cells in disease progression. Phenolic compounds of natural origin including tyrosol are known to mitigate hepatic fibrosis through the regulation of NADPH oxidases (NOXs), whose exaggerated expression has been related to increased ROS-induced oxidative stress. This study aims at unravelling whether and how tyrosol modulates the hepatic recruitment of immune cells in a murine model of NASH.
Method: The murine model of NASH was obtained by feeding male C57BL6 mice with a high fructose-high fat diet for 14 weeks, combined to the IP administration of CCl_4 (0.05 mg/kg) in the last 4 weeks. Starting from week 4, tyrosol was administered daily by oral gavage (10 mg/kg). Behavioral and motor tests, e.g. grid, rotarod and open field test, were performed to assess signs of extrahepatic manifestations of NASH, e.g. sarcopenia and mood disorders. Inflammation, fibrosis, and steatosis were evaluated by liver histology by means of HandE, Masson's trichrome, and Oil Red O staining, respectively. NOX1 and aSMA expression was assessed by means of IHC. The presence of immune cells (CD4+, CD8+ lymphocytes, Tregs, M1- and M2- macrophages) in the liver was assessed by means of flow cytometry.
Results: Tyrosol attenuated fatigue and anxious behavior in NASH mice, restoring performances similar to those of healthy animals. Furthermore, tyrosol reduced steatosis, fibrosis and aSMA expression, that were significantly lower than those of NASH untreated animals ($p < 0.01$). Accordingly, tyrosol-treated NASH mice had less inflammatory foci in the liver than untreated ones ($p < 0.05$), a decreased expression of NOX1 ($p < 0.05$), suggesting a reduction of hepatic inflammation and oxidative stress. This was confirmed by the significant reduction in proinflammatory M1-type macrophages ($p < 0.05$), CD4+ ($p < 0.05$) and T helper effector lymphocytes ($p < 0.05$), and the significant increase of Treg cells ($p < 0.05$) observed in tyrosol-treated mice, with respect to untreated ones.
Conclusion: In a mouse model of NASH, tyrosol modulates the different populations of immune cells in the liver, counteracting steatosis, fibrosis, oxidative stress and inflammation, all hallmarks of this complex liver disease.

WED-457

Biomarkers of endothelial dysfunction in patients with non-alcoholic fatty liver disease (NAFLD)

Email: jampuero-ibis@us.es

Background and aims: The main aim was to identify endothelial dysfunction biomarkers in serum and hepatic tissue in biopsy-proven NAFLD patients.

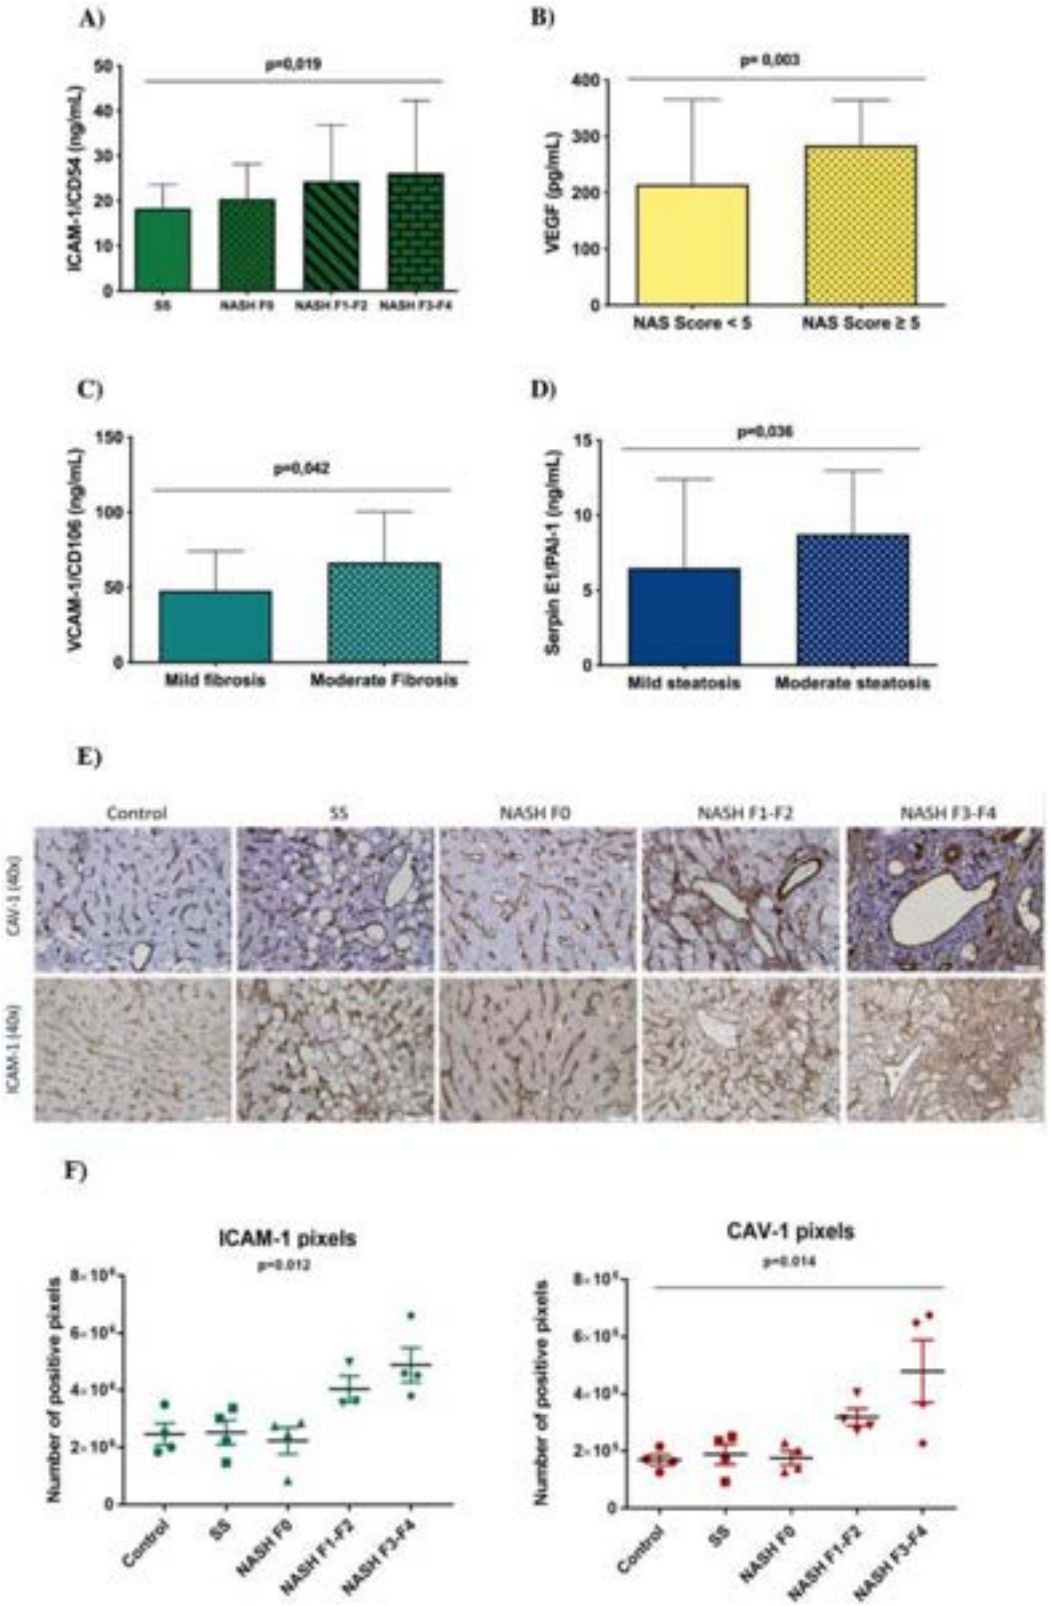

Fig 1. (abstract: WED-457) A) Circulating levels of ICAM-1/CD54 in biopsy-proven NAFLD patients (steatosis simple (SS), nash without fibrosis (NASH F0), nash with fibrosis F1/F2 (NASH F1-F2) and NASH with moderate fibrosis (F3-F4). B) VEGF expression in NAFLD patients with respect to NAS Score. C) VCAM-1/CD106 serum levels related to the levels of fibrosis in the disease. D) Circulating levels of Serpin E1/PAI-1in NAFLD patients correlated to with steatosis levels. E) Immunohistochemistry of endothelial dysfunction markers CAV-1 and ICAM-1, of the different stages of patients biopsied for NAFLD suspected. F) Quantification of positive pixels of immunohistochemical images for ICAM-1 and CAV-1 antibodies with ImageJ.

Method: Forty patients were included with different stages of the disease (steatosis simple group (n = 7), NASH F0 group (n = 11), NASH F1-F2 group (n = 10) and NASH F3-F4 group (n = 12)). ELISA techniques were performed for the selected endothelial dysfunction markers (ICAM-1/CD54, VCAM-1/CD106, VEGF, Serpin E1/PAI-1 and ADAM12). The following outcomes were analysed: mild/moderate steatosis, mild/moderate fibrosis and NAS score. Due to relevant analyses results, subsequent validation of ELISA in ICAM included a total of 120 patients recruited. In addition, immunohistochemistry of hepatic sections was performed in 20 patients with different stages of the disease following the same groups as described below together with a control group (n = 4 patients/group) for caveoline-1 (CAV-1), angiotensinogen (AG) and intercellular adhesion molecule 1 (ICAM-1). Cardiovascular events were also recorded and Castelli index was calculated.

Results: Mean age was 60 ± 9, of them, 52.5% (21/40) were women. Circulating levels of ICAM-1 were associated with liver fibrosis (SS: 18.35 ± 5.26 *vs.* NASH-F0 20.48 ± 7.79 *vs.* F1-F2 24.38 ± 12.34 *vs.* F3-F4 26.21 ± 16.05 ng/ml, p = 0.019; n = 120; Figure 1A). Moreover, ICAM positively correlated with the NAS Score (r: 0, 413; p < 0.001). Circulating levels of VCAM-1 were associated with the presence of significant fibrosis (F0-F1 47.9 ± 26.2 *vs.* F2-F4 66.5 ± 33.9 ng/ml; p = 0.042; n = 40; Figure 1C); and a positive correlation was found between VCAM and ICAM (r: 0.523; p = 0.001). VEGF circulating levels were increased in patients with NAS Score >5: 284.05 ± 80.8 *vs.* 214.4 ± 151.4 pg/ml; p = 0.03; n = 40; Figure 1B). Circulating levels of Serpin E1 increased with the degree of hepatic steatosis (mild steatosis 6.49 ± 5.9 *vs.* moderate/severe steatosis 8.73 ± 4.2 ng/ml; p = 0.036; n = 40; Figure 1D), and correlated with the Castelli index (r: 0.368; p = 0.023). No significant differences in circulating ADAM12 were found in this study. Moreover, the hepatic expression of CAV-1 and ICAM-1 were found to be increased following the hepatic injury, and no significant differences in angiotensin were found (Fig 1E and 1F). Finally, a correlation with liver fibrosis was observed in both ICAM-1 (r = 0.706; n = 19; p = 0.001) and CAV-1 (r = 0.681; n = 20; p = 0.001).

Conclusion: Markers of endothelial dysfunction are related to the main histopathological features of NAFLD, such as fibrosis, hepatic steatosis or NASH, both at the circulating and the hepatic level in NAFLD patients.

WED-458

Increasing gut microbiota produced secondary bile acids to protect against non-alcoholic steatohepatitis

Justine Gillard[1,2], Martin Roumain[3], Corinne Picalausa[1], Morgane Thibaut[2], Giulio G. Muccioli[3], Anne Tailleux[4], Bart Staels[4], Laure Bindels[2], Isabelle Leclercq[1]. [1]*Université catholique de Louvain, Laboratory of Hepato-Gastroenterology, Belgium,* [2]*Université catholique de Louvain, Metabolism and Nutrition Research Group, Belgium,* [3]*Université catholique de Louvain, Bioanalysis and Pharmacology of Bioactive Lipids, Belgium,* [4]*University of Lille, Inserm, CHU Lille, Institut Pasteur de Lille, U1011-EGID, France*
Email: justine.gillard@uclouvain.be

Background and aims: Bile acids (BAs) regulate immunometabolic pathways impaired in NASH by activating BA-receptors, such as FXR and TGR5. Hence, BAs are attractive candidates for therapeutic development. An imbalance between primary BAs (reflecting hepatic synthesis) and secondary BAs (reflecting transformation by gut microbes) is a recurrent feature in NASH. We previously reported that secondary BAs were low in mice with NASH. Here, we aimed at restoring the balance between primary and secondary BAs by (1) a dietary supplementation with deoxycholic acid (DCA), a secondary BA, or (2) a probiotic approach to enhance endogenous production of secondary BAs by gut bacteria. We evaluated the effects of both approaches on the composition and signaling of BAs and on NASH progression.

Method: We used high fat diet (HFD)-fed *foz/foz* mice as a model of NASH whose BA pool is depleted in secondary BAs. They received (1) a HFD containing DCA or a plain HFD or (2) an oral suspension of *C. scindens*, a gut bacterium supporting the conversion of primary BAs to secondary BAs, or vehicle for 12 weeks.

Results: Supplementation of the HFD with DCA increased total BAs, total secondary BAs and DCA concentrations in *foz/foz* mice, shifting the BA pool towards a more TGR5- and FXR-agonistic pool. Notably, DCA elevated the TGR5 activation capacity of the portal blood. The restoration of BA signaling by DCA supplementation significantly lowered body weight gain, fasting glycemia and insulinemia and protected from NASH (Figure). Indeed, DCA reduced steatosis, macrophage infiltration and ballooning. Hence, only 15% of treated mice still presented NASH, while 100% of untreated mice met the criteria for NASH diagnosis. We next aimed at increasing endogenous DCA production by targeting the gut microbiota with a probiotic approach. We confirmed by a functional assay that *C. scindens* transforms primary BAs to secondary BAs. However, *C. scindens* administration to *foz/foz* mice did not change the endogenous production of secondary BAs, the portal BAs pool and the activation of BA-receptors FXR and TGR5. Coherently, it had no significant effect on liver and metabolic phenotype (Figure), despite a massive increase of the fecal load of *C. scindens* and its survival in the gut of treated mice.

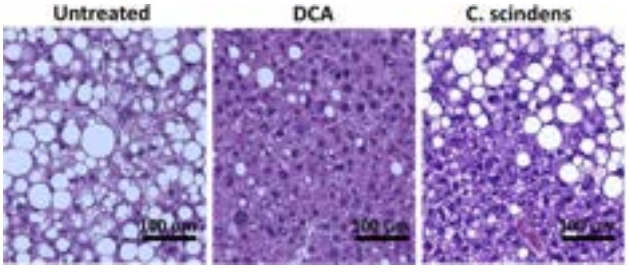

Figure:

Conclusion: The administration of *C. scindens* did not enhance the endogenous production of secondary BAs. A too low dose and frequency of administration, a too low biological effect of *C. scindens* on a complex microbial community or a high hepatic reconversion of secondary BAs to primary BAs are possible explanations for the lack of impact of *C. scindens* on the BA pool of a mouse model with a complex gut microbiota. Nevertheless, we demonstrated that the restoration of the balance between primary and secondary BAs by a dietary supplementation with the secondary BA DCA protected from NASH and associated dysmetabolic features.

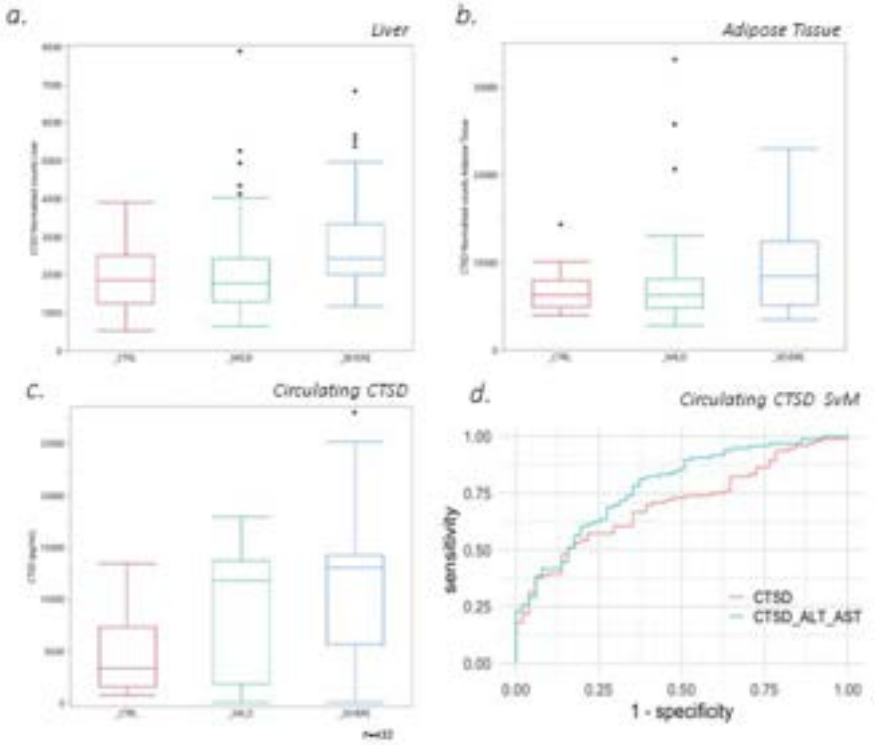
Combined hepatic and adipose tissue transcriptomics highlights circulating NASH biomarkers

Marica Meroni[1], Emilia Rita De Caro[1], Federica Chiappori[2], Miriam Longo[1], Erika Paolini[1], Ettore Mosca[2], Ivan Merelli[2], Rosa Lombardi[1], Sara Badiali[1], Marco Maggioni[1], Alessandro Orro[2], Alessandra Mezzelani[2], Luca Valenti[3], Anna Ludovica Fracanzani[1,3], Paola Dongiovanni[1]. [1]*Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy; General Medicine and Metabolic Diseases; Milan, Italy,* [2]*Institute for Biomedical Technologies, National Research Council (ITB-CNR), Segrate, Italy,* [3]*University of Milan, Department of Pathophysiology and Transplantation, Milan, Italy*
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: Obesity represents the main contributor to non-alcoholic fatty liver disease (NAFLD) and adipose tissue is strongly interlaced with the liver in the disease pathogenesis and progression. Previous studies were restricted to investigate the hepatic transcriptome across the entire spectrum of NAFLD, whereas the transcriptomic changes which occur in white adipose tissue (WAT) in relation to liver damage have been poorly investigated. Therefore, we aimed to compare hepatic and adipose tissue



Serum cathepsin D (CTSD) as possible biomarker to detect severe NAFLD. CTSD expression is stratified according to the severity of NAFLD in both liver (**A**) and adipose tissue (**B**). Boxes span from 25° to 75° percentile, while whiskers indicate the 10° and 90° percentile. Normal liver (CTRL) is plotted in red, mild in green, while Severe NAFLD in blue. CTSD serum concentration was evaluated in n=432 patients (Liver Clinic cohort) (**C**). $p<0.05$ at one-way ANOVA. ROC curves describe the accuracy of circulating CTSD (pg/mL) in foreseeing severe NAFLD from mild NAFLD (SvM) (D), obtained considering CTSD alone, or in a generalized linear model with transaminases (ALT and AST).

Figure: (abstract: WED-459).

transcriptome in NAFLD patients with the purpose to identify shared biomarkers useful for the diagnosis of advanced liver damage.
Method: We performed high-throughput RNA-sequencing in 167 hepatic samples from obese patients and in a subset of 79 matched adipose tissues. Patients were subdivided in normal liver, mild and severe NAFLD according to histology. Circulating cathepsin D (CTSD) was assessed by ELISA.
Results: We identified a specific transcriptomic signature that may discriminate patients with severe NAFLD and isolated steatosis, including 424 deregulated genes in liver and 209 in adipose tissue. According to pathway and network analyses, inflammation, ECM remodeling and mitochondrial dysfunction were upregulated whereas oxidative phosphorylation was downregulated in both tissues. We highlighted 13 genes commonly deregulated in both tissues and among them, CTSD showed the most robust diagnostic accuracy in discriminating mild and severe NAFLD. In 52 obese subjects and in a validation cohort of 432 histologically-characterized NAFLD patients, serum CTSD progressively increased from normal liver to severe NAFLD and it was associated with steatosis, necroinflammation, fibrosis, steatohepatitis (NASH) and NAS>5. The area under the curve (AUC) weighted for transaminases to foresee severe NAFLD *versus* mild and normal liver was 0.78 and 0.87, respectively.
Conclusion: CTSD may be a possible biomarker of severe NAFLD since its hepatic/adipose tissue expression as well as circulating levels correlated with liver damage thus allowing to discriminate advanced disease.

WED-460

Thermoacoustic assessment of fatty liver disease-an early clinical feasibility study

Jang Hwan Cho[1], Michael Thornton[1], Jing Gao[2], Colby Adamson[2], Idan Steinberg[1]. [1]*ENDRA Life Sciences inc, ANN ARBOR, United States,* [2]*Rocky Vista University, Ultrasound Research medical center, Ivins, United States*
Email: thornto@gmail.com

Background and aims: Thermoacoustics (TA) is a non-invasive, non-ionizing, molecular-sensitive imaging technology based on the absorption of radio frequency waves combined with low-cost ultrasound. Unlike purely ultrasonic approaches (such as backscatter and attenuation) that are sensitive to changes in the speed of sound, and tissue density, that may be confounded by fibrosis, TA signals are similar to Magnetic Resonance Proton Density Fat Fraction (MRI-PDFF) as they both represent stoichiometric mixing of adipose and lean tissue and thus provide a high diagnostic value. The Thermo-Acoustic Enhanced Ultrasound (TAEUS) Fatty Liver Imaging Probe (FLIP) is a hand-held, point-of-care system that quantitatively assesses liver fat content. This work describes an early clinical feasibility study with TAEUS-FLIP and a comparison to MRI-PDFF for demonstrating the potential of TA for assessing fatty liver disease.
Method: 16 subjects with suspected Non-Alcoholic Fatty Liver Disease (NAFLD) were scanned at Rocky Vista University, Ultrasound Research medical center, USA. For each subject, after fasting for 6–8 hours, an anatomic B-mode ultrasound scan was obtained by a trained sonographer to determine the locations of the

liver capsule and overlying tissue (muscle, fat, and skin), followed by up to 10 consecutive FLIP scans over a 5–8 minute procedure. MRI-PDFF measurements were obtained to assess liver fat fraction. The median value of their individual FLIP scans was used to avoid outlier acquisitions. 3 subjects were excluded from the analysis based on FLIP measurements that were not concordant with the study subject's muscle thickness obtained by B-mode ultrasound. Linear regression and unpaired t-test were used to compare the estimated FLIP metric with liver fat fraction as measured by MR-PDFF. In a 2nd study, a trained user of the FLIP system performed 12 separate exams, each consisting of 6–8 measurements per exam, to determine intra-operator variability.

Results: Figure 1 shows the median FLIP metric for each subject compared to MRI-PDFF. The two methods are strongly correlated, with a Pearson correlation coefficient of r = 0.79. Linear regression reveals that the FLIP metric of only 3 out of 13 subjects falls out of the 95% confidence interval, indicating a clear relation between the FLIP-derived measurements and MRI-PDFF values, with 85% of the subjects staged the same by both. To assess the FLIP method's ability to discriminate early stages of NAFLD (S0 and S1) from later stages (S2 and S3), an unpaired t-test was performed on the FLIP metric with $p < 0.02$. In a second study involving 12 FLIP procedures, intra-operator variability was 9.4% (S.D. 4.5%).

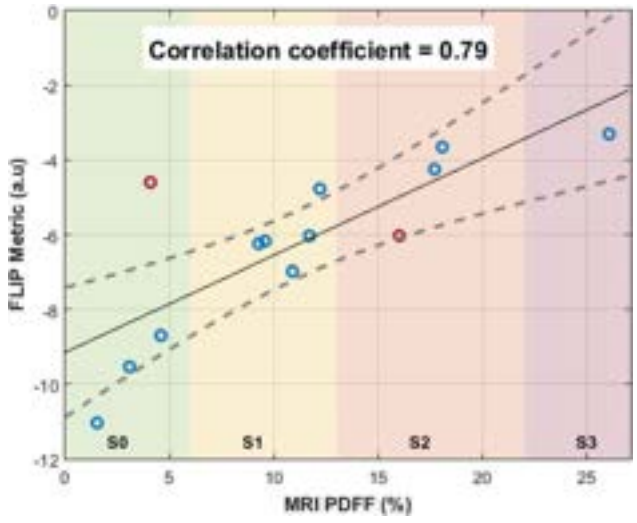


Figure:

Conclusion: This early feasibility liver fat fraction study compares TAEUS-FLIP to MRI-PDFF. It provides insight into the potential of TA methods to assess liver fat content, similar to MRI-PDFF, at the point of care, at a fraction of the cost.

WED-461

BMP-SMAD pathway upregulation in hepatocytes delays NAFLD-NASH development

Laura Silvestri[1,2], Mariateresa Pettinato[3], Valeria Furiosi[3], Letizia Bavuso Volpe[3], Shuling Guo[4], Antonella Nai[2,3], Alessia Pagani[3]. *[1]IRCCS Ospedale San Raffaele, Regulation of Iron Metabolism Unit, Division of Genetics and Cell Biology, Milan, Italy, [2]Università Vita-Salute San Raffaele, Italy, [3]IRCCS Ospedale San Raffaele, Regulation of Iron Metabolism Unit, Division of Genetics and Cell Biology, Italy, [4]Ionis Pharmaceutical, United States*
Email: silvestri.laura@hsr.it

Background and aims: Non-alcoholic Fatty Liver Disease (NAFLD) is characterized by liver fat accumulation and insulin resistance, and may progress to steatohepatitis (NASH), cirrhosis and hepatocellular carcinoma. Currently, the molecular players involved in its progression are poorly defined and no specific therapies are available. Lipid and iron metabolisms are interconnected since excess iron in hepatocytes favors NAFLD. Iron homeostasis is regulated by the hepatic hormone hepcidin, whose expression is increased by iron-mediated BMP-SMAD activation, and downregulated by the BMP-SMAD inhibitor TMPRSS6. Tmprss6-KO mice show attenuated hepatosteatosis and insulin resistance in high-fat diet, independently of body iron, suggesting a role for the BMP-SMAD pathway/hepcidin in lipid and glucose metabolisms. To deeply define the mechanism, we re-evaluated liver differentially expressed genes from Tmprss6-KO and control mice, demonstrating that increased BMP-SMAD/hepcidin upregulates Ppara and its target genes. Since PPARa activation improves NAFLD-NASH, we hypothesize that Tmprss6 targeting might be a potential therapeutic approach to this disorder.

Method: Wild-type male mice were kept a NAFLD-NASH-inducing diet (FPC) for 18 weeks. Antisense oligonucleotides (ASOs) against *Tmprss6* (*Tmprss6*-ASO) or control-ASO were injected biweekly for 6 weeks, when hepatosteatosis was established. Histological and gene expression analysis was performed for phenotypic characterization.

Results: Liver *Tmprss6* is downregulated and BMP-SMAD target genes (*hepcidin/Id1*) increased as expected. *Tmprss6*-ASO treatment counteracts FPC-induced hepatomegaly, improves hepatosteatosis and ameliorates lipid metabolisms, decreasing the expression of genes involved in lipid, storage and *de novo* lipogenesis. *Tmprss6*-ASO treatment improves FPC-induced liver mitochondrial dysfunction, decreases the expression of pro-inflammatory cytokines and oxidative stress. In addition, *Tmprss6* targeting prevents collagen deposition and fibrosis.

Conclusion: Tmprss6 downregulation, by activating the hepatocyte BMP-SMAD pathway, counteracts NASH development. Although the molecular mechanisms are still under investigation, our approach could be considered highly translatable to patients since TMPRSS6-ASOs are currently in Phase 2 clinical trials for iron-loaded diseases due to impaired erythropoiesis. Our study highlights a new therapeutic application of this drug, worth to be tested in NAFLD-NASH patients.

WED-462

Hepatocyte depletion of ERK5 impairs the response to lipotoxic oxidative stress resulting in defective insulin receptor signaling

Alessio Menconi[1], Giovanni Di Maira[1], Giulia Lori[1], Benedetta Piombanti[1], Claudia Campani[1], Maria Letizia Taddei[1], Salvatore Petta[2], Rosaria Pipitone[2], Stefania Grimaudo[2], Armando Curto[1,3], Elisabetta Rovida[1], Fabio Marra[1]. *[1]University of Florence, Italy, [2]University of Palermo, Italy, [3]Careggi, DMSC, Firenze, Italy*
Email: fabio.marra@unifi.it

Background and aims: Insulin resistance is an early event in non-alcoholic fatty liver disease (NAFLD), but the molecular mechanisms underlying the reduced response to insulin are still elusive. The mitogen-activated protein kinase ERK5 has been implicated in the development of hepatic fibrosis and cancer. Aim of this study was to investigate the role of ERK5 in the regulation of hepatocyte sensitivity to insulin.

Method: A murine hepatocyte cell line (MMH) was silenced using lentiviral vectors encoding shRNA for the ERK5 gene. Mitochondrial depolarization was assayed using the TMRE staining protocol. OXPHOS was measured by Seahorse. Mice with hepatocyte-specific deletion of ERK5 (ERK5ΔHep) were fed with a high-fat diet (HFD) for 16 weeks. For Glucose and insulin tolerance tests were conducted injecting 1 g/kg BW glucose or 0.8 U/kg BW insulin, respectively, i.p.

Results: MMH stably silenced for ERK5 showed reduced Akt activation following insulin stimulation. When ERK5-silenced cells were exposed to palmitic acid and then stimulated with insulin, Akt activation was abrogated, and expression of the insulin receptor (IR) reduced. Additionally, ERK5 silencing induced phosphorylation and activation of JNK, resulting in phosphorylation of IRS-1 on inhibitory residues (S307). In parallel, an increase of mitochondrial ROS generation was observed in ERK5-depleted MMH. ERK5 is known

to induce a NRF2-dependent anti-oxidative stress response. Expression of the NRF2-target genes HMOX1 and NQO1 was reduced in ERK5-silenced MMH. Treatment with NAC, a free-radical scavenger, prevented the downregulation of the IR and the increase in IRS1 phosphorylation on S307. Measurement of the mitochondrial membrane potential indicated a strong depolarization in ERK5-silenced cells, together with an impairment of mitochondrial OXPHOS, associated with up-regulated expression of PGC-1alpha and TRIB3, a negative regulator of insulin signalling through inhibition of Akt. ERK5ΔHep mice exhibited impaired glucose tolerance and reduced insulin sensitivity. Hepatocyte depletion of ERK5 in vivo was also associated with reduced expression of IR, and increased expression of PGC-1α and TRIB3.
Conclusion: We have elucidated a new role of ERK5 in maintaining hepatocyte insulin sensitivity, via an antioxidant response involving IRS-1, PGC-1α, and TRIB3, and converging on Akt activation.

WED-463
Hepatic Apolipoprotein J facilitates metabolic disease progression by promoting mTOR-mediated suppression of autophagy
Duan Shuangdi[1], Qin Nong[1], Pi Jiayi[1], Wang Hsin-Tzu[2], Sun Hung-Yu[2]. [1]*Hunan University, China,* [2]*National Cheng Kung University, Taiwan*
Email: s5893149@gmail.com

Background and aims: Ectopic lipid accumulation increases vulnerability of the liver to promote liver injury and metabolic syndromes (MetS). Previously, our group had showed that Apolipoprotein J (ApoJ), a Golgi-resident molecular chaperone, participated in pathogen- and nutrient-induced aberrant lipid accumulation. Herein, we demonstrated that ApoJ modulates mTOR-TFEB-autophagy axis to facilitate development of MetS, e.g. metabolic-associated fatty liver disease (MAFLD) and diabetic nephropathy (DN).
Method: The ApoJ-mTOR interaction was identified and validated by differential proteomic approach and co-immunoprecipitation assay. The function of ApoJ on mTOR-TFEB-autophagy axis and intracellular lipid deposition was evaluated using in vitro and in vivo gain- or loss-of-function experiments. The autophagic flux was addressed GFP-RFP-tagged LC3 construct and live image analysis.
Results: mTOR was demonstrated as a novel client protein for ApoJ chaperone. ApoJ interacted with mTOR kinase domain and prevented proteasomal degradation of mTOR by competing with FBW7 E3 ubiquitin ligase through its R324 residue. Persistent mTOR activation impeded autophagy and lysosomal function and disturbed hepatic lipid homeostasis, which promoted MAFLD progression. Notably, accumulation of ApoJ in proximal tubule was found in mouse models of diabetic kidney disease. Pathologically, ApoJ interfered TFEB-autophagy axis by increasing mTOR-TFEB interaction, leading to lipid and ROS accumulation and promote epithelial-mesenchymal transition of proximal tubular cells. By using liver- and kidney-specific ApoJ knockout mice, hepatocyte-derived ApoJ was identified to coordinate with renal ApoJ to accelerate the development of DN.

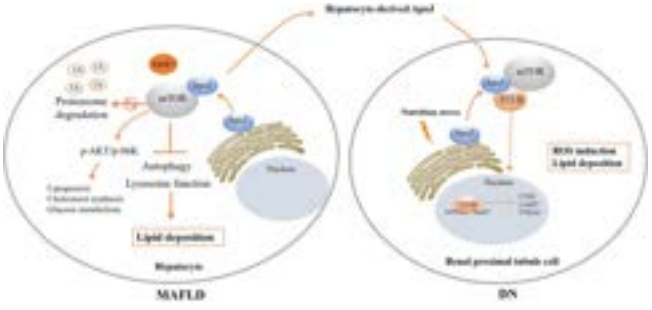

Figure:

Conclusion: The present study highlighted the pathological role of hepatic ApoJ in lipid homeostasis and suggested ApoJ as a therapeutic target for MetS.

WED-464
Bridging the gap-how human microphysiological systems improve the translatability of NASH drug discovery
Ovidiu Novac[1], Raul Silva[1], Tomasz Kostrzewski[1]. [1]*CN Bio, Milton, United Kingdom*
Email: Ovidiu.Novac@cn-bio.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is one of the most prominent forms of chronic liver disease worldwide, reflecting the epidemic of global obesity. Those with progressive variant of NAFLD, non-alcoholic steatohepatitis (NASH), are at significantly greater risk of multisystem morbidity and mortality. Traditionally, preclinical trials are mainly based on 2D and in vivo animal models but have failed constantly to predict human drug efficacy as they lack translatability and inadequately recreate the complexity and multifaceted nature of this human disease. Building more predictive, human-relevant models is crucial to successfully bringing efficient anti-NASH therapies to the market. Microphysiological systems (MPS) recapitulate key aspects of human organs' phenotype and architecture. MPS models are currently undergoing rigorous validation studies so that in the future they may be fully adopted as standard preclinical assessment tools.
Method: Our in vitro NASH model uses a triple culture consisting of primary human hepatocytes, Kupffer and hepatic stellate cells, which are cultured together in 3D microtissue structures in a perfused MPS. The microtissues are cultured in medium containing free fatty acids for at least 2 weeks to induce a NASH-like phenotype.
Results: The PhysioMimix™ NASH model captures all key aspects of the human disease: intracellular hepatic fat accumulation, inflammation (secreted cytokines and chemokines such as IL-6, IL-8 and TNFα) and fibrosis (extracellular matrix components and profibrotic markers such fibronectin, and TIMP-1). Recently we validated our advanced MPS NASH model using two anti-NASH compounds, Obeticholic acid and Elafibranor. Both compounds matched clinical findings by significantly reducing inflammatory and fibrosis markers. Here, we further expand the validation of our NASH model by measuring the effects of two more anti-NASH compounds that are currently in late-stage NASH/NAFLD clinical trials. Selonsertib showed no antifibrotic or anti-inflammatory effects in our MPS NASH model at clinically relevant dosage, matching results from phase III STELLAR trials, despite reduced fibrosis and inflammation being detected in alternative 3D spheroid models. Aramchol showed a significant reduction in fibrosis (matching data from ARMOR Phase III study) and proved to be safe at highest tested concentration without altering liver microtissues' functionality.
Conclusion: Overall, we demonstrate how this NASH liver MPS provides translatable insights into drug efficacy for NASH therapeutics and brings a promising, sensitive alternative for pre-clinical NASH screening to help fast-track decision making and access to the market.

WED-465
Human skin stem cell-derived hepatic cells with genetic predisposition for liver fat accumulation mimic susceptibility to develop metabolic dysfunction-associated fatty liver disease
Alexandra Gatzios[1], Robim M Rodrigues[1], Joery De Kock[1], Matthias Rombaut[1], Dinja De Win[1], Vera Rogiers[1], Joost Boeckmans[1], Tamara Vanhaecke[1]. [1]*Vrije Universiteit Brussel, In vitro Toxicology and Dermato-cosmetology, Brussels, Belgium*
Email: alexandra.gatzios@vub.be

Background and aims: Recently, a polygenic risk score was developed to predict hepatic fat content (PRS-HFC) based on single nucleotide polymorphisms (SNPs) in four genes, namely patatin-like phospholipase domain-containing protein 3 (*PNPLA3*) rs738409 C > G, transmembrane 6 superfamily member 2 (*TM6SF2*) rs58542926 C > T, glucokinase regulator (*GCKR*) rs1260326 C > T and membrane bound O-acyltransferase domain-containing 7 (*MBOAT7*) rs641738 C

> T. Here, we aim to investigate the impact of the PRS-HFC on the metabolic effects induced by triggers related to metabolic dysfunction-associated fatty liver disease (MAFLD), employing human skin-derived precursors (hSKP) differentiated towards hepatic cells (hSKP-HPC).

Method: The PRS-HFC was determined for 79 hSKP cell lines established from different donors and they were classified in three risk categories (R1, R2 and R3). Five cell lines were selected per category and differentiated towards hSKP-HPCs. The cultures were incrementally exposed for 24 hours to environmental MAFLD triggers, including fatty acids/fructose (condition 1) + ethanol (condition 2) + lipopolysaccharide (LPS)/tumor necrosis factor alpha (TNFa) (condition 3). The neutral lipid load was quantified and the expression of genes related to inflammation, oxidative stress, and lipid processing and synthesis was measured.

Results: Minor allele frequencies of 0.31, 0.04, 0.38 and 0.41 were found for *PNPLA3, TM6SF2, GCKR* and *MBOAT7*, respectively, which is in line with frequencies reported for the general population. The triggers from condition 3 induced the neutral lipid load significantly in all risk categories. Yet, R3 hSKP-HPC cultures exhibited a 1.5- to 2-fold higher lipid load in every test condition compared to R1 and R2 cultures. In addition, in condition 3, the induction of interleukin 6 (*IL6*) was approximately twice as high in R3 cultures (77-fold) compared to the other categories (R1 29-fold and R2 55-fold), whereas C-C motif chemokine ligand 2 (*CCL2*) was increased equally (approximately 15-fold) over all three categories. *Glutathione peroxidase 7* (*GPX7*), a marker of oxidative stress, was 1.3-fold higher in both R2 and R3 cultures compared to R1 hSKP-HPC cultures. In all test conditions, R3 donors appeared to have impaired mitochondrial beta oxidation, as indicated by a 2.5-fold lower expression of very long-chain acyl-coenzyme A dehydrogenase (*ACADVL*). Furthermore, *PNPLA3* levels were at least 2-fold lower in R3 hSKP-HPC cultures for all tested conditions compared to both R1 and R2, suggesting deficient lipase activity in these donors.

Conclusion: With increasing PRS-HFC, hSKP-HPC cultures exhibit greater susceptibility to MAFLD-inducing triggers and therefore could represent a human- and disease-relevant *in vitro* model to investigate the impact of genetic predisposition in the pathogenesis of MAFLD.

WED-466

The pan-PPAR agonist Lanifibranor improves increased portal pressure, endothelial dysfunction and liver histology in a rat model of early NAFLD

Shivani Chotkoe[1], Yao Liu[1], Guillaume Wettstein[2], Jean Louis Junien[2], Luisa Vonghia[1,3], Hannah Ceuleers[1], Joris De Man[1], Benedicte De Winter[1,3], Wilhelmus Kwanten[1,3], Sven Francque[1,3].

Email: shivani.chotkoe@uantwerpen.be

Background and aims: An increased intrahepatic vascular resistance, related to endothelial dysfunction in early stages of non-alcoholic fatty liver disease (NAFLD), can potentially contribute to disease progression. The pan-peroxisome proliferator-activated receptor agonist Lanifibranor has demonstrated beneficial effects on liver histology in NAFLD patients, and in preclinical models of cirrhosis and portal hypertension. We studied the effects of Lanifibranor on the functional intrahepatic vascular alterations and on the histological features in early NAFLD in a preventive set-up in rats.

Method: Male Wistar rats (n = 8 per group) were fed a methionine-choline-deficient diet (MCD) or control diet (CD) for 4 weeks and received simultaneously vehicle or 100 mg/kg Lanifibranor daily via oral gavage QD. *In vivo* haemodynamics and blood pressures of the carotid artery, portal vein and inferior caval vein were measured, followed by *in situ ex vivo* liver perfusion in the same animal to assess baseline transhepatic pressure gradient (THPG) at different flows (10–50 ml/min). Dose-response curves were generated with vasoconstrictors endothelin-1 (ET-1), methoxamine (Mx), and vasodilator acetylcholine (ACh) after Mx preconstriction. Histological staining was performed on liver tissue for examination using the steatosis-activity-fibrosis score and particle analysis for % steatosis quantification.

Results: In vehicle-treated animals, livers of MCD rats showed severe, grade 3 steatosis, without inflammation or fibrosis, compared to normal livers in CD rats. Moreover, MCD rats showed a significantly increased portal pressure *in vivo* compared to CD rats (5.64 ± 0.63 vs. 3.52 ± 0.24 mmHg, $p < 0.0001$), and THPG *ex vivo* was increased as well at every perfusion flow velocity (e.g., at 30 ml/min: 8.78 ± 0.35 vs. 6.73 ± 0.28 mmHg) with $p < 0.001$. Furthermore, the MCD rats were significantly hyperreactive to ET-1 and Mx, and hyporeactive to ACh compared to their CD counterparts. Treatment with Lanifibranor induced no changes in *in vivo* and *ex vivo* THPG measurements in CD rats, but completely normalized the portal pressure *in vivo* (from 5.64 ± 0.63 to 3.08 ± 0.28 mmHg, $p < 0.0001$) and THPG *ex vivo* at all flows (e.g., at 30 ml/min: from 8.78 ± 0.35 to 6.31 ± 0.15 mmHg, $p < 0.001$) in MCD rats. Lanifibranor improved the hyperreactivity to Mx and the hyporeactivity to ACh in MCD rats. Histology confirmed that Lanifibranor also improved steatosis with a 19.7 ± 4.8% ($p = 0.0001$) decrease of steatosis in MCD rats compared to vehicle.

Conclusion: Lanifibranor substantially reduces the increased portal pressure and related functional intrahepatic vascular alterations associated with early NAFLD, and it improves liver histology as well. These data support the role of intrahepatic vascular alterations in the development of NAFLD and NAFLD-related portal hypertension, and the potential of Lanifibranor as treatment for NAFLD.

WED-467

A new nuclear-erythroid-2-related factor 2 activator for the treatment of non-alcoholic steatohepatitis: evidence of metabolic and anti-fibroinflammatory effects in human precision cut liver slices

Adel Hammoutene[1,2], Samira Laouirem[1], Nathalie Colnot[3], Miguel Albuquerque[3], Angélique Brzustowski[1], Dominique Valla[1], Nicolas Provost[2], Philippe Delerive[2], Valérie Paradis[1,3]. *[1]Université Paris Cité, Inserm, Centre de recherche sur l'inflammation, F-75018 Paris, France, France, [2]Cardiovascular and Metabolic Diseases Research, Institut de Recherches Servier, Suresnes, France, France, [3]Département de Pathologie, Hôpital Beaujon, Assistance Publique-Hôpitaux de Paris, Clichy, France, France*
Email: amsadel@hotmail.com

Background and aims: Oxidative stress triggers non-alcoholic steatohepatitis (NASH) and fibrosis. Previous animal studies demonstrated that the transcription factor NRF2, the master regulator of anti-oxidant response, protects against NASH and fibrosis. S217879, a next generation NRF2 activator has been shown to trigger NASH resolution and to reduce established fibrosis in rodents. Our aim was to evaluate the therapeutic potential of S217879 in NASH using the relevant experimental 3D model of human precision cut liver slices (PCLS), and to compare its effects to those of a reference molecule, Elafibranor (PPARalpha/delta agonist).

Method: We treated PCLS from ten patients with various stages of metabolic-associated fatty liver disease (MAFLD, from simple steatosis to advanced NASH with cirrhosis) with S217879 (3 µM) or Elafibranor (10 µM) for two days. Safety and efficacy profile including impact on steatosis, liver injury, inflammation and fibrosis were assessed. Mechanisms involved in NASH pathophysiology, namely anti-oxidative stress response, autophagy and endoplasmic reticulum-stress, were also evaluated.

Results: Neither Elafibranor nor S217879 had toxic effects on human PCLS with MAFLD. PPARalpha/delta target genes (*PDK4* and *FGF21*) and NRF2 target genes (*NQO1* and *HMOX1*) were strongly upregulated in PCLS in response to Elafibranor and S217879, respectively ($p <$

0.05). Compared to untreated PCLS, Elafibranor and S217879-treated slices displayed lower triglycerides and reduced inflammation (*IL-1beta*, *IL-6*, *CCL2*) ($p < 0.05$). Additional inflammatory markers (*CCL5*, STING, ICAM-1, VCAM-1) were downregulated by S217879 ($p < 0.05$). S217879 but not Elafibranor lowered DNA damages (p-H2A.X, *RAD51*, *XRCC1*) and apoptosis (cleaved Caspase-3), and inhibited fibrogenesis markers expression (alpha-SMA, *COL1A1*, *COL1A2*) ($p < 0.05$). Such effects were mediated through an improvement of lipid metabolism, activated anti-oxidant response and enhanced autophagic flux, without effect on endoplasmic reticulum-stress.

Figure:

Conclusion: This study highlights the therapeutic potential of a new NRF2 activator for NASH using patient-derived PCLS, and is a step towards the use of NRF2 activating strategies in clinical trials.

WED-468

The NRF2/b-TrCP axis: new therapeutic target in non-alcoholic steatohepatitis (NASH)

Raquel Fernández Ginés[1], Ana Isabel Rojo[1], José Antonio Encinar[2], Pilar López-Larrubia[1], Patricia Rada[1], Angela Martinez Valverde[1], Antonio Cuadrado[1]. *[1]Instituto de Investigaciones Biomédicas "Alberto Sols". IIBm (CSIC-UAM), Madrid, Spain, [2]Universidad Miguel Hernández de Elche, Elche, Spain*
Email: rfgines@iib.uam.es

Background and aims: Transcription factor NRF2 (nuclear factor erythroid 2-related factor 2) has been proposed recently as a promising target to treat non-alcoholic steatohepatitis (NASH). However, the most widely analysed NRF2 activators, acting on its main repressor, KEAP1, elicit many off-targets effects. As an alternative, we have described the first disrupter of the interaction between NRF2 and another NRF2 repressor, beta-TrCP, that we call PHAR.

Method: We evaluated the activity of this compound in the main cell types of the liver parenchyma: immortalized hepatocytes, hepatic resident macrophages (Kupffer cells) and hepatic stellate cells. Also, we tested the selective exposure to PHAR and NRF2 activation in liver through pharmacokinetics analysis in mice. Finally, we further analyzed the effect of this compound in the STAM model of progressive liver damage by Magnetic resonance imaging (NMR), measuring the fat/water ratio, and histochemistry of oil red (fat) and Sirius red (fibrosis), and correlated inflammatory and metabolic parameters with NRF2 activation.

Results: This compound activated NRF2 in the three main liver cell types. In hepatic resident macrophages (Kupffer cells) from wild type mice but not in Nrf2 knock-out mice, the compound protected against LPS-mediated inflammation. Moreover, PHAR protected against TGF-beta-induced fibrosis in stellate LX-2 cells. Importantly, mice that developed NASH in the STAM mouse model and were then submitted to chronic treatment with this compound for 2 weeks exhibited a significant protection against the fat accumulation, inflammation and fibrosis.

Figure:

Conclusion: These findings report an innovative mechanism to activate NRF2 that could be used as an alternative to conventional anti-inflammatory therapies and to protect the liver from NASH and fibrosis.

WED-469

Quantitative ultrasound for liver steatosis assessment: benefits of measurements over a large two-dimensional region of interest on the performance of image-brightness-based parameters

Baptiste Hériard-Dubreuil[1], Adrien Besson[1], Victor de Lédinghen[2,3], Dan Dutartre[4], Françoise Manon[2], Joëlle Abiven[2], Anne-Laure de Araujo[2], Rhizlane Houmadi[2], Julie Dupuy[2], Juliette Foucher[2], Joel Gay[5], Claude Cohen-Bacrie[5]. *[1]E-Scopics, Ultrasound RandD, Saint-Cannat, France, [2]Bordeaux University Hospital, Hepatology Unit, Pessac, France, [3]INSERM U1312, BRIC, Bordeaux University, Bordeaux, France, [4]Inria Bordeaux Sud-Ouest, Bordeaux, France, [5]E-Scopics, Saint-Cannat, France*
Email: baptiste.heriard-dubreuil@e-scopics.com

Background and aims: Ultrasound (US) imaging is recommended as the first line non-invasive modality to screen for significant steatosis, using qualitative assessment of liver US brightness. Quantitative brightness-derived parameters, US attenuation (UA) and backscatter coefficient (BSC), are known to be related to liver steatosis as US propagation properties of tissues correlate with fat content. Fibroscan® (FS) uses US signals captured with a 1D single element probe to measure UA, called Controlled Attenuation Parameter (CAP). The CAP measurement workflow requires a continuous acquisition and accumulation of independent values of UA over time so as to sample a large area of the liver with the 1D-single beam interrogation. This may lead to long screening times. We studied the benefits of a large region of interest (ROI) for the computation of UA and BSC based on US data collected with a new ultrafast point of care device, Hepatoscope™.

Method: 60 adult patients referred to routine hepatology consultation for chronic liver disease, including a FS exam, were enrolled in this prospective study (NCT04782050). Four Hepatoscope consecutive liver exams were added to routine care, performed by 2 operators (1 expert and 1 novice), during which 10 consecutive sets of US per-channel raw-data were collected. UA and BSC values, alongside individual quality indicators, were computed using three different sizes of ROI (small, medium and large). Medians of BSC and UA available values with sufficient quality were considered. Data were analysed to determine the intra- and inter-operator reproducibility and the r^2 correlation with FS new CAP.

Results: As show in the figure, the overall inter-operator reproducibility of medians of UA and BSC increased significantly with the size of ROI, starting from good and very good for small ROIs ($ICC_{UA} = 0.72$ and $ICC_{BSC} = 0.80$) and reaching excellent for large ROIs ($ICC_{UA} = 0.92$ and $ICC_{BSC} = 0.93$). The same trend was observed for intra-operator repeatability, reaching excellent for both experts ($ICC_{UA} = 0.93$ and $ICC_{BSC} = 0.94$) and novices ($ICC_{UA} = 0.91$ and $ICC_{BSC} = 0.93$). The

correlation between UA and BSC medians obtained with large ROIs and FS new CAP was good: $r^2_{UA} = 0.60$ and $r^2_{BSC} = 0.64$.
The use of large ROIs improved the robustness of brightness-derived parameters estimation such that only one single UA and BSC value was sufficient to yield very good inter-operator reproducibility ($ICC_{UA} = 0.84$ and $ICC_{BSC} = 0.87$), very good and excellent intra-operator repeatability for both experts ($ICC_{UA} = 0.86$ and $ICC_{BSC} = 0.93$) and novices ($ICC_{UA} = 0.84$ and $ICC_{BSC} = 0.90$), and still showed good correlation with FS new CAP: $r^2_{UA} = 0.54$ and $r^2_{BSC} = 0.62$.

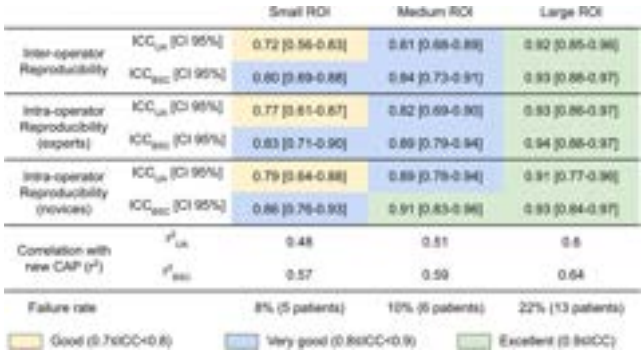

Figure:

Conclusion: UA and BSC measurements could be performed with the ultraportable point-of-care device Hepatoscope with very good intra- and inter-operator reproducibility. The performance of such measurements was directly linked to the size of the considered ROI, i.e., the volume of liver tissue that is being investigated. We found that using only one snapshot with a large ROI to estimate UA and BSC yielded excellent results, allowing low screening times for liver steatosis assessment. Future comparative studies with MRI-PDFF and histological scores will allow better assessment of the use of large ROIs UA and BSC estimation for steatosis staging.

PNPLA3 I148M substitution excerbate NAFLD under a long-term high fat diet

Huan Su[1], Madhuri Haque[1], Svea Becker[1], Karolina Edlund[2], Julia Duda[2], Qingbi Wang[1], Johanna Reißing[1], Hanns-Ulrich Marschall[3], Lena Susanna Candels[1], Mohamed Ramadan Mohamed[1], Wilhelm Sjöland[3], Till Strowig[4], Jörg Rahnenführer[2], Jan G. Hengstler[2], Maximilian Hatting[1], Christian Trautwein[1]. *[1]University Hospital RWTH Aachen, Aachen, Germany, [2]Technical University Dortmund, Dortmund, Germany, [3]Gothenburg University, Gothenburg, Sweden, [4]Helmholtz Centre for Infection Research, Braunschweig, Germany*
Email: hsu@ukaachen.de

Background and aims: Initiation and progression of non-alcoholic fatty liver disease (NAFLD) is dependent on different genetic risk factors. Here, PNPLA3 I148M mutation of the phospholipase patatin-like phospholipid domain containing protein 3 (PNPLA3) is associated with severe disease progression. However, the role of PNPLA3 in chronic liver disease was not completely understood. Our aim is to investigate how PNPLA3I148M mutation influences initiation and progression of chronic metabolic liver disease under high fat diet (HFD).
Method: Mice bearing wild-type *Pnpla3* (*Pnpla3^{WT}*), or the human polymorphism PNPLA3 I148M (*Pnpla3^{I148M}*) were subjected to a HFD for 24 and 52 weeks. The HFD contains 40 kcal% fat, 20 kcal% fructose and 2% cholesterol diet. The mice were set to fast for 3 hours before sacrifice. A detailed analysis was performed including the basic phenotype, inflammation, proliferation, cell death, fibrosis progression, microbiota as well bile acid (BA) metabolism.
Results: *Pnpla3^{I148M}* animals gained more body weight compared to *Pnpla3^{WT}* animals after the 17 weeks' time-point under HFD. After 24 weeks HFD liver injury marker AST/ALT were increased in I148M mice with 24 weeks HFD, in line with increased cell death and proliferation. *Pnpla3^{I148M}* mice had more immune cells infiltration in the liver compared to *Pnpla3^{WT}* animals only after 52 weeks HFD feeding. Moreover, *Pnpla3^{I148M}* mice fed with HFD for 52 weeks have stronger fibrosis and hepatic stellate cells activation as well as increased ductular proliferation and higher BA stool levels. Bacterial dysbiosis during HFD feeding were influenced by HFD feeding (36%) and the PNPLA3 I148M genotype (12%). RNA-sequencing analysis of liver tissue defined a *Pnpla3^{I148M}* specific expression pattern, which defines Kupffer cell and monocytes-derived macrophages as significant drivers of disease progression in *Pnpla3^{I148M}* animals.
Conclusion: The PNPLA3 I148M knockin model only develops a severe NASH liver phenotype after long-term feeding leading to obesity. Here significant differences were found compared to *Pnpla3^{WT}* animals showing that *Pnpla3^{I148M}* animals develop a specific phenotype triggered by bacterial dysbiosis and higher BA levels associated with a stronger Kupffer cell- and monocytes-derived inflammatory response leading to stronger fibrosis progression.

WED-471
A novel autophagy inducer attenuated non-alcoholic steatohepatitis by regulating the adneylate cyclase 6 in hepatocytes

Hyun Jin Jung[1], Ming Li Jin[1], Ju-hee Kang[1], Jung Ho Hwang[1], Min Woo Kim[1], Sumin Hur[2], Sun Kyoung Kim[3], Sung-Won Song[3], Jung Ju Kim[3], Hwan Mook Kim[1], Jae Hyun Kim[4], Ki Tak Nam[2], Gyoonhee Han[4], Kwang Won Jeong[1], Seung Hyun Oh[1], Se Yong Park[5]. *[1]College of Pharmacy, Gachon University, Korea, Rep. of South, [2]Yonsei University College of Medicine, Korea, Rep. of South, [3]Autophagy Sciences, Korea, Rep. of South, [4]Yonsei University, Korea, Rep. of South, [5]Seoul National University, College of veterinary medicine, Seoul, Korea, Rep. of South*
Email: eyeball@hanmail.net

Background and aims: Autophagy is a critical process that regulates cellular metabolic homeostasis and was recently shown to be associated with non-alcoholic steatohepatitis (NASH). However, although NASH is one of the most prevalent diseases, approved pharmaceutical treatments are lacking. Here, we report that the therapeutic effects of an autophagy inducer (A4368) on NASH involve adenylate cyclase 6 (AC6) regulation.
Method: A4368 was selected as an autophagy inducer from a focused library, and its effects were evaluated *in vitro* and *in vivo*. *In vitro* assays (kinase and enzyme-linked immunosorbent assays and immunoblotting) revealed that A4368 induced hepatic autophagy and decreased lipid accumulation and inflammatory and fibrogenic responses via AC6 regulation. Three different types of mouse models were used to investigate the therapeutic effects of A4368. NASH was induced by feeding mice a choline-deficient high-fat diet or western diet, and a Stelic animal model was developed.
Results: A4368 increased autophagic flux in hepatocytes but not in hepatic stellate cells or macrophages. It induced autophagy by directly binding to and inhibiting AC6, which resulted in accelerated clearance of lipid droplets in hepatocytes. A4368 significantly alleviated several parameters associated with NASH, including histological features in mouse models of NASH induced by three different types of high-fat diets.
Conclusion: In summary, the novel autophagy inducer A4368 could be a new therapeutic agent for NASH.

WED-472

Effect of vitamin D receptor signaling on endoplasmic reticulum stress in non-alcohol related steatohepatitis: exploring potential autophagy dependence

Basma Alaa[1], Olfat Hammam[2], Aiman El-Khatib[3], Yasmeen Attia[1]. [1]*The British University in Egypt-BUE, Department of pharmacology, Cairo, Egypt,* [2]*Theodor Bilharz research institute, Department of pathology, Giza, Egypt,* [3]*Faculty Of Pharmacy Cairo University, Department of pharmacology and toxicology, Cairo, Egypt*
Email: Basma.alaa@bue.edu.eg

Background and aims: Protecting the liver against cellular stress upon exposure to either exogenous or endogenous insults is a pivotal process governed by various processes among which is the endoplasmic reticulum (ER) protein folding in addition to autophagy induction, conserving cell homeostasis and fine-tuning apoptotic responses. A growing body of evidence suggests a correlation between ER stress and autophagy towards preserving the homeostatic immune response in the liver. The modulation of ER stress via autophagy induction has gained much traction recently, however, its role in a non-alcohol related steatohepatitis (NASH) context was little explored. Interestingly, vitamin D3 impact on either ER stress or autophagy was underscored in multiple pathological settings. This study, therefore, sought to unravel the potential impact of calcitriol (CAL), the active form of vitamin D3, on the modulation of ER stress in an experimental NASH model, providing insights on the likely autophagy dependence.
Method: Male C57BL/6 mice were kept on a dietary high-fat diet (HFD) to induce NASH and were allocated to the following 4 groups: (I) Normal group that was fed a balanced diet, (II) Positive control group (HFD) that was kept on a HFD, (III) CAL-treated group that received CAL at a dose of 5 ng/gm/day, i.p., twice per week, and (IV) CAL+HCQ-treated group that received CAL and the autophagy inhibitor, hydroxychloroquine (HCQ) at a daily dose of 60 mg/kg/day, p.o. Treatment started after 8 weeks of induction for a duration of 4 weeks. By the end of the experiment, livers were collected for histopathological examination, determining NASH score, and further analyses. Vitamin D receptor (VDR) gene expression levels were determined using qRT-PCR. Hepatic levels of inositol-requiring enzyme-1a (IRE1a) and caspase-3 were determined using ELISA for the assessment of ER stress and apoptosis, respectively. Statistical analysis was performed using one-way ANOVA followed by Tukey Kramer's post hoc test. Significance was considered at p values less than 0.05.
Results: Our findings demonstrated NASH amelioration and near-normal hepatic architecture with regard to hepatocytes, sinusoids, and portal tract arrangement in the livers of CAL-treated group. A reduction in NASH score with CAL treatment compared to the HFD group was also evident. This was coupled by an upregulation in hepatic VDR expression with CAL compared to the HFD untreated group. Regarding ER stress, IRE1a protein levels surged in the HFD group compared to normal, an effect that was curtailed by CAL treatment. Intriguingly, autophagy inhibition using HCQ reversed CAL effect on IRE1a, implying a likely autophagy dependency (Fig. 1). The increased hepatic levels of the apoptotic marker, caspase-3, observed in the HFD group were curbed by CAL treatment. Likewise, the latter effect was reversed when HCQ was given in combination.
Conclusion: The current study, therefore, suggests a potential autophagy-dependent impact of CAL on ER stress in NASH.

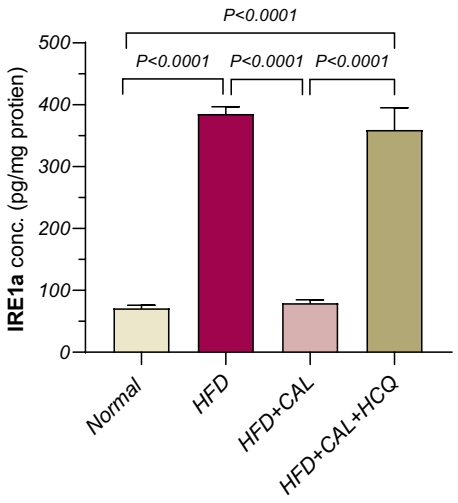

Figure: Effect of CAL on IRE1a protein levels in normal, HFD, CAL-treated, and CAL+HCQ-treated groups, as determined by ELISA. Statistical analysis was performed using One-way ANOVA followed by Tukey Kramer post hoc test for multiple comparisons. Data are presented as means ± SD.

WED-473

Improvement of liver fibrosis by a novel long acting Glucagon/GLP-1/GIP triple agonist, efocipegtrutide (HM15211) in carbon tetrachloride-induced mouse model of liver injury and fibrosis

Jong Suk Lee[1], Yohan Kim[1], Jung Kuk Kim[1], Hyunjoo Kwon[1], Eun Jin Park[1], Jeong A Kim[1], Sang Hyun Park[1], Sung Min Bae[1], Sang Hyun Lee[1], In Young Choi[1]. [1]*Hanmi Pharm.Co., Ltd., Korea, Rep. of South*
Email: iychoi@hanmi.co.kr

Background and aims: Fibrosis is the pathologic result of chronic inflammation due to NASH, which can progress to liver cirrhosis, and causes liver-related complications. However, no drug has been approved to date. Thus, to provide a novel therapeutic option with more predictable therapeutic benefits, a novel long-acting Glucagon/GIP/GLP-1 triple agonist, efocipegtrutide, was developed and its efficacy has been extensively evaluated in various animal models of NASH and/or fibrosis such as MCD, AMLN, CDAHFD, and TAA mice. To generalize its potential therapeutic benefits, anti-fibrotic effect of efocipegtrutide was further evaluated in carbon tetrachloride (CCl_4)-induced fibrosis mouse, one of the well-established models of liver fibrosis.
Method: To induce liver fibrosis, 20% CCl_4 was 3 times/week intraperitoneally injected to C57BL/6 male mouse for 10 weeks and efocipegtrutide was administrated during the last 6 weeks. To evaluate the therapeutic effect of efocipegtrutide on fibrosis, hepatic pro-collagen 1 alpha 1 contents, hydroxyproline contents (HP) and Sirius red staining area were measured. Additionally, blood surrogate markers and hepatic fibrosis related gene expression level were analyzed.
Results: CCl_4 mice showed various liver fibrosis profiles. However, treatment of efocipegtrutide effectively improved these fibrosis profiles such as hepatic pro-collagen 1 alpha 1 contents (0.89 μg/g vs. 1.22 μg/g for CCl_4, vehicle; $p < 0.05$), hydroxyproline contents (348.6 nmol/g vs. 430.5 nmol/g for CCl_4, vehicle; $p < 0.001$) and sirius red positive area (2.46% vs. 4.81% for CCl_4, vehicle; $p < 0.001$). Also, meaningful reduction of hepatic fibrosis marker genes expression (collagen 1 alpha 1, collagen 3 alpha 1 and alpha-smooth muscle actin) were observed in efocipegtrutide-treated group. Furthermore, blood surrogate biomarkers of fibrosis and inflammation (TIMP-1, PIIINP and TNF-alpha) were markedly improved by efocipegtrutide treatment.

Conclusion: Efocipegtrutide effectively improved liver fibrosis in CCl_4-induced fibrosis mice. These results are consistent with previous study results in various NASH/fibrosis animal models, in which further reinforcing the robust anti-fibrotic effect of efocipegtrutide via simultaneous action of GCG, GIP, and GLP-1. Human study is ongoing to assess the clinical relevance of these findings.

WED-474

A translational rat model to study metabolic associated fatty liver disease with fibrosis and portal hypertension

Aurora Barberá[1], Imma Raurell[1,2], María Martínez-Gómez[1], Mar Gil[1], Juan Manuel Pericàs[1,2], Joan Genesca[1,2], María Martell[1,2]. [1]*Liver Diseases, Vall d'Hebron Institut de Recerca (VHIR), Liver Unit, Hospital Universitari Vall d'Hebron (HUVH), Vall d'Hebron Barcelona Hospital Campus; Universitat Autònoma de Barcelona (UAB), Barcelona, Spain,* [2]*Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Madrid, Spain*
Email: maria.martell@vhir.org

Background and aims: The use of animal models is crucial to understand the underlying mechanisms in the onset and progression of metabolic associated fatty liver disease (MAFLD) and to develop novel therapeutic strategies. Moreover, the concept of MAFLD is not as restrictive as NAFLD and other potential causes of liver damage can coexist with metabolically-induced fatty liver and steatohepatitis (NAFLD), being alcohol consumption the most frequent liver injury in Southern European countries (MAFLD-OH). Although several animal models have been used in the field, there is an ongoing challenge to identify those models that best mimic human pathology to allow good translation of the obtained results into the clinics. We aimed to develop a dietary rat model that reproduces the full MAFLD phenotype observed in human disease, including features of the metabolic syndrome, steatohepatitis with liver fibrosis and portal hypertension.

Method: For model development, male Sprague-Dawley rats were fed 16 weeks with control diet (CD), high-fat high-cholesterol diet with glucose/fructose beverage (HFHC/GF) or the same diet plus 1–3% ethanol added to the GF drink (HFHC/GF-OH). Liver biopsies were performed on some individuals at 12 weeks to evaluate fibrosis. By the end of week 16, liver hemodynamics, histology and metabolic parameters were characterized.

Results: Sirius Red staining revealed that the rats from HFHC/GF and HFHC/GF-OH groups developed perisinusoidal fibrosis by week 12. The HFHC/GF and HFHC/GF-OH livers also showed severe steatosis and inflammatory infiltrates. The diet intervention did not induce significant increments in body weight at any time point. However, the liver to body weight ratio increased significantly more in the HFHC groups compared with the CD at 16 weeks. Portal pressure (PP) significantly increased in both HFHC/GF and HFHC/GF-OH groups compared to CD group (13.29 and 12.16 mmHg vs 8.74 mmHg, respectively). No significant differences in PP were found between HFHC groups. HFHC diet was associated with significant increases in fasting blood concentrations of AST, ALT, cholesterol, alkaline phosphatase, creatine kinase and albumin.

Conclusion: This translational animal model could become a suitable model for basic research of advanced stages of MAFLD and also for drug testing in this pathology.

Funded by Instituto de Salud Carlos III [PI18/00947, PI21/00691].

Secretomics identifies IGFBP1 as a stress signaling marker in human models for NAFLD

Ruth Walker[1], Maria Emilia Dueñas[1], Jeremy Palmer[2], Jose Luis Marin-Rubio[1], Quentin Anstee[2,3], Matthias Trost[1], Olivier Govaere[3,4]. *[1]Newcastle University, Biosciences Institute, Faculty of Medical Sciences, Newcastle Upon Tyne, United Kingdom, [2]Newcastle University, Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle Upon Tyne, United Kingdom, [3]Newcastle upon Tyne Hospitals NHS Trust, Newcastle NIHR Biomedical Research Centre, Biomedical Research Building, Newcastle Upon Tyne, United Kingdom, [4]KU Leuven, Translational Cell and Tissue Research lab, Department of Imaging and Pathology, Leuven, Belgium*
Email: r.h.walker2@newcastle.ac.uk

Background and aims: Lipid accumulation is a key part of the pathogenesis of non-alcoholic fatty liver disease (NAFLD) and has recently been associated with endoplasmic reticulum (ER) stress. *In vitro* lipid loading is often used as an experimental model for NAFLD, though an understanding of the metabolic changes and lipotoxicity is still lacking. This work explored the proteomic and secretomic differences induced by ER stress or lipid accumulation in cell models by using mass spectrometry (MS)-based approaches to gain an insight into the mechanism underlying NAFLD.
Method: Primary human hepatocyte cells were treated with saturated and unsaturated fatty acids including linoleic (LA), oleic (OA), and palmitic acid (PA) at 400 µM, or with the ER stress inducer thapsigargin (1 mM) for 24 hours. Secreted proteins in the culture media were isolated 3 hours before collection. Treated samples were screened by Matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry (MALDI-TOF MS) to determine differences in the phenotypic profiles of metabolites and high molecular weight biomolecules, and proteins were identified by data-independent acquisition on an Orbitrap Fusion Lumos Tribrid MS (LC-MS/MS).
Results: Distinctive metabolite profiles were established for each condition by MALDI-TOF MS, allowing multiplexing and identification of biomarkers. LA and PA, especially, induced a comprehensive switch in metabolites, while substantial protein changes were observed upon PA and ER-stress treatment. LC-MS/MS proteomics analysis of the primary cells identified 170 differentially expressed proteins in the LA condition, 8 in the OA, 225 in the PA, and 966 in the ER-stress condition. Changes in the expression of NAFLD-relevant markers as p62 or GDF15 proved to be dependent on the treatment condition. Interestingly, ER-stress induction showed an increase in metabolic-related proteins, including perilipin-2 and glucokinase. A strong increase in Insulin-like growth factor-binding protein 1 (IGFBP1) expression was observed in LA, PA, and ER-stress treatments. The secretomic phenotype of primary human hepatocytes differed drastically depending on the underlying lipid or ER-stress challenge. The analysis characterized 21 differentially expressed proteins upon LA treatment, only 1 with OA, 1789 with PA, and 77 upon ER stress induction, when compared to their respective controls. The release of perilipin-2 was observed in each lipid treatment condition. PA and ER-stress treatments had an intersection of 42 proteins, many relating to metabolic processes such as retinol or steroid metabolism, with IGFBP1 being the top marker in both comparisons.
Conclusion: This study identified commonalities but also distinct different secretomic and proteomic profiles of stress mediators in NAFLD.

WED-476

Serum exosomal mir-4668-5p in Non-alcoholic Fatty liver Disease (NAFLD) patients with significant liver fibrosis

Jong Eun Yeon[1], Young-Sun Lee[1], Eunjung Ko[1], Yoonseok Lee[1], Sun Young Yim[2], Young Kul Jung[3], Ji Hoon Kim[1], Yeon Seok Seo[2], Hyung Joon Yim[3]. *[1]Korea University Medical College Guro Hospital, Internal Medicine, Seoul, Korea, Rep. of South, [2]Korea University Medical College Anam Hospital, Korea, Rep. of South, [3]Korea University Medical College Ansan Hospital, Korea, Rep. of South*
Email: jeyyeon@hotmail.com

Background and aims: In worldwide, fatty liver disease in non-significant amount of alcoholic drinker (Non-alcoholic fatty liver disease (NAFLD)) are on the rise as obesity and diabetes increase. Among the histologic changes, degree of liver fibrosis is the most important factor for predicting long term outcomes. Although liver biopsy is the gold standard for diagnosis, serious complication and variability of sampling and interpretation made it difficulties in routine clinical practice. Aim of our study is to explore the clinical significance of serum exosomal miRNA in liver fibro-genesis of NAFLD patients.
Method: 47 biopsy-proven NAFLD patients were included. Exosome was isolated from serum samples and serum exosomal miRNA was analyzed with GeneChip miRNA 4.0 array (Affymetrix, U.S.A). Also, we analyzed the expression of miRNA in liver tissues of the same patient who had been tested for serum exosomal miRNA. To define the role of miRNA in liver fibrogenesis, human hepatic stellate cell was transfected with miRNA of interests. Serum and liver samples from mice feed with high fat high fructose (HFHF) diet for 24 weeks were analyzed for comparison with human.
Results: NAFLD patients with advance fibrosis group (Gr1) were older, having more metabolic syndrome, lower platelet counts, prolonged PT INR compared to that of non-significant fibrosis group (Gr2). A total of 86 serum exosomal miRNA were significantly changed between Gr.1 and Gr.2, Of which 42- and 44-miRNA showed significantly higher or lower expression in Gr.1 compared to Gr.2. Of them, MiR4668-5p was selected because of it were one of the highest altered miRNA in Gr.1 compare to Gr.2. When human hepatic stellate cell (LX2 cell) was transfected with 4668-5p mimics or inhibitors, mRNA of TGF-β, α-SMA and collagen1A1 expression were significantly elevated and reduced after each transfection. In mice feed with HFHF diets, mRNAs involved in lipid uptake, transport, and oxidation were altered. TGF-b1 and a-SMA and col1A1 expression were altered in HFHF group.
Conclusion: Serum exosomal miRNAs were significantly altered in NAFLD patients with advanced fibrosis. Among them, serum exosomal miRNA-4668-5p has significant role in liver fibrosis. Although additional researches are required, serum exosomal miRNA may has a diagnostic value or therapeutic target of liver fibrosis in NAFLD patients.

Rilpivirine as an anti-inflammatory agent in non-alcoholic fatty liver disease: evidence from human hepatocytes, hepatic stellate cells and blood cells

Isabel Fuster-Martínez[1,2], Ángela B. Moragrega[1,2], Aleksandra Gruevska[1,2], Ana Benedicto[1,2], Joan Tosca[3], Cristina Montón[3], Elena Muñoz[4], Dimitri Dorcaratto[4], Juan V. Esplugues[1,2,5], Nadezda Apostolova[1,2,5], Ana Blas-García[2,5,6]. *[1]University of Valencia, Department of Pharmacology, Valencia, Spain, [2]FISABIO-University Hospital Dr. Peset, Valencia, Spain, [3]Hospital Clínic Universitari de València, Department of Digestive Medicine, Valencia, Spain, [4]Hospital Clínic Universitari de València, Department of Surgery, Liver, Biliary, and Pancreatic Unit, Biomedical Research Institute INCLIVA, Valencia, Spain, [5]Biomedical Research Networking Center in Hepatic and Digestive Diseases (CIBERehd), Spain, [6]University of Valencia, Department of Physiology, Valencia, Spain*
Email: ana.blas@uv.es

Background and aims: Drug repurposing is emerging as an attractive approach to identify compounds with potential applications in non-alcoholic fatty liver disease (NAFLD). Rilpivirine (RPV), an antiretroviral used to treat HIV infection, has been described as an anti-fibrotic, anti-inflammatory and anti-steatotic drug in several *in vivo* studies. We aimed to characterize the mechanisms underlying its anti-inflammatory effects, focusing on its specific actions on blood and hepatic cells.
Method: The effects of RPV were evaluated both *in vitro* (human hepatic cell lines, primary hepatic stellate cells -HSC- and monocyte-derived macrophages -MDM-, both from healthy donors) and *ex vivo* (peripheral blood mononuclear cells -PBMC- isolated from patients with chronic liver disease). To reproduce NAFLD conditions, cells were incubated for different periods of time with RPV in the absence or presence of fatty acids and/or pro-inflammatory (LPS) or fibrogenic cytokines (TGF beta) in the medium. The molecular routes involved were studied using transcriptomic analysis and standard molecular biology techniques (RT-PCR, Western Blot and ELISA).
Results: RPV reduced the phosphorylation and the nuclear translocation of p65, as well as its pro-inflammatory target genes *IL1B*, *IL18*, *CASP1*, *TNFA* and *CXCL8* in fatty acid-overloaded hepatocytes. Similar effects were observed in activated HSC and LPS-treated MDM, in which RPV also inhibited the NLRP3-inflammasome pathway, decreasing NLRP3 protein expression, Caspase-1 activation and *IL1B* gene expression. RNA sequencing transcriptomic analysis and gene set enrichment analysis in activated HSC demonstrated that RPV downregulated GO processes associated with response to cellular stress, including the positive regulation of stress-activated MAPK cascade. In line with these results, analysis of stress-activated protein kinases by Western Blot showed a clear inhibition of the JNK-mediated pathway induced by this drug in these cells as well as in FA-overloaded hepatocytes and MDM. RPV also significantly decreased the synthesis and release of the chemoattractant CCL2 in HSC and MDM, downregulating leukocyte chemotaxis and migration. Finally, *ex vivo* experiments with PBMC demonstrated that RPV exerted an anti-inflammatory effect by enhancing the expression of STAT3-mediated pathways and downregulating the activation of STAT1 and its target genes.
Conclusion: The antiretroviral drug RPV exerts anti-inflammatory actions on injured hepatocytes, activated HSC, macrophages and PBMC. The findings point to a beneficial role of RPV in NAFLD.

WED-506

Characterization of portal inflammation and hepatic fibrosis in non-alcoholic fatty liver disease

Annie Masters[1], James M Estep[1,2], Lakshmi Alaparthi[3], Gary Bratthauer[3], Aybike Birerdinc[1,2], Fanny Monge[3], Cassandra Sharp[3], Daisong Tan[4], Hala Abdelaal[3], Zachary Goodman[3], Zobair Younossi[1,2,3]. *[1]George Mason University, School of Systems Biology, United States, [2]Inova Health System, Beatty Liver and Obesity Research Program, Department of Medicine, United States, [3]Inova Health System, Center for Liver Disease, Department of Medicine, United States, [4]Inova Health System, Center for Liver Disease, Department of Medicine, Falls Church, United States*
Email: zobair.younossi@inova.org

Background and aims: The relationship between inflammation and the progression of hepatic fibrosis in the context of non-alcoholic

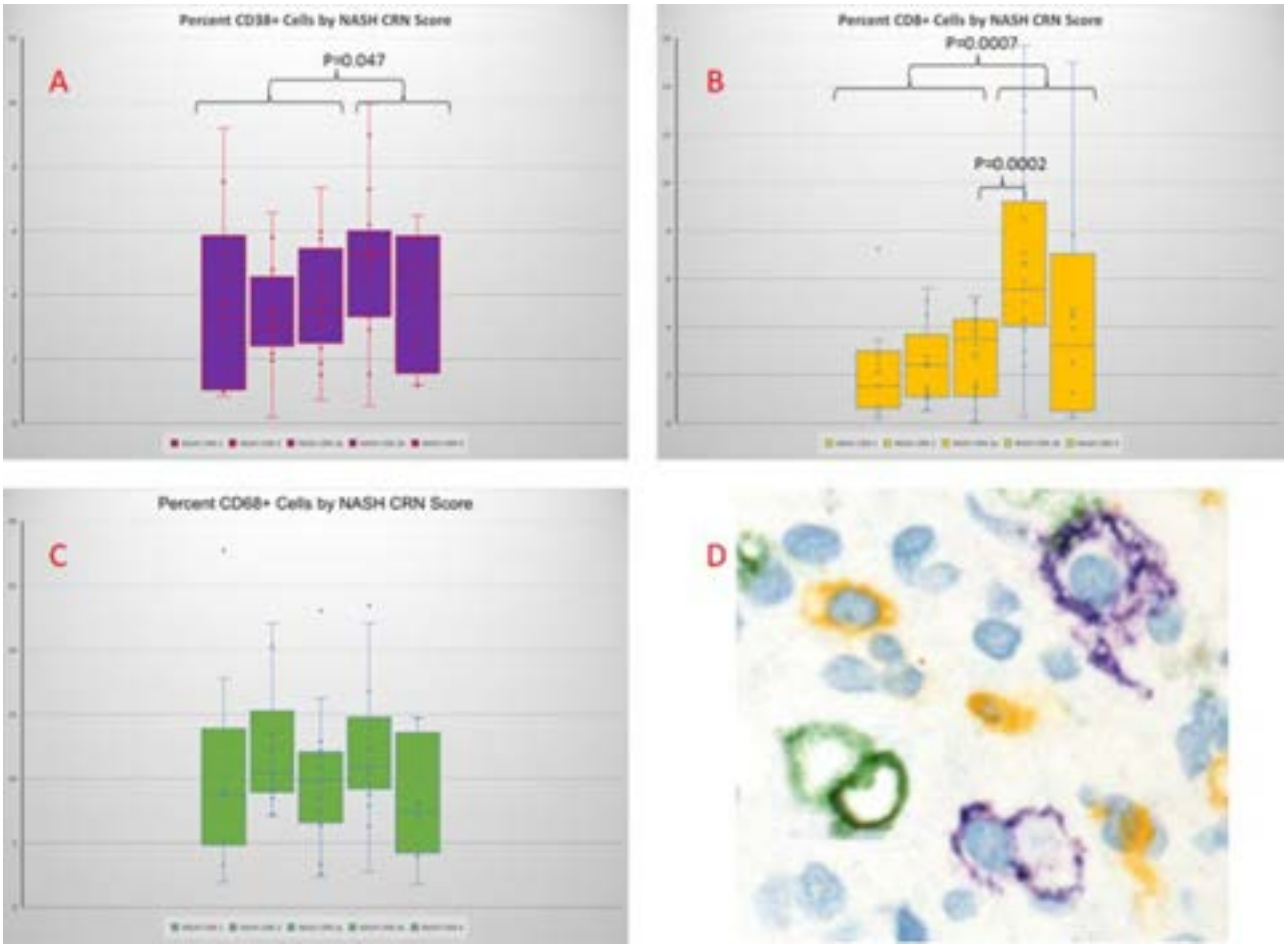

Figure: (abstract: WED-506) Hepatic Expression of CD8, CD38, and CD68: **"A"–"C"**; Box and whisker plots showing assessed expression of surface markers by modified NASH CRN score. **"D"**; Representative photograph of showing staining of CD8 (yellow), CD38 (purple), and CD68 (green).

fatty liver disease (NAFLD) has not been formally characterized. The aim of this pilot study is to histologically quantify lymphocytic effector cells and Kupffer cell/macrophage populations in the liver biopsies of NAFLD patients with various stages of fibrosis.
Method: Liver needle biopsy slides from patients with NAFLD and a range of NASH CRN scores (N = 65) were immunohistochemically stained on a Discovery Ultra (Roche) in multiplex CD8 (Yellow; cytotoxic T-cells), CD68 (Green; Kupffer cells/macrophages), and CD38 (Purple; plasma cells). Stained biopsies were scanned using an Aperio AT2 (Leica Microsystems) and analyzed using HALO's Multiplex IHC module. Cells were segmented using a combination of the nuclear/cytoplasmic staining and each cell is individually measured for nuclear/or cytoplasmic Frequency of stained cell types by NASH CRN score was assessed by descriptive statistics and Mann-Whitney analysis.
Results: Of the biopsies analyzed in this pilot study (N = 65), 10 subjects were categorized as NASH CRN stage 1, 14 stage 2, 33 stage 3 which was split into 3a (mild bridging, N = 16) and 3b (marked bridging, N = 17) inspired by the Ishak scoring system, and 8 were stage 4. The relative frequency of effector lymphocytes increased with NASH CRN stage ($p = 0.03$). Pairwise analysis revealed a significant increase in cytotoxic T-cells between NASH CRN stages 3a and 3b ($p = 0.0002$), as well as an overall increase in both plasma cells and cytotoxic T-cells when comparing stages 3b and above to stages 1 through 3a ($p = 0.047$, and $p = 0.0007$, respectively) (Figure).
Conclusion: Progression to advanced fibrosis in NAFLD is characterized by an increase in effector B and T cell types. In this pilot study, our method has been effectively used to objectively quantify inflammatory cell types as they relate to hepatic fibrosis in NAFLD patients. This quantification method can be used in future studies to assess the contribution region specific immune cell infiltration to the progression of fibrosis in NASH.

WED-507
b-Klotho deficiency in hepatic stellate cells (HSCs) prompts inflammation, oxidative stress and a pro-fibrotic phenotype
Giada Tria[1], Erika Paolini[1], Miriam Longo[1], Nadia Panera[2], Roberto Piciotti[1], Anna Alisi[2], Marica Meroni[1], Paola Dongiovanni[1].
[1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy; General Medicine and Metabolic Diseases; Milan, Italy, [2]Bambino Gesù Children's Hospital-IRCCS, Research Unit of Molecular Genetics of Complex Phenotypes, Italy
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: β-Klotho (*KLB*) gene encodes the hepatic co-receptor of fibroblast growth factor receptor 4 (FGFR4). We previously reported that the rs17618244 G > A *KLB* gene variant dampened KLB hepatic and plasma levels, leading to inflammation, ballooning and fibrosis both in pediatric and adult patients with non-alcoholic fatty liver disease (NAFLD). Hepatic stellate cells (HSCs) are directly involved in the fibrotic processes, playing a crucial role in the switching to severe forms of NAFLD. Aim of this study was to generate a cell line of hepatic stellate cells (HSCs), responsible for hepatic fibrosis, which are deleted for *KLB*, and to investigate the impact of its deficiency on their pro-fibrotic phenotype, inflammation and oxidative stress.
Method: We stably silenced *KLB* gene in LX2 cells (referred to as HSCs $KLB^{-/-}$) by Crispr-Cas9 technology. Then, markers of activation, cellular stress, inflammation and proliferation have been investigated.
Results: KLB mRNA and protein levels were reduced in HSC $KLB^{-/-}$ cells ($p < 0.05$). Markers of activation (i.e., *αSMA, COL1A1/3A1/4A1, TGFβ, PDGFRB*) were increased in $KLB^{-/-}$ cells at both gene and protein levels. Accordingly, retinol synthesis (*RALDH*) and the expression of *BAMBI* were reduced ($p < 0.05$), suggesting a more pro-fibrotic phenotype. Moreover, *KLB* deletion strongly induced oxidative stress, enhancing ROS/reactive nitrite species (RNS) and aldehyde derivate concentrations (MDA) ($p < 0.05$). These events triggered the release of pro-inflammatory cytokines (TNFα, IL1β and IL6) into the $KLB^{-/-}$ cultured media. Finally, *KLB* shortage leads to reduced ATP synthesis and higher lactate release, which may be suggestive of enhanced glycolytic rate and of a trend towards a pro-cancerous microenvironment. In keeping with these findings, $KLB^{-/-}$ cells also showed an elevated proliferative rate, more rapid would healing repair and higher invasiveness compared to wild-type counterpart ($p < 0.05$).

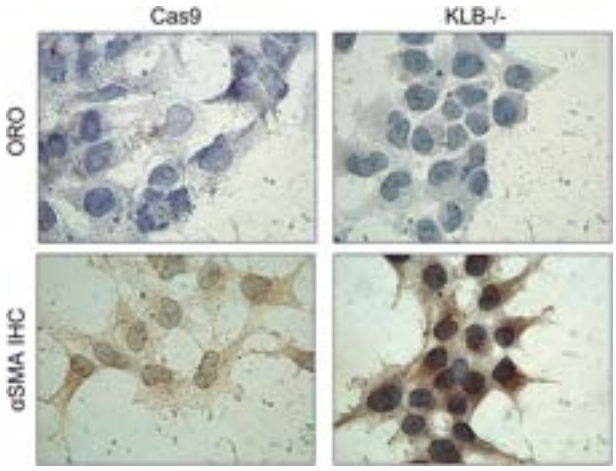

Figure: Oil Red O (ORO) staining (upper panel) and αSMA IHC (lower panel) on LX2 control (Cas9 positive) and silenced for KLB gene in 1000x magnification.

Conclusion: We generated, for the first time, a stable knock-out of *KLB* in HSCs. Our preliminary results outlined that *KLB* deficiency induced an enhanced pro-fibrotic phenotype with increased proliferation, inflammation and oxidative stress, thus possibly explaining the association between the rs17618244 *KLB* at-risk variant and more severe forms of liver damage. Altogether, these observations pointed KLB a novel target to prevent severe NAFLD.

WED-508
A functional investigation of NASH-associated gene polymorphisms in human liver tissue
Amy Shepherd[1], Jack Leslie[1], Fiona Oakley[1], Derek Mann[1], Jelena Mann[1]. *[1]Biosciences Institute, Newcastle Fibrosis Research Group, 4th Floor, William Leech Building, Biosciences Institute, Newcastle University, Medical School, Newcastle upon Tyne, United Kingdom*
Email: jelena.mann@newcastle.ac.uk

Background and aims: Development of NAFLD has a multifactorial etiology that includes a strong genetic component. A number of single nucleotide polymorphisms (snps) have been identified within genes involved in regulation of hepatic fat metabolism; these snps have been shown in population studies to be associated with differential long-term disease outcome. We have established precision cut liver slices (PCLS) that maintain the architectural integrity, functionality and metabolic activities of the tissue over an extended period, which for the first time allows in vitro modelling of liver disease using genotypically diverse human donor tissue.
Method: PCLS were generated from 44 liver donors and tissue genotyped using the primers for: MBOAT7 rs641738 C > T, GCKR rs1260326 (P446L) and PNPLA3 rs738409 C > G (I148M). PCLS were exposed to profibrogenic stimuli or to lipid loading to examine the effect of the snps on induction of fibrosis, lipid accumulation and inflammation in the human liver tissue. PCLS media was sampled longitudinally and assayed for Collagen1a1 and IL6 while tissue harvested at the end of experiments was assayed for triglyceride content and stained with Picrosirius Red to measure fibrosis induction.
Results: Presence of MBOAT7 rs641738 C > T, GCKR rs1260326 (P446L) and PNPLA3 rs738409 C > G (I148M) snps on one or both

alleles caused an increase in triglyceride accumulation in the lipid loaded donor tissue, which was in some patients associated with increase in inflammatory markers but not always associated with increase in fibrogenesis. For some snps, the increase in donor age or gender had an effect on triglyceride accumulation in PCLS.
Conclusion: Human PCLS modelling of liver fibrosis and lipid loading has, for the first time, provided experimental evidence of the effect that MBOAT7 rs641738 C > T, GCKR rs1260326 (P446L) and PNPLA3 rs738409 C > G (I148M) snps exert on liver tissue responses to profibrogenic and lipid mediated stimuli. This provides new mechanistic insights into disease processes and provides an unrivalled platform for study of genotype and phenotype in aged tissue.

WED-509
Effect of housing temperature on non-alcoholic fatty liver disease development in C57BL/6N mice
Olga Horakova[1], Gabriella Sistilli[1], Veronika Kalendova[1], Tomas Cajka[2], Carolin Lackner[3], Martin Rossmeisl[1]. *[1]Institute of Physiology of the Czech Academy of Sciences, Laboratory of Adipose Tissue Biology, Prague, Czech Republic, [2]Institute of Physiology of the Czech Academy of Sciences, Laboratory of Translational Metabolism, Prague, Czech Republic, [3]Medical University of Graz, Institute of Pathology, Graz, Austria*
Email: olga.horakova@fgu.cas.cz

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with obesity and metabolic syndrome. NAFLD can progress to more severe stages, such as steatohepatitis. Recently, thermoneutral housing (TN) was found to promote human-like NAFLD in high-fat diet (HFD)-fed C57BL/6J mice, characterized by obesity and increased pro-inflammatory liver responses. Given the known differences in the development of steatohepatitis between substrains of C57BL/6 mice, we aimed to determine how TN affects NAFLD pathogenesis in another frequently used substrain, i.e. C57BL/6N.
Method: Male C57Bl/6N mice were fed standard diet or HFD (lipids ~60 energy%) for 24 weeks starting at 11 weeks of age. Mice were housed in either standard (22°C) or TN (30°C) environment. At week 21, tail blood was collected from overnight fasted mice to measure glycemia and plasma levels of metabolites and hormones. Metabolipidomic profiling of liver samples (~20 mg) was performed using an untargeted workflow combining lipidome, metabolome and exposome (LIMeX) and partial least squares discriminant analysis (PLS-DA). Histopathologic analysis of hepatic steatosis, inflammation and fibrosis was also performed.
Results: Weight gain and hepatic steatosis were increased in HFD-fed mice, regardless of ambient temperature. No difference was observed in histological scores of liver inflammation and fibrosis, which were generally low and did not correspond to increased tissue expression of inflammatory and tissue remodeling markers in HFD-fed mice, showing only marginal increase due to TN. Although the results of liver metabolipidomic profiling in HFD-fed mice supported the involvement of autophagy-related metabolites in HFD-induced NAFLD, they did not reveal a substantial effect of TN. Conversely, in standard-diet-fed mice, TN increased weight gain, overall adiposity, adipocyte hypertrophy, hepatic steatosis, and NAFLD activity score. This was accompanied by increased de novo lipogenesis and marked changes in the hepatic metabolome characterized by a complex decrease of various phospholipid species and metabolites involved in the urea cycle and oxidative stress defense.
Conclusion: In conclusion, TN appears to exacerbate NAFLD phenotype depending on C57BL/6 substrain and diet.

WED-510
Preclinical characterization of HPG7233, a potent, liver-target and highly selective thyroid hormone receptor beta agonist for non-alcoholic steatohepatitis
Michael Xu[1], Shijia Chen[1], Fang Guo[1], Que Liu[1], Yongheng Liu[1], Cheng Mo[1], Yihong Peng[1], Yating Xiong[1], Peibin Zhai[1], Pan Zhang[1], Xinpeng Zhao[1], Xin Zhou[1], Xin-Jie Chu[1]. *[1]Hepagene, Shanghai, China*
Email: michael.xu@hepagene.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is rapidly becoming the most common chronic liver disease worldwide, with an approximate prevalence of 20–30% in western countries. An estimated 20–25% of these patients will further progress to non-alcoholic steatohepatitis (NASH), marked by steatosis, inflammation and hepatocyte ballooning with or without fibrosis. HPG7233 is a novel liver-targeted and highly selective small molecule thyroid hormone receptor beta (THR-beta) agonist aimed at serum and liver lipid metabolism. Here we report favorable pharmacology and pharmacokinetic profiles of HPG7233 for NAFLD and NASH treatment.
Method: In vitro binding assay: The binding assay of THR alpha and THR beta in vitro is determined by coactivator peptide to the receptors. In vivo pharmacokinetic study: Both selected and control compounds are evaluated in Sprague-Dawley rats at 3 mg/kg and in beagle dog at 10 mg/kg for single dose of oral administration. In vivo efficacy study: Liver index, serological markers and NAFLD activity score (NAS) in the efficacy study are evaluated in a HFD-CCl4 NASH model at 5 mg/kg.
Results: HPG7233 shows a superior liver targeting profile in vivo. L/P (liver/plasma) exposure ratio is about 20 in animals, meanwhile, the relative beta/alpha binding selectivity in vitro is about 7-fold normalized to T3, offering enhanced liver-targeting property and potentially less off-target effects. In model animals, compared to the NASH control, HPG7233 induced a pronounced reduction in hepatic fat and serum lipid levels, especially in hepatic triglyceride (TG) levels. Furthermore, HPG7233 significantly reduced ballooning and steatosis, thus significantly lowered NAS score ($p < 0.001$).
Conclusion: HPG7233 demonstrated high selectivity and potency, great liver-enrichment and liver/plasma exposure profile in rodent and non-rodent animals, significant reduction of liver index and serological markers level, and significant reduction of NAS score in NASH model. These results provide strong evidence to support continuing efforts in HPG7233 development for NAFLD and NASH treatment.

WED-511
Plasma short chain fatty acids are associated with non-alcoholic fatty liver disease and fibrosis severity
Mira Thing[1], Mikkel Werge[1], Liv Hetland[1], Elias Rashu[1], Puria Nabilou[1], Anders Junker[1], Elisabeth Galsgaard[2], Nina Kimer[1], Johnny Laupsa-Borge[3], Adrian McCann[3], Lise Lotte Gluud[1]. *[1]Copenhagen University Hospital Hvidovre, Gastro Unit, Medical section, Hvidovre, Denmark, [2]Novo Nordisk A/S, Research and Early Development, Målev, Denmark, [3]Bevital AS, Bergen, Norway*
Email: mira.thing@regionh.dk

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and progression to non-alcoholic steatohepatitis and cirrhosis have been linked to microbiome-derived metabolites, including short-chain fatty acids (SCFAs). Acetate, propionate, and butyrate have been described as beneficial and anti-inflammatory in studies measuring fecal levels, yet the role of circulating levels of SCFAs in the pathophysiology of NAFLD and NASH remains unclear. This exploratory study investigated circulating levels of SCFAs in NAFLD patients with fibrosis scores ranging from F0 to F4.
Method: 100 patients with histologically verified NAFLD (49 with F2-F4 fibrosis and 51 with F0-F1 fibrosis) and 50 healthy controls were included from the Fatty Liver Disease in Nordic Countries (FLINC) prospective cohort. Using fasting blood samples, we measured

plasma concentrations of eight SCFAs by gas chromatography-tandem mass spectrometry (GC-MS/MS). Data were analysed by logistic regression models adjusted for age and sex.
Results: The mean BMI in healthy controls and patients with NAFLD was 23.6 (SD 2.67) and 34.7 (SD 6.73) kg/m^2, respectively. Plasma concentrations of formate (p = 0.004), propionate (p = 0.02), valerate (p = 0.02), and alpha methyl-butyrate (p = 0.01) were increased, while acetate was decreased (p = 0.0001) in NAFLD patients compared with healthy controls. Among NAFLD patients, plasma concentrations of propionate (p = 0.02), butyrate (p = 0.03), valerate (p = 0.03), and alpha methyl-butyrate (p = 0.02) were increased in patients with significant fibrosis (F2-F4). See figure 1 for odds ratios and 95% CI.

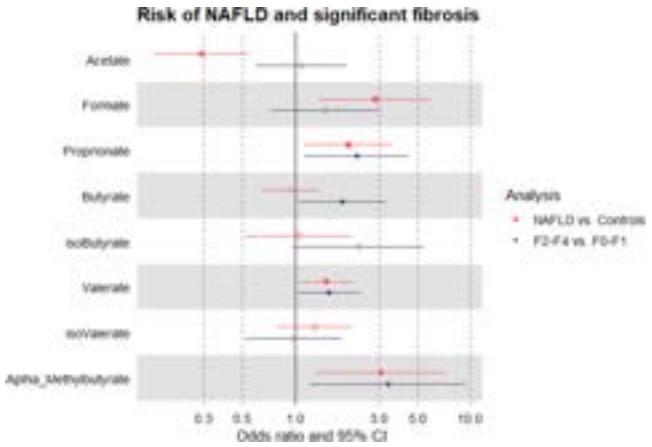

Figure 1. Odds Ratio and 95% CI of having NAFLD and significant fibrosis. SCFA values were log2-transformed in the analysis. Empty squares or circles indicates non-significant results.

Conclusion: SCFAs differed between patients with NAFLD and healthy controls and between patients with significant and non-significant fibrosis. In particular, we found higher plasma concentrations of propionate, valerate, and alpha methyl-butyrate in patients with NAFLD and increased fibrosis severity. The implications of our observations are yet unknown and warrant further investigation.

WED-512
Artificial neural networks predict via label-free imaging analysis cellular injury in a human steatohepatitis model

Julian Weihs[1], Milad Rezvani[1,2,3,4]. [1]*Charité Campus Virchow Clinic, Department of Pediatrics, Division of Gastroenterology, Nephrology and Metabolic Medicine, Berlin, Germany,* [2]*Berlin Institute of Health, Clinician Scientist Program, Berlin, Germany,* [3]*Berlin Institute of Health, Center for Regenerative Therapies, Berlin, Germany,* [4]*Cincinnati Children's Hospital Medical Center, Division of Gastroenterology, Hepatology and Nutrition, Cincinnati, United States*
Email: milad.rezvani@charite.de

Background and aims: Drug screenings on human cellular injury models can be time-consuming and are often limited to detecting specific protein markers. An unbiased imaging algorithm that utilizes high-throughput microscopy of unprocessed cells to predict cellular injury would expand the capabilities of such screens. Artificial neural networks (ANNs) in imaging analysis have become a powerful tool for identifying phenotypic nuances at scale. We hypothesized that ANN-guided, label-free brightfield imaging analysis could predict hepatocellular injury. For proof of principle, we established a screening pipeline involving a non-alcoholic fatty liver disease (NAFLD) model with hepatocytes from human pluripotent stem cells (iHeps) exposed to different grades of subcellular injury.
Method: We modeled different severities of NAFLD-related subcellular injuries by exposing iHeps to free fatty acids or combining the same with extrahepatic signaling molecules relevant to NAFLD (Resistin, Myostatin; "augmented injury"). To model steatohepatitis (a more advanced form of NAFLD), we co-cultured iHeps with human peripheral blood mononuclear cells (PBMCs) using a transwell system. We experimentally evaluated injury severity by measuring hallmarks of NAFLD, namely steatosis, mitochondrial function (assessed by mitochondrial membrane potential), and endoplasmatic reticulum (ER) stress. Using unstained brightfield images of the monoculture conditions, we trained ANNs to distinguish cells from different hepatocyte injuries and let them define respective "injury scores." The trained ANNs then computed injury scores for cells from wells that were left out during the training process and were projected to score iHeps in the steatohepatitis condition that was not used to train the model.
Results: Our results demonstrate that in all injury conditions, iHeps displayed similar levels of steatosis and a significantly increased ER stress response upon exposure to free fatty acids. The augmented injury compromised mitochondrial function. The steatohepatitis condition exacerbated mitochondrial dysfunction further. The ANNs could identify all injury conditions from untreated cells with extremely high accuracy (p < 0.001). Of note, the ANNs could also distinguish cells from the different injury conditions, scoring cells of the augmented NAFLD model with higher injury scores than cells that underwent basic free fatty acid injury (p < 0.01). The projection of ANN to the steatohepatitis conditions revealed higher injury scores, which was consistent with our experimental data. The injury scores correlated highly with mitochondrial dysfunction (R = −0.45, p = 3.3*10–6). Thereby, ANNs predicted subcellular stress responses upon varying degrees of cellular injury.
Conclusion: Here, we describe how ANN-based image analysis allows label-free prediction of cellular injury in a human NAFLD model. ANNs could distinguish conditions ranging from steatosis to subcellular toxicity and returned injury scores that we could correlate with impaired mitochondrial function. In sum, combining human liver disease models and ANNs can identify cellular stress or its relief, enabling large-scale drug screenings to identify novel treatments for liver diseases quickly.

Email: hg@ajou.ac.kr

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a broad and continuous spectrum of liver diseases ranging from fatty liver to steatohepatitis. The study is aimed to obtain an integrative insight into genomic and transcriptomic alterations during NAFLD progression.
Method: We performed RNA-Seq profiling (n = 146) and whole exome sequencing (WES) from the biopsied tissues of NAFLD patients (n = 132).
Results: We identified three transcriptomic subtypes of NAFLD (G1-G3), demonstrating their associations with distinct pathologic features and genetic variations. In particular, single nucleotide variations (SNVs) of IFI16 (rs6940) were closely associated with its transcriptional levels and the molecular subtypes. This finding could

be validated using the blood samples of the pair-matched patients (n = 94), indicating the clinical utility of the rs6940 in predicting NAFLD progression. In addition, cell type analysis revealed that *IFI16* expression is largely due to increased macrophage infiltration during the molecular progression of NAFLD. We also report that structural conformation by the al alteration of *IFI16* rs69450 enhances its DNA binding affinity, which may aggravate subsequent inflammatory responses.

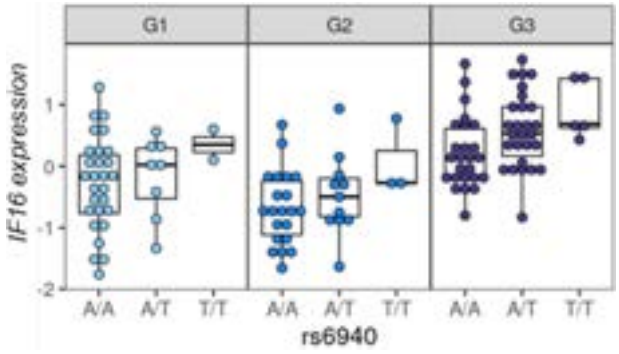

Figure:

Conclusion: We suggest that IFI16 polymorphism and expression levels are associated with the aggressive progression of NAFLD through macrophage activation.

WED-514

Knockdown of a novel target gene enhances liver regeneration and attenuates chronic liver damage related liver fibrosis

Shainan Hora[1], Rong Gao[1], Viktoriia Iakovleva[1], Yong-An Lee[1], Amanpreet Kaur[1], Agnes Bee Leng Ong[1], Torsten Wuestefeld[1].
[1]*Genome Institute of Singapore, Singapore*
Email: Shainan_Hora@gis.a-star.edu.sg

Background and aims: Non-alcoholic fatty liver disease (NAFLD), characterised by excessive fat accumulation and coupled with rising incidence of acute and chronic liver disease, remains a healthcare burden. A distinct phenomenon seen in NAFLD patients is the aberrant regenerative capacity that limits liver re-compensation. Our unbiased genome wide *in-vivo* functional genetic screen aims at identifying novel regulators of NAFLD to reverse this end-stage liver disease and to contribute towards hepatic regenerative therapy.
Method: A genome-wide mouse shRNA library (shERWOOD-UltramiR) was cloned into transposon-based doxycycline (Dox)-inducible vector, divided into 32 pools and delivered into C57BL/6 mice liver using hydrodynamic-tail vein (HDTV) injections. Mice were fed western diet and fructose-supplemented water for 8 weeks followed by induction of shRNA expression by Dox administration and continued diet feeding for additional 16 weeks. Animal livers were harvested, primary NGS analysis performed, and abundance of each shRNA determined using differential expression analysis method. Top candidate genes were selected based on several stringent criteria, validated *in-vitro* and reinjected into fumarylacetoacetate hydrolase (FAH) knockout animals to test for liver repopulation and liver regeneration after partial hepatectomy. Additionally, mouse model of chronic liver disease, Non-Alcoholic Steatohepatitis (NASH), was employed to test for pathological findings, such as fibrosis score as well as other associated microscopic markers such as oval cell hyperplasia, inflammation and necrosis, among others.
Results: We have identified several shRNAs that confer a negative or positive effect on the regenerative capacity of hepatocytes when subjected to a detrimental environment such as a high fat diet. Among the many top scoring genes, knockdown of a novel gene, Target Gene 1 accelerated cell migration and proliferation, followed by enhanced clonal expansion using FAH knockout mouse model. Furthermore, increased liver regeneration and a significant reduction in fibrosis score was observed compared to control animals, confirming an attenuation of NASH related liver fibrosis.

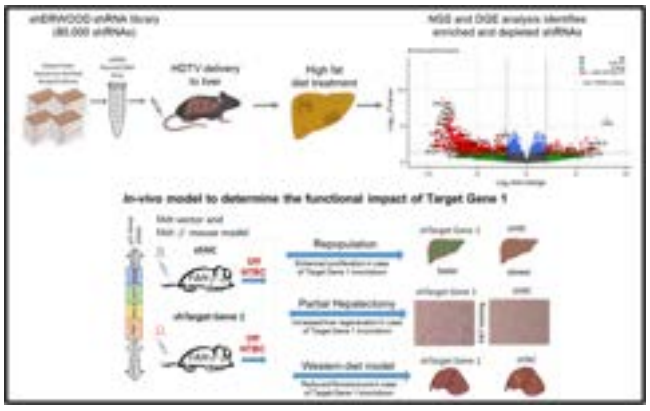

Figure:

Conclusion: Knockdown of a novel gene about which very little is known except that is a protein coding gene and enables RNA binding activity accelerates liver repopulation, regeneration and attenuates chronic liver damage related fibrosis.

Email: eveline.gart@tno.nl

Background and aims: NAFLD progression, from steatosis to inflammation and fibrosis, results from an interplay of intra- and extrahepatic mechanisms. Disease drivers likely include signals from white adipose tissue (WAT) and gut. However, the temporal dynamics of disease development remain poorly understood.
Method: High-fat-diet (HFD)-fed Ldlr-/-.Leiden mice were compared to chow-fed controls. At t = 0, 8, 16, 28 and 38w mice were euthanized, and liver, WAT depots and gut were analyzed biochemically, histologically and by lipidomics and transcriptomics together with circulating factors to investigate the sequence of pathogenic events and organ cross-talk during NAFLD development.
Results: HFD-induced obesity was associated with an increase in visceral fat mass, plasma lipids and hyperinsulinemia at 8 weeks, along with an increase in liver steatosis and circulating biomarkers indicative of liver damage (ALT, AST, CK18-M30, TIMP1). Liver steatosis was mainly attributable to increased triacylglycerols and to a lesser extent free-fatty acids, cholesteryl esters and diacylglycerols. In parallel, regulators involved in lipid catabolism (e.g., ACOX1) were deactivated and in lipid synthesis (e.g., SREBF1) activated by HFD. Subsequently, hepatocyte hypertrophy, oxidative stress (4-HNE) and hepatic inflammation developed. Hepatic collagen accumulated at t = 16w and became particularly prominent after 28–38 weeks. Epididymal WAT adipocytes were maximally hypertrophic from t = 8w, which coincided with inflammation development in this depot.

Mesenteric and subcutaneous WAT hypertrophy developed slower and did not appear to reach a maximum within the period studied, with minimal inflammation. In the gut, HFD significantly increased permeability, induced a major shift in microbiota composition (ileum and colon) from t = 8w and associated with circulating gut-derived metabolite changes (short-chain fatty acids and bile acids).

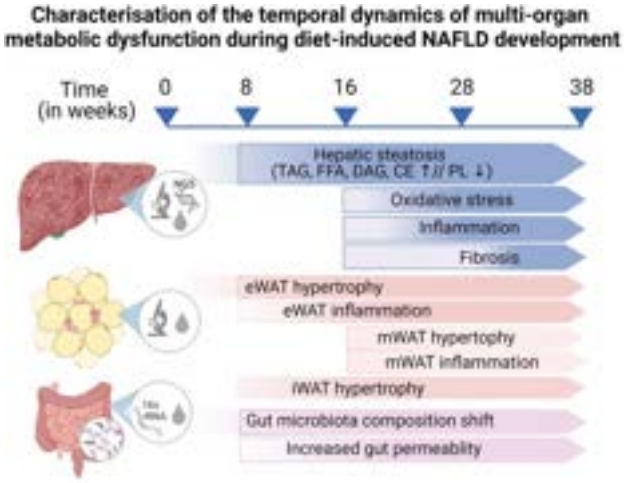

Figure:

Conclusion: Ldlr-/-.Leiden mice on a HFD develop obesity, dyslipidemia and insulin resistance, essentially as observed in obese NASH patients. We demonstrate that marked epididymal-WAT inflammation, and gut permeability and dysbiosis precede the development of NAFLD stressing the importance of a multiple-organ approach in the prevention and treatment of NAFLD.

WED-516

Novel bariatric surgery models in mice-differential effects on body weight loss and fatty liver disease

Louis Onghena[1,2,3], Anneleen Heldens[2,3], Milton Antwi[2,3,4], Hans Van Vlierberghe[2,3], Xavier Verhelst[2,3], Lindsey Devisscher[2,4], Yves Van Nieuwenhove[1], Anja Geerts[2,3], Sander Lefere[2,3]. *[1]Ghent University Hospital, Department for Human Repair and Structure, Department of Gastrointestinal Surgery, Gent, Belgium, [2]Ghent University Hospital, Liver Research Center Ghent, Ghent University, Gent, Belgium, [3]Ghent University Hospital, Department of Internal Medicine and Paediatrics, Hepatology Research Unit, Gent, Belgium, [4]Ghent University, Department for Basic and Applied Medical Sciences, Gut-Liver Immunopharmacology unit, Ghent, Belgium*
Email: Louis.onghena@ugent.be

Background and aims: Bariatric surgery (BS) is an effective treatment for obesity and associated comorbidities, including non-alcoholic fatty liver disease (NAFLD). In recent years, the number of available bariatric procedures has increased, yet their outcome and mechanisms of action have not been compared in detail. We performed vertical sleeve gastrectomy (VSG) and plication (VSP), Roux-en-Y gastric bypass (RYGB), and one-anastomosis gastric bypass (OAGB) with three different biliary limb lengths (25% = $Omega_1$, 50% = $Omega_2$, 75% = $Omega_3$) for comparison, as the latter are gaining in popularity.
Method: Mice were fed a Western diet (WD) for 12 weeks, followed by surgery, and subsequent sacrifice at week 20. Six different types of BS were performed and compared with each other, with a sham and a control group (WD, no surgery). Weight loss, NAFLD severity, fat cell hypertrophy, and intestinal remodeling were evaluated by histology and biochemistry. Intestinal and hepatic inflammation and bacterial translocation were measured. Statistical differences between group mean values were assessed by one-way ANOVA tests with Tukey post-hoc test.
Results: Notably, the $Omega_3$ procedure resulted in 100% mortality after just three weeks due to severe malnutrition and rapid weight loss. Relative weight loss differed significantly ($p < 0.0001$) amongst the groups (sham +12.71%, VSG −9.18%, VSP +6.05%, RYGB −33.52%, $Omega_1$ −22.47%, and $Omega_2$ = −24.03%, Figure 1). Average food intake was significantly lower in VSG and VSP compared to RYGB ($p < 0.05$), $Omega_1$ ($p < 0.01$), and $Omega_2$ ($p < 0.001$). In RYGB, $Omega_1$, and $Omega_2$, relative visceral adipose tissue weight was significantly lower compared to the sham mice ($p < 0.0001$). Fat cell diameter and area were significantly decreased ($p < 0.0001$) in all BS groups compared to sham mice and differed significantly amongst each other as well. RYGB, $Omega_1$, and $Omega_2$ significantly attenuated the elevated serum ALT levels and liver triglyceride content ($p < 0.01$). Histologically, sham-operated mice had developed severe liver steatosis and moderate inflammation after 20 weeks of WD feeding, which was attenuated by BS, especially by $Omega_1$ ($p < 0.05$), and $Omega_2$ ($p < 0.01$). Bacterial translocation in the liver was observed in RYGB, $Omega_1$, and $Omega_2$ ($p < 0.001$). Signs of intestinal inflammation were detected in the terminal ileum, but not jejunum, in mice that underwent $Omega_2$ ($p < 0.01$). The jejunal tunica muscularis was thicker after RYGB, $Omega_1$, and $Omega_2$ ($p < 0.0001$).

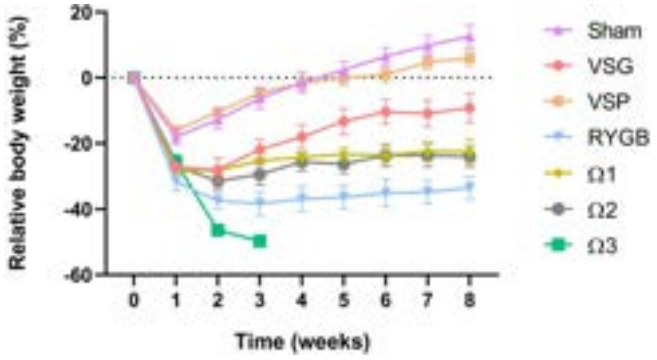

Figure:

Conclusion: BS procedures in mice, especially RYGB, $Omega_1$, and $Omega_2$, improved histological NAFLD. However, the observed bacterial translocation in these models requires further investigation regarding long-term effects. Our models open up the field of research into the mechanisms of action of BS on hepatic and intestinal physiopathology, and on how the gut and the liver interact following surgery.

WED-517

The effect of cholesterol and its metabolites on human pluripotent stem cell-derived hepatic stellate cells

Ingrid Wilhelmsen[1,2], Kristina Kømurcu[3], Aleksandra Aizenshtadt[1], James Thorne[4], Steven Wilson[1,3], Hanne Røberg-Larsen[3], Stefan Krauss[1,2]. *[1]University of Oslo, Institute of Basic Medical Sciences, Hybrid Technology Hub, Oslo, Norway, [2]Oslo University Hospital, Institute of Clinical Medicine, Department of Immunology, Oslo, Norway, [3]University of Oslo, Department of Chemistry, Oslo, Norway, [4]University of Leeds, School of Food Science and Nutrition, Leeds, United Kingdom*
Email: ingrid.wilhelmsen@medisin.uio.no

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a major health concern that encompasses a range of diseases initiated by the accumulation of excessive lipids in the liver. The progression of NAFLD eventually leads to fibrotic scarring in which hepatic stellate cells (HSCs) play a crucial role. In the homeostatic liver, HSCs exhibit a quiescent phenotype. However, upon liver injury such as NAFLD, HSCs transdifferentiate to an activated phenotype and become the main drivers towards hepatic fibrosis. It is known that NAFLD is associated with elevated levels of cholesterol and cholesterol derivatives such as the oxysterols 25-hydroxycholesterol (25-HC) or 26- hydroxycholesterol (26-HC), regulating the key NAFLD modulator liver x-receptor (LXR). Increased levels of oxysterols were detected in

supernatant medium samples from *in vitro* steatosis models based on liver organoids comprising predominantly liver parenchymal cells. As the role of cholesterol and its metabolites on HSCs and in particular the HSC activation status is unknown, we aimed to investigate the effect of cholesterol and oxysterols on HSCs.
Method: HSCs were differentiated from three human pluripotent stem cell (PSC) lines (H1, WTC-11 and WTSli013-A). At the end of the differentiation protocol, the PSC-derived HSCs were treated with cholesterol, 25-HC or 26-HC both alone and in combination with the potent pro-fibrotic inducer TGF-beta 1 for 48 hours. Changes in HSC phenotype were assessed by RT-qPCR and imaging of intracellular vitamin A storage.
Results: PSC-derived HSCs displayed an increase in LXR target gene *ABCA1* expression upon treatment with both cholesterol and oxysterols, confirming successful stimulation of the intended pathway. The fibrosis-associated gene *ACTA2* was downregulated in HSCs in the presence of 25-HC and 26-HC. Expression of *CCL2*, encoding a chemokine crucial for monocyte recruitment, was reduced after treatment with 26-HC. Yet, the presence of cholesterol, 25-HC and 26-HC had no effect on the response of the HSCs to TGF-beta 1, which was evident by increased expression of *ACTA2*, *COL1α1* and *CCL2*. These results connect HSCs to existing literature that implicates oxysterols in the attenuation of early-stage NAFLD; however, without affecting more advanced NAFLD as modeled by pro-fibrotic stimulation with TGF-beta 1.
Conclusion: Collectively, the results implicate cholesterol metabolites 25-HC and 26-HC as modulators of the HSC activation status and suggest that PSC-derived HSCs can be suitable for *in vitro* models of NAFLD.

WED-518
Opposite correlations between hepatic β-oxidation activity and triglyceride levels in male and female rats after a high-fat diet supplemented with liquid fructose

Roger Bentanachs[1,2], Laia Blanco[1], Maria Montesinos[1], Aleix Sala-Vila[3], Iolanda Lázaro[3], Juan Carlos Laguna[1,2,4], Núria Roglans[1,2,4], Marta Alegret[1,2,4]. [1]*University of Barcelona, School of Pharmacy and Food Sciences, Pharmacology, Toxicology and Therapeutic Chemistry, Spain,* [2]*Institute of Biomedicine of the University of Barcelona, Spain,* [3]*Hospital del Mar Medical Research Institute (IMIM), Cardiovascular Risk and Nutrition, Spain,* [4]*CIBER de Fisiopatología de la Obesidad y Nutrición, Instituto de Salud Carlos III, Spain*
Email: alegret@ub.edu

Background and aims: We previously reported that the administration of a high-fat diet supplemented with 10% w/v fructose in drinking water (HFHFr diet) results in hypertriglyceridemia and a moderate increase in hepatic triacylglycerol (TAG) levels in males, while females showed less hypertriglyceridemia but more than doubled their liver TAG content. Moreover, hepatic β-oxidation activity was reduced in female rats, whereas males showed a significant increase (Bentanachs et al. 8th MetNet International Annual Meeting). Our aim is to study the mechanisms involved in the sexual dimorphic response to this diet.
Method: Two-month-old male (n = 16) and female (n = 16) Sprague Dawley rats were randomly assigned to two groups (n = 8 in each) and fed ad libitum for 3 months. The control groups were fed regular chow diet (2018 Teklad Global, 18% of provided calories as fat), whereas the high-fat-high-fructose groups (HFHFr) were fed an HFD (Teklad Custom Diet TD180456, 46.9% of energy as fat, of which 21% w/w was cocoa butter) and had free access to a 10% w/v fructose solution as the drinking beverage. Total liver TAG was determined by a colorimetric method, and then hepatic TAG were isolated by solid-phase extraction and fatty acid methyl esters from this fraction were determined by gas chromatography. Hepatic diacylglycerols (DAG) and ceramides (Cer) were determined by liquid chromatography-tandem mass spectrometry. β-oxidation activity was determined by the method of Lazarow (Methods Enzymol. 1981, 72, 315). Correlation analysis between plasma/hepatic TAG and β-oxidation activity was performed using GraphPad prism software (v. 9.0.0).
Results: The fatty acid composition of the hepatic TAG in male rats was significantly altered by the HFHFr diet, with significant increases of several saturated (C14:0, C16:0, C:18:0) and monounsaturated fatty acids (C16:1 n-7, C18:1 n9). The opposite was observed for many polyunsaturated fatty acids (C18:2 n-6, C20:4 n-6, C20:5 n-3). Several DAG species were increased by the diet (DAG-C16:0, DAG-C18:0, DAG-C18:1 and DAG-C18:0/18:2). No significant changes were observed for ceramide levels in the livers of male rats. These changes in lipid species were qualitatively similar to those observed in female rats in response to the same diet (Velázquez et al., Mol. Nutr. Food Res 2022, 2101115). However, correlation analysis showed striking differences: liver β-oxidation activity in females inversely correlated with plasma TAG levels (Spearman's $r = -0.60$, $p = 0.022$) and total hepatic TAG levels (Spearman's $r = -0.64$, $p = 0.012$); in male rats, liver β-oxidation activity correlated with both plasma (Pearson's $r = 0.78$, $p = 0.0007$) and hepatic TAG (Spearman's $r = 0.66$, $p = 0.08$).
Conclusion: The sexual dimorphism observed in rats in response to a HFHFr diet cannot be explained by qualitative changes in the liver lipidome. Only in female rats, the decrease in liver β-oxidation activity significantly contributes to increase the hepatic and plasma TAG, whereas in males these correlations are direct. This work was supported by grants PID2020-112870RB-I00, funded by MCIN/AEI/10.13039/501100011033 and 2021SGR-00345.

WED-519
Prophylactic and therapeutic hepatoprotective effects of lanifibranor in the CDAA-HFD mouse model of advanced NASH with progressive fibrosis

Jacob Nøhr-Meldgaard[1], Ditte Denker Thorbek[1], Denise Oró[1], Henrik B. Hansen[1], Michael Feigh[1]. [1]*Gubra, Hørsholm, Denmark*
Email: jnm@gubra.dk

Background and aims: The pan peroxisome proliferator-activated receptor (PPAR-α/δ/ɣ)) agonist has recently been reported to improve liver histological outcomes in patients with non-alcoholic steatohepatitis (NASH) and fibrosis (NATIVE study; Francque et al, NEJM, 2021). Lanifibranor is currently in phase-3 clinical trial (NATiV3) for the treatment of NASH. The present study aimed to evaluate prophylactic vs. therapeutic lanifibranor intervention in the non-obese choline-deficient L-amino-acid defined high-fat diet (CDAA-HFD) mouse model of advanced NASH with progressive fibrosis.
Method: C57BL/6JRj mice were fed chow or CDAA-HFD (45 kcal% fat, 0.1% methionine, 1% cholesterol, 28 kcal% fructose) for 3 or 6 weeks prior to treatment start (i.e. before or after onset of fibrosis, respectively). Animals were randomized into treatment groups based on body weight. A baseline group (n = 12) was terminated at study start (3 and 6 weeks). CDAA-HFD fed mice (n = 12 per group) received treatment (PO) with vehicle or lanifibranor (30 mg/kg) for 8 or 9 weeks. Chow-fed mice (n = 8) served as normal controls. Terminal end points included plasma biomarkers metallopeptidase inhibitor 1 (TIMP-1) and amino terminal peptide of type III procollagen (PIIINP), liver biochemistry, NAFLD Activity Score (NAS), fibrosis stage and quantitative liver histology..
Results: Prophylactic and therapeutic lanifibranor interventions reduced body weight, liver weight and concomitantly reduced levels of liver triglycerides and total cholesterol content. Furthermore, prophylactic and therapeutic lanifibranor intervention significantly improved NAS, mainly driven by reduced steatosis and lobular inflammation scores. These effects were supported by quantitative liver histology, demonstrating reduced levels of liver fat accumulation (%-area of lipids, number of lipid-laden hepatocytes) and inflammation (%-area of galectin-3, number of inflammatory foci). Prophylactic treatment with lanifibranor improved fibrosis stage, while no effect on fibrosis stage was observed with therapeutic

treatment. In contrast, both interventions equally reduced liver hydroxyproline concentrations and quantitative levels of fibrosis (% area of PSR). Moreover, a decrease in plasma levels of metallopeptidase inhibitor 1 (TIMP-1) and amino terminal peptide of type III procollagen (PIIINP) were reduced in the prophylactic setting, which further supports the anti-fibrotic effect of lanifibranor in the current model.

Conclusion: The beneficial effects of early and late lanifibranor intervention in the non-obese CDAA-HFD mouse model are in good agreement with clinical trial outcomes in NASH patients, thus highlighting the suitability of the CDAA-HFD mouse model for profiling novel drug therapies targeting advanced NASH with progressive fibrosis.

WED-520

Light cytokine-deficiency effects in inmune cells subpopulations in a murine non alcohol-related steatohepatitis model

María Aguilar Ballester[1], Elena Jiménez-Martí[1,2], Gema Hurtado-Genovés[1], Alida Taberner-Cortés[1], Ángela Vinué[1], Andrea Herrero-Cervera[1], Sergio Martínez-Hervás[1,3], Herminia González-Navarro[1,2]. Email: herminia.gonzalez@uv.es

Background and aims: Hepatic inflammation is known to increase fibrosis in non-alcoholic fatty liver disease (NAFLD) as well as in the transition to non-alcohol-related steatohepatitis (NASH) and hepatocellular carcinoma (HCC). Specifically, several studies have pointed to a key role for natural killer T (NKT) cell sublinages in this progression. In our previous studies, Light cytokine-deficient mice provoked a decreased expression of the master transcription factor for NKT differentiation, PLZF. In the present study, we investigated the role of LIGHT at determining NKT cell differentiation subsets in the context of NAFLD.

Method: Both Wt and Light-deficient mice were fed a control or a high fat high cholesterol diet (HFHC) for 16 weeks. At the end of the study mice were analysed for NAFLD development, using hepatic triglyceride content and NAS score, and for hepatic fibrosis using collagen content in Masson thrichromic-stained cross- sections. Inflammatory status, including NKT cell determination, was evaluated by analysing circulating and hepatic leucocyte subpopulations by flow cytometry.

Results: Compared with control diet-fed mice, all mice fed with HFHC diet displayed increased hepatic collagen content and NAS score, although collagen was significantly lower in Light-deficient mice. Hepatic leukocyte determinations demonstrated significantly reduced anti-inflamatory F4/80+Cd206c+ macrophages in HFHC diet-fed mice, compared with control diet-treated mice regardless of their genotype. Notably, NKT17 subpopulation was significantly increased in Wt mice fed the HFHC diet compared with Wt mice fed control diet, but this increase was not observed in HFHC diet fed Light-deficient mice compared with their control diet-fed mice counterparts.

Conclusion: Our results suggest that Light-deficiency in HFHC diet fed mice reduces hepatic NKT17 subpopulation content and suggest a possible role of Light in NKT subpopulation differentiation in the context of NAFLD.

Evaluation of genetic risk score of a dysmetabolic and obese population of southern Italy

Benedetta Maria Motta[1], Mario Masarone[2], Pietro Torre[2], Pietro Calabrese[2], Marco Aquino[2], Federica Belladonna[2], Vincenzo Pilone[2], Marcello Persico[2]. [1]*University of Salerno, Department of Medicine, Surgery and Dentistry, "Scuola Medica Salernitana", Italy,* [2]*University of Salerno, Dipartimento di Medicina, Chirurgia e Odontoiatria "Scuola Medica Salernitana", Baronissi, Italy*
Email: bmotta@unisa.it

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the leading cause of liver diseases, ranging from simple steatosis to non-alcoholic steatohepatitis, and the susceptibility to develop NAFLD is highly variable and influenced by environmental and genetic factors. The gold standard for diagnosis and staging of NAFLD is liver biopsy, however, it is an invasive procedure, subject to sampling errors and inter-observer variability. Several non-invasive methods aim at diagnosing hepatic steatosis and predicting significant/advanced fibrosis. GWAS studies identified genetic risk factors, and genetic risk scores (GRS) were developed for risk stratification. NAFLD susceptibility is associated with four genetic variants: *PNPLA3* rs738409, *TM6SF2* rs58542926, rs641738 close to *MBOAT7* locus, *GCKR* rs1260326. Our aim was to evaluate how these variants are distributed in an obese and dysmetabolic population of Southern Italy and how our polygenic risk score (PRS) correlates with liver steatosis and biochemical phenotypes.

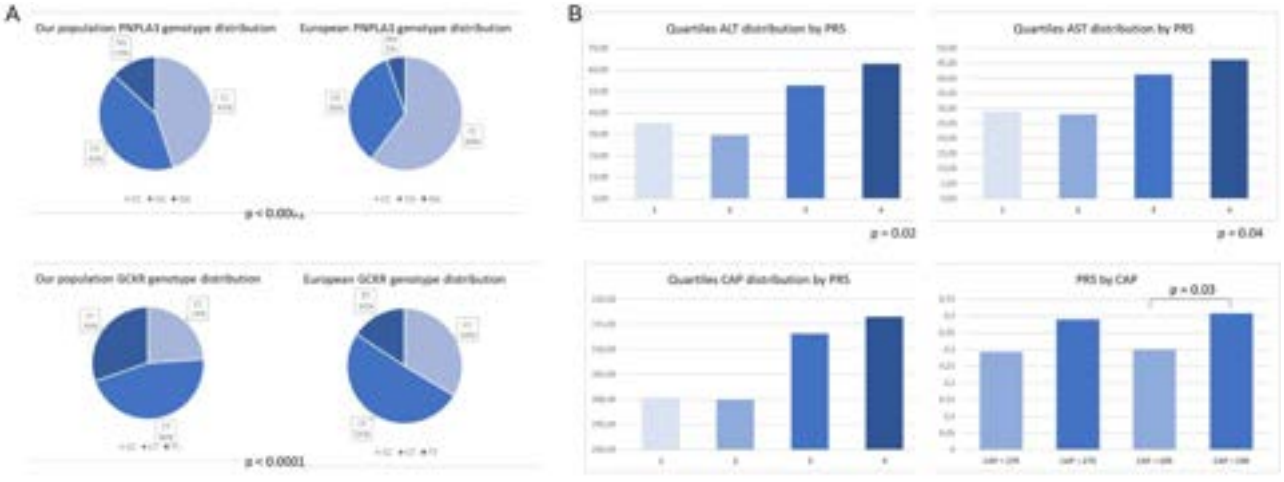

Figure 1. Characterization of dysmetabolic and obese population. A) PNPLA3 and GCKR variants distribution. Chi-Square test. B) Biochemical parameters stratified by GRS. One-way ANOVA test.

Figure: (abstract: WED-521).

Method: We enrolled 205 patients attending our Hepatology Clinic and Surgery department, which were genotyped for rs738409, rs58542926, rs641738, rs1260326 by TaqMan 5′-nuclease assays. We calculated a weighted PRS by multiplying the effect size (beta-coefficient) on steatosis by respective risk alleles and summing the products. Anthropometric data, FibroScan measurments, and blood test results were collected.
Results: In our population, we observed a higher MAF of PNPLA3 and GCKR variants compared to the ones reported in European population of 1000Genomes Project ($p < 0.0001$). The rs738409 G allele frequency is 34.1% vs. 23%. The rs1260326 T allele frequency is 53.2% vs. 41%. In a sub-cohort of 98 patients, we recorded Fibroscan parameters and biochemical data and evaluated the effect of the 4 variants together by PRS. PRS increased proportionally with ALT levels ($p = 0.02$), AST ($p = 0.04$), total cholesterol, triglycerides, and CAP ($p = N.S$). PRS is higher in subjects with a CAP value of 275 dB/m, considered a cut-off for moderate/severe steatosis in general population; moreover, considering a CAP value >295 dB/m PRS is significantly higher in these subjects ($p = 0.03$).
Conclusion: This study shows that in our population, PNPLA3 and GCKR risk alleles frequency are higher, and that the polygenic risk score correlates with biochemical and Fibroscan parameters, identifying the most dysmetabolic subjects.

WED-522

Characterizing the histologic implications of resmetirom-induced liver volume reduction using artificial intelligence-powered digital pathology

Pratik Mistry[1], Adam Stanford-Moore[1], Robert Egger[1], Jonathan Glickman[1], Brian Baker[1], Nidhi Chandra[1], Dinkar Juyal[1], Archit Khosla[1], Michael Drage[1], Murray Resnick[1], Katy Wack[1], Jim Hennan[2], Rohit Loomba[3], Stephen Harrison[4], Rebecca Taub[2], Janani Iyer[1]. *[1]PathAI, Boston, United States, [2]Madrigal Pharmaceuticals, Conshohocken, United States, [3]UC San Diego School of Medicine, San Diego, United States, [4]Pinnacle Clinical Research, San Antonio, United States*
Email: janani.iyer@pathai.com

Background and aims: In non-alcoholic steatohepatitis (NASH) clinical trials, liver biopsies are evaluated for histologic evidence of NASH/fibrosis at screening and drug effect at study completion. An emerging hypothesis suggests drug-induced fat and/or liver volume (LV) reduction may complicate histologic interpretation and thus impact trial outcomes. Here, we train artificial intelligence (AI) models to characterize cell types present in NASH and identify morphologic correlates of LV reduction in biopsies from the Phase 2 trial of resmetirom for treatment of NASH.
Method: An AI cell classification model was trained using annotations provided by hepatopathologists on whole slide images (WSIs) of NASH HandE tissue sections from trials and diagnostic samples. Model performance accuracy was confirmed via agreement between model predictions for each cell type and consensus across five pathologists. This model and previously developed tissue segmentation models were deployed on WSIs from 101 patients enrolled in the Phase 2 trial of resmetirom for treatment of NASH (NCT02912260). Extracted quantitative proportion, count, and density features were correlated with MRI-derived LV measurements using Pearson's r.
Results: AI quantification revealed a statistically significant increase in overall cell density in resmetirom- versus placebo-treated patients ($p = 0.037$), where increasing cell density was directly associated with decreasing LV (A). Moreover, change in the count proportion of hepatocytes exhibiting steatosis was positively associated with LV change (LVC), while the count proportion of normal hepatocytes was negatively associated with LVC (B). By contrast, changes in the abundance and density of immune cells in the portal tract versus lobule had little to no correlation with LVC (D). AI quantification of fibrosis subcategories revealed that adjusting for the presence of steatosis affected quantification of perisinusoidal and periportal fibrosis specifically, with greater drug-induced changes observed in these fibrosis subcategories relative to others (median change from baseline in proportionate area of F1 + F2 fibrosis = 27% versus 13% with versus without adjustment, respectively).

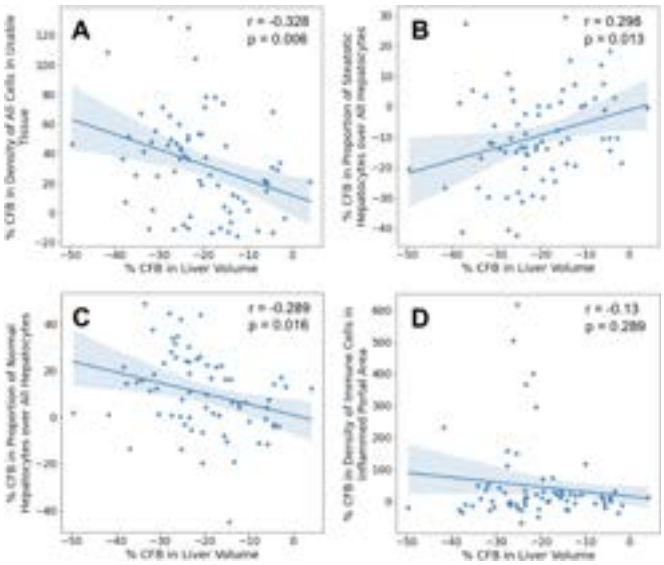

Figure: Percent CFB in LV is associated with overall cell density (A), steatosis (B), and normal hepatocytes (C), but not immune cell density (D) in resmetirom-treated patients.

Conclusion: These results suggest LVC is reflected in the abundance and densities of steatotic and normal hepatocytes, consistent with a model in which disintegration of large triglyceride-filled vesicles results in macroscopic LV reduction. These findings motivate further investigation into the morphologic biomarkers of LVC in NASH clinical trials and how these changes should be adjusted for when evaluating drug effect, particularly in fibrosis.

WED-523

Unraveling the individual contributions of the PPAR isotypes to the pan-PPAR agonist Lanifibranor-induced improvements of the vascular alterations and liver histology in a rat model of early NAFLD

Shivani Chotkoe[1], Yao Liu[1], Guillaume Wettstein[2], Jean Louis Junien[2], Luisa Vonghia[1,3], Hannah Ceuleers[1], Joris De Man[1], Benedicte De Winter[1,3], Wilhelmus Kwanten[1,3], Sven Francque[1,3]. *[1]University of Antwerp, Laboratory of experimental medicine and pediatrics, Antwerpen, Belgium, [2]Inventiva, Daix, France, [3]Antwerp university hospital, Gastroenterology and hepatology, Edegem, Belgium*
Email: shivani.chotkoe@uantwerpen.be

Background and aims: The pan-peroxisome proliferator-activated receptor agonist Lanifibranor completely normalized the intrahepatic vascular resistance (IHVR), the related endothelial dysfunction, and liver histology in a rat model of early NAFLD. We studied the underlying mechanism by exploring the mono-PPAR agonists Fenofibrate (PPAR-alpha agonist), GW501516 (PPAR-delta agonist) and Rosiglitazone (PPAR-gamma agonist) using a rat model of early NAFLD.
Method: Male Wistar rats ($n = 8$ per group) were fed a methionine-choline-deficient diet (MCD) or control diet (CD) for 4 weeks simultaneously with either vehicle, 30 mg/kg Fenofibrate, 10 mg/kg GW501516, or 5 mg/kg Rosiglitazone treatment via oral gavage daily QD. *In vivo* blood pressure of portal vein was measured, followed by *in situ ex vivo* liver perfusion in the same animal to assess baseline transhepatic pressure gradient (THPG) at different flows (10–50 ml/min). Liver histology staining was performed using the steatosis-activity-fibrosis score and for morphometric steatosis quantification.

Results: In vehicle-treated animals, livers of MCD rats showed severe, grade 3 steatosis, without inflammation or fibrosis, compared to normal livers in CD rats. MCD rats showed a significantly increased portal pressure *in vivo* compared to CD rats (5.64 ± 0.63 vs. 3.52 ± 0.24 mmHg, $p < 0.0001$) and THPG *ex vivo* was increased at every perfusion flow velocity (e.g., at 30 ml/min: 8.78 ± 0.35 vs. 6.73 ± 0.28 mmHg) with $p < 0.001$. Fenofibrate, GW501516 and Rosiglitazone significantly decreased portal pressure *in vivo* (from 5.64 ± 0.63 to 4.37 ± 0.20; 4.34 ± 0.16; 4.43 ± 0.27 mmHg, respectively) with $p < 0.0001$ in MCD rats. THPG *ex vivo* was significantly decreased by Fenofibrate (e.g., at 30 ml/min: from 8.78 ± 0.35 to 6.63 ± 0.41 mmHg) with $p < 0.001$, by GW501516 (e.g., at 30 ml/min: from 8.78 ± 0.35 to 7.61 ± 0.34 mmHg) with $p < 0.01$, and by Rosiglitazone (e.g., at 30 ml/min: from 8.78 ± 0.35 to 7.95 ± 0.28 mmHg) with $p = 0.043$. Histology showed that Lanifibranor caused amelioration of steatosis in MCD rats with 19.7 ± 4.8% ($p = 0.0001$) decrease in steatosis, whereas Fenofibrate improved the degree of steatosis in MCD rats comparable to CD rats. GW501516 only weakly decreased steatosis with 11.72 ± 5.28%. Rosiglitazone caused only minimal histological improvement of steatosis (decrease of 7.15 ± 6.73%) in MCD rats.
Conclusion: The mono-PPAR agonists reduce the increased portal pressure and related functional vascular intrahepatic alterations associated with early NAFLD. However, with Lanifibranor all improvements in vascular function were more pronounced than with each specific agonist. Together with the impact on histology, these data suggest that there is an additive effect of combined PPAR agonism compared to mono-agonism leading to an improvement of the vascular alterations in early NAFLD.

WED-524

GTX-011 improves fibrosis and hepatic stellate cells phenotype in human precision cut liver slices

Maria Andres-Rozas[1], Zoe Boyer-Diaz[1], Eugenia Ruiz-Canovas[2], Sergi Guixe-Muntet[3], Peio Aristu[1], Juanjo Lozano[3], Raul Pasto[3], Noemi Garcia-Delgado[2], Jaume Mercade[2], Jaime Bosch[3,4], Jordi Gracia-Sancho[1,3,4]. [1]*Barcelona Liver Bioservices, Spain,* [2]*GAT Therapeutics, Spain,* [3]*IDIBAPS-Hospital Clinic Barcelona-CIBEREHD, Liver Vascular Biology Lab, Spain,* [4]*Inselspital-University of Bern, Switzerland*
Email: jgracia@recerca.clinic.cat

Background and aims: GTX-011 is a first-in-class drug with anti-inflammatory and anti-fibrotic properties mediated by the inhibition of the TGFβ pathway. Previously, we demonstrated its beneficial effects on portal hypertension and hepatic fibrosis in a preclinical model of non-alcoholic steatohepatitis (NASH) by means of hepatic stellate cells (HSC) de-activation and endothelial cells re-differentiation. The aim of this study was to assess the effects of GTX-011m, the active metabolite of GTX-011, in Precision-Cut Liver Slices (PCLS) from human liver tissues, a 3D *ex vivo* model that preserves the structure and cellular composition of the liver, constituting an intermediate step between pre-clinical and clinical research.
Method: PCLS were obtained from human hepatic resections and individually cultured with GTX-011m (1–10 µM) or vehicle (DMSO 0.1%) for 24 hours. Changes in gene expression were evaluated by RNAseq (n = 6/group). Furthermore, gene deconvolution analysis was performed, combining our bulk RNAseq with previously published single-cell data, in order to better understand the changes in the phenotype of each liver cell type in response to treatment.
Results: PCLS treated with GTX-011m 1 µM and 10 µM revealed a total of 723 and 866 differentially expressed genes ($p < 0.05$, f.c.>1.5), respectively, of which 345 were commonly modified in both concentrations. Transcriptomic analysis manifested that treatment with GTX-011m promoted HSC de-activation and inhibition of pro-fibrogenic pathways. Specifically, HSC activation and proliferation markers alpha-smooth muscle actin (α-sma) and desmin were down-regulated, together with higher expression of remodelling extracellular matrix enzymes (matrix metallopeptidases 1, 3, 10 and 14), and lower expression of their inhibitors (tissue metallopeptidase inhibitors 3 and 4). Lastly, a reduction in collagens expression (col6α6 col14α1) was observed. On the other hand, gene deconvolution analysis confirmed the effects of GTX-011m on HSC, decreasing their cell population and promoting their de-activation compared to vehicle, with no effects on other cell types proportion (see Figure). These effects were associated with the activation of apoptotic pathways defined by the up-regulation of tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), fas, fas-ligand, caspases 3, 8, 9 and 10 and BAX/BAK, as well as reduction of HSC activation markers (SRY-box transcription factor 9 (sox9) and desmin).

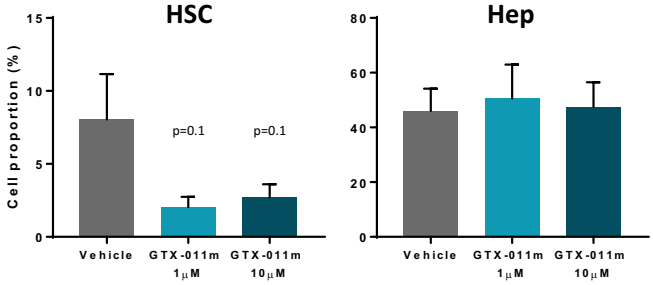

Figure:

Conclusion: This study shows for the first time the antifibrotic effects of GTX-011 in human liver tissue, confirming our previous results obtained in a preclinical model of NASH and encouraging its clinical evaluation as a possible new treatment for this disease.

WED-525

Beneficial effect of extravirgin olive oil on hepatic fatty acid accumulation and fibrogenesis: oleocanthalic acid as a promising compound for the treatment of NAFLD and NASH

Martina Colognesi[1], Ilaria Zanotto[1], Daniela Gabbia[1], Yahima Frion-Herrera[1], Maria Carrara[1], Alice Rossi[1], Maria Digiacomo[2], Doretta Cuffaro[2], Marco Macchia[2], Sara De Martin[1]. [1]*University of Padova, Department of Pharmaceutical and Pharmacological Sciences, Padova, Italy,* [2]*University of Pisa, Department of Pharmacy, Pisa, Italy*
Email: sara.demartin@unipd.it

Background and aims: Extravirgin olive oil (EVOO) is one of the major components of the Mediterranean diet, and its consumption has been correlated with beneficial effects on human health. EVOO gained a renewed interest for its ability to influence pathways involved in inflammation and oxidative stress. Recent preclinical studies stressed the importance of the EVOO phenolic oleocanthal (OC) in the modulation of these processes, and further established its possible role as an antifibrotic agent by counteracting NADPH oxidases upregulation, and reducing the expression of proinflammatory cytokines and metalloproteinases. Recently, the mono-oxidized derivative of OC oleocantalic acid (OcA) was isolated from aged EVOO, but its biological activities are still controversial. In the light of these considerations, we evaluated OcA direct effect on lipid accumulation and fibrogenesis in 2D and 3D in vitro models of NASH.
Method: In this study, OcA modulation of fatty acid (FA) uptake was assessed in different *in vitro* models. Firstly, HepG2 cells were treated for 24 hours with a mixture of palmitic and oleic acid (PA/OA 1: 1, 0.1 mM) to obtain a 2D in vitro model of steatosis. The same cells were cocultured with LX-2 cells and M0 macrophages and treated with PA/OA, to obtain 3D spheroids simulating NASH-like microenvironment. Both models underwent a 24 h treatment with different concentrations of OcA (0.5 µM, 1 µM, 2 µM, and 5 µM), and intracellular neutral lipids were stained with Bodipy or Nile red stain. Subsequently, OcA modulation of lipid accumulation was evaluated in cocultures of HepG2 treated with PA/OA for 24 hours and THP-1-derived M1 proinflammatory macrophages, simulating the NASH-like

microenvironment. Lastly, the antifibrotic effect of OcA was evaluated in two different *in vitro* models, i.e., in LX2 cells activated either by a 24 hours treatment with TGF-beta1 (2 ng/ml) or by cocultures with HepG2 and THP-1 derived M0 macrophages. To assess OcA effect on fibrogenesis, the intracellular expression of alphaSMA, a well-known marker of LX2 activation, was evaluated by immunocytochemistry coupled to confocal microscopy.

Results: OcA-treated HepG2 cells incubated with the PA/OA mix reported a significant, dose-dependent, reduction of FAs uptake after treatment compared to control. In accordance with these results, OcA reduced the FAs overload in the coculture of HepG2 and M1-like macrophages compared PA/OA-treated cells ($p < 0.0001$), and in the 3D spheroids coculture of HepG2 and LX2 cells treated for 24 hours with PA/OA mix ($p < 0.01$), providing evidences of its positive effect on the intracellular accumulation of lipids. Concerning fibrogenesis modulation, LX2 activation was significantly decreased after 24 hours of OcA treatment ($p < 0.0001$), in both fibrogenesis models.

Conclusion: This study provides preliminary in vitro evidence of the beneficial effect of OcA on NASH onset, since it significantly reduced the accumulation of FAs and prevent HSC activation in a panel of in vitro models of NASH, acting on the two main mechanisms involved in NASH development.

WED-526

Novel image analysis and immunohistochemistry advances to accompany pathologist driven non-alcoholic fatty liver disease diagnosis

Maroua Tliba[1], Manon Motte[1], Christophe Sattonnet[2], Viviana Lamberti[1], Elena Baranova[1], Marie Gérus-Durand[1], Renaud Burrer[1], Amanda Finan[1]. [1]*Cerba Research, France,* [2]*Diag, France*
Email: afinan@cerbaresearch.com

Background and aims: The prevalence of non-alcoholic fatty liver disease (NAFLD) is roughly 30% worldwide, a percentage that has rapidly increased over the past decade. There exist two types of NAFLD, non-alcoholic fatty liver (NAFL) and non-alcoholic steatohepatitis (NASH). Both subtypes are associated with lipid accumulation in the liver, the latter being more severe with inflammatory cell infiltration, fibrosis and subsequent hepatocyte damage and impaired organ function. The current gold standard for NAFLD diagnosis is liver biopsies evaluated by experienced pathologists who assign scores for several features (fibrosis, steatosis, inflammation and ballooning). However, documented inter-pathologist variability in scoring and the semi-quantitative nature of the scoring system itself highlight the need for new methods to ensure the unbiased, consistent assessment of disease. Cerba Research has developed tools that could be implemented to solve the variability in NAFLD diagnosis.

Method: A digital pathology approach involving 30 NASH needle core biopsies stained with hematoxylin and eosin (HandE) and Masson's Trichrome was developed. A pathologist evaluated the classic diagnostic parameters on these matched stains for each liver sample to serve as the gold standard. The imaging team of Cerba Research developed in parallel an application on Visiopharm® software to quantify fibrosis and steatosis on Masson's Trichrome stained slides with help from the pathologist's annotations. Supplementary chromogenic multiplex immunohistochemistry panels were also developed at Cerba Research to assist in the analysis of the liver contexture.

Results: The development of the Masson's Trichrome application and the correlation with the pathologist will be presented. The evolution of an HandE application using Deep Learning will also be shown. Two multiplex panels were designed. The first includes CD45 for inflammation analysis, CD138 as a plasma cells marker, and adipophilin that allows for visualization of lipid droplets associated with metabolic dysregulation in the hepatocytes. The second panel allows for the detection of cytokeratin 8 and 18, the loss of which allows for a facilitated identification of ballooned hepatocytes that may increase the accuracy of distinguishing NASH from NAFL. Example images and quantification of the markers will be presented.

Conclusion: The approaches presented could provide a toolbox for clinical pathologists to aid in a more accurate and quantifiable classification of NAFLD as either NAFL or NASH.

WED-527

Evaluating the hepatic efficacy and cardiometabolic profile of PNPLA3, TM6SF2, and other therapeutic targets for NALFD: a drug-target Mendelian randomization analysis

Daniel Rosoff[1], Lucas Mavromatis[1], Andrew Bell[1], Ali Hamandi[1], Lauren Park[1], Jeesun Jung[1], Josephin Wagner[1], David Ray[2], Falk Lohoff[1]. [1]*National Institutes of Health, National Institute on Alcohol Abuse and Alcoholism, Bethesda, United States,* [2]*University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, United Kingdom*
Email: daniel.rosoff@linacre.ox.ac.uk

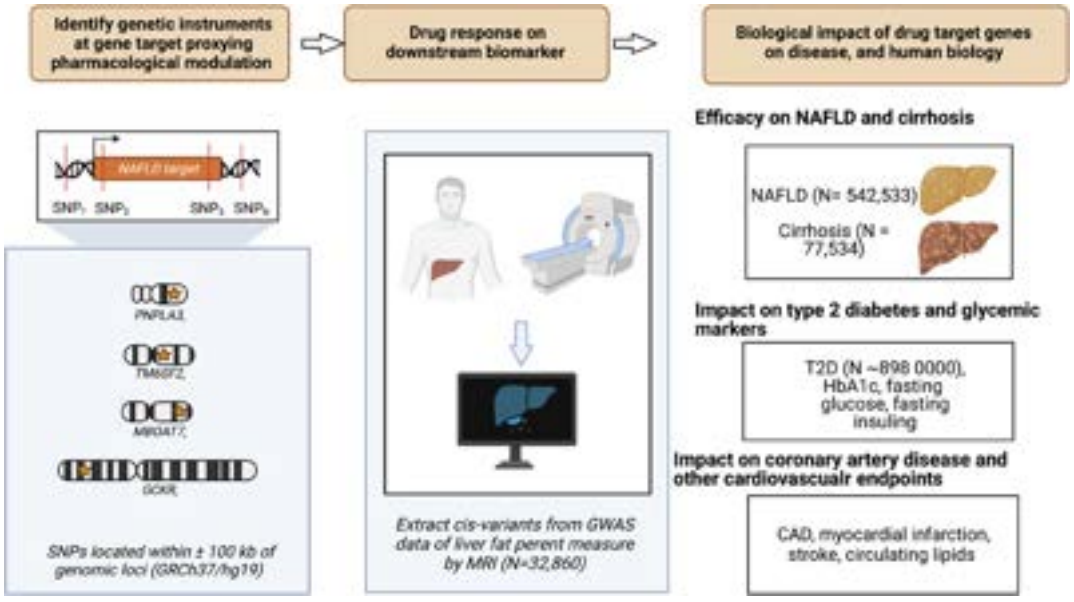

Figure: (abstract: WED-527).

Background and aims: While Non-alcoholic fatty liver disease (NAFLD) is the most prevalent cause of end-stage liver disease worldwide, including cirrhosis, and has been linked with increased risk for type 2 diabetes (T2D) and cardiovascular disease (CVD), there are currently no approved therapies. Previous studies have shown that NAFLD heredity is derived primarily from genes involved in hepatic lipid metabolism, i.e., *PNPLA3*, *TM6SF2*, *GCKR*, and *MBOAT7*, targeting these genes may be an important approach for developing NAFLD therapeutics. However, whether lowering liver fat via these targets impacts T2D, and CVDs remains unknown.
Method: Here, we used drug-target Mendelian randomization (MR) and data from large genome-wide association studies to investigate whether genetic variants within these genes that mimic the pharmacological reduction liver fat content (measured via magnetic resonance imaging) impact NAFLD, T2D, CVDs.
Results: Variants corresponding to a hepatic fat content reduction via these genes were each associated with a lower risk of NAFLD: *PNPLA3* OR = 0.30, P value = 2.03×10^{-42}; *TM6SF2* OR = 0.52, P value = 5.47×10^{-7}; and *GCKR* OR = 0.18, P value = 5.98×10^{-6}). Reduced liver fat content via *PNPLA3*, *TM6SF2* variants were also associated with reduced cirrhosis risk (e.g., PNPLA3 OR = 0.18, P value = 3.13×10^{-17}). Genetically-proxied PNPLA3 inhibition was also protective against the risk for T2D (OR = 0.844, P value = 4.28×10^{-8}). *PNPLA3* variants were linked with a slight increased risk for CVDs (e.g., coronary artery disease (CAD) OR = 1.11, P value = 2.52×10^{-7}). PNPLA3 associations were robust to sensitivity analyses using PNPLA3 instruments comprised of only the I148M variant and additional PNPLA3 instruments derived from circulating alanine aminotransferase levels. MR estimates were broadly consistent across complementary MR methods, which strengthens causal inference.
Conclusion: These findings extend existing literature highlighting these genes as therapeutic targets for NAFLD, suggest protective effects for T2D, and replicate previous studies linking liver fat and cardiometabolic diseases, including the impact of *PNPLA3* variants on heart disease.

WED-528
High-fat diet exacerbates lipopolysaccharide-induced liver injury in obese KK-Ay mice

Satoshi Sakuma[1], Kazuyoshi Kon[2], Akira Uchiyama[1], Hiroo Fukada[1], Toshifumi Sato[1], Shunhei Yamashina[1], Kenichi Ikejima[1]. [1]*Juntendo University School of Medicine, Department of Gastroenterology, Japan,* [2]*Juntendo University School of Medicine, Department of Gastroenterology, Tokyo, Japan*
Email: kazukon@juntendo.ac.jp

Background and aims: Cytokine storm is the primary event for fatal multiple organ damage during systemic infections such as sepsis. Although obesity is an etiological risk factor for cytokine storm, the mechanisms underlying the exacerbation remains unclear. Therefore, the aim of this study was to investigate the role of obesity and high-fat diet (HFD) load in exacerbation of cytokine storm and liver damage following lipopolysaccharide (LPS) challenge using obese diabetic KK-A^y mice.
Method: Male KK-A^y mice were fed a diet containing high-fat (HFD; D12492, Research Diets, Inc.) or control (D12450J) for 4 weeks. Wild C57Bl6/J mice (BL6) was used as a control strain. Mice were sacrificed at 1–24 hr after intraperitoneal injection of LPS 5 mg/kg BW or saline. Serum AST and ALT levels were determined by an enzymatic method. Hepatic expression levels of cytokine mRNA were measured by RT-PCR. Apoptotic cell death in the liver specimen was detected by TUNEL staining.
Results: Following HFD feeding for 4 weeks, Bl6 controls and KK-A^y mice gained body weight nearly 15% and 40% over basal values, respectively. KK-A^y mice fed an HFD showed prominent hepatic steatosis after HFD feeding, whereas Bl6 mice developed trivial steatosis even after HFD feeding. Indeed, liver weight increased greatly in HFD-fed KK-A^y from 2.44 ± 0.08 g to 3.41 ± 0.11 g, whereas the values only increased from 0.77 ± 0.05 g to 0.91 ± 0.02 g in BL6 fed an HFD. After a single intraperitoneal injection of LPS of 5 mg/kg, all Bl6 mice fed a control diet survived for 24 hr, indicating that this dose was sublethal. HFD-fed BL6 died within 24 hr after injection of LPS nearly 20%, which was not statistically significant. In sharp contrast, the mortality rate 24 hr after LPS injection reached 86% in HFD-fed KK-A^y mice, which was significantly higher than 16% of control diet-fed KK-A^y mice given LPS (p = 0.029). Serum AST and ALT levels 12 h after LPS in HFD-fed KK-A^y mice increased to 492 ± 112 IU/L and 673 ± 191 IU/L, which were obviously higher than those in HFD-fed BL6 reaching 247 ± 35 IU/L and 193 ± 58 IU/L, respectively. Indeed, HFD-fed KK-A^y mice showed marked apoptotic cell expression after LPS administration. Further, hepatic expression levels of TNFα mRNA 1 hr after LPS challenge were almost doubled in HFD-fed KK-A^y mice as compared to control diet-fed KK-A^y mice. Moreover, the induction levels of inflammasome-associated IL1β mRNA in the liver was also significantly higher in HFD-fed KK-A^y mice 1–3 h after LPS than those in control diet-fed KK-A^y mice.
Conclusion: These findings clearly indicate that KK-A^y mice, which develop obesity and severe fatty liver following HFD-feeding, are obviously vulnerable to LPS, showing higher mortality and severer liver injury. The underlying mechanisms most likely involve sensitization of hepatic macrophages and inflammasome-related reactions against LPS, as well as increased sensitivity to proapoptotic cell death in hepatocytes. It is therefore concluded that metabolic dysfunction-associated fatty liver appears to be an important risk factor of exacerbation in multiple organ failure including severe liver damage under condition of cytokine storm.

WED-529
Exploring transcriptome profiles to combat non-alcoholic fatty liver disease

Eva Kocar[1], Tadeja Rezen[1], Pablo J Giraudi[2], Silvia Palmisano[2,3,4], Claudio Tiribelli[2], Natalia Rosso[2], Damjana Rozman[1]. [1]*Faculty of Medicine, Institute of biochemistry and molecular genetics, Centre for functional genomics and bio-chips, Ljubljana, Slovenia,* [2]*Fondazione Italiana Fegato Onlus, Area Science Park Basovizza, Trieste, Italy,* [3]*University of Trieste, Department of Medical, Surgical and Health Sciences, Trieste, Italy,* [4]*Cattinara Hospital, Surgical Clinic Unit, Trieste, Italy*
Email: damjana.rozman@mf.uni-lj.si

Background and aims: The incidence of non-alcoholic fatty liver disease (NAFLD) is increasing, making it the most common chronic liver disease in industrialized countries, with no evidence of decline. People with advanced stages of NAFLD are at high risk of developing other comorbidities. The biochemical mechanisms and signaling pathways that classify a particular stage of NAFLD and anticipate disease development remain to be determined. We applied transcriptome analysis and statistical modeling to the histologically identified fibrosis stages of NAFLD to find novel target genes that could better indicate the particular stage of NAFLD.
Method: Sixty liver samples were obtained by biopsy from an Italian population of morbidly obese individuals who had undergone bariatric surgery (discovery cohort). The stages of NAFLD fibrosis, ranging from S0 to S4, were determined histologically based on the Kleiner classification system. RNA was isolated from the preserved liver samples, but because of its low quality, expression profiling was performed using Affymetrix microarrays. Statistical analysis was performed using Transcriptome Analysis Console (TAC) software to identify genes that differ in expression. Enrichment analysis of KEGG and Reactome pathways was performed using Enricher and G:profiler tools. Several differentially expressed genes from the discovery cohort were selected for validation in another group of NAFLD patients (78 patients, validation cohort), along with a subset of genes recently published by others (PMID: 33268509; PMID: 35654907). Correlation of gene expression with fibrosis stage in a discovery

cohort of patients was performed in Orange. Patients' medical data and clinical parameters were also included in the statistical analysis.
Results: Several known and unknown gene candidates with FDR ≤0 .05 were differentially expressed when comparing different fibrosis stages in the discovery cohort of patients, including *ITGBL1*, *ANKRD29*, *PTGDS*, and *LUM*. Differential expression of some genes was successfully validated by RT -qPCR in a discovery and a validation cohort of patients. In addition, source of variation analysis revealed the influence of several clinical parameters on gene expression in a discovery cohort of patients. Interestingly, BMI, fatty acids, and age had a greater impact on gene expression than fibrosis stage itself. The latter may be one of the reasons for the low number of differentially expressed genes. Correlation of gene expression with fibrosis stage in a discovery cohort of patients showed *ITGBL1* as the best candidate gene with a positive correlation of +0.66. Reactome and KEGG enrichment analysis revealed significant changes (FDR ≤0 .05) in metabolic pathways comparing early stages (S0, S1) and later fibrosis stages (S3/S4) in a discovery cohort of patients.
Conclusion: Our study revealed several differentially expressed candidate genes that could differentiate between different fibrosis stages and thus contribute to better patient stratification and appropriate treatment. Genes that can be observed in serum samples by their transcripts or proteins (*e.g. ITGBL1, LUM)* are particularly relevant as potential blood biomarkers.

WED-530
Effects of HSD17B13-targeting siRNA-R0737072 on Liver Fibrosis and Steatosis in a mouse model of NASH

Li Ming Gan[1], Shuquan Zheng[2], Junshi Liang[2], Di Li[2], Hongyan Zhang[2], Zicai Liang[2], Shan Gao[2]. [1]*Ribocure Pharmaceuticals AB, Sweden,* [2]*Ribo Life Science Co., Ltd, China*
Email: ganlm@ribolia.com

Background and aims: HSD17B13 has been reported to correlate with NASH development. A siRNA targeting HSD17B13 (R0737072) is designed, GalNAc conjugated, and demonstrated good activity both in cell lines and mouse livers. The purpose of this study was to evaluate the potential therapeutic effects of R0737072 on liver steatosis and fibrosis in a mouse model of human non-alcoholic steatohepatitis (NASH).
Method: A NASH mouse model was induced by western diet and a fructose drinking protocol. After a period of 56 days' dietary challenge, a single dose of R0737072 was administrated subcutaneously into the NASH mice, and liver tissues were analyzed at D15, D29, and the end of the study (D43), with regard to HSD mRNA expression, as well as degree of hepatic fibrosis and steatosis, using Picro Sirus Red and hematoxylin staining, respectively.
Results: 1. Single dose of R0737072 resulted in robust and durable knockdown of HSD17B13 mRNA in NASH mice. Compared with the PBS group, the inhibitory rates of R0737072 on *HSD17B13* mRNA expression were maintained at 98.53%, 89.85%, and 74.20% on D15, D29, and D43, respectively (Figure 1E). 2. R0737072 resulted in improvement of liver steatosis and fibrosis in the NASH mouse model. Following the dietary challenge, the NASH mouse model displayed signs of liver steatosis and fibrosis over time, which peaked at D15 and plateaued thereafter. At the end of the experiment on D43 post administration, a clearer reduction of damage of both fibrosis and steatosis was seen, Single sc dose of R0737072 resulted in significantly improved fibrosis IPP score at D15 and D43 compared to placebo. (Figure 1A–D and F).
Conclusion: R0737072 demonstrated durable and potent inhibitory effects on HSD17B13 mRNA expression, and is capable of halting worsening of steatosis and fibrosis in a mouse model of NASH.

WED-531
Discovery biomarker to optimize obeticholic acid treatment for non-alcoholic fatty liver disease

Eileen Yoon[1], Dae Won Jun[1], Huiyul Park[2], Sang Bong Ahn[3], Hyo Young Lee[4], Hyunwoo Oh[4], Joo Hyun Oh[3], Joo Hyun Sohn[1], Jihyun An[1], Jang Han Jung[5], Eun Chul Jang[6], Sung Eun Kim[7]. Email: noshin@hanyang.ac.kr

Background and aims: Though obeticholic acid (OCA) is a promising drug for non-alcoholic fatty liver disease (NAFLD), the response rate of OCA is limited. This study aimed to develop a biomarker to optimize OCA treatment for NAFLD.
Method: C57BL/6N mice males were fed on a western diet for 24 weeks. Pre-study liver biopsy performed at 12 weeks, and stratified according to disease severity. Next, the mice were administered with OCA (5 mg/kg/day) or vehicle for additional eight weeks. Hepatic transcriptome, metabolome and intestinal microbiome analyses compared according to OCA treatment responder and non-responder using pre-study and end of study samples. LX-2 cells transfected with short-interfering RNA against *CYP7B1* (siCYP7B1) and/or treated with OCA to evaluate the role of CYP7B1 in NAFLD.
Results: Resolution rate of steatohepatitis in the OCA and vehicle groups were 36.8% and 0%, respectively. The hepatic transcriptome and bile acid metabolite profile analyses revealed that the alternative bile acid synthesis pathway (Cyp7b1 and muricholic acid) in the OCA-responder group were upregulated compared with those in the OCA-non-responder group. Intestinal microbiome analysis also revealed that the abundances of *Bacteroidaceae*, *Parabacteroides*, and *Bacteroides*, which were positively correlated with the alternative bile acid synthesis pathway, were higher in the OCA-responder group than in the non-responder group. Pre-study hepatic mRNA levels of *Cyp8b1* (classic pathway) were downregulated in the OCA-responder group. The OCA response rate increased up to 80% in cases with a hepatic Cyp7b1/Cyp8b1 ratio ≥5.0. CYP7B1 expression was regulated by glucose concentration, and anti-fibrotic effect of OCA showed CYP7B1 dependent manner.
Conclusion: The upregulated alternative bile acid synthesis pathway or high hepatic CYP7B1 can be a potential biomarker for predicting OCA response.

WED-532
Unravelling an autophagy-dependent role of vitamin D in preserving gut integrity in experimental NASH

Andrew Hakeem[1], Basma Alaa[1], Olfat Hammam[2], Mahmoud Khattab[3], Aiman El-Khatib[3], Yasmeen Attia[1]. *[1]Faculty of Pharmacy, The British University in Egypt, Department of Pharmacology, Cairo, Egypt, [2]Theodor Bilharz Research Institute, Department of Pathology, Egypt, [3]Faculty of Pharmacy, Cairo University, Department of Pharmacology and Toxicology, Cairo, Egypt*
Email: andrew.hakeem@bue.edu.eg

Background and aims: The widespread prevalence of non-alcoholic fatty liver disease (NAFLD) exacts a heavy toll on global economy posing an unmet medical need. Clinical data suggest a putative role for gut barrier integrity as a critical determinant of NAFLD progression towards non-alcoholic steatohepatitis (NASH) in a large subset of patients. Calcitriol (CAL), a vitamin D receptor (VDR) agonist, was previously shown to restore intestinal homeostasis under various pathological contexts. However, its effect on gut barrier integrity and the possible molecular underpinnings mediating its gut-protective effects in a NASH setting is little explored. Induced autophagy was previously linked to barrier maintenance in response to intestinal insults. VDR signaling has been shown to promote the activation of autophagy directly and indirectly. The current study was therefore set out to investigate the potential impact of CAL in modulating intestinal tight junction protein expression in NASH and whether these effects could potentially be mediated in an autophagy-dependent manner.
Method: A dietary NASH model was adopted in the current study using male C57BL/6 mice that were divided into four groups: (1) Normal standard chow-fed group; (2) high-fat diet (HFD)-fed NASH group; (3) CAL group, which received CAL (5 ng/gm/day, i.p., twice weekly); and (4) CAL+HQ group, which received CAL and the autophagy inhibitor hydroxychloroquine (HQ; 60 mg/kg/day, p.o., daily). Treatments were initiated at week 12 and mice were sacrificed at the end of week 16. Hepatic and ileal tissues were harvested and preserved in 10% formalin for histopathological analysis. Tight junction proteins, claudin-1 and occludin, were estimated in ileal sections using immunohistochemistry to assess barrier integrity.
Results: Hematoxylin and eosin (HandE)-stained liver sections of HFD-fed mice showed macro- and microvesicular steatosis, hepatocyte ballooning, and increased portal lymphocytic infiltrates, insults reminiscent of NASH that were mitigated upon treatment with CAL. Meanwhile, HandE-stained ileal sections of NASH mice revealed atrophic mucosa with moderate inflammatory cells infiltration as well as partial loss of goblet cells. These histological derangements were ameliorated in CAL-treated mice with ileal sections showing preserved villous architecture, near normal goblet cells, and mild infiltration in mucosal and submucosal villous cores. Addition of HQ largely abolished CAL mediated improvement primarily manifesting in inflammatory cells infiltration. Furthermore, treatment with CAL resulted in surged ileal immunoreactivity to tight junction protein claudin-1 which was partially negated in the CAL+HQ treated group (Fig. 1). On the other hand, occludin showed augmented expression in NASH ileums which further increased upon treatment with CAL but did not significantly alter with HQ addition.

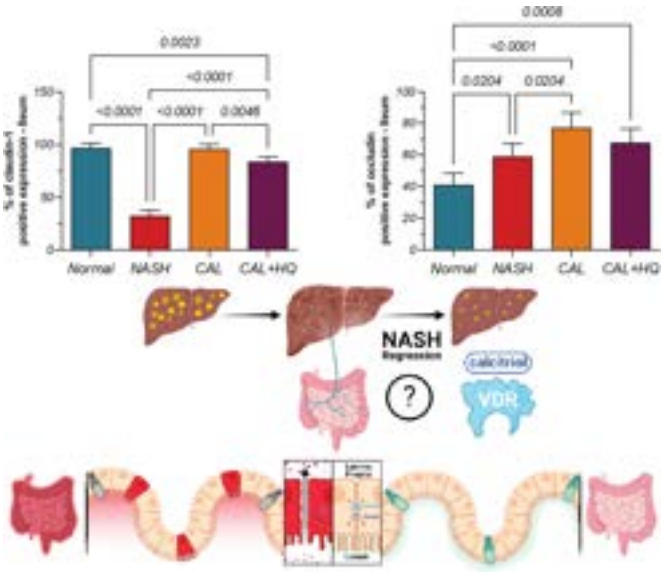

Figure: Immunohistochemical analysis against tight junction proteins, claudin-1 and occludin, in ileal sections of mice belonging to different treatment groups presented as means ± S.D. of the percentages of cytoplasmic and membranous expression. Statistical significance was inferred at $p < 0.05$ using one-way ANOVA followed by Tukey's *post hoc* test.

Conclusion: The current study findings suggest that CAL confers gut-protective effects in NASH. These effects were mediated, at least in part, by modulating different tight junction proteins expression that is autophagy dependent.

WED-533
Selective modulation of mitochondrial complex I ameliorates steatosis and hepatic inflammation in MCD-diet fed rats

Laura Giuseppina Di Pasqua[1], Oriana Bosco[1], Marta Cagna[1], Peng Sun[2], Stefan Günther Kauschke[2], Mariapia Vairetti[1], Anna Cleta Croce[3], Andrea Ferrigno[1]. *[1]University of Pavia, Department of Internal Medicine and Therapeutics, Pavia, Italy, [2]Boehringer Ingelheim Pharma GmbH and Co. KG, Department of CardioMetabolic Diseases Research, Germany, [3]Institute of Molecular Genetics-Italian National Research Council (CNR), Pavia, Italy*
Email: lauragiuseppin.dipasqua01@universitadipavia.it

Background and aims: NAFLD is one of the most common liver diseases worldwide. Inflammation and ROS production play a key role in the pathology progression. ROS scavengers are currently employed to sustain natural antioxidant defense, however no specific pharmacological target has been identified yet. Recently, it has been demonstrated that metformin targets mitochondrial complex I, making it a new interesting target. NAFLD is strictly related with mitochondrial dysfunction: lipid accumulation increases beta-oxidation, causing an overproduction of reducing equivalents and ROS. Aim of this work was to investigate if the selective modulation of mitochondrial complex I, the main ROS producer in mitochondria, could play a role in decreasing hepatic lipid accumulation and NAFLD progression.
Method: male Wistar rats fed by a Methionine and Choline deficient (MCD) diet or Control diet for 6 weeks were orally administered, starting from the fourth week with complex I modulator (CIM, Boerihnger Ingelheim) 10 mg/Kg/day or vehicle for 3 weeks. Lipid peroxidation and ROS were assayed by TBARS and DCHF-DA methods. ATP content and NAD (P)H bound/free ratio were measured. Hepatic Nitrate and Nitrite concentration was established and total lipid content was measured using Nile Red dye. The area of lipid droplets and the rate of inflammatory cells infiltration was calculated on HandE stained liver sections.
Results: TBARS increased in MCD-treated rats compared with Control rats, without changes after CIM administration. MCD groups showed a ROS content increase, but a significant reduction in CIM-treated Controls was detected, compared with vehicle-treated Controls. ATP content decreased in CIM-treated controls, but no significant differences were appreciated in MCD treated groups. The same trend was observed for NAD (P)H bound/free ratio. Nitrate and Nitrite were reduced in CIM-treated MCD rats compared with vehicle-treated MCD rats. Total lipid content was significantly reduced in CIM-treated MCD rats compared with vehicle-treated MCD rats. A significant decrease in lipid droplet areas was observed in MCD rats treated with CIM, compared with untreated MCD rats. A significant reduction in inflammatory cell infiltration was observed in MCD rats treated with CIM. Lastly, a significant reduction in AST and ALT was observed in CIM-treated control rats, compared with untreated control rats.
Conclusion: our work demonstrated that the complex I modulator administration could be a promising strategy in the reduction of lipid accumulation and inflammatory process in our model of steatosis. At the best of our knowledge, although further investigation is needed to clarify the mechanisms underlying this process, this is the first attempt to demonstrate a possible role of complex I modulator in reducing lipid accumulation and NAFLD progression in a model of benign steatosis.

WED-534
Inhibition of NLRP3 inflammasome activation by MK571, a multidrug resistance-associated protein (MRP) inhibitor
Oh Seung Seok[1], Jeongwoo Park[1], Keon Wook Kang[1]. [1]*Seoul Nat. University, Korea, Rep. of South*
Email: kwkang@snu.ac.kr

Background and aims: The NLR family pyrin domain containing 3 (NLRP3) inflammasome is an intracellular multiprotein complex involved in the production of mature interleukin 1-beta (IL-1β), and has been known to induce metabolic inflammation such as non-alcoholic steatohepatitis (NASH). Multidrug resistance-associated protein 4 and 5 (MRP4and MRP5, also known as Abcc4 and Abcc5) functionally control intracellular levels of glutathione and cAMP via regulating their efflux amounts. Here, we tried to reveal the role of MRP4 and MRP5 in NLRP3 inflammasome activation during liver injury.
Method: To assess the function of MRP4 and MRP5, MK571, a selective inhibitor of MRP transporter family, was used. Protein and mRNA expression of MRP family was assessed in primary hepatocytes, kupffer cells, hepatic stellates cells and bone marrow-derived macrophages (BMDMs). For determining *in vivo* protective effect of MK571 on NLRP3 inflammasome-mediated liver injury, LPS/galactosamine-induced fulminant hepatitis model was used.

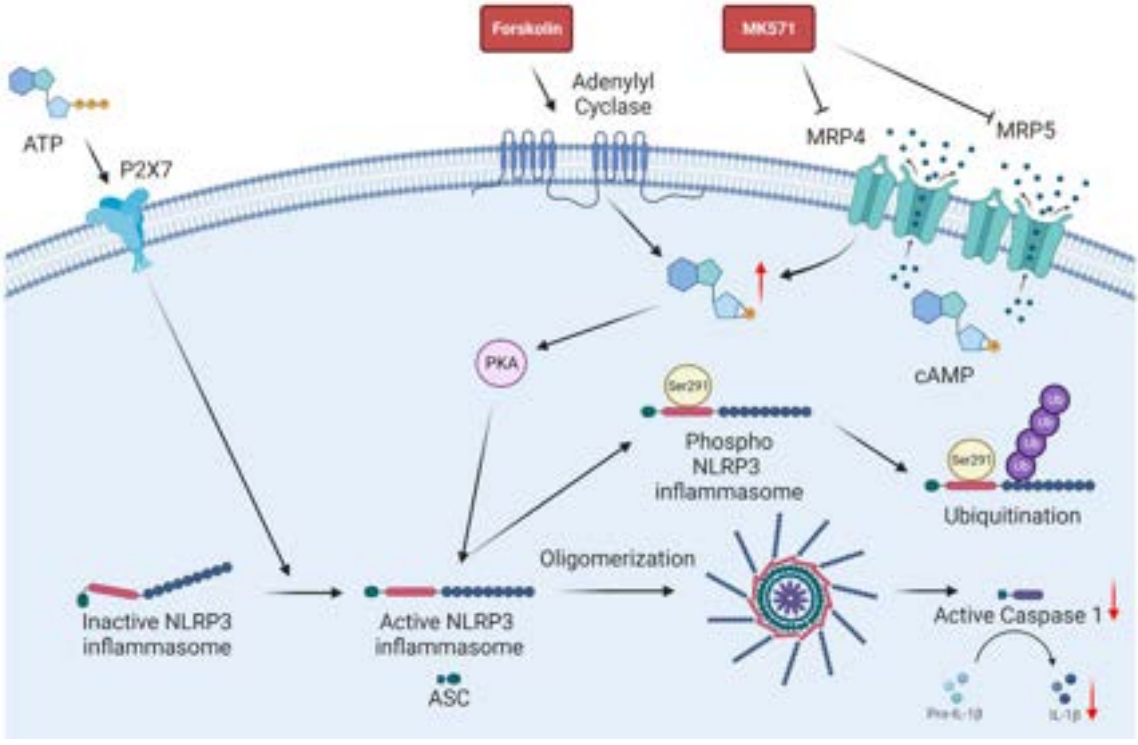

Figure: (abstract: WED-534).

Results: Protein levels of MRP4 were increased in kupffer cells from acetaminophen-injected mice. cAMP accumulation by MK571-mediated MRP4/5 inhibition concentration-dependently suppressed NLRP3 inflammasome via either transcriptional control of nuclear factor-kB or ubiquitnation of NLRP3 protein. In lipopolysaccharide/D-galactosamine-induecd acute hepatitis mouse model, oral administration of MK571 suppressed the increases in several inflammatory marker proteins and serum IL-1β.
Conclusion: These findings indicate that the MRP4 and 5 as energy-dependent transporters for the cyclic nucleotide, are involved in the regulation of NLRP3 inflammasome during liver injury.

WED-535
A formulation of palmitoylethanolamide and phenolic compounds improves NAFLD-associated hepatic lipid dysmetabolism and oxidative stress in obese mice
Stefania Melini[1], Claudio Pirozzi[1], Adriano Lama[1], Filomena Del Piano[2], Federica Comella[1], Nicola Opallo[1], Chiara Annunziata[1], Giuseppina Mattace Raso[1], Rosaria Meli[1].
[1]*University of Naples Federico II, Pharmacy, Italy,* [2]*University of Naples Federico II, Department of Veterinary Medicine and Animal Production, Italy*
Email: stefania.melini@unina.it

Background and aims: Gluco-and lipotoxicity, as well as insulin resistance, play a key role in the development of NAFLD associated with metabolic disorders characterizing obesity (Petersen et. Al 2017). The excess of free fatty acids (FFA) facilitates the generation of lipotoxic metabolites contributing to the development of hepatic oxidative stress and inflammation (Hong et al 2021) which leads to insulin resistance and glucose intolerance (Tangvarasittichai et al. 2015). The N-acylethanolamine palmitoylethanolamide (PEA) and some phenolic compounds from olive leaves, such as rutin and hydroxytyrosol (HT), have shown different metabolic, anti-inflammatory and antioxidant effects (Annunziata et al. 2020, Pirozzi et al. 2016, Li et al 2022). This study evaluates the possible beneficial activity of a formulation containing PEA co-micronized with rutin and associated with HT in counteracting hepatic damage and metabolic alterations occurring in a mouse model of high-fat diet (HFD)-induced obesity.
Method: Male C57Bl/6J mice were divided into 3 groups: a control group receiving standard chow diet; mice fed with HFD for 19 weeks; a HFD group administered NORM3 (PEA 10 mg/kg/die-Rutin 2 mg/kg/die, HT 0, 5 mg/kg/die *per os*) from week 12 up to week 19. Biochemical and molecular analysis were performed by ELISA assay and Western blot and Real-Time PCR analysis, respectively.
Results: The treatment with NORM3 reduced body weight and fat mass of obese mice compared with untreated HFD group. The protective effect of NORM3 was confirmed by the decrease of serum hepatic and metabolic parameters, (i.e transaminases, triglycerides, and cholesterol). Moreover, NORM3 improved glucose homeostasis altered by HFD reducing fasting glycaemia and gluconeogenesis process, as shown by PTT. Consistently, NORM3 induced the activation of PI3K/AKT pathway, leading to the restoration of insulin signaling. AKT can also activate glycogen synthase kinase (GSK)3beta, which may promote the activity of antioxidant mediators. NORM3 demonstrated a significant antioxidant effect reducing the production of ROS and malondialdehyde levels as well as increasing the hepatic transcription of nuclear factor erythroid (NRF)2 and its downstream antioxidant genes. We also demonstrated the effect of NORM3 on the hepatic inflammation induced by lipid overnutrition. NORM3 treatment reduced the protein expression of NFkb as well as the transcription of *Il1b* and *Ccl2*. Finally, since FFA accumulation is another hallmark in NAFLD and obesity, we investigated the effect of NORM3 on hepatic lipid dysmetabolism induced by HFD. The administration of NORM3 counteracted lipogenesis, reducing the hepatic mRNAs of fatty acid synthase (*Fasn*) and increasing PPAR-alpha, as a key upstream target of fatty acid oxidation.
Conclusion: Taken together, our findings identify NORM3 as a potential hepatoprotective approach in dampening the hepatic dysmetabolism and associated oxidative stress in NAFLD and obesity.

WED-536
Deletion of no-sensitive guanylyl cyclase protects from metabolic obesity but not from fibrosis in murine non-alcoholic fatty liver disease
Muhammad Ashfaq-Khan[1], Jan-Luca Wasser[1], Andreas Friebe[1].
[1]*Universität Würzburg, Germany*
Email: m.ashfaq_biotech@yahoo.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) comprises bland steatosis that progresses to its more aggressive form, non-alcoholic steatohepatitis (NASH), which can finally develop into hepatocellular carcinoma in a subset of patients. The underlying mechanisms and the endogenous drivers of the development of NAFLD/NASH have not yet been fully elucidated. Recently, a stimulator of NO-sensitive guanylyl cyclase (NO-GC), the receptor for the signaling molecule nitric oxide (NO), was shown to inhibit fibrosis, inflammation and steatosis in rodent models of NASH. In our current study, we have characterized the role of NO-GC in an experimental model of NAFLD/NASH.
Method: 8–10-week old male mice carrying a global deletion of NO-GC and their wildtype siblings (C57BL/6J background) were fed a Western diet (21% fat, 0.2% cholesterol and 42 g/l fructose) for 16 weeks. Thereafter, mice were sacrificed, and liver tissues were fixed in paraformaldehyde for histological analysis.
Results: NO-GC knock mice had significantly lowered liver ($p = 0.0048$) and body weights ($p = 0.00019$) compared to wildtype control. In addition, epididymal, mesenteric and inguinal fat was strongly decreased in NO-GC KO mice compared to controls. Moreover, Western diet-fed wildtype mice showed highly elevated blood glucose levels in the intra-peritoneal glucose tolerance test after 120 min (341 ± 104 mg/dl) whereas levels in NO-GC KO were normal (156 ± 25 mg/dl). In line with this, steatosis was not observed in the livers of NO-GC KO mice whereas wildtype livers showed a steatosis score of 3 (≥66%). Despite the lack of peripheral and hepatic obesity in the NO-GC KO mice, the extent of fibrosis was similar in both genotypes.
Conclusion: Deletion of NO-GC protects from peripheral and hepatic obesity but not from fibrosis upon feeding a Western diet. Our results indicate that hepatic fibrosis may result from Western diet independent of the development of steatosis.

WED-537
Empagliflozin improves non-alcoholic fatty liver disease in a new translational mice model even without impact on weight loss
Katharina Luise Hupa-Breier[1], Janine Dywicki[1], Björn Hartleben[1], Noyan Fatih[1], Heiner Wedemeyer[1], Matthias Hardtke-Wolenski[1,2], Elmar Jaeckel[1,3]. [1]*Hannover Medical School, Germany,* [2]*University Duisburg-Essen, Germany,* [3]*University of Toronto, Canada*
Email: hupa.katharina@mh-hannover.de

Background and aims: Non-alcoholic steatohepatitis (NASH) is currently one of the most common causes of chronic liver disease with the metabolic syndrome as the main risk factor. However, current mice models only partial represent the human phenotype of the metabolic syndrome. Beside weight loss and lifestyle intervention, treatment options are very rare. Due to their insulin-independent mechanism leading to weight loss and improvement of hyperglycemia, SGLT-2 inhibitors seem to be a promising therapy in the field of NAFLD. The aim of this study was to investigate the effect of SGLT-2 inhibitor empagliflozin in a new dietary mice model for NAFLD with a polygenetic background for the metabolic syndrome.
Method: TALLYHO/JngJ (TH) mice received 16 weeks of high-fat/high-carbohydrate (HF-HC) diet with a surplus of cholesterol. After 12 weeks of HF-HC, mice were additionally treated with empagliflozin (Fig.1).

Results: After 16 weeks of HF-HC treatment, TH mice developed obesity, hyperglycemia and histological proven NAFLD (median NAS = 5). Treatment with empagliflozin led to a significant improvement of hyperglycemia, but had interestingly no effect on body weight in this mice model. Nevertheless, empagliflozin significantly improved both histological onset of NAFLD (median NAS = 3, p = 0.0312) and fibrosis (p = 0, 0017). Detailed analysis demonstrated that empagliflozin significantly decreased intrahepatic B (p < 0.0001) and Tcells (p = 0.0031) and in particular diminished proinflammatory $CD8^+$ (p = 0.0028) as wells as $CD4^+$ (p = 0.0051) cells. In addition, empagliflozin attenuated intrahepatic infiltration of proinflammatory macrophages (p = 0.039). Furthermore, empagliflozin revealed anti-inflammatory potential by gene-downregulation of TNF and nitric oxide synthase and improvement of catalase and superoxiddismutase (SOD), which are both involved in oxidative stress.
Conclusion: This is the first study testing empagliflozin in a new mouse model for NAFLD with a polygenetic background for the metabolic syndrome. Most important, empagliflozin improves the histological outcome of NAFLD even without any impact on weight loss and thereby reveals anti-inflammatory potentials. As these results might have important impact on the treatment of NAFLD, further studies are needed for confirmation.

WED-538
The effects of lipopolysaccharides on inducing non-alcoholic fatty liver disease in human precision-cut liver slices

Mei Li[1], Ke Luo[1], Vincent de Meijer[2], Anika Nagelkerke[1], Peter Olinga[1], Yana Geng[1]. [1]*University of Groningen, Netherlands,* [2]*University Medical Center Groningen, Netherlands*
Email: yana.geng@rug.nl

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is one of the most common chronic liver diseases, ranging from simple non-alcoholic fatty liver (NAFL) to non-alcoholic steatohepatitis (NASH), which may ultimately progress to cirrhosis, and eventually hepatocellular carcinoma (HCC). Pre-clinical studies suggested that lipopolysaccharides (LPS) from the gut microbiota contribute to the pathogenesis of NAFLD. However, the interplay between LPS and human NAFLD remains less clear. In our lab, we successfully developed an *ex vivo* NAFLD model from NAFL to fibrosis in precision-cut liver slices (PCLS). In this study, we aimed to assess the effects of LPS on NAFLD-PCLS in terms of inflammation, fibrosis and oncogenic signaling which would provide a potential model to investigate the relationship between LPS and human NAFLD.
Method: PCLS used in this study were derived from leftover liver material after transplant procedures. They were cultured in GFIPO (William's E Medium supplemented with Glucose (36 mM), Fructose (5 mM), Insulin (1 nM), Palmitic acid (0.24 mM) and Oleic acid (0.48 mM)) to mimic the NAFLD conditions, or WEGG (William's E Medium supplemented with Glucose (25 mM)) as control for 96 h. To investigate the effects of LPS stimulation, PCLS were treated with 100 ng/ml LPS in both WEGG and GFIPO medium. After incubation, PCLS were collected to assess viability and fat accumulation by measuring ATP levels and triglyceride (TG) content. Liver inflammation, fibrosis, cell proliferation and angiogenesis were evaluated by RT-qPCR to indicate the development of NAFLD and oncogenic signaling.
Results: PCLS remained viable for up to 96 h of incubation whilst being treated with LPS. TG content was increased significantly in GFIPO compared with WEGG group ($p < 0.0001$), but LPS had no significant influence on fat accumulation. mRNA expression of the inflammatory biomarkers *IL6, IL1β* was upregulated by LPS in GFIPO or WEGG, whereas *TNFα* only showed a trend towards upregulation. *COL1a1, ACTA2* and *TIMP-1* showed an increasing trend as well, suggesting the contribution of LPS to fibrogenesis. To evaluate the early onset of HCC, we measured gene expressions related to cell proliferation and angiogenesis. The upregulation in proliferation biomarkers (*MKI67, PCNA*) only occurred under the incubation of GFIPO, regardless of whether LPS was present, suggesting that LPS may have no effect on hepatocyte proliferation in PCLS. *CD34* and *VEGFA* expression showed a similar trend as was seen for cell proliferation, with LPS having a moderate impact on angiogenesis.
Conclusion: LPS mainly caused the development of liver inflammation, and may trigger fibrogenesis. Cell proliferation and angiogenesis were induced in non-alcoholic fatty liver disease in PCLS, with LPS having limited effect. This *ex vivo* model of human PCLS could be used to investigate the interplay between LPS and NASH, with inflammation and fibrosis being the primary factors affected.

WED-539
Oral antibiotic treatment protects mice against the development of diet-induced non-alcoholic fatty liver disease but not against diet-induced intestinal barrier dysfunction

Annette Brandt[1], Katja Csarmann[1], Angelica Hernández-Arriaga[2], Anja Baumann[1], Raphaela Staltner[1], Amélia Camarinha-Silva[2], Ina Bergheim[1]. [1]*University of Vienna, Austria,* [2]*University of Hohenheim, Germany*
Email: ina.bergheim@univie.ac.at

Background and aims: Alterations in intestinal barrier function and an elevated translocation of bacterial endotoxin and induction of toll-like receptor 4 (TLR4)-dependent signaling cascades in the liver are discussed as major factors in development of non-alcoholic fatty liver disease (NAFLD). To date, molecular mechanisms underlying these alterations are not yet fully understood. Here the effects of an oral treatment with an antibiotic mixture on intestinal barrier function in a model of diet-induced NAFLD was assessed.
Method: For 7 weeks, male C57BL/6J mice were pair-fed either a liquid standard diet (control, C) or a liquid high-fat and high-fructose diet (FFr) ± an antibiotic mixture (ampicillin, vancomycin, metronidazole, gentamycin, AB). Markers of liver damage and intestinal barrier function were examined and intestinal microbiota composition was determined. Moreover, everted gut tissue sacs from naïve male C57BL/6J mice were treated with fructose ± antibiotics or ± the inducible NO synthase (iNOS) inhibitor aminoguanidine *ex vivo*.
Results: The addition of AB to the diet almost completely abolished the development of NAFLD, e.g. macrovesicular steatosis and inflammatory alterations, being associated with a significantly lower Tlr4 mRNA expression in liver tissue and suppression of subsequent signaling cascades. In contrast, intestinal permeability was similarly significantly elevated in both FFr diet fed groups compared to the respective controls, while tight junction proteins in small intestinal tissue were significantly lower in both FFr-groups compared to C-fed mice. Furthermore, NOx levels were also similarly higher in both FFr-fed groups than in C-fed groups. Moreover, AB treatment had no effect on fructose-induced permeability in everted gut tissue sac, while the iNOS inhibitor aminoguanidine affected the development of intestinal permeability ex vivo.
Conclusion: Taken together, our results indicate that antibiotic treatment protects mice against the development of diet-induced NAFLD, but this is not primarily associated with an improvement in gut barrier function. Funded in parts by JPI HDHL-INTIMIC/FFG.

WED-540
MicroRNA as novel biomarker for disease severity evaluation and therapeutic target in NAFLD

Yoonseok Lee[1,1], Young-Sun Lee[1], Ji Hoon Kim[1], Eunho Choi[1], Tae Hyung Kim[1], Sun Young Yim[1], Young Kul Jung[1], Yeon Seok Seo[1], Jong Eun Yeon[1], Kwan Soo Byun[1]. [1]*Korea University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South*
Email: lys810@hanmail.net

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is chronic and progressive liver disease with high prevalence of 30% of the general population. As global prevalence of NAFLD is increasing, it has become a major public health problem and major cause of chronic liver disease. Non-alcoholic steatohepatitis (NASH) with

hepatic fibrosis has poor prognosis compared with non-alcoholic fatty liver (NAFL) or NASH without hepatic fibrosis. Micro RNA (miR) is a non-coding RNA with about 20 nucleotides, and it can bind to the target mRNA, resulting in epigenetic reprogramming. Recently, many studies found that miRNA could be used as therapeutic targets and novel biomarkers for diagnosis and evaluation of severity in various diseases including NAFLD.

Method: Circulating miRNAs were analysed in sera from 24 patients with biopsy-proven NAFLD using small RNA sequencing. We treated palmitic acid to various cell lines to induce lipotoxicity, and checked miRNA4449 expression in supernatant and cells. We identified merlin, an important inhibitory regulator of YAP-TAZ signaling, as the target of miR-4449 by TargetScan (targetscan.org). We confirmed in human liver tissue whether the expression level of merlin changes depending on the presence of fibrosis, and tested the interaction with miR-4449 in vivo.

Results: Among 24 NAFLD patients, 15 patients were NAFL or NASH without fibrosis, whereas 9 patients were NASH with fibrosis. 31 miRNAs showed significant difference in expression level between two groups and miR-4449 was the most prominent among miRNAs that showed higher expression level in NASH with fibrosis compared to NAFL or NASH without fibrosis. Expression of miR-4449 increased in most supernatant and pellets from various cell lines when lipotoxicity was induced (Figure 1.). Therefore, hepatocytes are major source of miR-4449 during lipotoxicity and miR-4449 can be excreted to extracellular milieu. mRNA sequencing and quantitative PCR were performed on human liver tissue. Three patients were simple steatosis or NASH without fibrosis and three patients were NASH with fibrosis. Merlin showed significantly decreased in group of NASH with fibrosis (Figure 2.). When miR-4449 mimics and inhibitors were treated to Hep 3B cell lines, miR4449 mimic suppress merlin expression, whereas miR-4449 inhibitor increase expression of merlin (Figure 3.).

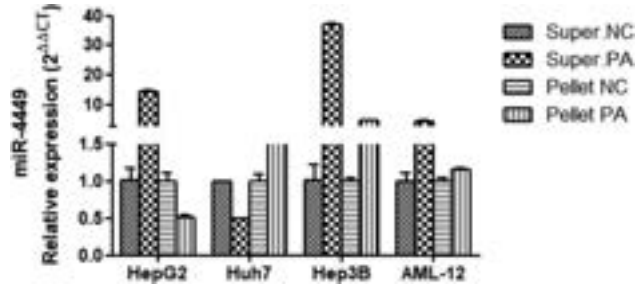

Figure 1:

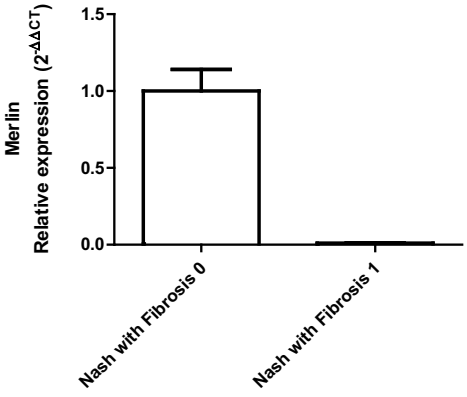

Figure 2:

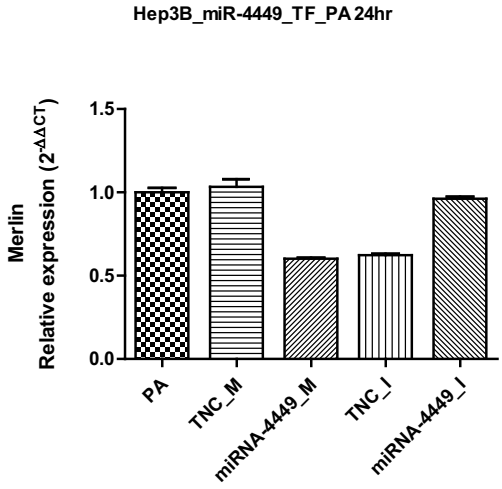

Figure 3:

Conclusion: miR-4449 might be used for novel therapeutic target of NASH-fibrosis.

WED-541

The role of chronic ER stress and calcium signalling in NASH associated carcinogenesis

Muhammad Umair Latif[1], Sercan Mercan[1], Ivan Bogeski[2], Volker Ellenrieder[1]. [1]*University Medical Center Goettingen, Department of Gastroenterology and Gastrointestinal Oncology, Goettingen, Germany,* [2]*University Medical center Goettingen, Molecular Physiology, Institute of Cardiovascular Physiology, Goettingen, Germany*
Email: umair.latif@med.uni-goettingen.de

Background and aims: The worldwide incidence of non-alcoholic fatty liver disease (NAFLD) continues to increase rapidly. It has become one of the most prevalent causes of progressive liver inflammation and a significant number of patients are at risk of developing cirrhosis and hepatocellular carcinoma (HCC). A better understanding of the processes leading to the development and progression of NASH and subsequent cancer development is essential to develop preventive strategies. We aim to investigate the role of ER-stress-induced NFATc1 activation in NASH associated carcinogenesis and define the underlying oncogenic mechanisms.

Method: We will perform comprehensive biochemical, molecular and functional analysis using *in-vitro* and *in-vivo* models, to scrutinize the impact of CRAC-NFATc1 activation in HCC. This study will certainly contribute to a better understanding of NASH-associated carcinogenesis and help to establish new strategies to prevent disease acceleration.

Results: NFATc1 is aberrantly activated in human NAFLD and advanced HCC. High NFATc1 activation correlates with the extent of liver damage and NASH incidence. We have demonstrated an important function of the Ca^{2+}-responsive NFATc1 signaling and transcription pathway in mediating chronic ER-stress responses and subsequent manifestation of NASH. In numerous cancers, NFATc1 orchestrates cell adaptation mechanisms and converts stress signals into gene signatures involved in tumor initiation and progression.

Conclusion: Persistent ER-stress leads to increased Ca^{2+}-dependent NFATc1 activation in hepaocytes *via* activation of Ca^{2+}-release-activated Ca^{2+} channels (CRAC). We propose that CRAC-NFATc1 activation drives NASH-associated HCC development and formation of a tumor permissive immune microenvironment *via* transcriptional regulation of oncogenic gene signatures and interfering with CRAC-NFATc1 signaling has potential to prevent NASH acceleration and tumor formation.

WED-542

A N-acylethanolamines mixture counteracts hepatic dysmetabolism induced in high-fat diet-fed obese mice

Claudio Pirozzi[1], Stefania Melini[1], Nicola Opallo[1], Adriano Lama[2], Filomena Del Piano[3], Federica Comella[1], Giuseppina Mattace Raso[1], Rosaria Meli[4]. [1]*University of Naples Federico II, Pharmacy, Naples, Italy,* [2]*University of Naples Federico II, Pharmacy, Naples, Italy,* [3]*University of Naples Federico II, Veterinary Medicine and Animal Production, Naples, Italy,* [4]*University of Naples Federico II, Phamacy, Naples, Italy*
Email: claudio.pirozzi@unina.it

Background and aims: Obesity is a multisystem disease characterized by the increased risk of many co-morbidities including hyperlipidemia, hyperglycemia, diabetes, metabolic syndrome and Non-Alcoholic Fatty Liver Disease (NAFLD) (Perumpail et al. 2017; James et al. 2008). NAFLD is the hepatic manifestation of metabolic syndrome due to the fat accumulation leading to hepatocyte death, inflammation, and fibrosis (Sharma et al. 2021). Several studies have shown metabolic and anti-inflammatory effects of specific N-acylethanolamine (NAE)s such as palmitoylethanolamide (PEA) and oleoylethanolamide (OEA) (Annunziata et al. 2022; Annunziata et al. 2020; Lama et al. 2020). The aim of this study is to evaluate the possible beneficial effects of a patented derivative of olive oil, consisting in a mixture of NAEs, named Olaliamid® (OLA) on hepatic glucose e lipid dysmetabolism induced by high-fat diet (HFD) in obese mice.
Method: Male C57Bl/6J mice were randomly divided into 3 groups: control group (STD) receiving standard chow diet; mice fed with HFD for 19 weeks (HFD); HFD group treated with OLA (OEA, PEA, and LEA in the same ratio as that of the fatty acids naturally found in the oil) from week 12 to week 19. Body weight of all groups were monitored throughout the experimental period. Oral glucose tolerance test (OGTT) was performed at the 7th week of treatment and then the animals were sacrificed and livers were collected for the following molecular determinations.
Results: First, we found that OLA markedly reduced body weight and fat mass, measured by impedenziometric analysis. During OGTT, OLA treatment reduced hyperglycemia due to lipid overnutrition at different time point, suggesting an improvement of tissue insulin sensitivity. Consistently, OLA restored HFD-altered insulin signaling pathway in the liver of obese mice, inducing the phosphorylation of insulin receptor and the activation of PI3K/AKT pathway. Notably, we demonstrated that OLA treatment counteracted the alterations of hepatic lipid homeostasis by HFD, normalizing the phosphorylation of AMPK, and the protein expression of carnitine palmitoyltransferase (CPT)1, a rate-limiting enzyme of fatty acid oxidation. OLA also reduced the mRNA expression of a key marker of steatosis, such as cluster of differentiation (CD)36, and different genes involved in the regulation of lipid metabolism (i.e. peroxisome proliferator-activated receptor gamma, its coactivator PGC1alpha, fatty acid synthase, and SREBP1). Finally, regarding the strict relationship between insulin resistance and hepatic inflammation in obesity, we showed an anti-inflammatory effect of OLA in reducing the expression of different pro-inflammatory cytokines and enzyme, altered in HFD-fed obese mice.
Conclusion: Taken together, our results indicate a therapeutic potential of OLA in counteracting and limiting the hepatic gluco- and lipotoxicity and the metabolic impairment associated with obesity and its co-morbidities.

WED-543

Preclinical efficacy and clinical translatability of resmetirom in the GAN diet-induced obese and biopsy-confirmed mouse model of NASH

Michael Feigh[1], Jacob Nøhr-Meldgaard[1], Susanne Pors[1], Henrik B. Hansen[1]. [1]*Gubra, Hørsholm, Denmark*
Email: mfe@gubra.dk

Background and aims: Resmetirom, a selective THR-β agonist, has in a recent phase-3 clinical trial (MAESTRO-NASH) in NASH patients with liver fibrosis, demonstrated significantly higher rate of NASH resolution and improvement in fibrosis stage as compared to placebo. The present study aimed to *(i)* evaluate the metabolic, biochemical and histopathological effects of resmetirom treatment in the Gubra-Amylin NASH (GAN) diet-induced obese (DIO) mouse model of fibrosing NASH; and *(ii)* compare primary histopathological end point analysis to the MAESTRO-NASH trial.
Method: Male C57BL/6 mice were fed the GAN diet high in fat, fructose and cholesterol for 38 weeks prior to study start. A liver biopsy was sampled 4 weeks prior to study start. Only animals with biopsy-confirmed NAFLD Activity Score (NAS ≥ 5) and fibrosis stage ≥F1 were included and stratified into treatment groups. Mice were administered (PO, QD) vehicle (n = 16) or resmetirom (3 mg/kg, n = 15) for 12 weeks. Vehicle-dosed chow-fed C57BL/6J mice (n = 10) served as normal controls. Histopathological pre-to-post individual assessment of NAS and fibrosis stage was performed and evaluated against primary end points applied in the corresponding MAESTRO-NASH trial (resolution of NASH with no worsening of liver fibrosis; ≥1-stage fibrosis improvement without worsening of NASH). Other terminal end points in GAN DIO-NASH mice included quantitative liver histology, blood and liver biochemistry.
Results: Resmetirom was weight-neutral, improved hepatomegaly, plasma alanine transaminase and plasma/liver lipid levels compared to vehicle-dosed GAN DIO-NASH mice. The efficacy of resmetirom on primary clinical end points in GAN DIO-NASH mice was comparable to corresponding clinical phase-3 trial outcomes. Accordingly, resmetirom treatment demonstrated ≥2 point significant improvement in NAS and 1-point significant improvement in Fibrosis Stage. The benefits on liver histology were further supported by reduced quantitative histological markers of steatosis (% area of lipids, % lipid-laden hepatocytes, lipid droplet density and size) and fibrosis (% area of PSR).
Conclusion: Resmetirom treatment improved metabolic, biochemical and liver histological markers of steatosis and fibrosis in biopsy-confirmed GAN DIO-NASH mice. Therapeutic efficacy of resmetirom on primary clinical histopathological end points were recapitulated in GAN DIO-NASH mice. These findings further validate clinical translatability of the GAN DIO-NASH mouse model, highlighting its utility in preclinical drug development.

WED-544

Loss of gut barrier integrity in non-alcoholic fatty liver disease is associated with severe vibriosis

Punnag Saha[1,2], Dipro Bose[1], Subhajit Roy[1], Anna Mae Diehl[3], Saurabh Chatterjee[4]. [1]*University of California, United States,* [2]*University of California Irvine, Environmental and Occupational Health, Irvine, United States,* [3]*Duke University, Medicine, United States,* [4]*University of California, Medicine, United States*
Email: saurabhc@hs.uci.edu

Background and aims: Non-alcoholic Fatty Liver Disease (NAFLD) is now considered as a pandemic and is a huge public health challenge. Rising obesity and type 2 Diabetes incidences have led a spurt of NAFLD cases worldwide with 25% of cases progressing to an inflammatory phenotype also termed as non-alcoholic steatohepatitis. Parallelly, climate change stressors, global warming and sea level rise has led to increase in cases of non-cholera vibriosis in coastal areas across the globe. Vibriosis often has poor outcomes in patients with underlying chronic liver disease. *Vibrio Vulnificus* and *Vibrio Parahaemolyticus* are mostly responsible for the vibriosis cases. We tested the hypothesis that underlying NAFLD can have severe inflammatory surge in patients with poor outcomes and sepsis-like symptoms.
Method: We used a murine model (C57BL6/J mice) of NAFLD that were fed with high fructose-high cholesterol diet for 12 weeks. We used a clinical strain of *Vibrio Vulnifcus* (VV) to induce vibriosis. Mice were euthanized and gut and liver pathology were evaluated.

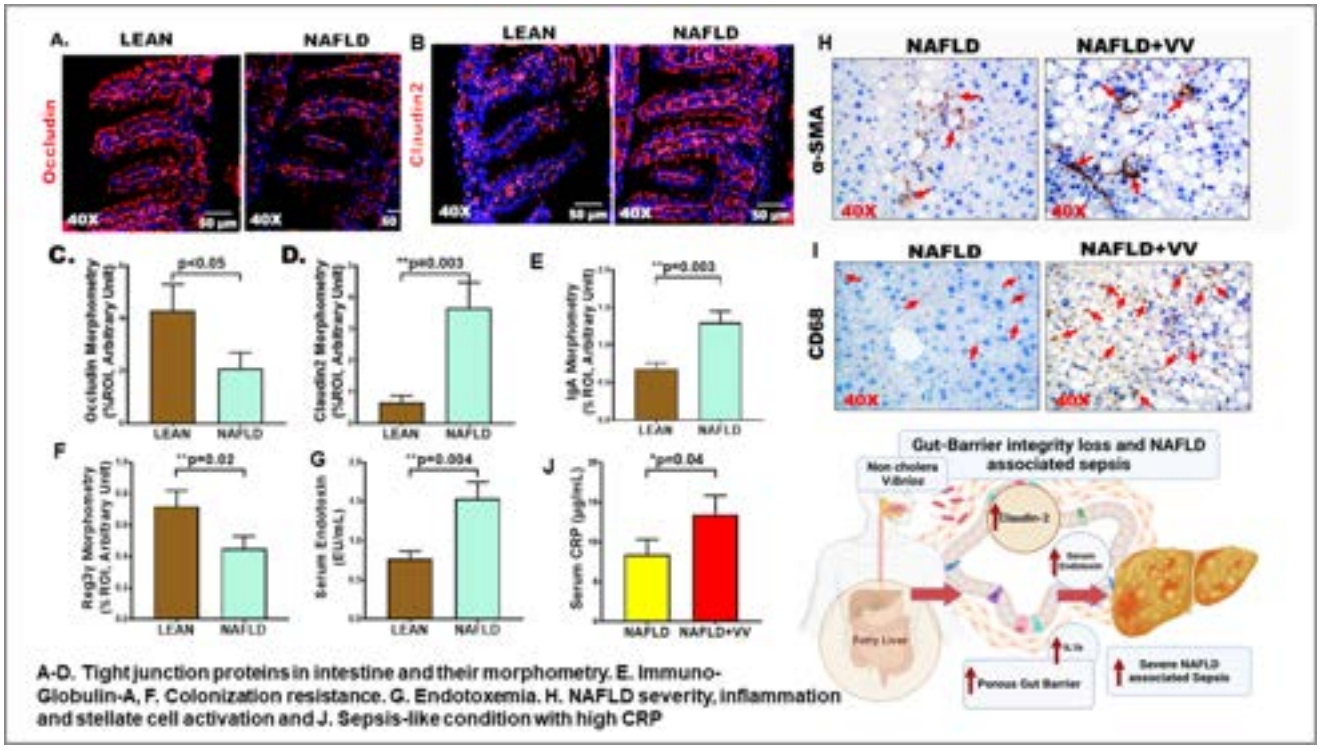

Figure: (abstract: WED-544).

Results: Results showed that NAFLD mice had an increased loss of gut barrier integrity with significantly higher levels of claudin-2 and a concomitant decrease in Occludin, both crucial proteins for maintaining tight junctions. Serum endotoxin and IL1beta levels were significantly increased in mice with NAFLD when compared to lean controls. Mice with NAFLD had an elevated IgA and decreased levels of Reg3γ, a colonization resistance marker associated with gut barrier integrity. NAFLD mice also had higher intestinal permeability when assessed by FITC-dextran. NAFLD mice challenged with 10^8 CFU of Vibrio Vulnificus had significantly higher levels of Kupffer cell activation (CD68) and parallel higher stellate cell activation (increased α-SMA) when compared to control mice infected with VV. Histopathology showed severe leukocyte infiltration and necroptosis in liver lobules in NAFLD mice infected with VV when compared to matched controls. Serum CRP levels were significantly higher in NAFLD+VV group when compared to controls suggesting septicaemia and liver damage.
Conclusion: In conclusion we show a novel outcome of Non-cholera Vibriosis in NAFLD that is primarily associated with increased gut-barrier integrity loss and provides a Vibriosis risk assessment of patients with NAFLD.

WED-545
A guinea pig model of pediatric non-alcoholic steatohepatitis
Kamilla Pedersen[1], Jens Lykkesfeldt[1], Pernille Tveden-Nyborg[1].
[1]*University of Copenhagen, Department of Veterinary and Animal Sciences, Frederiksberg C, Denmark*
Email: ptn@sund.ku.dk

Background and aims: Paediatric non-alcoholic fatty liver disease (NAFLD) affects 5–10% of children/adolescents; progressing to non-alcoholic steatohepatitis (NASH) in 25–50% of cases. Importantly, pediatric NASH differs from NASH in adults, e.g. displaying increased histological variation and disease severity, and leads to significant liver damage. However, studies in children are scarce and translational animal models few, leaving putative disease characteristics and associated mechanisms largely undisclosed. Driven by an adverse diet and life-style that promotes inflammation and a state of oxidative stress, NASH progression may be exacerbated by a low vitamin C (VitC) intake. In addition, low VitC levels have been linked to several lifestyle-associated co-morbidities in humans, including NAFLD. The aim of this study was to explore a juvenile guinea pig model of NASH and investigate if a poor VitC status affects disease progression.
Method: Sixty-two male, one to two weeks old guinea pigs were block-randomized based on weight into four diet groups receiving either: Control High-VitC (n = 16), Control Low-VitC (n = 16), High-Fat High-VitC (n = 15), or High-Fat Low-VitC (n = 15). High-VitC diets contained 1500 mg VitC/kg feed while Low-VitC diets contained 50 mg VitC/kg feed.
Results: Irrespective of VitC deficiency, a high-fat diet promoted advanced NASH and reduced hepatic health, based on the calculated NAS index (median = 6; $p < 0.0001$) and elevated alanine aminotransferase levels ($p < 0.001$) compared to controls. Comparing histopathological findings to previous studies in adult guinea pigs on the high-fat diet (n = 28), the juvenile NASH guinea pigs (high-fat diet, n = 30) displayed decreased steatosis but increased inflammation score ($p < 0.0001$ and $p < 0.05$, respectively). The median fibrosis score was grade 2 for both juvenile and adult NASH guinea pigs, but contrary to adults, the degree of steatosis did not correlate with fibrosis grade in the juvenile NASH guinea pigs. A low intake of VitC increased plasma cholesterol in high-fat fed guinea pigs ($p < 0.05$) and also appeared to increase inflammation.

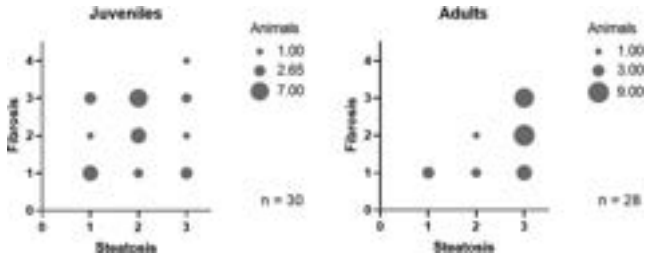

Figure:

Conclusion: NASH in young guinea pigs differed from the adult form, mimicking disease severity and histopathology of pediatric NASH, hereby supporting the guinea pig as a disease model with a high translational potential for pediatric NASH. Though our findings indicate a role of VitC in disease progression, specific links between VitC, deficiency and disease-associated mechanisms will require further investigations.

WED-546

Pemafibrate abrogates lipid liver accretion in a dietary model of fatty liver in rat

Roger Bentanachs[1,2], Laia Blanco[1], Maria Montesinos[1], Marta Alegret[1,2,3], Núria Roglans[1,2,3], Juan Carlos Laguna[1,2,3].
[1]*University of Barcelona, School of Pharmacy and Food Science, Pharmacology, Toxicology and Therapeutic Chemistry, Spain,* [2]*Institute of Biomedicine of the University of Barcelona, Spain,* [3]*CIBER de Fisiopatología de la Obesidad y Nutrición, Instituto de Salud Carlos III, Spain*
Email: jclagunae@ub.edu

Background and aims: Nowadays, there is not an approved drug therapy for the prevention/treatment of NAFLD. From a repurposing perspective, we aimed to investigate the effect of pemafibrate, mirabegron, and their combination in a dietary model of NAFLD, the high-fat high-fructose fed rat (HFHFr) (Velázquez et al., Mol. Nutr. Food Res 2022, 2101115).
Method: Female Sprague-Dawley rats were randomly distributed into 5 groups (n = 8): (1) control (CT; standard rodent chow); (2) high-fat diet with 10% w/v fructose in drinking water (HFHFr); (3) HFHFr plus pemafibrate at 1 mg/Kg/day (PemA); (4) HFHFr plus mirabegron at 10 mg/Kg/day (MBG); (5) HFHFr plus pemafibrate and mirabegron at 0.5 and 5 mg/Kg/day, respectively (P+M). Rats were fed the HFHFr diet for three months, while groups 3, 4, and 5 received high fat diet supplemented with the corresponding drug for the last month. Plasma and hepatic triglycerides (TG) and cholesterol (Cho) and carnitinepalmitoyl trasferase 1 (*cpt1*) and acyl-CoA (*aco*) gene expression in hepatic tissue were determined.
Results: As shown in the table, neither dietary nor drug-treatment interventions modified the total amount of ingested calories and final body weight, although HFHFr rats and those receiving pemafibrate (PemA and P+M groups) showed an increase in the ratio of liver/body weight. Only pemafibrate-treated rats (PemA and P+M groups) had significant reductions in liver lipids (both TG and Cho). No drug intervention reduced the hypertriglyceridemia associated to the HFHFr diet. Gene expression of liver *cpt1* and *aco*, which are directly involved in mitochondrial and peroxisomal fatty acid beta-oxidation, respectively, were markedly increased in pemafibrate-treated rats (PemA and P+M groups). Mirabegron administrated did not significantly modified any of the studied parameters.

Table:

	CT	HFHFr	PemA	MBG	P+M
AUC Kcal liquid/ cage/90 days	0	7280 ± 1768	7821 ± 1068	7323 ± 1374	7180 ± 920
AUC Kcal solid/ cage/90 days	6868 ± 198	4919 ± 1580$^{\#}$ (x0.72)	4530 ± 389	4951 ± 353	4958 ± 692
AUC total Kcal/ cage/90 days	6868 ± 198	12199 ± 263$^{\#\#\#}$ (x1.78)	12351 ± 892	12274 ± 1159	12147 ± 436
Final body weight (g)	248 ± 13	257 ± 21	268 ± 14	260 ± 13	273 ± 6
% liver/body weight	3.1 ± 0.2	3.7 ± 0.4$^{\#}$ (x1.19)	5.6 ± 0.5*** (x1.81)	3.6 ± 0.5	5.1 ± 0.5*** (x1.64)
TG liver (mg/g prot)	47 ± 11	129 ± 69$^{\#\#\#}$ (x2.74)	62 ± 15* (x0.48)	129 ± 70	50 ± 13** (x0.39)
Cho liver (mg/g prot)	36 ± 4	43 ± 8	32 ± 6*** (x0.74)	34 ± 8	29 ± 3** (x0.67)
TG blood (mg/dl)	101 ± 21	138 ± 29$^{\#}$ (x1.37)	182 ± 38	149 ± 31	148 ± 30
cpt1 mRNA (a.u)	100 ± 56	104 ± 62	362 ± 186**	137 ± 84	300 ± 81**
aco mRNA (a.u)	100 ± 30	97 ± 9	761 ± 322***	107 ± 13	633 ± 185**

$^{\#}$p > 0.05, $^{\#\#\#}$p > 0.001 vs CT; *p > 0.05, **p > 0.01; ***p > 0.001.

Conclusion: In our dietary model of NAFLD in rat, only pemafibrate treatment was able to restore liver lipids (TG and Cho) to CT values. These changes were associated to liver hypertrophy and increased expression of liver markers of fatty acid beta-oxidation, pointing to a perosixome proliferator activated receptor alpha-activation related effect. At this moment, we are searching possible molecular mechanisms involved in the lack of hypotriglyceridemic effect of pemafibrate. This work was supported by grants PID2020-112870RB-I00, funded by MCIN/AEI/10.13039/501100011033 and 2021SGR-00345.

WED-547

The overexpression of TM6SF2 and/or MBOAT7 wild-type genes restores the mitochondrial lifecycle and activity in an in vitro NAFLD model

Erika Paolini[1], Miriam Longo[1], Marica Meroni[1], Giada Tria[1], Roberto Piciotti[1], Massimiliano Ruscica[2], Anna Ludovica Fracanzani[1], Paola Dongiovanni[1]. [1]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, Italy,* [2]*University of Milan, Italy*
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: Mitochondrial dysfunction is a key player in the transition from NASH up to HCC. The knock-out (KO) of *MBOAT7* and/or *TM6SF2* hampers the mitochondrial dynamics in HepG2 cells resulting in an enrichment of misshapen and failed mitochondria. The overexpression of *MBOAT7* and/or *TM6SF2* wild-type genes in KO models through lentiviral vectors decreases the number of damaged-globular mitochondria, while increases the normo-shaped ones.
In the attempt to deepen the impact of *PNPLA3/MBOAT7/TM6SF2* loss-of-function mutations on mitochondrial aberrances, we investigated the mitochondrial lifecycle and activity in KO cells overexpressed for the wild-type forms of *MBOAT7* and/or *TM6SF2*.
Method: Mitochondrial lifecycle and activity were assessed through RT-PCR, Western Blot, Seahorse assay and immunohistochemistry.
Results: The overexpression of *MBOAT7*, *TM6SF2* or both decreased PGC1α levels, the master regulator of mitobiogenesis, which was activated in KO cells in response to fusion-fission unbalance, boosted the expression of Mfn1, Mfn2 (mitochondrial outer membranes proteins involved in fusion) and OPA1 (inner mitochondrial membranes fusion protein) whereas decreased FIS1 and DRP1 (fission proteins) levels, thus re-establishing the mitochondrial turnover. Consistently, the mitophagy pathways (PINK/PARKIN/BNIP3/BNIP3-L/LC3/phospho-UBIQUITIN) increased after the *MBOAT7* and/or *TM6SF2* overexpression, prompting the disruption of damaged mitochondria. The balance of mitochondrial biogenesis is essential for organelles' homeostasis and activity. Indeed, the overexpressed models augmented the COX-I/SDHA ratio, COX-III, and citrate synthase activity alongside the oxygen consumption rate, thus

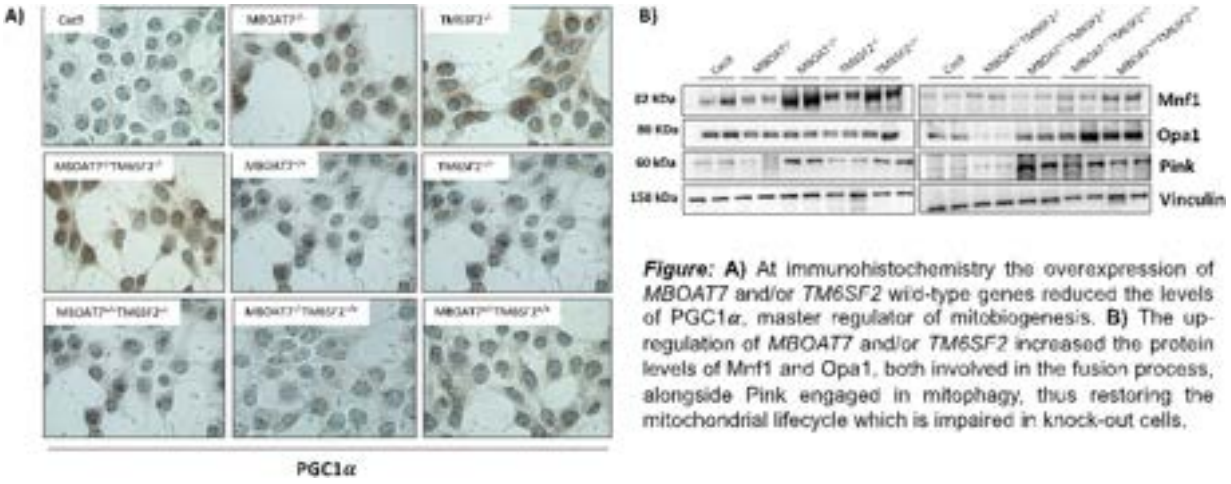

Figure: **A)** At immunohistochemistry the overexpression of *MBOAT7* and/or *TM6SF2* wild-type genes reduced the levels of PGC1α, master regulator of mitobiogenesis. **B)** The up-regulation of *MBOAT7* and/or *TM6SF2* increased the protein levels of Mnf1 and Opa1, both involved in the fusion process, alongside Pink engaged in mitophagy, thus restoring the mitochondrial lifecycle which is impaired in knock-out cells.

Figure: (abstract: WED-547).

recovering the OXPHOS capacity and Krebs cycle which were impaired in KO cells. Finally, lactate levels decreased after the upregulation of *MBOAT7* and/or *TM6SF2* wild-type genes together with the glycolytic extracellular acidification rate, thereby inhibiting the switch to anaerobic glycolysis which was promoted in KO cells to trigger tumorigenesis.

Conclusion: Genetics impacts on mitochondrial maladaptation during NAFLD and the overexpression of *MBOAT7* and/or *TM6SF2* wild-type genes in KO HepG2 cells re-balances the mitochondrial lifecycle and turnover, thus ensuring the organelles' function and possibly reversing hepatocellular damage.

WED-548

Development of a 2D nonalcohol-related steatohepatitis (NASH) model

Esther Arnaiz Gonzalez[1], Tahmid Choudhury[1], Ana Miar[1], Kenny Moore[1], Yuan-Yu Lin[2], Tess Lu[2], Quin Wills[1]. *[1]Ochre Bio, Oxford, United Kingdom, [2]Ochre Bio, Taipei, Taiwan*
Email: estherarnaiz@ochre-bio.com

Background and aims: One of the metabolic functions of the liver is to store excess energy (from sugars or fats) as lipid droplets. However, over time accumulation of lipids within hepatocytes can trigger pathological complications including immune activation and fibrosis resulting in nonalcohol-related steatohepatitis (NASH). Due to the silent nature of liver disease, diagnosis is usually performed at late stages (fibrosis and cirrhosis), when the only option for the patient is a transplant. Currently, there are no clinical therapies for NASH, and the research strategies for NASH often rely on complex 3D models such as spheroids, specific microfluidic devices or precision cut slices (PCLS), which are not suitable for the high throughput screening of new therapeutic targets. To overcome this limitation, we have developed an in vitro 2D NASH model using human primary cells, which maintains hepatic function, responds to dietary overload and fibrotic inducers in ways that resemble the stages of NASH and is modifiable with siRNA or drug intervention.

Method: Primary human hepatocytes are cultured alongside growth arrested 3T3-J2 mouse fibroblasts, human stellate cells and human peripheral blood mononuclear cell-derived monocytes. After cell adhesion, the media is changed to either lean or fat inducing co-culture media. Fibrosis induction is initiated on day 7 and the cells can be maintained to day 12, or longer if desired.

Results: Using LPS to demonstrate immunological function of the co-culture, we observe an increase in IL6 and MCP1. This can also be observed using our nutritional overload conditions which results in heavily lipid loaded hepatocytes and an inflammatory signature. Upon stimulation of the cultures with fibrosis inducers (PDGFbb and TGFb) fibrotic markers were significantly upregulated and secreted, resulting in hepatocytes coated in collagen and known biomarkers of NASH (e.g. TIMP1) being released. These effects were diminished using an inhibitor of TGFb signaling and phenocopy those from more complex models such as PCLS.

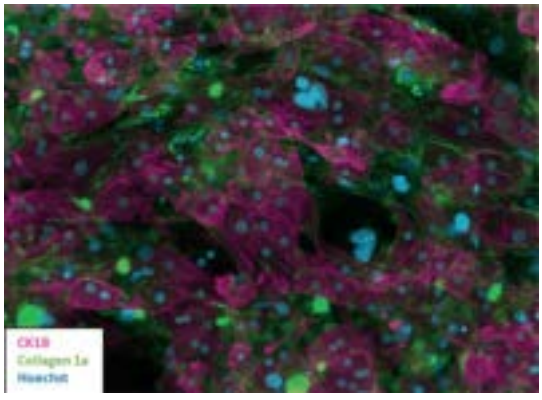

Figure:

Conclusion: Our 2D primary cell NASH model provides a useful tool to study different stages of the disease and to easily screen for both new targets and therapies.

Email: graziapennisi901@gmail.com

Background and aims: Programmed cell death 1/programmed cell death-ligand 1 (PD-1/PDL-1) axis has been reported to modulate liver inflammation and progression to hepatocellular carcinoma (HCC) in patients with non-alcoholic fatty liver disease (NAFLD). Here, we examined whether the *PDCD1* variation associates with NAFLD severity in individuals with liver biopsy.
Method: We examined the impact of *PDCD1* gene variants on HCC, as robust severe liver disease phenotype in UK Biobank participants. The strongest genetic association with the rs13023138 G > C variation was subsequently tested for association with liver damage in 2,889 individuals who underwent liver biopsy for suspected non-alcoholic steatohepatitis (NASH). Hepatic transcriptome was examined by RNASeq in a subset of NAFLD individuals (n = 121). Transcriptomic and deconvolution analyses were performed to identify biological pathways modulated by the risk allele.
Results: The rs13023138 C > G showed the most robust association with HCC in UK Biobank *(p = 5.28E-4, OR = 1.32, 95% CI [1.1, 1.5])*. In the liver biopsy cohort, *rs13023138* G allele was independently associated with severe steatosis (OR 1.17, 95%C.I. 1.02–1.34; p = 0.01), NASH (OR 1.22, 95%C.I. 1.09–1.37; p < 0.001) and advanced fibrosis (OR 1.26, 95% C.I. 1.06–1.50; p = 0.07). At deconvolution analysis, rs13023138 G > C allele was linked to higher hepatic representation of M1 macrophages, paralleled by upregulation of pathways related to inflammation and higher expression of CXCR6.
Conclusion: The *PDCD1 rs13023138* G allele was associated with HCC development in general population and with liver disease severity in patients at high risk of NASH.

WED-550

Obeticholic acid administration increases hepatic eNOS levels counteracting lipid accumulation and fibrosis in a diet-induced ob/ob mouse model of NASH

Marta Cagna[1], Giuseppina Palladini[1,2], Anna Cleta Croce[3], Massimiliano Cadamuro[4], Luca Fabris[4,5], Luciano Adorini[6], Andrea Ferrigno[1], Mariapia Vairetti[1], Laura Giuseppina Di Pasqua[1].
[1]University of Pavia, Department of Internal Medicine and Therapeutics, Pavia, Italy, [2]Fondazione IRCCS Policlinico San Matteo, Pavia, Pavia, Italy, [3]Institute of Molecular Genetics-Italian National Research Council (CNR), Italy, [4]University of Padua, Department of Molecular Medicine (DMM), Italy, [5]Yale University, Department of Internal Medicine, Liver Center and Section of Digestive Diseases, United States, [6]Intercept Pharmaceuticals, San Diego, United States
Email: lauragiuseppin.dipasqua01@universitadipavia.it

Background and aims: This study evaluated endothelial nitric oxide synthase (eNOS) as a potential Farnesoid X receptor (FXR)-mediated mechanism in the treatment of non-alcoholic steatohepatis (NASH). We previously reported that Obeticholic acid (OCA), a potent FXR agonist, restores RECK, an inverse modulator of metalloproteases, involved in fibrogenic processes (1). Recently, hepatic eNOS, a key regulator of liver vascular tone, was found strongly associated with the progression of NAFLD to NASH. Here, the effect of OCA was evaluated on hepatic eNOS content, lipid accumulation and fibrosis in a diet-induced ob/ob mouse model of NASH.
Method: Lep ob/ob (ob/ob) NASH mice fed the high fat (HF) diet (AMLN-diet; D09100301, with trans-fat, cholesterol and fructose) or control diet were used. After 9 weeks on diet, mice were treated with OCA dosed via dietary admixture 0.05% (30 mg/kg/d) or HF diet for 12 weeks. Liver weight, serum transaminase, bilirubin, cholesterol as well as hepatic eNOS and histological analysis of lipid droplets and fibrosis (by Sirius Red) were quantified. Type I procollagen carboxy-terminal propeptides (PICP) and type I procollagen aminoterminal propeptides (PINP), type I collagen synthesis markers, were also quantified; an increase in PICP/PINP ratio represents abnormal deposition of type I collagen (2).
Results: Histological results showed an accumulation of large lipid droplets in HF diet mice and the positive role of OCA treatment by reducing the number and diameter of lipid droplets. The same trend occurred for collagen deposition as documented by Sirius red and PICP/PINP ratio. A marked increase in eNOS was observed in livers from HF diet mice treated with OCA when compared with HF diet group. An inverse correlation was found comparing liver eNOS versus lipid droplets number (p < 0.05) and diameter (p < 0.059) as well as fibrosis by Sirius Red staining (p < 0.01). OCA treatment restored liver weight, serum bilirubin and cholesterol levels compared with HF-treated mice. No changes in serum transaminase were found.
Conclusion: In conclusion, OCA confers liver protection in a NASH model as shown by reduced hepatic lipid accumulation and fibrosis as well as serum bilirubin and cholesterol. This study also shows increased hepatic eNOS levels following OCA treatment associated with reduced lipid accumulation and fibrosis. Our data support the emerging role of eNOS as a key regulator and important target of NAFLD progression to NASH.

Cholesterol-free ketogenic diet feeding improves experimental non-alcoholic fatty liver disease (NAFLD)

Alessia Provera[1], Ramavath Naresh Naik[1,2], Laila lavanya Gadipudi[1], Cristina Vecchio[1], Marina Caputo[1], Alessandro Antonioli[1], Simone Reano[1], Nicoletta Filigheddu[1], Marcello Manfredi[3], Luca Simone Cocolin[4], Ilario Ferrocino[4], Emanuele Albano[1], Flavia Prodam[1,5], Salvatore Sutti[1]. *[1]University of East Piedmont, Dept. of Health Sciences, Italy, [2]Washington University in St- Louis, Dept. of Pediatrics, Endocrinology, and Diabetes, United States, [3]University of East Piedmont, Dept. of Translational Medicine, Italy, [4]University of Turin, Dept. of Agricultural, Forestry and Food Science, Italy, [5]University of East Piedmont, SCDU Endocrinology, Italy*
Email: alessia.provera@uniupo.it

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is now recognized as the most common liver disease worldwide. Despite continuous advances in the understanding of the disease pathogenesis and identifying therapeutic targets, up to now, there is not an approved therapy for NAFLD. Lifestyle changes, including diet, are, so far, the most effective interventions in NAFLD, even though there is not a definitive agreement on the most suitable dietary regimen. In recent years, low carbohydrates ketogenic diets (KDs) have been increasingly used for weight loss. However, the efficacy of KDs in improving NAFLD is controversial due to contradictory data obtained in animal experiments. In this study, we investigated the capacity of a cholesterol-free KD to improve NAFLD in mice.
Method: NAFLD was induced in C57BL/6 mice by feeding with a cholesterol-enriched Western Diet (WD) for up to 16 weeks, followed by switching animals to KD or standard diet (SD) for additional eight weeks.
Results: We observed that KD administration increased by three folds ketone bodies production and significantly reduced liver weights. Moreover, liver proteomic analysis and functional tests evidenced an improved glucose and lipid metabolism along with insulin resistance

in KD fed mice. These metabolic effects were associated with an amelioration in transaminase release and in the histological severity of steatosis and necro-inflammation. Mice receiving KD also showed a lowering in the hepatic expression of pro-inflammatory/pro-fibrogenic markers such as CCL2, IL-12, CD11b, α1-procollagen, TGF-β1, osteopontin and galectin-3, which were accompanied by a significant reduction in hepatic monocyte-derived macrophage infiltration and collagen fibres deposition as assessed by the Sirius-red staining. The improvement in liver damage and fibrosis likely relies on the capacity of KD of improving NAFLD associated dysbiosis leading to a recovery in gut bacterial flora similar to that of healthy mice.
Conclusion: Altogether, these results indicate that a cholesterol-free ketogenic diet is effective in improving metabolic derangements and steatohepatitis, and it might represent a potential therapeutic strategy for NAFLD.

Metabolic effects of n-3 fatty acids administered as Calanus oil to transgenic mice lacking functional peroxisome proliferator-activated receptor alpha

Martin Rossmeisl[1], Veronika Kalendova[1], Olga Horakova[1]. [1]*Institute of Physiology of the Czech Academy of Sciences, Laboratory of Adipose Tissue Biology, Prague 4, Czech Republic*
Email: martin.rossmeisl@fgu.cas.cz

Background and aims: Polyunsaturated fatty acids of n-3 series, specifically eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), exert hypolipidemic and anti-inflammatory effects. They act as endogenous ligands of the transcription factor peroxisome proliferator-activated receptor alpha (PPARalpha), which primarily regulates genes involved in lipid metabolism in the liver. We aimed to determine to what extent the metabolic effects of Calanus oil, an alternative source of EPA and DHA bound to wax esters, depend on the presence of functional PPARalpha.
Method: Twelve-week-old male 129S1/SvImJ mice, including wild-type (WT) and PPARalpha-deficient (KO) mice, were either maintained on a low-fat standard chow or given a high-fat corn oil-based diet (cHF; 32% lipids by weight) for 8 weeks (n = 8). To supplement EPA and DHA, 15% of dietary lipids in the cHF diet was replaced by Calanus oil (cHF+CO diet; 6 mg EPA+DHA/g diet). Tissue lipid content quantification, gene expression analysis (quantitative PCR) and metabolipidomic profiling (LC-MS) were performed in liver samples. Glucose production and its suppression by insulin were evaluated in cultured hepatocytes isolated from different groups of mice. One-way ANOVA was used to determine statistical significance ($p < 0.05$ was considered significant).
Results: Administration of cHF increased liver fat accumulation in WT mice by 2.6-fold, whereas in KO mice by 6.9-fold, resulting in a 3-fold higher liver fat content in KO animals (cHF; WT, 82 ± 4 vs. KO, 256 ± 13 mg/g tissue). As expected, cHF-fed KO mice showed reduced expression of genes involved in beta-oxidation, as well as lower levels of acylcarnitines and coenzyme Q levels, as detected by metabolipidomic analysis. Interestingly, administration of cHF+CO was associated with a reduction in hepatic steatosis in the KO group, whereas it had no effect on liver fat content in WT mice (cHF+CO; WT, 84 ± 8 vs. KO, 174 ± 13 mg/g tissue). Altered composition of various triacylglycerol and phospholipid species was found in cHF+CO-fed mice compared to their cHF-fed counterparts, but regardless of genotype. Furthermore, hepatocytes isolated from KO (but not WT) mice fed cHF showed impaired glucagon-stimulated glucose production and its suppression by insulin, a phenotype that was not restored in hepatocytes isolated from KO animals fed cHF+CO.
Conclusion: Chronic administration of Calanus oil can alter the liver lipid profile independently of the presence of functional PPARalpha. However, its beneficial effects on hepatic steatosis can only occur under conditions of greatly increased lipid accumulation in the liver, probably due to some indirect mechanisms induced by Calanus oil outside the liver.

Semaglutide has beneficial effects on non-alcoholic steatohepatitis in Ldlr-/-.Leiden mice

José A. Inia[1,2,3], Geurt Stokman[3], Martine C. Morrison[3], Nicole Worms[3], Lars Verschuren[4], Martien P. M. Caspers[4,5], Aswin L. Menke[3], Mathieu Petitjean[6], Louis Petitjean[6], Li Chen[6], J. Wouter Jukema[1,2,7], Hans Princen[3], Anita M. van den Hoek[3]. [1]*Leiden University Medical Center (LUMC), Cardiology, Leiden, Netherlands,* [2]*Leiden University Medical Center (LUMC), Einthoven Laboratory for Experimental Vascular Medicine, Leiden, Netherlands,* [3]*TNO, Metabolic Health Research, Leiden, Netherlands,* [4]*TNO, Microbiology and Systems Biology, Leiden, Netherlands,* [5]*The Netherlands Organization for Applied Scientific Research (TNO), Department of Microbiology and Systems Biology, Leiden, Netherlands,* [6]*PharmaNest, Princeton, United States,* [7]*Netherlands Heart Institute, Utrecht, Netherlands*
Email: jose.inia@tno.nl

Background and aims: Semaglutide, a glucagon-like peptide-1 receptor agonist, is an antidiabetic medication that has recently been approved for treatment of obesity as well. Semaglutide is also postulated to be a promising candidate for treatment of non-alcoholic steatohepatitis (NASH). Here, we evaluated the effects of semaglutide in a translational diet-induced model with advanced NASH and fibrosis.
Method: Ldlr-/-.Leiden mice received a fast food diet (FFD) for 25 weeks, followed by another 12 weeks on FFD with daily subcutaneously injections of semaglutide or vehicle (control). Plasma parameters were evaluated, livers and hearts were examined and hepatic transcriptome analysis was performed.
Results: In the liver, semaglutide significantly reduced macrovesicular steatosis (−74%, $p < 0.001$), inflammation (−73%, $p < 0.001$) and completely abolished microvesicular steatosis (−100%, $p < 0.001$). Histological and biochemical assessment of hepatic fibrosis showed no significant effects of semaglutide. However, digital pathology revealed significant improvements in the degree of collagen fiber reticulation (−12%, $p < 0.001$). Semaglutide did not affect atherosclerosis relative to controls. Additionally, we compared the transcriptome profile of FFD-fed Ldlr-/-.Leiden mice with a human gene set that differentiates human NASH patients with severe fibrosis from those with mild fibrosis. In FFD-fed Ldlr-/-.Leiden control mice, this gene set was upregulated as well, while semaglutide predominantly reversed this gene expression.
Conclusion: Using a translational model with advanced NASH, we demonstrated that semaglutide is a promising candidate with particular potential for treatment of hepatic steatosis and inflammation, while for reversal of advanced fibrosis, combinations with other NASH agents may be necessary.

Utilization of multicellular liver-on-chip to study non-alcohol-related fatty liver disease

Victoria Palasantzas[1], Isabel Tamargo[2], Gwen Weijer[2], Alfredo Rios-Ocampo[3], Sebo Withoff[2], Johan Jonker[3], Jing Fu[1]. [1]*University Medical Centre Groningen, Department of Genetics and Pediatrics, Netherlands,* [2]*University Medical Centre Groningen, Department of Genetics, Netherlands,* [3]*University Medical Centre Groningen, Department of Pediatrics, Netherlands*
Email: v.e.j.palasantzas@umcg.nl

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent liver disease, affecting nearly one-third of the global population. To study NAFLD, current experimental models e.g., animals and 2D cell cultures, pose various limitations including species-specific differences and lack of complexity. Here, I employ the innovative, human-based organ-on-chip system to overcome these limitations and explore lifestyle -based NAFLD interventions. Overcoming the limitations of current liver model systems with the liver-on-chip, I aim to study the effect of medicinal-implied nutrients ('nutriceuticals') to prevent or reverse NAFLD and the underlying molecular mechanism.

Method: We have recently established a hepatocyte-on-chip model utilizing healthy control-derived human induced pluripotent stem cells (hiPSCs) and a human hepatocyte cell line in our lab. Here, I present data on the development and characterization of a NAFLD-on-chip. Characterization of the NAFLD-on-chip includes steatohepatitis readouts e.g. lipid accumulation and detection of very-low-density lipoprotein and inflammatory cytokine excretion.
Results: Preliminary data reveals that the hepatocyte-on-a-chip models available in our lab exhibit important features of normal human hepatocyte physiology (e.g. expression of transport proteins and albumin production) and features often not observed in 'static' cell culturing models (e.g. lipoprotein excretion). Additionally, we identified the conditions to induce NAFLD in vitro for our further studies on nutriceuticals.

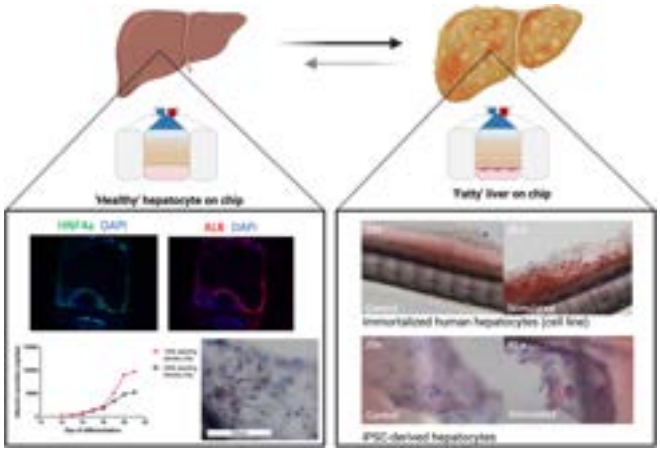

Figure:

Conclusion: We provide the first indications for the liver-on-chip model as a physiologically relevant model for complex diseases like NAFLD and how to study such a disease in our platform. Future perspectives include adding liver resident macrophages ('Kupffer cells') to recapitulate the inflammatory cross-talk present in NAFLD. Ultimately, we aim to use this model to assess NAFLD therapeutics as well as assess the impact of patient specific mutations on NAFLD.

Improvement of NAFLD by Totum-448: effects in the liver, adipose tissue and gut in western-diet fed hamsters

Vivien Chavanelle[1], Yolanda Otero[1], Marie Vallier[1], Doriane Ripoche[1], Cédric Langhi[1], Florian Le Joubioux[1], Thierry Maugard[2], Valerie Hervieu[3], Sébastien Peltier[1], Pascal Sirvent[1], Clement Besqueut-Rougerie[1], Gael Ennequin[4]. *[1]Valbiotis, France, [2]LIENSs, France, [3]Hospices Civils de Lyon, France, [4]Clermont Auvergne University, AME2P, Clermont-Ferrand, France*
Email: vivien.chavanelle@valbiotis.com

Background and aims: The concerning rise in NAFLD prevalence worldwide urgently calls for therapeutic solutions. We have previously demonstrated the beneficial effects of Totum-448 (T448), a novel patented polyphenol-rich combination of 5 plant extracts and choline, on liver steatosis, inflammation, and fibrosis in a diet-induced hamster model of NAFLD. This new work sheds some light on the action of T448 on the liver-gut-adipose tissue axis to unveil some of the mechanisms that could be involved in the preventive effects of the product on NALFD progression.
Method: Male golden Syrian hamsters were fed a western-diet (WD, high fat, mostly saturated, high cholesterol, N = 12), or a WD supplemented with T448 5% w/w (WD-T448, n = 12) for 12 weeks. A group of hamsters was fed a normal diet (ND, N = 6) and used as control. Body weight and composition (MRI) was monitored all throughout the study. NAFLD-associated features were assessed by RT-PCR or through biochemical and histological biomarkers in serum, liver, adipose tissue pads, ileum, colon, and caecal content.
Results: Despite slightly higher body weight and fat mass, T448-supplemented hamsters displayed improved circulating lipid profile (lower triglycerides, TG, total cholesterol, TC, free fatty acids, FFA and phospholipids, PL). Liver weight was significantly reduced by T448 supplementation as well as hepatic lipid content (TG, TC, FFA, and PL). This improvement of steatosis was confirmed by histological analyses of Oil-Red-O-stained sections and was associated with concomitant reduction of hepatic expression of inflammatory and fibrotic gene markers. Interestingly, consistent with the slight increase in total fat mass, the weights of epididymal, perirenal, inguinal, and mesenteric fat pads were higher in T448-supplemented animals. In caecal content, T448 elicited a reduction of lipopolysaccharides (LPS) levels and subsequent serum LPS, which was associated with down-regulated inflammatory gene markers in the ileum. Additionally, faecal TC was found elevated in T448 supplemented hamsters.

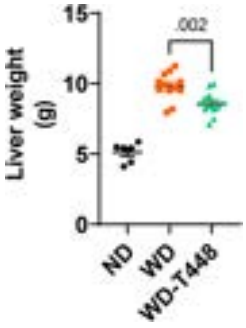

Figure:

Conclusion: This new work confirms the effects of T448 in improving circulating lipids and liver steatosis, inflammation, and fibrosis, some major hallmarks of NAFLD progression, in WD-fed hamsters. The reduction of ectopic fat accumulation in the liver was accompanied by an increased fat storage capacity in the different adipose tissue pads and LPS levels were reduced, both in caecal content and serum, suggesting improved metabolic endotoxemia.

NAFLD Therapy

A deep exploration of bridging fibrosis evolution and individual septa parameters in NASH using quantitative second harmonic generation imaging reveals fibrosis changes in natural history and treatment-induced not seen with conventional histology

Elaine Chng[1], Nikolai Naoumov[2], David E Kleiner[3], Dominique Brees[4], Chandra Saravanan[5], Yayun Ren[6], Dean Tai[7], Arun Sanyal[8,9]. *[1]Histoindex Pte. Ltd., Singapore; [2]London, United Kingdom; [3]National Cancer Institute, 2Post-Mortem Section, Laboratory of Pathology, Bethesda, MD, United States; [4]Novartis Pharma AG, Basel, Switzerland; [5]Novartis Pharma AG, Novartis Institute of Biomedical Research, MA, United States; [6]HistoIndex Pte. Ltd, Singapore; [7]Histoindex Pte Ltd, Singapore; [8]Stravitz-Sanyal Institute of Liver Disease and Metabolic Health, United States; [9]Virginia Commonwealth University School of Medicine, Richmond, United States*
Email: elaine.chng@histoindex.com

Background and aims: Non-alcoholic steatohepatitis (NASH) with bridging fibrosis (stage F3) is a critical stage in the evolution of fatty

liver disease, which can progress to cirrhosis or reverse to milder disease with better prognosis. Second harmonic generation/two photon excitation fluorescence (SHG/TPEF) microscopy of unstained liver sections with artificial intelligence (AI) provides sensitive and reproducible quantitation of liver fibrosis. Using this novel approach, the present study aims to gain in-depth understanding of changes in liver fibrosis and individual septa parameters over time in a homogenous, well-characterised group of patients with NASH F3 fibrosis stage.

Method: Paired liver biopsies from 57 patients [placebo, n = 17) or tropifexor (TXR) [n = 40], all with bridging fibrosis (F3 stage) according to the CRN scoring system at baseline (BL), who participated in the FLIGHT-FXR clinical trial (NCT02855164), were included in this study. Unstained liver sections from BL and end-of-treatment (EOT) were examined using SHG/TPEF microscopy. Changes in liver fibrosis overall and in five different zones of liver lobules were quantitatively assessed by qFibrosis-a cumulative index based on measuring 184 collagen features on a continuous scale. Radar maps were developed as a novel approach for assessing fibrosis changes in liver lobules. In addition, septa morphology-progressive or regressive septa and 12 individual septa parameters were analysed at BL and EOT biopsies.

Results: SHG revealed fibrosis progression or regression (BL to EOT) in 14/17 (82%) of patients receiving placebo, in contrast the CRN scoring where changes were detected in 6/17 (35%) patients while the majority 11/17 (65%) were adjudged as "no change." Radar maps of qFibrosis readouts illustrated fibrosis dynamics in 5 areas of liver lobule (Figure A). Quantitation of 12 septa parameters objectively demonstrated significant differences between regressive and progressive septa (Figure B). Regressive changes in individual septa parameters (BL and EOT) were significantly greater in the TXR-treated patients, than in the placebo group, in particular-septa area, septa width, fiber interactions and aggregated septa, which were present both in the "no change" and the "regression" subgroups, as defined by the CRN scoring. qFibrosis readouts at BL were able to predict the outcomes-fibrosis regression vs non-progression.

Conclusion: SHG/TPEF microscopy with AI provides greater granularity and precision in assessing fibrosis dynamics in NASH patients with bridging fibrosis and reveal worsening or improvement undetectable by conventional microscopy, enhancing the understanding of pathogenesis and treatment response. These results support the use of digital approaches for quantitative fibrosis assessment, in the natural history and treatment of NASH and other liver diseases.

Safety, tolerability, and preliminary efficacy of ascending doses of Human Allogeneic Liver-derived Progenitor Cells (HepaStem®) in patients with cirrhotic and pre-cirrhotic non-alcoholic steatohepatitis (NASH)

Sven Francque[1], Christophe Moreno[2], Faouzi Saliba[3], Victor Vargas[4], Luis Ibañez[5], German Soriano[6], Jordan Genov[7], Krum Katzarov[8], Ewa Janczewska[9], Elena Laura Iliescu[10], Anja Geerts[11], Noelia Gordillo[12], Yelena Vainilovich[12], Mustapha Najimi[12], Virginie Barthel[12], Frederic Lin[12], Etienne Sokal[12,13]. *[1]Antwerp University Hospital, UZA, Division of Gastroenterology and Hepatology, Edegem, Belgium; [2]CUB Hôpital Erasme, Université Libre de Bruxelles, Department of Gastroenterology, Hepatopancreatology and Digestive Oncology, Brussels, Belgium; [3]Paul Brousse Hospital, France; [4]Hospital Vall d'Hebron, Universitat Autònoma, Barcelona, Spain; [5]Hospital General Universitario Gregorio Marañon, Spain; [6]Hospital de la Santa Creu i Sant Pau, Spain; [7]University Multiprofile Hospital for Active Treatment "Tsaritsa Yoana-ISUL", Bulgaria; [8]Multiprofile hospital for active treatment (MHAT), Bulgaria; [9]ID Clinic, Poland; [10]Fundeni Clinical Institute, Bucharest, Romania; [11]UZ Gent, Belgium; [12]Cellaion, Belgium; [13]University Hospital Saint-Luc, Belgium*
Email: etienne.sokal@cellaion.com

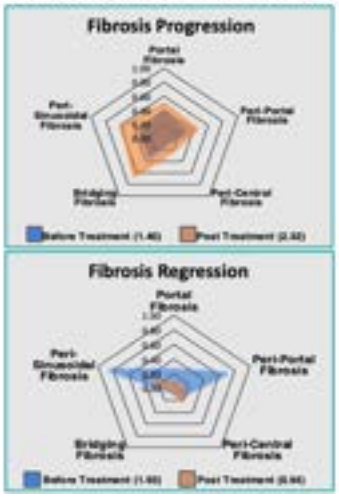
Background and aims: Inflammation plays a major role in the progression of non-alcoholic steatohepatitis (NASH). As previously demonstrated, Human Allogeneic Liver-derived Progenitor Cells (HepaStem®) have immunomodulatory effects and the capacity to modulate liver tissue inflammation. No anti-NASH treatments have been approved yet.

Method: In the HEP201 (PANASH) study, adult patients from 6 European countries with either F3 or F4 NASH (SAF fibrosis score) received a single or 3 repeated weekly infusions of either 0.5 or 1.0 × 10^6 cells of HepaStem/kg body weight and were followed up for 6 months post infusion. No formal statistical analyses were performed as the number of patients was small.

Results: Twenty-three patients were included: mean age 56.5y, 14 T2D; 18 obese, 5 overweight; 11 had F3 and 12 F4, all compensated

SHG assessment of liver fibrosis changes in patients with NASH F3 stage

A) Radar maps of qFibrosis readouts illustrate fibrosis dynamics in 5 areas



B) Comparison of individual parameters in Regressive septa vs Progressive septa

No.	Septa parameters	Progressive septa N = 43, mean	Regressive septa N=50, mean	p value
1	Septa Area	234638.21	27002.33	<0.001
2	Cellular/acellular	0.75	0.56	0.082
3	Cellular/Collagen	1.27	0.93	0.169
4	Septa length	947.27	543.95	<0.001
5	Septa width	167.45	40.88	<0.001
6	Intersection Septa	2475.00	262.00	<0.001
7	Number Thick Fiber Septa	64.00	5.00	<0.001
8	Number Thin Fiber Septa	3016.00	344.50	<0.001

Figure: (abstract: WED-076).

except for 2 early decompensated (total bilirubin >2 mg/dL). Safety. Up to 3 infusions at the highest dose were safe and well tolerated. No death or dose-limiting toxicity was detected. No adverse event (AE) led to study discontinuation. The majority (91.7%) of the AEs were non-serious and considered not study drug-related. Of the 4 serious AEs, 2 were considered by the Investigator as possibly related: a mild ischaemic stroke (in a context of pre-existing hypertension, T2D and carotid plaques) and a resected dysplastic liver nodule (which was present before study participation). Both events resolved without sequelae. Most coagulation parameters did not change, except for some transient increase in D-dimers 24 h after infusion. Plasminogen activator inhibitor-1 levels tended to slightly decrease 24 hours after infusion. Three patients (13.0%) developed de novo anti-HLA Class I or II donor-specific antibodies transitorily on D28 and/or M3. Efficacy. Serum levels of ALT and AST, which were mildly elevated at baseline, tended to normalize by M6, particularly in F3 patients. Bilirubin, as well as triglyceride levels, gradually decreased over time, particularly in patients with higher values at baseline. Adiponectin levels were increased in most patients (70%) on D28. No change was noted in glycaemic or anthropometric parameters. MELD score, which was low at baseline, further decreased slightly by M6. Serum levels of inflammatory parameters (CRP, IFN-gamma, and TNF-alpha), which were low at baseline, did not change over a period of 6 months, except for IL-6 which tended to decrease by D28, particularly in patients with higher levels at baseline. Regarding fibrosis, APRI and FIB-4 scores tended to decrease by M6, particularly in F3 patients. No decompensation of cirrhosis was reported.

Conclusion: This first dose-finding, safety, and preliminary efficacy study of HepaStem in adult NASH patients with F3 or cirrhosis confirmed previous safety findings. Preliminary indicators of efficacy on liver health, metabolic and inflammation markers support further study of HepaStem's potential to prevent progression towards cirrhosis and decompensation.

Email: reshma@akerotx.com

Background and aims: Non-invasive tests (NITs) to predict histological improvement in clinical trials are of great unmet need. Efruxifermin (EFX), a long-acting Fc-FGF21 fusion protein decreased liver fat content and markers of liver injury, inflammation fibrosis, as well as improved metabolic health of NASH patients with F1-F3 fibrosis or compensated cirrhosis.1, 2 These observations were confirmed in the phase 2b HARMONY study.3 The current analysis evaluated the responses of NITs to EFX treatment for 24 weeks, and potential association with observed resolution of histopathology.
Method: Changes in NITs were explored across 115 patients randomized within the ongoing, randomized, placebo-controlled phase 2b HARMONY study evaluating EFX 28 and 50 mg once-weekly for 96 weeks, with primary end point evaluation at 24 weeks.3 NITs were analyzed for correlation with histological improvements, based on evaluation at week 24 of fibrosis improvement without NASH worsening; NASH resolution without fibrosis worsening; and both fibrosis improvement and NASH resolution.
Results: Both EFX treatment groups met all key histological end points3 at week 24. In parallel, Pro-C3, enhanced liver fibrosis (ELF) score, NIS4, and liver stiffness by transient elastography were significantly reduced in the treated groups (Table 1). The composite imaging and serum biomarker test, FibroScan-AST (FAST), indicated a significantly smaller proportion of patients at moderate or high risk of disease progression after treatment. High rates (>50% with 50 mg EFX) of normalization for LFC (≤5% LFC) or serum ALT, appeared to underlie the substantial resolution of steatohepatitis (>60%, placebo adjusted).
Conclusion: Consistent with observed histological benefits, EFX significantly improved circulating and imaging-based biomarkers of liver injury, inflammation and fibrosis compared to placebo. In a substantial proportion of patients, EFX treatment for 24 weeks was associated with normalization of liver fat and serum ALT, which appeared to underlie improvements in NASH histopathology. Thus, changes in NITs with EFX therapy can be extrapolated to predict improvement in liver histology, enabling non-invasive monitoring of EFX response among patients with moderate-to-advanced fibrosis and NASH.

FRI-466
Efficacy and safety of LPCN 1144 in hypogonadal and eugonadal subjects for the treatment of non-alcoholic steatohepatitis (NASH) with fibrosis

Benjamin Bruno[1], Josh Weavil[1], Jonathan Ogle[1], Kongnara Papankorn[1], Anthony DelConte[1,2], Nachaippan Chidambaram[1], Mahesh Patel[1], Somaya Albhaisi[3], Arun Sanyal[3]. *[1]Lipocine Inc, Salt Lake City, United States; [2]Saint Joseph's University, Department of Food, Pharma, and Healthcare, Philadelphia, United States; [3]Virginia Commonwealth University, Division of Gastroenterology, Hepatology and Nutrition, Richmond, United States*
Email: bjb@lipocine.com

Background and aims: NASH is the fastest growing chronic liver disease and can progress to cirrhosis, hepatocellular carcinoma, and death. Recently, data from the Phase 2 clinical trial LiFT support LPCN 1144, an oral prodrug of testosterone (T), as a novel therapeutic treatment for patients with NASH. Although there is a high prevalence of low T in NASH, not all patients present with this diagnosis. Thus, the aim of the current analysis was to examine the efficacy and safety of LPCN 1144 in hypogonadal and eugonadal subjects of the LiFT trial.
Method: In LiFT, biopsy-confirmed NASH (F1-F3) males were randomized 1:1:1 to three arms for 36 weeks; 1) Treatment A (n = 18): oral LPCN 1144 twice daily (BID), 2) Treatment B (n = 19): oral LPCN 1144 with d-alpha tocopherol BID, and 3) oral matching placebo (n = 19) BID. Due to similar positive outcomes in LiFT, the two LPCN 1144 treatment arms were pooled (n = 37) to examine the impact of baseline gonadal status on the safety and efficacy of LPCN 1144 treatment in men with NASH. Subjects were stratified into hypogonadal (HYPO), defined as subjects with at least two baseline T measurements <300 ng/dl or a documented history of hypogonadism, and eugonadal (EU) groups.
Results: Within the pooled treatment arms, 41% (15/37) were eugonadal and 59% (22/37) were hypogonadal. Baseline characteristics were similar between EU and HYPO, with the exception of a lower basal T and higher basal BMI and whole-body fat mass in HYPO. When stratified by gonadal status at baseline, the positive effects of LPCN 1144 therapy were not significantly different between EU and HYPO for MRI-PDFF (−8.5 vs −7.8%), total NAS (−2.1 vs −2.3), proportion of patients with NASH resolution without worsening of fibrosis (50% vs 61%), ALT (−15.7% vs −12.0%), AST (−15.2% vs −11.7%) or whole-body fat mass (−3.9% vs −5.6%), respectively. The number of participants with treatment emergent adverse events (TEAEs) were similar between EU (11/15), HYPO (16/22), and placebo (15/19). TEAEs of interest (diarrhea, nausea, vomiting, pruritis, benign prostatic hyperplasia, increased prostate-specific antigen, new or worsening hypertension, and peripheral edema) were less frequent in the EU subjects (2) than HYPO (7) and placebo (8) subjects.
Conclusion: The efficacy and safety of LPCN 1144 therapy for treatment of NASH in male patients is independent of basal gonadal status. These data suggest that oral LPCN 1144 treatment is a safe and effective therapy for the male NASH population which is comprised of both hypogonadal and eugonadal patients. The observed benefit to risk profile warrants further investigation of LPCN 1144 in a larger trial with a longer duration.

FRI-467
Incidence and risk of dyslipidemia and hyperglycemia in a phase 3 study of obeticholic acid for the treatment of non-alcoholic steatohepatitis

Manal Abdelmalek[1], Thomas Capozza[2], Pamela Davis[2], Amarita Randhawa[2], Sangeeta Sawhney[2]. *[1]Mayo Clinic, Gastroenterology and Hepatology, Rochester, United States; [2]Intercept Pharmaceuticals Inc, Morristown, United States*
Email: sangeeta.sawhney@interceptpharma.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is associated with increased cardiovascular (CV) risk due to atherogenic dyslipidemia and insulin resistance. Therapies for NASH should have a well-characterized profile showing they do not increase CV risk. We aimed to characterize changes in lipid and glycemic markers and the incidence of dyslipidemia and hyperglycemia in the REGENERATE trial of obeticholic acid (OCA) for NASH (NCT02548351).
Method: The incidence of dyslipidemia and hyperglycemia was determined using standard Medical Dictionary for Regulatory Activities queries and laboratory tests for lipid and glycemic markers in the safety population (all randomized patients [pts] receiving ≥1 dose of placebo, OCA 10 mg, or OCA 25 mg).
Results: In this population, 976/2477 (39.4%) pts had exposures >4 years (median, 39 months). At baseline (BL), 496/825 (60.1%), 489/825 (59.3%), and 511/827 (61.8%) pts in the placebo, OCA 10 mg, and OCA 25 mg groups had low-density lipoprotein (LDL) ≥100 mg/dL;

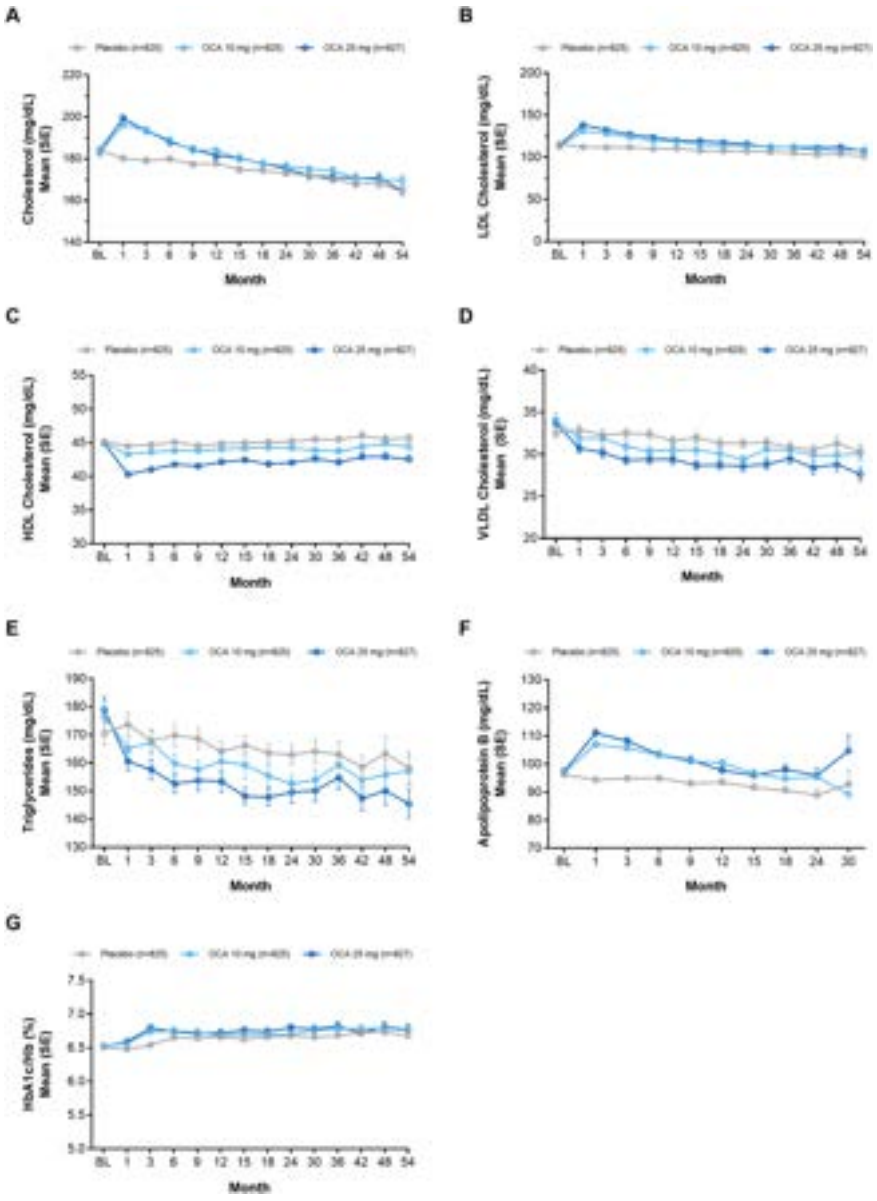

Figure: (abstract: FRI-467) Mean concentrations of (A) total cholesterol, (B) low-density lipoprotein (LDL), (C) high-density lipoprotein (HDL), (D) very low-density lipoprotein (VLDL), (E) triglycerides, (F) apolipoprotein B, and (G) hemoglobin A1c (HbA1c) over time.

450 (54.5%), 436 (52.8%), and 452 (54.7%) were on lipid-lowering drugs; and 470 (57.0%), 476 (57.7%), and 479 (57.9%) had diabetes, respectively. Most dyslipidemia and hyperglycemia events were mild/moderate; <0.5% of pts discontinued treatment due to these events. Dyslipidemia AEs were reported in 193 (23.4%), 354 (42.9%), and 390 (47.2%) pts who received placebo, OCA 10 mg, or OCA 25 mg, respectively. No serious adverse events (SAEs) were reported. In the OCA groups, mean LDL increased from BL to month 1 (M1) but returned to near BL by M18 with no difference from placebo through M54 (Figure 1B). This reduction occurred regardless of statin use. The incidence of hyperglycemia was similar in the placebo (190 [23.0%]), OCA 10 mg (223 [27.0%]), and OCA 25 mg (201 [24.3%]) groups. Hyperglycemia SAEs occurred in 2 (0.2%), 5 (0.6%), and 11 (1.3%) pts, respectively, and were mostly related to hospitalization for glycemic control in pts with type 2 diabetes (1, 3, and 9 pts, respectively). There was an early transient increase in mean hemoglobin A1c (HbA1c) from BL (6.52%) to M3 (6.77%) in the OCA groups. After M9, HbA1c levels did not differ between placebo and OCA groups (Figure 1G).
Conclusion: OCA 25 mg is associated with an early transient increase in LDL, which returned to BL independent of the addition of a statin. After an early increase in HbA1c, there was no evidence of increased hyperglycemia risk with long-term treatment. These results suggest transient changes in lipids and glycemic markers can be managed per guidelines in pts with pre-cirrhotic liver fibrosis due to NASH.
Abbreviations: BL, baseline; OCA, obeticholic acid.

FRI-468

Prospective, multi-center, open-label, randomized, omega-3-acid ethyl ester-controlled trial to assess the impact of the pemafibrate on liver function in hypertriglyceridemia patients with non-alcoholic fatty liver disease (Portrait study)

Yoshio Sumida[1], Masashi Yoneda[1], Kiyoaki Itoh[1], Yukiomi Nakade[1], Satoshi Kimoto[1], Kazumasa Sakamoto[1], Hidenori Toyoda[2]. *[1]Aichi Medical University, Japan; [2]Ogaki Municipal Hospital, Japan*
Email: sumida@koto.kpu-m.ac.jp

Background and aims: Hypertriglyceridemia is a frequent complication of non-alcoholic fatty liver disease (NAFLD), but its treatment has not been established. We conducted a multicenter, randomized, open-label study of pemafibrate versus omega-3 fatty acid ethyl esters (PORTRAIT study: jRCTs041200011) in patients with hypertriglyceridemia and NAFLD to compare their effects on liver function.
Methods: Patients with hypertriglyceridemia and NAFLD who provided written consent to participate in the study were randomly assigned to receive pemafibrate 0.2 mg/day or the omega-3 fatty acid ethyl esters 2 g/day for 24 weeks. The primary end point was the change in ALT from baseline to week 24, and the secondary end points were the change in liver function-related markers, lipid profiles, HbA1c, and liver fibrosis markers. This study was approved by a Certified Review Board (CRB4200004).
Results: A total of 199 patients were enrolled, among which 80 were eligible, and 39 were assigned to the pemafibrate group and 41 to the omega-3 fatty acid ethyl esters group. The mean change in ALT (U/L) at 24 weeks was −19.7 and 6.8 in the pemafibrate group and omega-3 fatty acid ethyl esters group, respectively, where the difference between the groups was significant (−26.5 U/L, 95% confidence interval −42.3 to −10.7 U/L, p = 0.001). The adjusted mean TG, non-HDL-C, γ-GTP, ALP, M2BPGi in the secondary end points were significantly lower and the adjusted mean HDL-C was significantly higher in the pemafibrate group compared with the omega-3 fatty acid ethyl esters group. There were no cases of discontinuation due to adverse drug reactions in either group with no safety concerns.
Conclusion: Pemafibrate is recommended over omega-3 fatty acid ethyl esters for lipid management and treatment of NAFLD in patients with hypertriglyceridemia and NAFLD. This study demonstrated the short-term efficacy and safety of pemafibrate. Further large-scale and long-term studies, including evaluation of liver histology, are expected in the future.

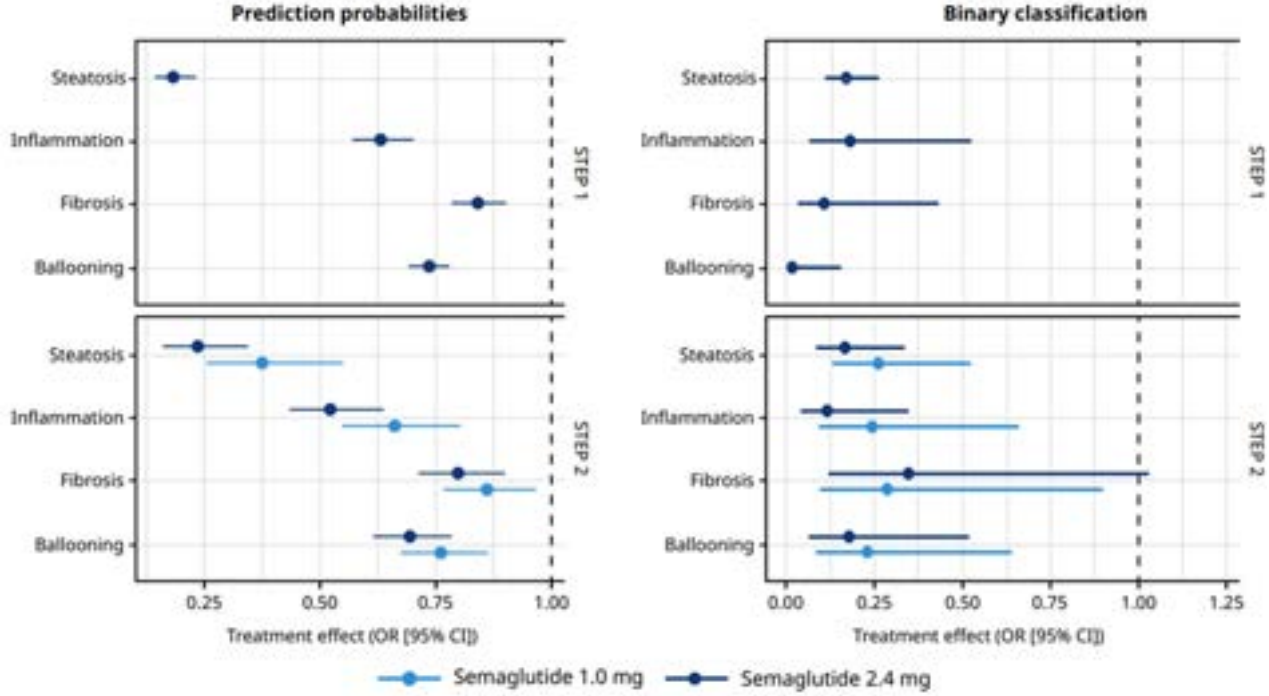
FRI-469

Prevalence of, and effect of semaglutide on, features of non-alcoholic steatohepatitis in patients with obesity with and without type 2 diabetes: analysis of data from two randomised placebo-controlled trials using SomaSignal tests

Jörn Schattenberg[1], Henning Grønbæk[2], Iris Kliers[3], Steen Ladelund[3], Michelle Long[3], Sune Boris Nygård[3], Arun Sanyal[4], Melanie Davies[5,6]. *[1]Metabolic Liver Research Program, University Medical Center Mainz, Mainz, Germany; [2]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark; [3]Novo Nordisk, Søborg, Denmark; [4]Division of Gastroenterology, Hepatology and Nutrition, Virginia Commonwealth University School of Medicine, VA, USA, United States; [5]Diabetes Research Centre, University of Leicester, Leicester, United Kingdom; [6]NIHR Leicester Biomedical Research Centre, Leicester, United Kingdom*
Email: joern.schattenberg@unimedizin-mainz.de

Background and aims: Novel, non-invasive biomarkers to grade and stage non-alcoholic fatty liver disease (NAFLD) and its progressed form, non-alcoholic steatohepatitis (NASH), are urgently needed. A targeted proteomics signature derived from patients with histologically-defined NASH has been developed collaboratively with the NASH Clinical Research Network (SomaSignal tests) to relate to the presence and severity of NASH components and changes over time. In this analysis, SomaSignal tests were applied to proteomics data

Figure: Odds ratios for presence of NASH components at the end of the study for semaglutide (s.c.) vs placebo in STEP 1 (top panels) and STEP 2 (bottom panels) based on SomaSignal prediction probabilities (left) and binary classification (right)



Prediction probabilities based on ANCOVA on log-odds scale. Binary classifier based on repeated measurement mixed logistic regression.
ANCOVA, analysis of covariance; CI, confidence interval; NASH, non-alcoholic steatohepatitis; OR, odds ratio; s.c., subcutaneous.

Figure: (abstract: FRI-469).

generated from two weight-loss trials in order to characterise the prevalence of NASH components at baseline and investigate the effect of semaglutide.
Method: STEP 1 (NCT03548935) and STEP 2 (NCT03552757) were phase 3a, randomised, placebo-controlled trials of once-weekly subcutaneous semaglutide (2.4 mg in STEP 1; 1.0 mg and 2.4 mg in STEP 2) vs placebo for weight reduction in adults with overweight/obesity without (STEP 1) or with (STEP 2) type 2 diabetes (T2D). Patients received treatment for 68 weeks. Prediction probabilities (PP) for NASH components at baseline were derived using SomaSignal models. The efficacy of semaglutide vs placebo was analysed as presence or absence of NASH components using a binary classifier derived from the PP (PP ≥0.5) at the end of the trial (EOT) and as odds ratios at EOT based on PPs directly. The SomaSignal categories included: steatosis grade 1–3 vs 0; lobular inflammation grade 2–3 vs 0–1; hepatocyte ballooning grade 1–2 vs 0; and fibrosis stage 2–4 vs 0–1. Based on the SomaSignal classifiers, patients were characterised into NAFLD stages: NAFL if steatosis was present but with no other NASH components; indeterminate if some, but not all, NASH components or fibrosis were present; and NASH if steatosis, inflammation and ballooning (with or without fibrosis) were present.
Results: Proteomics data were available for 1307/1961 and 643/1210 randomised patients in STEP 1 and 2; these patients were representative of the full study populations in each trial. At baseline, steatosis was present in 43% of patients in STEP 1, and the prevalence of the other components was 5% or less. In STEP 2, steatosis was present in 72% of patients, 15% had NASH and 12% had NASH with fibrosis. The odds of having each NASH component were significantly lower at EOT for patients who received semaglutide vs placebo, with a dose-dependency trend in STEP 2, using both PP and binary classification (Figure). Further, semaglutide was associated with significantly lower odds of having a more severe NAFLD stage after treatment vs placebo.
Conclusion: Steatosis is highly prevalent in people with overweight/obesity, with NASH likely present in 15% of patients with overweight/obesity and T2D (STEP 2). Semaglutide had a favourable effect on NASH components in the current analysis in populations with overweight/obesity, with and without T2D, as measured by SomaSignal models.

FRI-470
HPG1860 in patients with NASH: a phase II double-blind, placebo-controlled, dose-ranging study

Naim Alkhouri[1], Yongheng Liu[2], Nian Liang[2], Peibin Zhai[2], Sandra Wu[2], Xin Zhou[2], Michael Xu[2], Que Liu[2], Stephen Harrison[3].
[1]Liver Health II LLC dba Arizona Liver Health, Chandler, United States; [2]Hepagene, Shanghai, China; [3]Pinnacle Clinical Research-PLLC, Austin, United States
Email: stephenharrison87@gmail.com

Background and aims: HPG1860 is an oral non-steroidal, next generation farnesoid X receptor (FXR) agonist with selective liver distribution under investigation for treatment of non-alcoholic steatohepatitis (NASH). A phase I study of HPG1860 in healthy subjects demonstrated a benign safety profile and strong target engagement. Therefore, we aimed to evaluate safety, tolerability and efficacy of HPG1860 in patients with non-cirrhotic NASH.
Method: In this double-blind, placebo-controlled, dose ranging phase IIa RISE study (NCT05338034), patients with non-cirrhotic NASH, diagnosed by historical liver biopsy or met following criteria: liver stiffness ≥8.0 kPa and controlled attenuation parameter >300 dB/m or T2DM patients with elevated ALT and BMI ≥27 kg/m^2, were randomized in a 1:1:1:1 ratio to receive HPG1860 3 mg (n = 22), 5 mg (n = 21), 8 mg (n = 22) or placebo (n = 22) orally once daily for 12 weeks. All patients were required to have liver fat content (LFC) ≥10% at screening based on magnetic resonance imaging proton density fat fraction (MRI-PDFF). The primary end point of this study was safety and tolerability. The key secondary efficacy end point of this study was the change from baseline in relative LFC measured by MRI-PDFF at week 12.
Results: Between November 2021 and May 2022, 87 patients with either liver biopsy proven NASH or phenotypic diagnosis of NASH were enrolled and included for intent-to-treat analysis.
The most common (≥10%) adverse events were pruritus, nausea, fatigue, headache and dizziness. Treatment-related pruritus occurred in 9.1%, 9.5%, 27.3% of patients in the 3, 5, 8 mg and only 1 patient in 3 mg cohort withdrew from the study due to grade 2 pruritus. No significant change in LDL cholesterol (LDL-C) was observed in the 3 mg, 5 mg and 8 mg HPG1860 cohorts as compared to placebo. Mean LFC at baseline was 20.11%, 19.74%, 14.83% and 19.29% in placebo, 3 mg, 5 mg and 8 mg cohort, respectively. At week 12, mean relative change of LFC in placebo, 3 mg, 5 mg and 8 mg cohort was 0.68%, −20.15% ($p = 0.004$ vs placebo), −7.08% ($p = 0.965$ vs placebo), and −38.64% ($p < 0.001$ vs placebo) respectively. 25.0% patients in 3 mg cohort, and 63.2% patients in 8 mg cohort achieved ≥30% relative LFC reduction at week 12. For patients with ALT >ULN at baseline, mean ALT in placebo, 3 mg, 5 mg and 8 mg cohort was 70, 62, 62 and 72 U/L, respectively. At week 12, mean ALT percentage change from baseline in placebo, 3 mg, 5 mg and 8 mg cohort was 32.6%, −7.0%, −7.6% and −22.5% respectively, indicating dose-dependent reduction of ALT in HPG1860 treated patients.
Conclusion: HPG1860 was safe and well tolerated. LFC significantly reduced with 3 mg and 8 mg cohorts over 12 weeks in patients with NASH. HPG1860 demonstrated a differentiated pruritus and LDL-C profile, providing favorable risk-benefit data to support further clinical development by assessing histological biopsy end points in patients with NASH.

FRI-471
The effects of a structured dietetics intervention in patients with non-alcoholic fatty liver disease

Dominic Crocombe[1,2], Antonio Liguori[1,2], Mirko Zoncapè[1,2], Jennifer-Louise Clancy[1,2], Atul Goyale[1,2], Davide Roccarina[1,2], Anna Mantovani[1,2], Laura Iogna Prat[1,2], Roshni Patel[1,2], Emmanuel Tsochatzis[1,2]. *[1]Royal Free London NHS Foundation Trust, Sheila Sherlock Liver Centre, London, United Kingdom; [2]University College London, Institute of Liver and Digestive Health, London, United Kingdom*
Email: dominic.crocombe@nhs.net

Background and aims: Diet and lifestyle modification to aid weight loss remains the cornerstone of NAFLD management. Since 2014, selected patients attending a multi-disciplinary NAFLD clinic have been referred to a specialist dietitian. They either receive a single appointment (SA) with follow-up after 3 months and as required thereafter, or a comprehensive, structured package of care (POC) consisting of 4 sessions within 6 months. Our aim was to assess whether this dietetic POC is associated with more favourable outcomes.
Method: In this retrospective service evaluation, we reviewed the outcomes (changes in weight and liver stiffness) of patients in 3 groups: those who had completed ≥3/4 sessions in the dietetic POC, those who had completed a SA, and those who had not seen a specialist dietitian (controls). In the POC and SA groups, weight was recorded from the first dietetic appointment (baseline), final dietetic appointment (intervention end), and at 18 months from baseline (long term). For controls, weight at baseline, 6 months, and 18 months was recorded. Fibroscan (TE) results before and after intervention were recorded. Significant improvement in TE was considered ≥20% reduction if baseline ≥6kPa; significant worsening was considered ≥20% increase if baseline ≥5 kPa, or a change to ≥6 kPa if baseline <5 kPa.
Results: 381 patients were included: 89 POC, 49 SA, and 243 controls. Mean weight changes from baseline to intervention end were −2.9 kg (−2.8%) for POC, −1 kg (−0.9%) for SA, and −1.3 kg (−1.2%) for controls (Figure 1a). Patients who received the POC lost significantly more

weight (both kg and %) than controls (Tukey post-hoc test, p = 0.02). There was also a significant difference between POC and controls in weight change of ≥5% (X^2, p = 0.017) but not ≥7% or ≥10%. There was no significant difference in weight loss between POC and SA, or SA and controls. At multivariate logistic analysis, the POC was associated with ≥5% weight loss (OR 2.15, p < 0.01) independent of time interval, age, sex, and metabolic comorbidities. At long term (mean 18 months) follow-up, all groups achieved further weight loss (−3.4% SOC, −2.3% SA, −2.3% controls, Figure 1b) but there was no longer a significant difference in weight change from baseline between groups. Regarding liver stiffness, the mean interval between Fibroscans was 24 months. Overall, 28.1% patients had a significant improvement and 22.7% had a significant worsening. There was no significant difference in changes of TE between groups. Overall, ≥5% weight loss after 6 or 18 months was associated with a significant improvement in TE (X^2, p < 0.01).

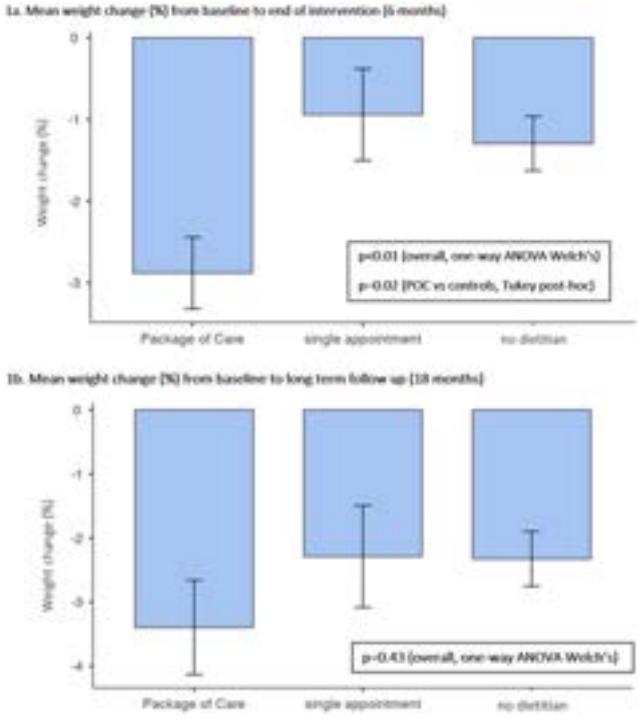


Figure:

Conclusion: A structured dietetics POC consisting of 3 or 4 sessions over 6 months was associated with greater rate of ≥5% weight loss than controls, and the effect was maintained beyond the end of the intervention. ≥5% weight loss after 6 or 18 months was associated with significant improvement in liver stiffness.

FRI-472

Resmetirom improves the lipid/lipoprotein profile in patients with non-alcoholic fatty liver disease

Naim Alkhouri[1], Rebecca Taub[2], Guy Neff[3], Kathryn Jean Lucas[4], Dominic Labriola[2], Sam Moussa[5], Mustafa Bashir[6], Stephen Harrison[7,8]. *[1]Arizona Liver Health, Tucson, United States; [2]Madrigal Pharmaceuticals, Conshohocken, United States; [3]Covenant Metabolic Specialists, Sarasota, United States; [4]Lucas Research, Morehead City, United States; [5]University of Arizona for Medical Sciences, Tucson, United States; [6]Duke University Medical Center, Durham, United States; [7]University of Oxford, Oxford, United Kingdom; [8]Pinnacle Clinical Research, San Antonio, United States*
Email: nalkhouri@azliver.com

Background and aims: Patients with non-alcoholic fatty liver disease (NAFLD)/non-alcoholic steatohepatitis (NASH) have an increased risk of cardiovascular disease (CVD). Resmetirom is an oral liver-targeted thyroid hormone receptor-beta selective agonist in clinical development for treatment of NASH. In addition to significantly reducing hepatic fat, data from Phase 2/3 clinical trials have consistently demonstrated that resmetirom significantly reduces low-density lipoprotein cholesterol (LDL-C), apolipoprotein B (apoB), and triglyceride (TG) levels in patients with NAFLD/NASH. Here we report data from the Phase 3 MAESTRO-NAFLD-1 trial on the effect of resmetirom treatment on additional components of the lipid/lipoprotein profile.
Method: MAESTRO-NAFLD-1 (NCT04197479) was a Phase 3 trial to evaluate the safety and tolerability of resmetirom over 52 weeks of treatment in adults with NAFLD (presumed NASH) diagnosed via non-invasive tests. Patients were randomized 1:1:1:1 to 3 double-blind arms (resmetirom 100 mg, resmetirom 80 mg, or placebo administered once daily) or an open-label arm (resmetirom 100 mg administered once daily). Lipid, lipoprotein, and lipid particle levels were measured at baseline, Week 24, and Week 48.
Results: At Week 24, remnant-like particle cholesterol (RLP-C), very low-density lipoprotein cholesterol (VLDL-C), and VLDL and chylomicron TG levels were significantly reduced from baseline in all resmetirom groups compared with placebo (p < 0.05 vs placebo for all); these significant reductions were maintained at Week 48 (TABLE). In addition, lipoprotein (a) (Lp (a)) and apolipoprotein CIII (apoCIII) levels were significantly reduced from baseline with

TABLE. Percent change from baseline in lipid, lipoprotein, and lipid particle levels at Week 48.

Figure: (abstract: FRI-472).

resmetirom 100 mg and 80 mg versus placebo at Week 24 ($p < 0.0001$ vs placebo for all); the significant reductions in lipoproteins were maintained at Week 48 with continued resmetirom treatment. Atherogenic lipoprotein particles, including LDL, small LDL, and VLDL and chylomicron, were also significantly reduced from baseline in the resmetirom groups compared with placebo at Week 24 ($p < 0.05$ vs placebo for all) with these significant reductions maintained at Week 48.

Conclusion: In addition to significantly reducing hepatic fat, resmetirom significantly improved the overall lipid/lipoprotein profile in adults with NAFLD/NASH. Both resmetirom 100 mg and 80 mg significantly reduced atherogenic lipids/lipoproteins, including RLP-C, VLDL-C, Lp (a), and apoCIII, at Week 24. Furthermore, improvements in the lipid/lipoprotein profile were maintained throughout the entire treatment period of MAESTRO-NAFLD-1. As CVD is the most common cause of mortality in patients with NASH, the effect of potential therapies on cardiovascular risk factors, including elevated atherogenic lipids/lipoproteins, is important to consider.

Different class effects of oral hypoglycemic agents on non-alcoholic fatty liver disease regression and clinical outcomes: a nationwide cohort study

Heejoon Jang[1], Yeonjin Kim[2], Donghyeon Lee[1], Sae Kyung Joo[1], Bo Kyung Koo[1], Yong Jin Jung[1], Woojoo Lee[2], Won Kim[1]. [1]*Seoul Metropolitan Government Seoul National University Boramae Medical Center, Internal Medicine, Seoul, Korea, Rep. of South;* [2]*Graduate School of Public Health, Seoul National University, Public Health Sciences, Seoul, Korea, Rep. of South*
Email: wonshiri@yahoo.com

Background and aims: Sodium-glucose cotransporter 2 (SGLT2) inhibitors, thiazolidinediones, and dipeptidyl peptidase-4 (DPP-4) inhibitors are known to improve non-alcoholic fatty liver disease (NAFLD). We aimed to determine which drug is most effective for NAFLD in patients with type 2 diabetes mellitus (T2DM) in real-world settings.

Method: Based on the National Health Information Database covering over 50 million South Koreans, patients with NAFLD and T2DM who use SGLT2 inhibitors, thiazolidinediones, DPP-4 inhibitors, or sulfonylureas in combination with metformin for more than 80% of 90 consecutive days were included. Inverse probability of treatment weighting was used to adjust differences in baseline characteristics between the groups. NAFLD regression assessed by the fatty liver index was the primary outcome. Severe NAFLD was the secondary outcome, defined as a composite of liver-related hospitalization, liver-related mortality, or hepatocellular carcinoma (HCC). All-cause mortality and liver transplantation were considered competing risks.

Results: A total of 103,228 patients were followed for a median of 878 days, and 4,960 patients experienced NAFLD regression. Compared with sulfonylureas, SGLT2 inhibitors (adjusted subdistribution hazard ratio [aSHR] 2.15, 1.88–2.47), thiazolidinediones (aSHR 1.74, 1.47–2.06), and DPP-4 inhibitors (aSHR 1.58, 1.45–1.72) were associated with higher NAFLD regression. SGLT2 inhibitors were significantly associated with higher NAFLD regression than either thiazolidinediones (aSHR 1.38, 1.12–1.71) or DPP-4 inhibitors (aSHR 1.38, 1.24–1.54), whereas thiazolidinediones did not show a significant difference from DPP-4 inhibitors (aSHR 1.11, 0.95–1.29). SGLT2 inhibitors were not significantly associated with a lower incidence of severe NAFLD compared to thiazolidinediones (aSHR 1.06, 0.39–2.88) or DPP-4 inhibitors (aSHR 0.85, 0.40–1.79).

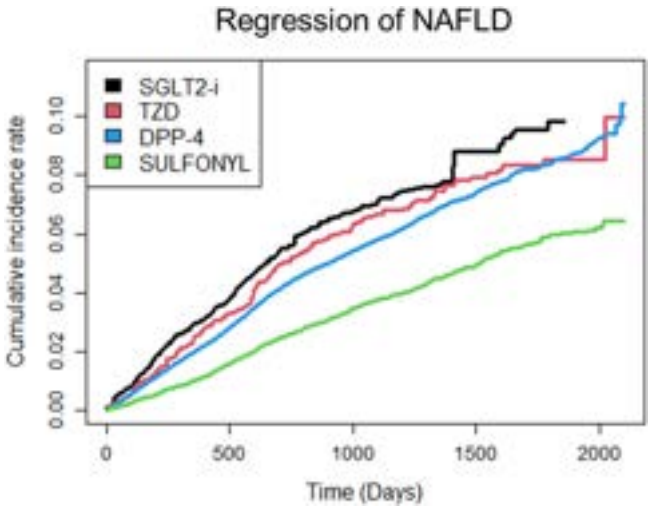

Figure:

Conclusion: NAFLD patients with T2DM may be preferred to use SGLT2 inhibitors as an oral hypoglycemic agent in terms of regression of NAFLD.

FRI-474

SGLT2 inhibitors improve hepatic fibrosis assessed by Fibroscan in NAFLD patients with type 2 diabetes: a five-year follow-up study

Rosa Lombardi[1,2], Alessandro Mantovani[3], Annalisa Cespiati[1,2], Gabriele Maffi[2], Elena Del Zanna[2], Paolo Francione[2], Felice Cinque[2], Rosanna Villani[4], Nicola Passigato[3], Emanuela Orsi[5], Valeria Grancini[5], Giuseppina Pisano[1], Claudio Maffeis[6], Daniela Bignamini[1], Gaetano Serviddio[4], Giovanni Targher[3], Silvia Fargion[2], Anna Ludovica Fracanzani[1,2]. Email: rosalombardi@hotmail.it

Background and aims: Subjects with non-alcoholic fatty liver disease (NAFLD) and type 2 diabetes mellitus (T2DM) present high progression of liver disease to fibrosis, which is the main determinant of long-term adverse outcomes. Data are accumulating on the benefits of sodium glucose cotransporter 2 inhibitors (SGLT-2i) on hepatic fibrosis mainly in pharmacologic or retrospective studies. to prospectively evaluate change in metabolic alterations and hepatic disease in patients with NAFLD and T2DM and predisposing factors.

Method: 237 patients with NAFLD (mean age 67 ± 9 years, 54% male) were enrolled at the diabetology outpatient clinics and re-evaluated after 5 years. Information about diabetic control, metabolic comorbidities and medications were collected at baseline and follow-up. Additionally, NAFLD was assessed by liver ultrasonography, whereas LSM was detected by Fibroscan® at baseline and after 5 years.

Results: During follow-up no change in the prevalence of metabolic alterations except for hypertension (81% vs 73%, $p < 0.001$) was observed, whereas an increase in LSM values (6.0 ± 2.8 vs 5.8 ± 2.7 kPa, $p = 0.02$) was registered, despite stability of diabetic control. In particular, LSM worsened in 133 (56%) subjects, with 92 (39%) having a worsening of >10% from baseline and 20 (8%) of at least 1 fibrosis stage at Fibroscan from baseline. Moreover, a higher

prescription of SGLT2i was seen (21% vs 6%, p < 0.001). Compared with those with no worsening of LSM, patients with worsening of LSM had a higher prevalence of increase in BMI during follow-up (45% vs 32%, p = 0.06). In multivariate analysis, after adjustment for age, sex, liver enzymes and HbA1c, the use of SGLT2-inhibitors at follow-up (adjusted-hazard ratio 0.34, 95% CI 0.13–0.91) was associated with a reduced risk of worsening of LSM by Fibroscan, even if considered>10% from baseline. However, this association was markedly attenuated after further adjusting for change in BMI over time.

Conclusion: Despite a high prevalence of fibrosis progression in NAFLD subjects with T2DM, we showed a potential effect of SGLT2-inhibitors in reducing the risk of worsening of liver stiffness, possibly also mediated by weight loss. Therefore, our data suggest that using this category of antidiabetic drug in NAFLD patients may prevent progression of fibrosis, especially if weight control is obtained in these patients.

Semaglutide improves non-alcoholic steatohepatitis: a 10-year retrospective study

Parth Shah[1], Megan White[1], Alex Sievert[2], Alexander Conway[3], Adam Kneepkens[2], Gregory Sayuk[1,4], Mauricio Lisker-Melman[1,4], Jill Elwing[1,4]. *[1]Washington University School of Medicine Department of Gastroenterology, St. Louis, United States; [2]Washington University School of Medicine, Internal Medicine, St. Louis, United States; [3]Washington University School of Medicine, St. Louis, United States; [4]St. Louis VA Medical Center-John Cochran Division, St. Louis, United States*

Email: parth@wustl.edu

Background and aims: The glucagon-like peptide-1 receptor agonist semaglutide (SEMA) has been studied in patients with non-alcoholic steatohepatitis (NASH) due to the potential benefit from weight loss on liver inflammation. Preclinical studies suggest that the NASH improvement may be independent of weight loss. We aim to assess the impact of SEMA on objective NASH measures independent of weight loss.

Method: This retrospective study evaluated 1236 patients with type II diabetes and included 420 patients that were on SEMA for at least 12 months between 2011 and 2022. Exclusion criteria were chronic liver disease other than NASH, decompensated cirrhosis, any malignancy, and bariatric surgery. Primary end points were clinically significant improvements in AST or ALT (defined as mean difference >6.3 U/L and >10.6 U/L respectively based on Ng et al. *Hepatology* 2022). Statistical analysis included Student's t-test/ANOVA, Wilcoxon signed-rank test/Friedman test as appropriate, and binary logistic regression.

Results: Within 420 patients (median 71 years old, 94% male, 79% Caucasian), the median duration of SEMA was 22.5 months and 80% received 1 mg/week. Ninety-nine percent of patients had diabetes and 87% had a body mass index (BMI) ≥30. BMI improved by a mean (SD) of 1.9 points (2.8), weight by 13.3 pounds (19.1), AST by 4.1 U/L (11.5), and ALT by 5.3 U/L (14.2). In 28% and 22% of patients, AST and ALT respectively, had a clinically significant improvement. The NASH scores (NFS, FIB4, and APRI), improved after SEMA (p <0.001). No statistically significant differences in AST or ALT improvement were found when patients were stratified by BMI prior to SEMA (BMI <25; ≥25 to <30; ≥30 to <35; ≥35 to <40; ≥40). No statistically significant differences were found in AST or ALT improvement when stratified by percentage of weight loss after SEMA (no weight loss; 0–5%; 5–10%; >10%). On logistic regression analysis (Table 1), duration of SEMA and pre-SEMA APRI score increased odds of clinically significant improvements of AST and ALT.

Figure: Table 1. Logistic regression analysis on SEMA with clinically significant improvement.

	Clinically significant AST improvement		Clinically significant ALT improvement	
	Univariate	Multivariate	Univariate	Multivariate
Months of treatment	OR 1.03 p = 0.002*	OR 1.06 p < 0.001*	OR 1.02 p = 0.08	OR 1.03 p = 0.02*
Compensated cirrhosis	OR 2.7 p = 0.03*	OR 1.2 p = 0.75	OR 3.9 p = 0.003*	OR 2.2 p = 0.14
APRI score 0.5 to 1.5 prior to treatment	OR 4.3 p < 0.001*	OR 4.4 p < 0.001*	OR 5.3 p < 0.001*	OR 4.8 p < 0.001*
Change in BMI after treatment	OR 0.95 p = 0.16	–	OR 0.92 p = 0.05	–
Weight loss after treatment	OR 0.99 p = 0.23	–	OR 0.99 p = 0.08	–

OR = odds ratio.
*statistically significant p < 0.05.

Conclusion: SEMA treatment was associated with beneficial effects on biochemical NASH measures, including transaminases and NASH scores in a diabetic population. Higher odds of positive SEMA effects were observed with longer treatment duration and were independent of weight loss.

FRI-476

Resmetirom helps regulate thyroid hormone levels within the liver in patients with non-alcoholic fatty liver disease

Stephen Harrison[1,2], Rebecca Taub[3], Guy Neff[4], Mustafa Bashir[5], Dominic Labriola[3], Sam Moussa[6], Naim Alkhouri[7], Kathryn Jean Lucas[8]. *[1]University of Oxford, Oxford, United Kingdom; [2]Pinnacle Clinical Research, San Antonio, United States; [3]Madrigal Pharmaceuticals, Conshohocken, United States; [4]Covenant Metabolic Specialists, Sarasota, United States; [5]Duke University Medical Center, Durham, United States; [6]University of Arizona for Medical Sciences, Tucson, United States; [7]Arizona Liver Health, Tucson, United States; [8]Lucas Research, Morehead City, United States*

Email: stephenharrison87@gmail.com

Background and aims: Thyroid hormone receptor (THR)-beta is responsible for regulating critical metabolic pathways in the liver. In patients with non-alcoholic fatty liver disease (NAFLD)/non-alcoholic steatohepatitis (NASH), THR-beta signaling within the liver is diminished. The lipotoxicity that occurs in NASH induces intrahepatic hypothyroidism resulting in reduced conversion of prohormone T4 to active hormone T3 (in favor of increased conversion of T4 to the inactive metabolite reverse T3 [RT3]). Exogenous thyroxine treatment does not improve intrahepatic hypothyroidism in patients with NAFLD/NASH. Resmetirom, an oral liver-targeted THR-beta selective agonist in clinical development for treatment of NASH, aims to address this underlying pathophysiology in NAFLD/NASH. Here we report data from the Phase 3 MAESTRO-NAFLD-1 trial on the effect of 52 weeks of resmetirom treatment on thyroid hormone levels.

Method: MAESTRO-NAFLD-1 (NCT04197479) was a Phase 3 trial to evaluate the safety of resmetirom treatment over 52 weeks in adults with NAFLD (presumed NASH) who were diagnosed using non-invasive tests. Patients were randomized 1:1:1:1 to 3 double-blind arms (resmetirom 100 mg, resmetirom 80 mg, or placebo administered once daily) or an open-label arm (resmetirom 100 mg administered once daily). Thyroid hormone levels (thyroid-stimulating hormone [TSH], free T3 [FT3], free T4 [FT4], and RT3) were evaluated at baseline and Week 52 in the overall trial population, thyroxine-treated population, and euthyroid population.

TABLE. Change from baseline in thyroid hormone levels at Week 52.	Resmetirom 100mg OL	Resmetirom 100mg DB	Resmetirom 80mg DB	Placebo DB

[a] $p < 0.0001$ vs placebo; [b] $p < 0.001$ vs placebo; [c] $p < 0.05$ vs placebo.
CFB, change from baseline; DB, double-blind; FT3, free T3; FT4, free T4; LSM, least squares mean; OL, open-label; RT3, reverse T3; SD, standard deviation; SE, standard error; TSH, thyroid-stimulating hormone.

Table: (abstract: FRI-476)

Results: At baseline, patients on thyroxine treatment had elevated RT3 levels relative to euthyroid patients (TABLE). At Week 52, no significant change from baseline was noted in TSH or FT3 levels in the overall population of any resmetirom group compared with placebo. In contrast, RT3 and FT4 levels were significantly reduced from baseline at Week 52 in the resmetirom groups when compared with placebo in the overall population ($p < 0.0001$ vs placebo). The FT3/RT3 ratio was also significantly improved in all resmetirom groups at Week 52 compared with placebo ($p < 0.0001$ vs placebo). Similar effects as reported for TSH, FT3, RT3, and FT4 in the overall population were observed with resmetirom treatment in the thyroxine-treated and euthyroid populations.

Conclusion: Resmetirom treatment significantly reduced RT3 and FT4 levels from baseline relative to placebo treatment at Week 52 in the overall population as well as among the thyroxine-treated and euthyroid populations of MAESTRO-NAFLD-1. These results are consistent with increased conversion of T4 to T3 and decreased conversion of T4 to RT3 in the resmetirom groups. Overall, these data indicate resmetirom treatment restores thyroid hormone signaling within the liver in patients with NAFLD/NASH.

FRI-505

CVI-301, a potent and selective thyroid hormone receptor beta full agonist, demonstrates profound total cholesterol and LDL-cholesterol reductions in a hyperlipidemic mouse efficacy model

Jingwen Liu[1,2], Zhenyu Wang[1], Gang Liu[3]. *[1]CVI Pharmaceuticals Shanghai Limited, Shanghai, China; [2]CVI Pharmaceuticals US, Inc, Mountain View, United States; [3]Shanghai Haoyuan Chemexpress Co., Ltd., China*
Email: jingwen.liu@cvishanghai.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is a severe form of non-alcoholic fatty liver disease and a leading cause of liver related mortality. While there are no FDA-approved treatments for NASH, selective thyroid hormone receptor beta (THR-β) agonism is emerging as a promising therapy for NASH. Selective THR-β agonist, Resmetirom (MGL-3196), has shown strong efficacy in improving hepatic lipid metabolism without THR-α mediated cardiac side effects in NASH patients. Applying a new screening method that combines computer assisted THR-β docking modeling and LDL receptor promoter reporter assay with rational new chemical synthesis, we have discovered a series of novel compounds including CVI-301 that are able to activate hepatic THR-β in single-digit nmol concentrations. Here we investigated the potency and selectivity of

CVI-301 in biochemical assays and assessed its *in vivo* efficacy in a hyperlipidemic mouse efficacy model.
Method: Potency and selectivity of CVI-301 in activation of THR were determined by cell based nuclear receptor protein-protein interaction assays using full-length human THR-β or THR-α with Triiodothyonine (T3) and MGL-3196 as reference compounds. Mice fed a diet containing high fat and high cholesterol for 4 weeks received vehicle (n = 9), MGL-3196 (5 mg/kg, n = 8) or CVI-301 (1 mg/kg, n = 8) for 14 days by intraperitoneal injection once a day. Serum total cholesterol (TC) and LDL-cholesterol (LDL-C) were measured at baseline and Day 15. Terminal liver and heart samples were collected for gene expression analysis by quantitative RT-PCR.
Results: CVI-301 activates THR-β with 100% T3 maximal activity at 4.5 nM EC_{50} and 20.1-fold β-selectivity, which is more potent and β-selective than MGL-3196 (THR-β EC_{50} = 4071 nM; β-selectivity = 3.2). In hyperlipidemic mice after two-week treatment, TC and LDL-C were significantly reduced to 56.9% and 49% of vehicle control ($p < 0.0001$), respectively by CVI-301 at 1 mg/kg dose, that were comparable to effects of 5 mg/kg MGL-3196 which lowered TC and LDL-C to 57.3% and 46% of vehicle control, respectively. Hepatic mRNA levels of THR-β direct target genes malic enzyme 1 (Me1) and deiodinase 1 (Dio1) were increased to 7.8-fold ($p < 0.0001$) and 3.3-fold ($p < 0.0001$) of vehicle control by CVI-301 treatment and to 5.1-fold ($p < 0.05$) and 2.7-fold ($p < 0.0001$) of vehicle control by MGL-3196 treatment. Furthermore, mRNA levels of THR-α regulated genes Myh6, Atp2a2 and Me1 in heart tissues remained unchanged in animals treated with CVI-301 or MGL-3196.
Conclusion: CVI-301 is a potent and highly selective THR-β full agonist *in vitro* and *in vivo*. These preclinical data warrant further investigation of CVI-301 as a potential treatment for NASH.

FRI-506
Effects of a novel tetra-specific drug (OGB21502) in the obese mice model of liver disease
Jihye Kim[1], Nakho Chang[1], Yunki Kim[1], Jaehyun Lee[1], Minsun Kim[1], Junyeob Lee[1], Jeonghwa Lee[1], DaeSeong Im[1], Sungjin Park[1]. [1]*Onegene biotechnology, Korea, Rep. of South*
Email: sungjin.park@onegene.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is a complex disease resulting from chronic liver injury associated with obesity and type 2 diabetes. In this study, we hypothesized that simultaneous regulation of multiple mechanisms within the NASH microenvironment could provide a holistic cure for the disease. OGB21502 is a novel tetra-specific drug developed using the multi-specific UniStac® platform, which targets GLP-1 (glucagon-like peptide 1), GCG (glucagon), FGF21 (fibroblast growth factor 21), and IL-1RA (interleukin-1 receptor antagonist) receptors. The aim of this study is to evaluate the metabolic and histopathological effects of OGB21502 in the GAN (Gubra-Amylin NASH) diet-induced obese (DIO) mouse model.
Method: Male C57BL/6 mice were divided into two groups and subjected to a normal diet or a GAN diet, high in saturated fat (40%), fructose (22%), and cholesterol (2%) for 38 weeks. In the remaining 8 weeks, the mice were administered either OGB21502 or reference drugs (Fc-FGF21, obeticholic acid and semaglutide). The mice were sacrificed, followed by determination of blood ALT, cholesterol, and liver weight.
Results: In GAN-DIO mice, OGB21502 treatment resulted in reduction in liver weight, ALT and cholesterol levels compared to reference drugs. Histological analysis further demonstrated a significant improvement in hepatic inflammation and steatosis as indicated by reduced NAFLD activity score (NAS). Notably, OGB21502 led to a remarkable improvement in levels of fasting blood glucose, insulin, and HOMA-IR.
Conclusion: OGB21502 treatment improved glucose level, insulin resistance, liver damage, as well as cholesterol accumulation in the GAN-DIO mice. OGB21502 treatment might also be effective in controlling glucose metabolism by targeting liver, compared to reference therapeutics. The results suggest that OGB21502 may be a promising multi-specific therapeutic option for the treatment of NASH.

Email: laurent.castera@bjn.aphp.fr

Background and aims: There is an unmet need to evaluate non-invasive biomarkers for monitoring and predicting change in fibrosis

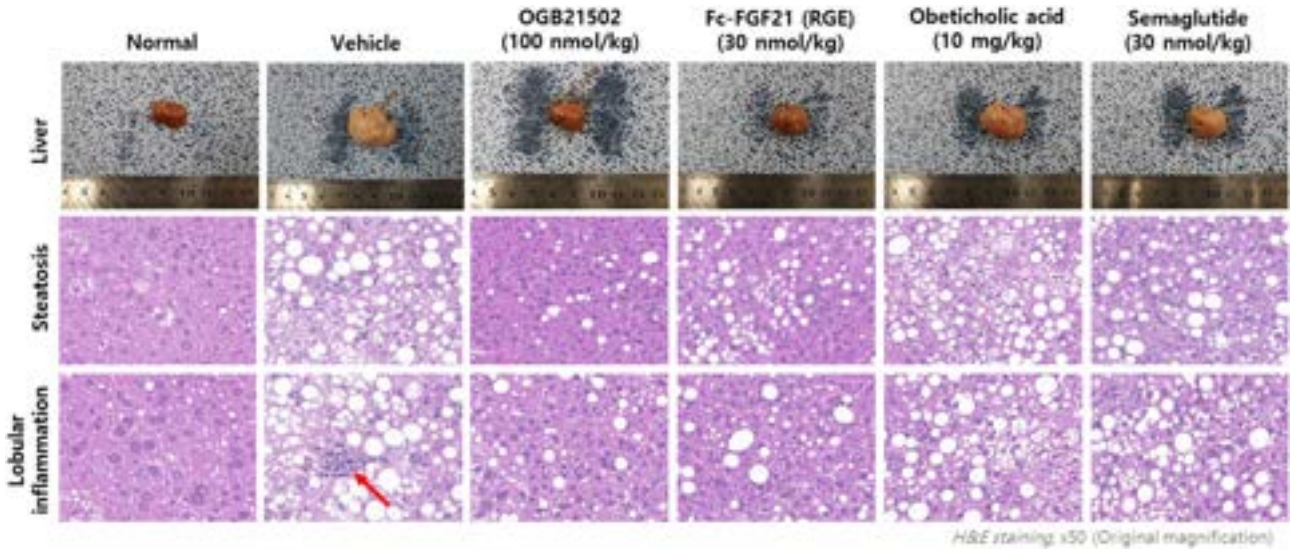

Figure: (abstract: FRI-506).

in patients with non-alcoholic steatohepatitis (NASH) who are receiving treatment. Several biomarkers have been validated for grading and staging in NASH, including the Agile 3+ score, which can identify advanced fibrosis in non-alcoholic fatty liver disease. Agile 3+ was applied to patients enrolled in a clinical trial of semaglutide to investigate the score's ability to monitor treatment effect and to predict change in fibrosis stage.

Method: Data were from a phase 2b study in which patients with NASH and fibrosis stage 1–3 were randomised to 72 weeks' treatment with subcutaneous semaglutide 0.1, 0.2 or 0.4 mg, or placebo, once daily (NCT02970942). For this analysis, Agile 3+ scores were calculated at baseline and weeks 28, 52 and 72 using liver stiffness measurements (LSM) from vibration-controlled transient elastography (VCTE) (where available), alanine- and aspartate aminotransferase levels, platelet count, age, sex and diabetes status. A mixed model for repeated measures was used to assess treatment effect on Agile 3+ (missing values were not imputed) during the on-treatment period. Change from baseline in Agile 3+ at weeks 28, 52 and 72 and its association with histological fibrosis improvement at week 72 in the 0.4 mg semaglutide and placebo arms was examined using logistic regression with an interaction effect between relative change in Agile 3+ and treatment. Odds ratios (OR) for improvement in fibrosis of ≥1 stage at week 72 associated with a 0.5-fold change in Agile 3+ at each time point were calculated.

Results: The numbers of patients with Agile 3+ data at baseline and weeks 28, 52 and 72 were 208, 210, 209 and 203, respectively. Mean baseline Agile 3+ (standard deviation) was 0.50 (0.28), 0.61 (0.27) and 0.55 (0.30) for semaglutide 0.1, 0.2 and 0.4 mg, respectively, and 0.46 (0.30) for placebo. Agile 3+ was significantly reduced with semaglutide 0.4 mg vs placebo at weeks 28 (estimated treatment ratio 0.64 [95% confidence interval (CI) 0.48; 0.87]; p = 0.004), 52 (0.63 [0.48; 0.83]; p = 0.001) and 72 (0.59 [0.41; 0.85]; p = 0.005) (Figure). In the placebo group, associations between a decrease in Agile 3+ at weeks 28 and 52 and improvement in fibrosis at week 72 were significant (OR [95% CI] 4.10 [1.50; 11.19]; p = 0.006 and 3.71 [1.28; 10.75]; p = 0.016, respectively). A similar trend was seen in the semaglutide 0.4 mg group, but this did not reach significance. For changes in Agile 3+ at week 72, the trend did not reach significance for either the placebo or semaglutide groups. Although this analysis is limited by the number of study participants, the results indicate that changes in Agile 3+ as early as week 28 may be predictive of histological changes at week 72.

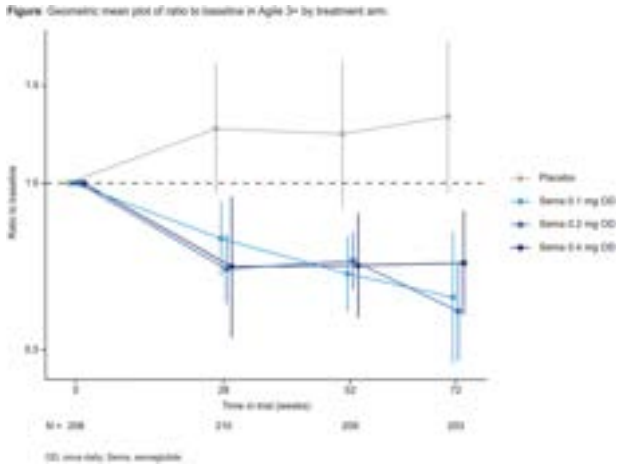

Figure:

Conclusion: Semaglutide demonstrated a significant treatment effect on Agile 3+, with change in Agile 3+ partially predicting histological outcomes, irrespective of treatment allocation. A decrease in Agile 3+ was associated with an improvement in histological fibrosis.

Background and aims: This study aimed to clarify the efficacy and safety of oral semaglutide in patients with non-alcoholic fatty liver disease (NAFLD) complicated by type 2 diabetes mellitus (T2DM).

Method: Eighty-seven patients with NAFLD who received oral semaglutide for T2DM were included in the analysis. Oral semaglutide was initiated at a dose of 3 mg once daily, and the dose was sequentially increased to 7 mg at 4 weeks and 14 mg at 8 weeks, all the while monitoring for any adverse events. Of the 87 patients, 51 could be verified at 24 weeks of treatment.

Results: Significant decreases in body weight, BMI, liver-related biochemistry (AST, ALT, and γ-GTP), plasma glucose, and HbA1c were found at 12 weeks, compared to the baseline values. These significant reductions were maintained at 24 weeks. As for changes in fasting lipids, LDL-cholesterol (112 mg/dL to 102 mg/dL, $p < 0.01$) and triglyceride (156 mg/dL to 119 mg/dL, $p < 0.01$) levels significantly decreased at 24 weeks. The median CAP values significantly decreased from 322 dB/m at baseline to 300 dB/m at week 24 ($p < 0.05$). Changes in body weight were correlated with those in CAP ($r = 0.57$, $p < 0.01$). In terms of changes in liver fibrosis markers, the platelet counts significantly increased from baseline to 24 weeks (232 × 103/μL to 242 × 103/μL, $p < 0.01$), while the FIB-4 index (1.22 to 1.00, $p < 0.001$) and type IV; collagen 7 s (4.1 ng/ml to 3.5 ng/ml, $p < 0.001$) significantly decreased. LSM values showed no significant changes from baseline to 24 weeks of the treatment. The 23 patients who switched from DPP-4 inhibitors also showed favorable effects in weight reduction, glycemic control, and liver transaminases. No grade 3 or higher adverse events were observed during the observation period. Grade 1–2 adverse events were mostly gastrointestinal disorders including nausea. Two patients were discontinued due to semaglutide-related adverse events, both due to nausea.

Conclusion: In patients with NAFLD complicated by T2DM, oral semaglutide may improve hepatic steatosis/inflammation and serum lipid metabolism as well as improve glucose metabolism and decrease body weight.

FRI-509

Lessons for the setting of an international integrated research platform to conduct adaptive trials in non-alcoholic steatohepatitis: results of the EU-PEARL project

Juan M Pericàs[1,2,3,4], Elena de Sena[1], Frank Tacke[5], Quentin Anstee[6], Nicholas Di Prospero[7], Mette Kjaer[8], Peter Mesenbrink[9], Franz Koenig[10], Joan Genescà[1,2,4], Vlad Ratziu[11], Sergio Muñoz Martínez[1]. Email: juanmanuel.pericas@vallhebron.cat

Background and aims: Traditional designs, methodological and operational features of clinical trials in non-alcoholic steatohepatitis (NASH) have several shortcomings and no drugs have been approved for almost two decades. The EU Patient-cEntric clinicAl tRial pLatforms (EU-PEARL) project (IMI2-853966) aims at developing the necessary tools to deploy integrated research platforms (IRP) to conduct adaptive-design trials in various diseases, including NASH. IRP consist of trial master protocols (MP) and supporting research resources (e.g., clinical and data networks, labs, governance, and legal and regulatory aspects) that represent a unique opportunity to accelerate drug development while lowering overall costs and creating a more patient-centric environment. Here, we describe the lessons from EU-PEARL regarding how the current NASH pipeline, stakeholders, operational and funding barriers and opportunities are at play in the setting of a European-based or global NASH platform trial in the years to come.

Method: Through interactions with regulatory agencies, academics, experts on methodology, patients and their representatives, and pharmaceutical industry and biotechs, we have designed a NASH Phase IIb/III MP for non-cirrhotic patients. Amongst other elements, simulations were conducted to assess whether a Bayesian approach is suitable and cost-efficient for a NASH IRP rather than a more traditional frequentist approach. We held meetings with the US Food and Drug administration (FDA) and European Medicines Agency (EMA), and two external advisory boards with key opinion leaders (KOLs) in the field of NASH from both academia and industry. The specific features of participating sites and clinical research organizations and labs was discussed and agreed upon. Moreover, a reach-out survey was conducted to ask NASH investigators about their knowledge on MP and their interest in joining a future NASH IRP.

Results: Building and operationalizing an IRP comes with different challenges and possibilities (Pericàs et al, J Hepatol 2022). Consulted KOLs in the NASH field as well as patients and regulators agree that MP are a promising tool to enhance drug development in a more patient-centric manner. Simulations suggested that for a Bayesian approach to prove superior to a frequentist approach the scope of the IRP would need a global clinical network and moderate-high recruiting rates (Laurin-Meyer et al, PLoS One 2023). However, due to the current situation of the NASH pipeline, it is unlikely that the first platform trial in NASH is funded by the industry in the short term, whereas an international IRP has largely demanding requirements in terms of operationalization and costs. The most likely sponsor institution for the NASH IRP is a large academic hospital, with potential support from non-profit organizations. Compared to other therapeutic areas, the involvement of the patient community in the design of clinical trials in NASH is low in Europe.

Conclusion: "Proof-of-platform" for NASH should be provided before escalating the scope of the IRP and therefore the most likely scenario is the set-up of a few countries platform first, mostly based on non-invasive end points, and public or mixed funding in order to validate the operational, statistical and regulatory tools developed within EU-PEARL before fully deploying a global NASH IRP.

FRI-510

The influence of probiotics on biologic and imagistic alterations in non-alcoholic steato-hepatitis

Elena Laura Iliescu[1,2], Adriana Mercan-Stanciu[1], Letitia Toma[1,2], Mircea Istrate[1,2], Razvan Rababoc[1,2], Radu Dumitru[2], Cristian Mugur Grasu[2]. [1]*Fundeni Clinical Institute, Internal Medicine, Bucharest, Romania;* [2]*"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania*
Email: laura_ate@yahoo.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver disease, with rising prevalence. By perpetuating a systemic inflammation, NAFLD is an independent cardiovascular risk factor. Furthermore, modulation of gut microbiota appears to have systemic anti-inflammatory effects than can prove beneficial in NAFLD. This study aims to determine the impact of a combination of probiotics (Bifidobacterium longum BB536®) fructooligozaccharides (Actilight) and B complex vitamins on steato-hepatitis (SH), gut inflammation and liver steatosis.

Method: We performed a prospective trial which included 148 consecutive patients with newly diagnosed SH, evaluated in our clinic between January 2021- September 2022. Patients with other causes of liver disease, uncontrolled diabetes or active infection were excluded. All patients received study medication as per the producer's recommendations (1 dose daily) for three months and were advised accordingly for life-style changes. Patients were monitored before and after therapy by serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma- glutamyl transpeptidase (GGT), fecal calprotectin, Fibroscan (for fibrosis) and controlled attenuation parameter (CAP) (for steatosis). In diabetic patients we also evaluated basal glycemia and glycosylated hemoglobin levels (HbA1c).

Results: The study included 95 non-diabetic and 53 diabetic patients. The mean age in the study group was 45.36 ± 14.28 years, with 58.1% female. Before treatment patients presented high levels of ALT and AST, with normal or mildly increased GGT. 28 patients (18.9%) had normal values of serum calprotectin. After therapy, we noticed a significant decrease in AST, ALT, fecal calprotectin levels, mean liver stiffness and CAP values (Table 1). In diabetic patients, we noted a decrease in glycemia (92.5 mg/dL versus 113 mg/dl, p = 0.03) and in HbA1c (5.7% versus 6.2%, p = 0.09). Regression of liver fibrosis was observed by the changes in distribution: F1: 28 versus 45 patients, F2: 71 versus 95 patients, F3: 49 versus 8 patients. For steatosis the distribution changes were: S1: 31 versus 67 patients, S2: 86 versus 81 patients. S3: 31 patients versus none.

Figure: Table Evolution of biologic and imagistic parameters

	Before therapy	After therapy	p value
ALT (U/L)	75.24 ± 24.13	36.29 ± 10.24	<0.01
AST (U/L)	62.57 ± 31.72	29.13 ± 15.81	<0.01
GGT (U/L)	46.23 ± 19.18	38.12 ± 11.08	=0.8
Fecal calprotectin (μg/mg)	129.35 ± 83.61	58.91 ± 24.17	=0.02
Liver stiffness (KPa)	7.33 ± 3.46	6.18 ± 1.15	=0.03
CAP (dB/m)	290.64 ± 40.82	244.93 ± 18.85	=0.02

Conclusion: Probiotic formulas may contribute to a decrease in liver inflammation, steatosis and fibrosis associated with NAFLD, by their modulating the inflammatory response triggered by gut dysbiosis. Considering the low risks associated with these therapies, we consider them useful future tools in the treatment of NAFLD.

FRI-511

Efficacy of pemafibrate in patients with non-alcoholic fatty liver disease complicated by dyslipidemia: a single-arm prospective study

Hiroki Ono[1], Masanori Atsukawa[1], Kaori Koyano[1], Yuta Hasegawa[1], Tadamichi Kawano[1], Tomohide Tanabe[2], Yuji Yoshida[3], Tomomi Okubo[3], Taeang Arai[1], Korenobu Hayama[3], Norio Itokawa[1], Katsuhiko Iwakiri[1]. *[1]Nippon Medical School Hospital, Gastroenterology and Hepatology, Bunkyo-ku, Tokyo, Japan; [2]Nippon Medical School Musashi Kosugi Hospital, Gastroenterology, Kawasaki, Japan; [3]Nippon Medical School Chiba Hokusoh Hospital, Gastroenterology, Inzai, Japan*
Email: h-ono0@nms.ac.jp

Background and aims: Patients with non-alcoholic fatty liver disease (NAFLD) are often complicated by dyslipidemia. In some patients, dyslipidemia is known to lead to the development of liver fibrosis. Pemafibrate, a novel selective peroxisome proliferator-activated receptor modulatorα (SPPARMα) is an agent approved in Japan for the treatment of hypertriglyceridemia. Previous clinical studies have shown that pemafibrate not only reduced TG level but also improved serum liver enzymes among patients with dyslipidemia. The aim of this study is to evaluate the long-term effect of pemafibrate in patients with NAFLD complicated by dyslipidemia in real world setting.
Method: Ninety-one NAFLD patients with dyslipidemia were treated with pemafibrate; lipid metabolism and liver-related factors were analyzed during 48 weeks.
Results: Significant decreases in triglyceride (198 mg/dL to 121 mg/dL, $p < 0.001$), total cholesterol (223 mg/dL to 205 mg/dL, $p < 0.001$), and a significant increase in HDL cholesterol (47 mg/dL to 50 mg/dL, $p < 0.001$) were found at 12 weeks, compared with the baseline values without body weight loss. These significant changes were maintained throughout 48 weeks, and LDL cholesterol (137 mg/dL to 131 mg/dL, $p < 0.05$) was significantly decreased at 48 weeks, compared with the baseline. Liver-related factors such as AST (36 U/L to 33 U/L at week 48, $p < 0.01$), ALT (52 U/L to 34 U/L, $p < 0.001$), γ-GTP (56 U/L to 32 U/L, $p < 0.001$), and ALP (118 U/L to 59 U/L, $p < 0.001$) also showed significant reductions from baseline throughout the 48 weeks. A significant reduction of HOMA-IR was observed (4.34 at baseline to 3.89 at week 48, $p < 0.05$) in the insulin-resistant group (HOMA-IR ≥2.5). As for changes in liver fat and fibrosis, CAP values did not change significantly throughout 48 weeks ($p = 0.42$), and the median levels of the WFA+-M2BP, type IV collagen 7 s, and NFS significantly decreased from 0.94 C.O.I., 4.3 ng/ml, and −1.183 at baseline to 0.65 C.O.I., 3.8 ng/ml, and −1.655 at week 48, respectively. Focusing on changes in platelets and albumin, both significantly increase from baseline to week 48, and notably platelets and albumin showed marked increased in patients with low platelets (<192 × 103/μL at baseline) (165 × 103/μL to 193 × 103/μL; $p < 0.001$) and low albumin levels (≤4.0 g/dL at baseline) (3.9 g/dL to 4.2 g/dL; $p < 0.01$). In all 38 patients for whom LSM could be measured, LSM did not show significant decreases. LSM significantly decreased in high-risk groups for liver fibrosis including 20 patients with ≥6.5 kPa at baseline (9.4 kPa at baseline to 8.8 kPa at week 48; $p < 0.05$).
Conclusion: Pemafibrate therapy for 48 weeks may improve not only lipid metabolism but also hepatic inflammation and fibrosis without body weight loss. Improvement of insulin resistance by pemafibrate may contribute to improvement of liver-related factors.

FRI-512

Characterization of the patterns of resolution of histopathology after efruxifermin treatment of patients with NASH fibrosis (F2/3) for 24 weeks

Cynthia Behling[1], Pierre Bedossa[2], Lan Shao[3], Erica Fong[4], Brittany de Temple[4], Doreen Chan[4], Reshma Shringarpure[4], Erik Tillman[4], Tim Rolph[4], Andrew Cheng[4], Kitty Yale[4], Stephen Harrison[5]. *[1]University of California, San Diego, United States; [2]LiverPat, France; [3]Labcorp, United States; [4]Akero Therapeutics, United States; [5]Pinnacle Clinical Research, United States*
Email: reshma@akerotx.com

Background and aims: Liver biopsy remains the regulatory standard for diagnosis and monitoring of NASH. Treatment with EFX for 16 weeks (Phase 2a, BALANCED)[1,2] or 24 weeks (Phase 2b, HARMONY)[3] was associated with rapid improvements in liver histology including regression of fibrosis and resolution of NASH. The rapid improvements in the Ph 2a study prompted a post-hoc qualitative evaluation of histopathology which revealed evidence of regression of fibrotic structures and extent of collagen deposition across not only subjects who had a categorical improvement of ≥1 stage but also those who had not.[4] The aim of this analysis was to further characterize these changes in biopsies from the Ph 2b study by qualitative and alternative quantitative analyses.
Method: HARMONY is an ongoing, randomized, placebo-controlled trial evaluating EFX 28 and 50 mg once weekly for 96 weeks, with a completed primary end point evaluation at 24 weeks.[3] Evaluation of histologic end points in the primary efficacy analysis was based on the NASH CRN scoring system, with all biopsies reviewed by consensus between two pathologists blinded to treatment and sampling sequence, without being paired. Additional post hoc evaluations are ongoing to assess effects of EFX on histopathology based on the steatosis-activity-fibrosis (SAF) score and other metrics.
Results: Of 128 patients randomized in HARMONY, 113 had baseline and Week 24 biopsies. Histologic end points, based on NASH CRN to quantitate primary efficacy, and a post hoc analyses based on the SAF score are provided in the Table below. Additional exploratory histological analyses are ongoing.
Conclusion: EFX treatment for only 24 weeks improved liver histopathology, with reversal of fibrosis and reductions in steatosis, ballooning, and inflammation as assessed by multiple measures in addition to the regulatory end point definitions. EFX 50 mg demonstrated striking rates of ballooning resolution, associated with improved NAS, SAF-Activity and total SAF scores. Resolution of histopathology was mirrored by normalization of non-invasive biomarkers of NASH disease activity (ALT, AST) and fibrogenesis (Pro-C3) in the majority (>60%) of treated patients.[3] Evaluation of qualitative patterns of regression of NASH and fibrosis with EFX may be useful in understanding the breadth of response across the NASH population and assessing the potential for further improvements with longer-term treatment.

Fat versus lean tissue loss in short term versus long term weight loss: a dynamic effect with implications for NASH trials

Lars Johansson[1,1], Magnus Sundbom[2], Edvin Johansson[1], Joel Kullberg[1]. *[1]Antaros Medical, Molndal, Sweden; [2]Uppsala University Hospital, Department of Surgery, Uppsala, Sweden*
Email: lars.johansson@antarosmedical.com

Background and aims: Weight loss via diet interventions, bariatric surgery and pharmacological interventions have been shown to improve non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). It has been reported in several clinical trials that substantial loss of lean tissue may occur secondary to weight loss. Early phase clinical trials of novel treatments based on weight loss for NASH are usually short term 8–16 weeks with a single point readout of adipose tissue and lean tissue volumes based on DEXA or MRI. Little is however known about the short-term effects of weight loss versus long term effects on the change in fat mass versus lean tissue mass. The purpose of this study was therefore to investigate the

Table 1. Proportion of Patients Achieving the Specified Histologic Endpoints

Endpoint	Placebo N = 41	EFX 28 mg N = 38	EFX 50 mg N = 34
Primary and Secondary Endpoints (NASH CRN)			
Fibrosis improvement without worsening of NASH[a]	8 (19.5%)	15 (39.5%)*	14 (41.2%)*
NASH resolution without worsening of fibrosis[b]	6 (14.6%)	18 (47.4%)**	26 (76.5%)***

Improvement in SAF-A by ≥2[f, nt]	4 (9.8%)	17 (44.7%)	24 (70.6%)
Improvement in total SAF by ≥2[nt]	9 (22%)	30 (78.9%)	30 (88.2%)

*p<0.05 ; **p<0.01; ***p<0.001 versus placebo [Cochran-Mantel-Haenszel (CMH) test]; nt = post-hoc analysis not tested for significance.

[a] Consistent with FDA published guidance, no worsening of NASH is defined as no increase in any one or more of steatosis, inflammation or ballooning score; [b] Consistent with FDA published guidance, NASH resolution is defined as a ballooning score of 0 and a lobular inflammation score of 0 or 1, with any score (0 to 3) for steatosis; [c] In contrast to FDA published guidance that permits any steatosis score (0 to 3) for a patient to achieve NASH resolution, this endpoint requires that a patient must achieve a ≥2-point reduction in overall NAS score, in addition to a ballooning score of 0 and lobular inflammation score of 0 or 1, to be deemed a NASH resolution responder; [d] Defined as ballooning score ≥1 at baseline and 0 at Week 24; [e] SAF scores were derived from NASH CRN scores in consultation with pathologists [f] SAF-A: Activity component of the SAF score defined as the sum of ballooning and lobular inflammation scores.

Table: (abstract: FRI-512)

dynamic effects on adipose and lean tissue loss during substantial weight loss.

Method: 7 obese subjects with a BMI of 43.7 kg/m^2 (range 38–48) undergoing Roux-and-Y bariatric surgery were investigated with whole body MRI assessing adipose tissue depots at baseline and 1-, 6- and 12-months post-surgery. Total Adipose Tissue (TAT) mass was investigated. The relative contribution of different tissue compartments to the total weight loss calculated at each timepoint with the assumption that 1 L of adipose tissue have a weight of 0.9 kg.

Results: The total weight and TAT weight, and the relative contributions to the total weight loss are shown in the figure.

Conclusion: The relative contribution of weight loss from adipose versus lean tissue changed over time, with more lean tissue being lost early on in weight loss and more adipose tissue being lost during prolonged weight loss. Non-adipose tissue loss constitutes 37% of the total body weight loss at 1 month while only 20.5% after 12 months. This could possibly be attributed to more excessive amount of water being lost in early weight loss while the negative energy balance over time will turn into loss of excessive adipose tissue. This finding has implications for investigations of body composition changes in short term NASH trials where weight loss is induced. Hence, one should be cautious when drawing conclusions on induction of sarcopenia from short-term weight loss data.

Months	Baseline	1	6	12
Weight (kg) (SD)	122 (±13)	110 (±12)	93 (±11)	80 (±11)
TAT (l) (SD)	66.9 (±9.0)	58.5 (±9.0)	41.9 (±9.0)	29.8 (±9.0)
TAT(kg)	60.2	52.7	37.7	26.8
Total Fat loss as % of total weight loss (mean)		63	77.6	79.6
Total non-fat loss as % of total weight (mean)		37	22.4	20.5
%Fat mass of total body mass (mean)	43.4	47.9	40.5	33.5

Efficacy of digital health-supported lifestyle modification on patients with non-alcoholic fatty liver disease: a systematic review and meta-analysis

Joo Hyun Oh[1], Yewan Park[2], Myungji Goh[3], Sang Bong Ahn[1], Wonseok Kang[3], Dong Hyun Sinn[3], Geum-Yon Gwak[3], Yong-Han Paik[3], Joon Hyeok Lee[3], Moon Seok Choi[3], Seung Woon Paik[3]. *[1]Eulji Medical Center, Korea, Rep. of South; [2]Kyung Hee University Hospital, Korea, Rep. of South; [3]Samsung Medical Center, Korea, Rep. of South*

Email: drms.choi@samsung.com

Background and aims: The current recommendation for patients with non-alcoholic fatty liver disease (NAFLD) is to achieve and

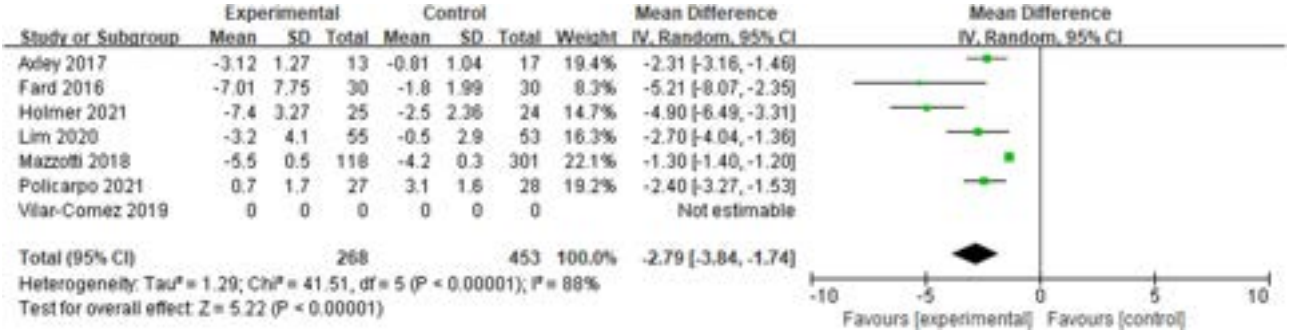

Figure: (abstract: FRI-514).

maintain weight reduction via counseling and calorie restriction. However, adherence to lifestyle modification is insufficient due to financial and time constraints. We investigated whether digital health-supported lifestyle change help patients with NAFLD lose weight and reduce hepatic inflammation.

Method: Relevant studies were selected from MEDLINE, EMBASE, and Cochrane Central Register of Controlled Trials until September 28th, 2022. The search terms included NAFLD, digital health, and telemedicine. The primary outcome is change in body weight and secondary outcome is change in alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Random effect method was performed for pooling the data.

Results: Seven studies (six randomized controlled trials and one prospective study) comprising 1,245 patients with NAFLD were analyzed. The mean reduction in body weight was greater for patients whose lifestyle modification were supported by digital health (weighted mean difference (WMD): −2.79 kg, 95% confidence interval (CI) −3.84, −1.74). Digital health-supported lifestyle modification was associated with greater reductions in ALT and AST compare to conventional treatment (WMD: −12.85, 95% CI −22.82, −2.88 and WMD: −8.57, 95% CI −12.23, −4.92, respectively). Lifestyle change assisted by digital health substantially reduced triglycerides levels (WMD: −12.30, 95% CI −19.96, −4.64) but had no significant effect on insulin resistance assessed by homeostatic model assessment for insulin resistance (WMD: −3.88, 95% CI −9.55, 1.79).

Conclusion: Digital health-supported lifestyle modification is effective in body weight, ALT, AST, and triglycerides reduction, indicating that NAFLD patients may benefit from digital health technology.

FRI-515

A novel prescription digital therapeutic for the treatment of non-alcohol related fatty liver disease: feasibility study

Naim Alkhouri[1], Katherine Edwards[2], Mark Berman[2], Erin Rudolf[2], Heather Finn[2], Heidi Dusky[2], Nicole Guthrie[2], Rafael Escandon[3], Angie Coste[1], Jesus Topete[1], Mazen Noureddin[4]. *[1]Arizona Liver Health, Fatty Liver Program, Chandler, United States; [2]Better Therapeutics, San Francisco, United States; [3]DGBI Consulting, LLC, Bainbridge Island, United States; [4]Houston Liver Institute, Houston Research Institute, Houston Methodist Hospital, Houston, United States*
Email: kate@bettertx.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a global public health crisis growing in parallel with the obesity and diabetes pandemics. Behavioral modification including weight loss, improving dietary quality, and increasing physical activity have been proven to have favorable effects on slowing or reversing the progression of liver steatosis and fibrosis; however, behavior change is difficult to facilitate in clinical practice and health systems are poorly equipped to scale behavioral interventions needed to address the enormous population with NAFLD. The aim of this feasibility study was to explore the safety, efficacy, and usability of a novel prescription digital therapeutic (PDT) platform, in individuals with NAFLD or non-alcoholic steatohepatitis (NASH).

Method: This single arm study was conducted at two affiliated specialty hepatology clinics. The PDT was created by Better Therapeutics using a novel form of cognitive behavioral therapy (CBT) intended to treat cardiometabolic disease. Participants accessed the PDT on their smartphone for up to 90 days. The intervention was delivered without requiring additional participation from clinic providers. Laboratory assessments, FibroScan and magnetic resonance imaging proton density fat fraction (MRI-PDFF) imaging were conducted at baseline and post-intervention. Percent change in steatosis was measured by MRI-PDFF in participants with elevated baseline liver fat (PDF ≥ 10%).

Results: The study enrolled 22 participants. At baseline, the mean age was 48 years, 77% were female, 50% Hispanic, and 46% had type 2 diabetes. The mean baseline fat fraction on MRI-PDFF was 19%. After 90 days of exposure to the PDT, the mean relative reduction in MRI-PDFF was −16% ($p = 0.011$) in the primary ITT population. ALT was reduced by an average of −17 IL/U ($p = 0.002$) (Fig). FibroScan Controlled Attenuation Parameter (CAP) Score was reduced (−19 dB/m, $p = 0.021$) and was accompanied by an average relative reduction of −20% in the FAST score ($p = 0.011$). Participants achieved an average weight loss of −3% ($p = 0.008$) of total body weight, following a pattern of gradual and consistent weight loss without any signs of a plateau or peak. No serious adverse events nor any device related adverse events were reported. Participants reported an improvement in their health-related quality of life (assessed via CDC HRQOL-4) with an average improvement of 2.2 Healthy Days per month added ($p = 0.500$) and a high degree of satisfaction with the treatment (mean Net Promoter Score of +75).

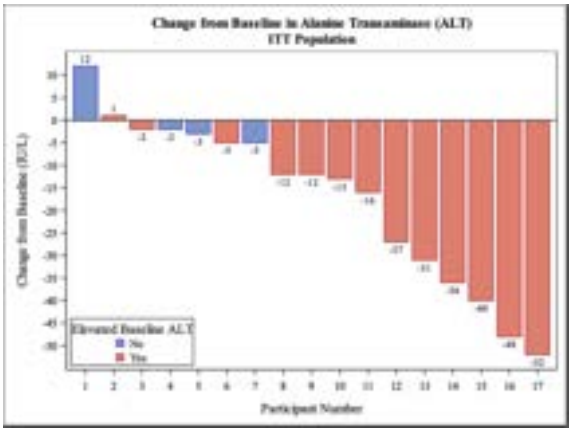

Figure:

Conclusion: Clinically meaningful improvements in liver health were observed in multiple end points after 90 days of digitally-delivered CBT without any adverse device effects. Weight data suggests that further liver health improvements may be possible with further PDT use beyond 90 days. The totality of safety, efficacy and usability data

collected strengthen the hypothesis that a PDT could be an important and scalable clinical tool for the treatment of NAFLD and NASH.

FRI-516

Incidence and median times to onset and resolution of pruritus adverse events in a phase 3 study of obeticholic acid in patients with non-alcoholic steatohepatitis

Zobair Younossi[1], Leighland Feinman[2], Amarita Randhawa[2], Rina Leyva[2], Maria Stepanova[3], Sangeeta Sawhney[2]. Email: sangeeta.sawhney@interceptpharma.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is associated with pruritus in real-world practice. In the REGENERATE study (NCT02548351) of obeticholic acid (OCA) for pre-cirrhotic liver fibrosis due to NASH, pruritus was the most common treatment-emergent adverse event, and its frequency was dose dependent. We report the incidence, times to onset and resolution, and management of pruritus adverse events (AEs) in an expanded safety population.
Method: Pruritus symptoms were monitored every 3 to 6 months. Pruritus was managed with drug holiday, reduced dosing frequency, discontinuation, or use of antipruritic therapies. The incidence of pruritus AEs was determined using Medical Dictionary for Regulatory Activities queries in the safety population of the REGENERATE study, which included all randomized pts who received at least 1 dose of placebo, OCA 10 mg, or OCA 25 mg.
Results: In this population (N = 2477), 976 pts were exposed >4 years (median 39 months) to study drug. Pruritus was the most common AE and the most common reason for study drug discontinuation; about half of discontinuations due to pruritus were mandated. Pruritus AEs were dose dependent and predominantly mild/moderate (Table). Most pruritus AEs did not require any intervention regardless of treatment arm. Drug holiday was the most frequent management, with most pts having a single interruption. Antihistamines were the most common concomitant therapy for grade 1 or 2 pruritus, followed by bile acid sequestrants and corticosteroids. In the placebo, OCA 10 mg, and OCA 25 mg arms, median time to onset of the first pruritus event was 191, 100, and 44 days, respectively. The impact of treatment-emergent pruritus on patient-reported outcomes is being analyzed.

Table: Pruritus AEs in patients with pre-cirrhotic liver fibrosis due to non-alcoholic steatohepatitis in the REGENERATE study

	Placebo (n = 825)	OCA 10 mg (n = 825)	OCA 25 mg **(n = 827)**
Patients with treatment-emergent pruritus, n (%)	221 (26.8)	289 (35.0)	476 (57.6)
Severity, n (%)			
Mild	161 (19.5)	180 (21.8)	181 (21.9)
Moderate	57 (6.9)	99 (12.0)	238 (28.8)
Severe	3 (0.4)	10 (1.2)	57 (6.9)
Not related to study drug, n (%)	56 (6.8)	58 (7.0)	39 (4.7)
Study drug management for pruritus (all grades) per protocol, n (%)			
No dose change	204 (24.7)	257 (31.2)	366 (44.3)
Interruption	17 (2.1)	34 (4.1)	133 (16.1)
Withdrawal	8 (1.0)	14 (1.7)	100 (12.1)
Time to event for first pruritus AE, median (Q1, Q3), days			
Time to onset	191 (69, 478)	100 (23, 372)	44 (15, 158.5)
Time to resolution	53 (17, 174)	60 (23, 154)	50 (19, 148)

Abbreviations: AE, adverse event; Q1, quartile 1; Q3, quartile 3.

Conclusion: The first pruritus AE associated with OCA generally occurred within the first 3 months of therapy, was mild/moderate, and was manageable with a single drug holiday or addition of antipruritic therapy.

FRI-517

Correlation between severity of hepatic steatosis and markers of cardiometabolic health, and effect of lanifibranor therapy in patients with non-cirrhotic NASH

Michael Cooreman[1], Sven Francque[2], Philippe Huot-Marchand[1], Lucile Dzen[1], Martine Baudin[1], Jean-Louis Junien[1], Pierre Broqua[1], Manal Abdelmalek[3]. [1]*Inventiva Pharma, Research and Development, Daix, France;* [2]*University Hospital Antwerp, Belgium;* [3]*Mayo Clinic, United States*
Email: michaelpcooreman@msn.com

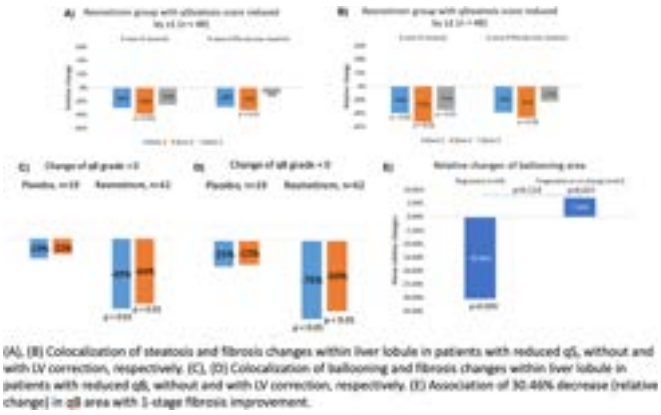
Background and aims: Lanifibranor has shown efficacy on 'histological NASH resolution and improvement of fibrosis' and on markers of cardiometabolic health (CMH) in the NATIVE phase 2b study. Hepatic steatosis is a known cardiovascular risk factor and the NAFLD-associated atherogenic lipid profile is considered a pathophysiological link. We therefore evaluated the correlation between steatosis and CMH markers at baseline (BL) and between steatosis reduction with lanifibranor and improvement of CMH markers.
Method: NATIVE evaluated lanifibranor 800 and 1200 mg/d versus placebo in 247 patients with non-cirrhotic NASH for a treatment duration of 24 weeks. Markers of CMH [adiponectin (ADP), insulin resistance (HOMA-IR), HbA1c, fasting triglycerides, HDL-c, apolipoproteins, blood pressure (BP)], liver tests and steatosis by histological NASH-CRN/SAF grading and Continuous Attenuation Parameter™ (CAP™ on Fibroscan®) were evaluated at BL and at end of treatment (EOT). Correlations between BL steatosis (histological and CAP™) and CMH markers were assessed for all randomized patients; correlations between changes at EOT were assessed in the pooled lanifibranor arms. BL CAP™ was considered quantitatively and categorized (≤302 and >302 $dB.m^{-1}$); changes in CAP™ at EOT were expressed as continuous variables or categorical (relative change <-10%, 10–20%, > +10%).
Results: BL CAP™ values correlates with BL HOMA-IR (Spearman p = 0.008), HbA1c, triglycerides, and inversely with HDL-c and Apo-A1; mean triglycerides were 1.72 and 2.04 mmol/L, and mean HDL-c values were 1.30 and 1.18 mmol/L for CAP™ ≤302 and >302 $dB.m^{-1}$, resp (p = 0.012 and 0.007, resp). BL CAP™ values also correlated with diastolic BP and ALT and AST. At EOT, improvement of HOMA-IR was seen independent of the degree of steatosis reduction; HbA1c lowering was correlated with improvement of the histological grade (p < 0.001) and with change in CAP™ (Spearman p = 0.05); triglyceride decreases correlated with changes in CAP™: −30, −13 and −2% from BL for <−10%, 10–20%, and >+10% relative CAP™ change, resp.; HDL-c increase correlated with histological steatosis improvement (p = 0.006). BL ADP did not differ with severity of steatosis (grading and CAP™), but steatosis improvement was correlated with pronounced increases in ADP at EOT: fold-increase ADP from BL was 3.1, 3.9, 5.3 and 6.0 for no change, 1, 2 and 3 points reduction of steatosis grade, resp (p < 0.001), and correlated similarly with continuous CAP™ value changes (Spearman p = 0.002).
Conclusion: Markers of cardiometabolic health are related with the severity of hepatic steatosis in patients with NASH. Improvement of steatosis with Lanifibranor therapy is significantly correlated with a robust ADP response and with an improvement of lipid and glycemic profile, supporting the concept that steatosis improvement with lanifibranor could translate in improved long-term cardiovascular outcomes.

FRI-518

Hepatic fat and liver volume reductions-impact on non-alcoholic steatohepatitis trials and potential solutions using concomitant fibrosis with ballooning with fibrosis

Jörn Schattenberg[1], Yayun Ren[2], Dean Tai[2], Elaine Chng[2], Stephen Harrison[3]. [1]*Metabolic Liver Research Center, Department of Medicine, Mainz, Germany;* [2]*HistoIndex Pte Ltd, Singapore;* [3]*Pinnacle Research, San Antonio, United States*
Email: elaine.chng@histoindex.com

Background and aims: Experimental treatment of non-alcoholic steatohepatitis (NASH) leads to reduction of hepatic fat and liver volume (LV) as assessed by Magnetic Resonance Imaging-Proton Density Fat Fraction (MRI-PDFF). The impact of hepatic fat and LV reduction on histological fibrosis interpretation using the CRN system remains unexplored. We propose analyzing the concomitant changes of qFibrosis (qF) with qSteatosis (qS) and qBallooning (qB) in zonal regions to evaluate the impact of hepatic fat and LV reduction on fibrosis changes.
Method: NASH patients were included from two phase 2b studies: 24-week study of Aldafermin (NCT02443116) and 36-week study of Resmetirom (NCT02912260). Steatosis correction (SC) was done by subtracting the steatosis area as detected by qS from total tissue area followed by an analysis of zonal fibrosis in the respective zones 1, 2, and 3. Concomitant fibrosis with drug-induced steatosis and ballooning changes were evaluated by co-localization of qF changes around qS and qB, respectively.
Results: qF continuous measures on the phase 2 Aldafermin study revealed 54% fibrosis regression in the treated group versus 19% in placebo group (p = 0.007). With SC, zonal qF assessment showed trends of dose-dependent fibrosis reduction in portal, periportal (p = 0.02) and zone 2 regions. In the Resmetirom study where the treated group had markedly reduced LV, LV correction was applied and there was a greater reduction in concomitant fibrosis, as well as significant zonal steatosis reduction across all zones (Figure 1A, 1B). In contrast, the impact of LV is negligible on concomitant qB/qF. Further qB analysis revealed an association between 1-stage fibrosis improvement with a decrease in qB area from baseline to end-of-treatment (Figure 1C). Using cut-off of –30.46%, the performance for predicting 1-point reduction was 50% sensitivity, 58% specificity with 39% negative predictive value and 68% positive predictive value.



(A), (B) Colocalization of steatosis and fibrosis changes within liver lobule in patients with reduced qS, without and with LV correction, respectively. (C), (D) Colocalization of ballooning and fibrosis changes within liver lobule in patients with reduced qB, without and with LV correction, respectively. (E) Association of 30.46% decrease (relative change) in qB area with 1-stage fibrosis improvement.

Figure:

Conclusion: Results from this proof-of-concept analysis highlights the impact of hepatic fat reduction on fibrosis regression in NASH. The impact of SC and LV correction is great on the concomitant fibrosis around steatosis, but minimal on the concomitant fibrosis around ballooning. Therefore, concomitant analyses with digital pathology can augment the interpretation of the mechanism of action of drugs in NASH as well as allow for a better understanding of the impact these drugs have on histopathology and should be considered in future trials. Validation with clinical outcomes is ongoing.

Effectiveness of prebiotic treatment in patients with non-alcoholic fatty liver disease (NAFLD)-a randomized trial

Yaakov Maor[1,2], Naama Reshef[3,4], Uri Gophna[5], Fred Konikoff[6,7], Hilla Knobler[2,3]. [1]*Kaplan Medical Center, Institute of Gastroenterology and Hepatology, Rehovot, Israel;* [2]*The Hebrew University, Hadassah School of Medicine, Jerusalem, Israel;* [3]*Kaplan Medical Center, Institute of Diabetes and Metabolism, Rehovot, Israel;* [4]*The Hebrew University, Faculty of Agriculture, Food and Environment, School of Nutritional Sciences, Rehovot, Israel;* [5]*Tel-Aviv University, Faculty of Life Sciences, Department of Molecular Microbiology and Biotechnology, Tel-Aviv, Israel;* [6]*Tel-Aviv University, Sackler School of Medicine, Tel-Aviv, Israel;* [7]*Sapir Medical Center, Institute of Gastroenterology and Hepatology, Kfar Sava, Israel*
Email: halishy@netvision.net.il

Background and aims: Several observations show that fecal microbial species of patients with NAFLD differ from that of healthy population. Recent studies explored pathways linking altered composition of gut microbiota with the pathogenesis of NAFLD. Prebiotics are dietary fibers that manipulate gut microbiota to a more favorable profile. The aim of the study was to explore the effectiveness of prebiotic supplementation in liver fat reduction and on the composition of the fecal microbiome.
Method: 19 patients with NAFLD were randomized to receive either 16 gr/day Inulin Type Fructans (ITF) (Inulin/OFS75/25) prebiotic or (n = 9) placebo-maltodextrin (n = 10) for 12 weeks. Patients were instructed to maintain their usual diet and physical activity to ensure stable weight throughout the study. Liver fat content was measured by magnetic resonance spectroscopy (MRS). Fecal microbiome was analyzed by 16S ribosomal DNA sequencing. We collected detailed anthropometric, metabolic, liver-related and inflammatory mediators from all participants.
Results: Baseline and end-of-study liver fat content did not change significantly in the prebiotic (22.1% ± 12.7% and 19.8% ± 11.7%) and in the placebo group (15.2% ± 8.6% and 12.5% ± 9.4%). Fecal samples from patients who received the prebiotic had higher proportions of Bifidobacterium, while there was no change in the concentration of Bifidobacterium species in the placebo group (Figure). We observed an increase in FGF-19 levels in the prebiotic group, compared with the placebo group, this however, did not reach a meaningful difference. Bifidobacterium negatively correlated with the difference in FGF-19: R = –0.88, $p = 0.03$. Body weight and body composition remained stable in both groups.

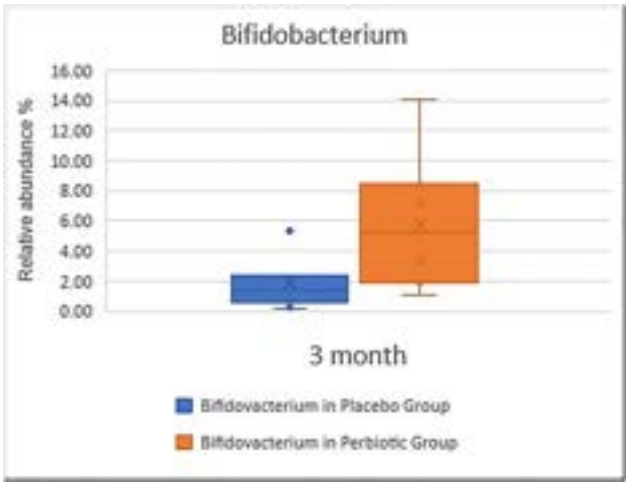

Figure:

Conclusion: Prebiotic treatment enriched fecal microbiota with Bifidobacterium compared with placebo, this did not result in

reduction of liver fat content. Weight loss may still have a pivotal role in NAFLD management.

FRI-520

B-cell activating factor in non-alcoholic steatohepatitis

Iris Gines Mir[1], Raju Kumar[1], Patricia Garrido[1], Wenhao Li[1], Hamish Miller[1], Hajar Saihi[1], Gillian Hood[1], William Alazawi[1]. *[1]Barts Liver Centre, Blizard Institute, Queen Mary University of London, Immunobiology, London, United Kingdom*
Email: i.g.mir@qmul.ac.uk

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is one of the most prevalent causes of liver disease worldwide. In a subset of patients, hepatic fat is associated with liver cell injury and inflammation; non-alcoholic steatohepatitis (NASH) and fibrosis. While NASH is the likely driver of disease, the extent of liver fibrosis is more predictive of liver-related clinical events, but the mechanisms that link metabolic dysfunction, inflammation and fibrosis in NASH are poorly understood. B cell-activating factor (BAFF) is a pro-inflammatory adipokine with 3 known receptors (BAFF-R, BCMA and TACI). It is associated with impaired insulin sensitivity, liver steatosis and inflammation in mice and serum BAFF is higher in human NASH patients compared to simple steatosis. In this study we test the hypothesis that BAFF signalling is associated with fibrosis in blood and liver tissue from people living with NAFLD.
Method: Concentration of BAFF in sera from 106 people with biopsy-proven NAFLD and NASH was measured using ELISA. The RNA and protein expression of BAFF and its receptors in liver tissue were evaluated using RT-PCR (GAPDH housekeeping gene), Western blot and immunofluorescence assays in liver biopsy tissue from patients with NASH and in hepatocyte-like cells and stellate-like cells, using B-cells as positive control.
Results: BAFF concentrations were higher in patients with NASH F3-4 compared to those with NASH F0 1118.06 pg/ml vs 1333.39 pg/ml, p = 0.03) (figure) with an association of BAFF concentration with age, fibrosis grade and BMI, but no association, with ballooning or inflammation nor with, ethnicity or type 2 diabetes. BCMA, BAFF-R and TACI mRNA were detectable in liver tissue, and this was recapitulated at the protein level, but TACI was not detected by either Western blot or immunofluorescence. BCMA relative gene expression was higher in patients with NASH F3 (no F4 patients in this analysis) compared to NASH F0-2 (4.5-fold, p = 0.05). In hepatocyte-like cells (HepG2) and stellate-like cells (LX-2), BAFF, BCMA and BAFF-R but not TACI were detected at RNA and protein levels. Treatment with a toxic combination of oleic acid and palmitic acid (1 mM and 0.5 mM) resulted in an up regulation of BAFF-R in LX-2 cells (1.7-fold, p = 0.02).

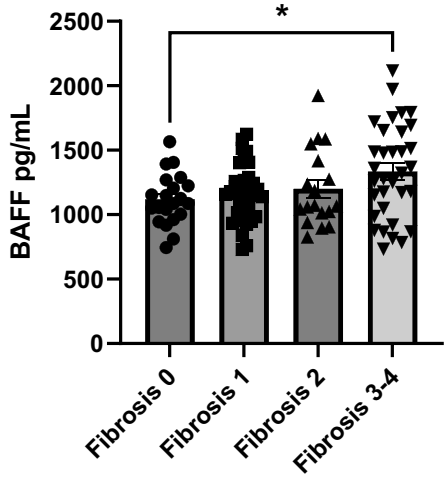

Figure:

Conclusion: BAFF is increased in patients with advance liver fibrosis. BAFF-R, BCMA, TACI and BAFF itself are detected in human liver. BAFF-R, BCMA and BAFF are detected in hepatocyte-like and stellate-like cells.

FRI-521

SNP-630, a novel compound with multiple mechanisms, reverses liver inflammation and fibrosis in preclinical model and NASH phase 2 clinical trial

Hsin-Tien Ho[1], Shin-Wei Chen[1,2], Yu-Lueng Shih[3], Tien-Yu Huang[3], Wen-Hui Fang[4], Jung-Chun Lin[3], Te-Yu Lin[5], Chang-Hsien Liu[6], Chih-Weim Hsiang[6], Kai-Min Chu[1], Cheng-Huei Hsiong[1], Yung-En Wu[1], Jia-Yu Hao[1], Guan-Ju Chen[1], Yi-Hsuan Lin[1], Yoa-Pu Hu[7,8]. *[1]Sinew Pharma Inc., Taipei, Taiwan; [2]Sinew Pharma Inc., TAIPEI City; [3]Division of Gastroenterology, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; [4]Department of Family Medicine, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; [5]Division of Infectious, Tri-Service General Hospital, National Defense Medical Center, Taiwan; [6]Department of Radiology, Tri-Service General Hospital, National Defense Medical Center, Taiwan; [7]National Defense Medical Center, School of Pharmacy, Taiwan; [8]Taipei Medical University, Taiwan*
Email: cwei207@gmail.com

Background and aims: Non-alcoholic steatohepatitis (NASH) is a metabolic liver disease characterized by hepatic lipid accumulation, chronic inflammation and fibrosis. Recent studies have been underlined the pathogenesis of NASH and the complex interplay between them will be essential for the developing therapies that can effectively against the multiple hits that lead to the disease. SNP-630 is a prospective novel synthetic molecule inhibits NASH processing by multiple mechanisms of action. In *in vitro* hepatocytes and hepatic stellate cells co-culture system, we elucidated that SNP-630 significantly decreases fibrosis markers expression with multiple mechanisms of action such as hepatic de novo lipogenesis (DNL) pathway inhibition and inflammation. Most importantly, we are already seeing improvement in both *in vivo* mouse model and the NASH patients clinically treated with SNP-630 and its active metabolites SNP-612.
Method: [*in vitro* model] HepG2 and LX2 were seeded in the same plate considering a ratio of 5:1 respectively. After 24 hours, cells were exposed to 750 µM of palmitic acid combined with SNP-630 for 24 hrs, then cells and supernatants were harvested for analysis. [*in vivo* model] Male C57BL/6 mice were fed with a high fat diet (HFD) for 21weeks. In week 21, the HFD-induced NASH mice continued to receive a HFD along with SNP-630 or its metabolites SNP-612 by oral gavage once daily for more 6–10 weeks. [phase2 clinical trial] SNP-612 tolerability, safety, and efficacy in 35 NASH patients were evaluated. The primary and secondary end points were the change in serum alanine aminotransferase (ALT), liver inflammation, steatosis and fibrosis at week 12 of administration
Results: NASH regression led to significant changes at haematological, histological, whole-liver transcriptional, and single-cell levels. In in vitro HepG2-LX2 co-culture model, the expression level of triacylglycerol synthesis enzyme (*DGAT1*), inflammation related cytokines (*IL1b, IL6, and CCL2*), and fibrosis-related markers (*ACTA2*, *COL1A1*, and *TIMP1*) were significantly decreased in SNP630-treatment. Also, in HFD-induced NASH mice, SNP-630 or SNP-612 treatment significantly decreased serum ALT, hepatic steatosis (triglyceride), inflammation (*Ccl2*), and fibrosis (*Col1A1* and *Timp1*). In the clinical trial, patients treated with the active metabolites, SNP-612, demonstrated a significant change in ALT at week 12 compared to baseline values, with no sever adverse events observed. In addition, SNP-612 demonstrated antifibrotic potential, including a significant decrease in fibrogenesis-related biomarkers (ie, CCL4 and CCL5). Moreover, FibroScan measurements indicated the efficacy of SNP-612 to ameliorate liver fibrosis in subgroup analysis.

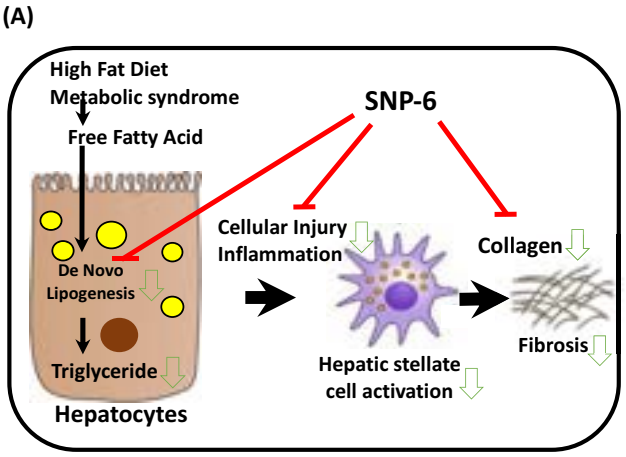

Figure A. The mechanism of SNP-630 and its active metabolites.
Figure B. SNP-612 achieves the primary endpoint of an improvement in ALT after 12-weeks treatment in the mITT population.

1. **Primary endpoint was met:** ALT at week 12 were both significant reduced from baseline in the two dosage groups.
2. **ALT improvements were also observed in all subgroups:** Subgroup analysis were performed based on PNPLA3 genotype, sex, age, BMI, MRI-PDFF, T2DM, and dose of SNP-612.

Figure: (abstract: FRI-521).

Conclusion: These preclinical and phase 2 clinical data demonstrated that SNP-630 and its metabolites can suppress NASH fibrosis through DNL inhibition and inflammation.

FRI-522

Serological biomarkers PRO-C3 and PRO-C6 reveal the anti-fibrotic and pro-metabolic effects of MSDC-0602 K, an insulin sensitizer, in non-alcoholic steatohepatitis patients during the EMMINENCE phase IIb study

Alejandro Mayorca Guiliani[1], Peder Frederiksen[1], Morten Karsdal[1], Diana Leeming[1], Jerry Colca[2]. [1]*Nordic Bioscience, Biomarkers and Research, Herlev, Denmark;* [2]*Cirius Therapeutics, Kalamazoo, United States*
Email: amg@nordicbio.com

Background and aims: MSDC-0602K is a second-generation insulin sensitizer designed to inhibit the mitochondrial carrier (MPC) without direct activation of the transcription factor PPARγ. The EMMINENCE trial evaluated efficacy and safety of MSDC-0602K in patients with non-alcoholic steatohepatis (NASH). As previously published, MSDC-0602K missed statistical significance on the pre-specified primary analysis of liver histology, but led to significant reductions in glucose, glycated Hb and liver enzymes. Notably edema, the principle PPARγ agonist-associated side effect, was not higher than placebo and there were more dropouts in the placebo than in the active arms Here, we assessed the serological extracellular matrix biomarkers PRO-C3, PRO-C4 and PRO-C6, which serve as surrogates of fibroblast activity, pericellular fibrosis formation and the profibrotic and proinflammatory fragment endotrophin.
Method: In the EMMINENCE study (NCT02784444), 392 NASH patients were randomized to placebo (PL), 62.5 mg, 125 mg or a 250 mg daily dose of MSDC-0602K for 12 months. The primary efficacy end point was defined as an improvement of ≥2 points in NAS score, with ≥1 decrease in either ballooning or inflammation and no increase in fibrosis at 12mo based on randomized readings of only completing subjects. Liver biopsy was performed at baseline (BL) and at 12mo. Plasma samples were collected at BL, 6mo and 12mo to measure PRO-C3, PRO-C4 and PRO-C6 and analyzed statistically at the end of the study.

Results: PRO-C3 levels increased along with fibrosis stage at baseline (p = 0, 0021). 125 and 250 mg doses of MSDC-0602K significantly reduced PRO-C3 at 6mo and 12mo (p = 0.003–0.03; PL: −3%, MSDC-0602K: −6 to −11% at 12mo). MSDC-0602K significantly reduced PRO-C6 at 12mo for all three doses (p = 0.026–0.047, PL: +3%, MSDC-0602K: −2.5 to −3.5% at 12mo) compared to PL (See figure below). Furthermore, our data suggested the presence of a F3/4 patient responder subgroup, characterized by lower levels of PRO-C3 at baseline.

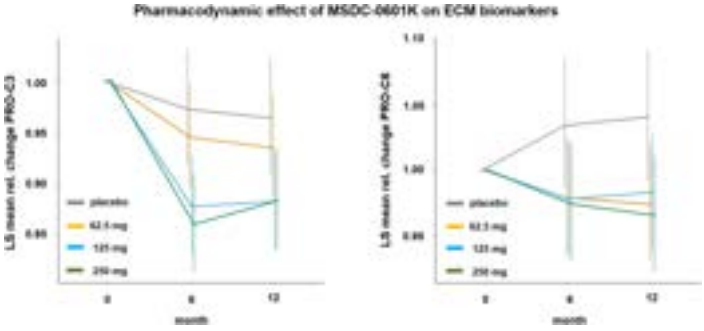

Figure:

Conclusion: MSDC-0602K reduced both PRO-C3 and PRO-C6 levels, indicating an anti-fibrotic and pro-metabolic effect. Furthermore, the biomarkers identified a subgroup of patients with lower baseline PRO-C3 and a F3-F4 diagnosis at BL that had a high likelihood of improvement in fibrosis. Our findings suggest that measuring ECM neo-epitope biomarkers may aid in understanding the pharmacodynamic effects of MSDC-0602K as well as support future exploration of MSDC-0602K in patients with NASH.

FRI-523

Similar weight loss with semaglutide regardless of diabetes and cardiometabolic parameters in individuals with non-alcoholic fatty liver disease

Matthew Armstrong[1], Takeshi Okanoue[2], Mads Sundby Palle[3], Anne-Sophie Sejling[3], Mohamed Tawfik[3], Michael Roden[4]. [1]*Liver Unit, Queen Elizabeth University Hospital Birmingham, UK, National Institute for Health Research, Birmingham Biomedical Research Centre at University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom;* [2]*Department of Gastroenterology and Hepatology, Saiseikai Suita Hospital, Osaka, Japan;* [3]*Novo Nordisk A/S, Søborg, Denmark;* [4]*Division of Endocrinology and Diabetology, Medical Faculty, Heinrich-Heine University and University Hospital, Düsseldorf, Germany; Institute of Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research, München-Neuherberg, Germany*
Email: asji@novonordisk.com

Background and aims: In the absence of any globally approved pharmacotherapy, current guidelines recommend lifestyle modification and weight loss in people with obesity and non-alcoholic fatty liver disease (NAFLD), including non-alcoholic steatohepatitis (NASH). Semaglutide, a glucagon-like peptide (GLP)-1 analogue indicated for management of body weight and type 2 diabetes (T2D), is under investigation in NASH. However, T2D seems to reduce GLP-1 analogue-mediated weight loss in people with overweight/obesity. We evaluated the impact of T2D and other cardiometabolic parameters on weight loss in randomised controlled trials of subcutaneous semaglutide in NAFLD including NASH.

Method: Data were taken from adults in NCT03357380 (NAFLD; semaglutide 0.4 mg or placebo once daily [OD] for 72 weeks), NCT02970942 (NASH and fibrosis stage [F] 1–3; semaglutide 0.1, 0.2 or 0.4 mg or placebo OD for 72 weeks) and NCT03987451 (NASH, F4 and compensated liver cirrhosis; semaglutide 2.4 mg or placebo once weekly [OW] for 48 weeks). This *post-hoc* analysis pooled data for semaglutide (0.4 mg OD and 2.4 mg OW) and placebo, with weight changes grouped by baseline T2D status (previously diagnosed or glycated haemoglobin [HbA_{1c}] ≥6.5%, pre-T2D [HbA_{1c} ≥5.7–<6.5%] or no T2D [HbA_{1c} <5.7%]). Mean on-treatment changes from baseline to 1 year were used to derive estimated treatment differences (ETDs) and 95% confidence intervals for semaglutide vs placebo. Impact of cardiometabolic factors including baseline fasting lipids, plasma glucose, diabetes duration and Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) were assessed.

Results: Of the 300 participants included, 209 (70%) had T2D, 51 (17%) pre-T2D and 40 (13%) non-T2D. ETDs ranged from-9.8 kg in the pre-T2D group to-11.6 kg in the non-T2D group; there was no significant difference between the non-T2D vs pre-T2D, pre-T2D vs T2D and non-T2D vs T2D groups in terms of weight change (Table). Weight change was not influenced by known diabetes duration, or baseline HOMA-IR or glucose and lipid levels.

Table:

	Semaglutide		Placebo				
	n	Weight change (kg)	n	Weight change (kg)	ETD (95% CI) (kg)	p value vs non-T2D	p value vs pre-T2D
Overall	163	−11.1	137	−0.7	−10.4 (−11.9; −8.9)	–	–
T2D	117	−11.1	92	−0.8	−10.2 (−12.0; −8.5)	0.57	0.84
Pre-T2D	25	−9.8	26	0.0	−9.8 (−13.4; −6.3)	0.54	–
Non-T2D	21	−12.7	19	−1.1	−11.6 (−15.7; −7.4)	–	–

CI, confidence interval; ETD, estimated treatment difference; T2D, type 2 diabetes.

Conclusion: Individuals with NAFLD including NASH treated with semaglutide had similar weight loss, and parameters of insulin resistance, and glucose and lipid metabolism, regardless of T2D status. Unlike previously reported differences in weight change in people with and without T2D, the presence of T2D did not influence efficacious weight loss with semaglutide; however, alternative explanations, such as hepatic steatosis, cannot be ruled out.

FRI-524

Safety and efficacy of oral semaglutide in overweight diabetic patients with non-alcoholic fatty liver disease: an interim analysis

Arun Valsan[1], Gauri Unnithan[2], Arathi Venu[2], Nipun Verma[3], Muhammed Shafi Pa[2], Arjun Santhosh[2], Ajee K L[4], Narmadha Mp[2], Harish Kumar[1], Nimitha K Mohan[5], Priya Nair[1], Shine Sadasivan[1], Sudhindran S[1], Manjima Nair[1], Arunima Sumith[2], Gouripriya Ls[2], Suja Kumari S[4], Vaishnavy S Vinod[1], Anoop Koshy[1]. Email: drarunvalsan@gmail.com

Background and aims: Currently there are no approved therapies for non-alcoholic fatty liver disease. Many drugs are in varying stages of approval for application in NAFLD. Semaglutide (Rybelsus) is a first-of-its-kind orally active glucagon-like peptide-1 (GLP-1) analogue that has recently been approved by US FDA for treatment of diabetes mellitus. Injectable semaglutide has proven to be efficacious in fibrosis reduction in a recently concluded phase 2 trial.

Method: This is a single-centre, single-arm, open-labelled study of oral semaglutide in a tertiary care hospital in southern India. Patients with co-existent liver disease (significant alcohol, viral hepatitis, autoimmune hepatitis etc) were excluded. All patients were administered lifestyle modification with advice for calorie restricted diet and gradually intensifying aerobic exercise regimen, culminating in 45 minutes aerobic exercise for at least 5 days per week. The compliance to dietary and exercise regimen was ensured by weekly telephonic interview by trained allied health personnel. The subjects were initiated on a 3 mg dose for one week, followed by a teleconsultation to assess tolerability. From week 2, all subjects who tolerated the drug were administered 7 mg drug on an empty stomach. The patients were followed up for 24 weeks.

Results: A total of 59 overweight (BMI>23.5 kg/m^2), diabetic patients with imaging evidence of NAFLD were recruited to the study; however, 9 patients were excluded from final analysis [Laprascopic sleeve gastrectomy (n = 2), drug non-compliance (n = 2), drug intolerance (n = 5)]. The mean age of study population was 50.4, with predominant males (62%), mean BMI-33.7 kg/m^2 and mean duration of diabetes of 7.8 years were included. The associated co-morbidities were systemic hypertension (26%), hypothyroidism (18%), dyslipidemia (64%), coronary heart disease (10%). At the start of the study, percentage of patients on insulin (34%), metformin (74%), saroglitazar (14%), statins/fibrates (42%), vitamin E (5%). After 24 weeks of semaglutide therapy, there was significant reduction in LSM, CAP, FIB-4, ALT, cholesterol, LDL, HDL ($p < 0.005$, each). The LSM and CAP improvements were consistently significant in 3 BMI strata (25–30, 30–35, >35 Kg/m^2) ($p < 0.016$, each). (Fig. 1).

Conclusion: Oral Semaglutide was safe and efficacious and well tolerated in overweight diabetic patients with NAFLD in this interim analysis at 24 weeks. There was a significant reduction in BMI, ALT, liver stiffness, CAP and lipid profile. There were no significant treatment-emergent adverse events. There is a need of randomized placebo-controlled trials to further explore its role in diabetes-associated NAFLD.

The effects of a novel online app (Noom Weight) on weight loss and liver biomarkers in patients with NAFLD: a single arm proof-of-concept study

Naim Alkhouri[1], Jesus Topete[1], Meaghan McCallum[2], Kelly Blessing[2], Mazen Noureddin[3], Angie Coste[1], Anita Kohli[1]. *[1]Arizona Liver Health, Phoenix, United States; [2]Noom, United States; [3]Houston Research Institute, United States*
Email: naim.alkhouri@gmail.com

Background and aims: Weight loss through lifestyle modifications remains the mainstay for NAFLD treatment; however, implementing effective lifestyle interventions in clinical practice has been challenging due to time and cost constraints. Having a comprehensive approach to weight loss in patients with NAFLD that can be scaled and provided at low cost is a key unmet need. The objective of this study is to assess the effects of a mobile weight management program on weight loss and liver health biomarkers in adults with obesity and NAFLD.

Method: Adults with obesity (BMI 30 to 49.9 kg/m^2 inclusive) and evidence of NAFLD based on Fibroscan CAP ≥274 dB/m were included. Patients were given access to the Noom Weight program for 16 weeks (midpoint) and then were followed for an additional 8 weeks (week 24 or end point). Measurements completed at baseline, midpoint, and end point included: weight/BMI, Fibroscan, routine labs (Complete Metabolic Panel and CBC), and the exploratory biomarker cytokeratin 18 fragment (CK18f). All tests of significance were performed at alpha = 0.05, two sided.

Results: 40 subjects were enrolled and 82.5% (33/40) completed the study. The mean age was 55.9 years (range 29–79) with a mean BMI of 38 kg/m2 (30.5–49.8) and a mean baseline CAP score of 331.9 db/m^2 (276–396) and a mean LSM of 7.54 kPa (4.9–13.3). The average change in body weight from baseline was a 4.0% reduction and 32.4% (11/34) achieved total body weight reduction by 5% or more. There was a significant reduction in the CAP score by end point of 21.35 dB/m (p = 0.024). The ALT decreased by 10 U/L or more in 27.3% (9/33). There was moderate correlation between BMI decrease and reduction in the CAP score (R = 0.533). There was no change in the LSM at the end point, and 62% (21) of subjects achieved >5% drop in CK18f. The change in CK18f correlated weakly (R = 0.215) with BMI drop but more strongly with Fibroscan CAP score (R = 0.468) and LSM (R = 0.764).

Conclusion: The Noom Weight program had beneficial effects in patients with obesity and NAFLD, including significant reduction in the CAP score and one third of patients achieving 5% or more reduction in their weight. Steatosis of the liver was affected by weight loss as a result of engagement with the Noom Weight program. Fibrosis was not significantly affected by the Noom Weight program in the timeframe of the study. Fibrosis may require a longer timeframe for changes to be measured.

FRI-526

The effect of standard of care lifestyle advice by a hepatologist in a routine clinical practice on steatosis and fibrosis development among NAFLD patients

Leen Heyens[1,2,3], Wouter Robaeys[1,3], Mathieu Struyve[3], Gert Stockmans[3], Sven Francque[4,5], Geert Robaeys[1]. *[1]Hasselt University, Faculty of Life Sciences and Medicine, Hasselt, Belgium; [2]Maastricht University, NUTRIM, Maastricht, Netherlands; [3]Hospital Oost-Limburg, Gastro-enterology, Genk, Belgium; [4]University of Antwerp, Gastro-enterology and Hepatology, Antwerpen, Belgium; [5]Antwerp University Hospital, Gastro-enterology and Hepatology, Edegem, Belgium*
Email: leen.heyens@uhasselt.be

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become the most frequent cause of chronic liver disease. The leading cause of NAFLD has been defined as a behavioural phenotype comprising low physical activity and an obesogenic diet. The primary therapeutic advice is lifestyle changes leading to weight loss. Previous studies indicated that a weight reduction of 5% or more could induce regression of steatosis or fibrosis. However, hepatologists only have time during consultations to give a short outline of the optimal lifestyle. As no data is available on the outcome of this routine practice, we evaluated the effect of this lifestyle advice on steatosis and fibrosis development among NAFLD patients.

Method: Data were collected retrospectively using the electronic patient files of NAFLD patients in whom a baseline and a follow-up FibroScan® measurement (for assessment of steatosis by CAP™ and of liver stiffness (LSM) as a surrogate for fibrosis) were performed between November 2019 and 2022 at Ziekenhuis Oost-Limburg, Genk, Belgium. At the start, patients received Mediterranean diet related-advice, tips on improving exercise, and an information brochure concerning NAFLD from the hepatologist. Clinically meaningful weight loss was defined as a loss of at least 1 kg.
Results: Of the 218 NAFLD patients evaluated, 130 (59.6%) were excluded due to the usage of semaglutide, not fasting, IQR/MED>30%, or bariatric surgery. In total, 88 (40.4%) patients were included, of whom 53 (60.2%) were men and 38 (43.2%) had type 2 diabetes mellitus (T2DM). The mean age, median BMI, and mean waist circumference were 54 ± 13 years, 31.0 (28.4–34.9) kg/m² and 105.2 ± 12.7 cm, respectively. On average, there were 186 (124–280) days between the measurements. The median weight loss between measurements was −1.2 (−4.1;1.4) kg. The decrease in LSM and CAP™ were −1.2 (−3.1;0.3) kPa and −7.0 (−50.5;8.8) dB/m, respectively. Within this group, 47 (53.4%) had clinically meaningful weight loss, while 41 (46.6%) did not lose any weight or gained weight. The group with weight loss developed a significantly ($p < 0.001$) lower CAP™ compared to baseline values, but there was no significant change in LSM during the same time period. Furthermore, within the weight loss group, there were no differences in magnitude of weight loss or CAP™ when stratified based on sex, age categories (≤50 years vs. >50 years), or having T2DM or not ($p > 0.05$).
Conclusion: To the best of our knowledge, this is the first study to assess the effect of routine lifestyle advice by a hepatologist on body weight, steatosis, and fibrosis, measured by FibroScan®. The lifestyle advice leads to a weight reduction of at least −1 kg in almost half of NAFLD patients and a significant reduction in steatosis over six months in those patients. However, the recommended reduction in body weight (at least 5%) is not reached. Other measures to support the advice on lifestyle change given by the hepatologist are hence necessary to improve efficacy.

FRI-527

Comparison of efficacy between liraglutide and phentermine/topiramate in obese patients with non-alcoholic fatty liver disease

Young Eun Chon[1], Kwan Sik Lee[1], Yeonjung Ha[1], Joo Ho Lee[1]. [1]*CHA Bundang Medical Center, CHA University, Korea, Rep. of South*
Email: nachivysoo@chamc.co.kr

Background and aims: Anti-obesity drugs are known to improve hepatic inflammation in patients with non-alcoholic fatty liver disease (NAFLD). We aimed to compare the effect of liraglutide and phentermine/topiramate in obese NAFLD patients.
Method: We retrospectively enrolled 65 obese NAFLD patients without type 2 diabetes mellitus (liraglutide group [n = 30], phentermine/topiramate group [n = 35]) who were treated with liraglutide or phentermine/topiramate for 12 months. Changes in laboratory data, body weight, degree of steatosis and fibrosis were compared between two groups. Steatosis was assessed using the fatty liver index, NAFLD liver fat score, and controlled attenuation parameter (CAP). Fibrosis was assessed using fibrosis index based on four factors (FIB4) and liver stiffness.
Results: The mean body weight (80.3 ± 12.3 kg) and body mass index (29.4 ± 3.2) were similar between two groups. After 12 month of treatment, phentermine/topiramate group showed significantly greater effect in weight loss than liraglutide group (−8.4 ± 0.6 vs. −6.3 ± 0.4 kg, $p = 0.003$). Both group showed similar effect showing significant steatosis reduction (phentermine/topiramate vs. liraglutide; Δfatty liver index: −8.9 ± 2.3 vs. −8.4 ± 1.7, $p = 0.449$; ΔNAFLD liver fat score: −0.5 ± 0.2 vs. −0.4 ± 0.2, $p = 0.835$; ΔCAP: −9.2 ± 6.9 vs. −8.3 ± 4.6 dB/m², $p = 0.129$). Fibrosis improvement was noted in both groups (Δliver stiffness, −2.2 ± 1.0 vs. −1.8 ± 0.9, $p = 0.052$; ΔFIB-4 index: −0.10 ± 0.10 vs. −0.11 ± 0.13, $p = 0.860$).
Conclusion: Liraglutide or phentermine/topiramate treatment significantly ameliorated liver steatosis and inflammation, but either treatment showed minimal effect on fibrosis improvement.

FRI-528

Development of physiologically based pharmacokinetic model to predict liver exposure of SRT-015, a next-generation inhibitor of apoptosis signal-regulating kinase 1

Artur Plonowski[1], Daniel Burge[1], Kathleen Elias[1], Neil D. McDonnell[1]. [1]*Seal Rock Therapeutics, Inc., United States*
Email: aplonowski@sealrocktx.com

Background and aims: SRT-015 is a novel, clinical-stage, small molecule inhibitor of Apoptosis Signal-regulating Kinase 1 (ASK1) in development for liver diseases, including alcoholic hepatitis (AH), acute-on-chronic liver failure (ACLF), and non-alcoholic steatohepatitis (NASH). In all preclinical species evaluated, SRT-015 is preferentially distributed to liver, with liver/plasma ratio ranging 10–60x. We aimed to develop a physiologically based pharmacokinetic (PBPK) model to non-invasively estimate liver exposure of SRT-015 in humans
Method: GastroPlus software (Simulation Plus, Lancaster, CA) was used first to build and validate PBPK models for SRT-015 PK in mouse, rat, and non-human primates to explain the observed plasma concentrations vs. time profiles following intravenous (IV) and oral administration. The model was further expanded with the addition of efficacious liver and plasma concentrations of SRT-015 determined in preclinical models of NASH (DIO-NASH model, Gubra), AH/ACLF and acetaminophen overdose toxicity. Knowledge gained during preclinical PBPK modeling was then applied to build a human PBPK model for SRT-015 and predict First-in-Human (FIH) exposure following oral administration. Actual plasma exposure of SRT-015 from the FIH study (NCT04887038) was then used to refine the human PBPK model and predict human liver exposure of SRT-015. The established model was also used to simulate human plasma and liver exposure after IV administration of SRT-015.
Results: The preclinical PBPK model was highly predictive of human SRT-015 plasma exposure with all observed values of C_{max} and AUC from FIH study falling within the predicted ranges across all dose levels (40, 80, 160, 320, and 640 mg; po) administered to healthy participants. After further refinement, the C_{max} and AUC values predicted by the model correlated well with the observed values (r^2 = 0.89 and r^2 = 0.99, respectively). The clinical PBPK model of orally administered SRT-015 predicted a robust exposure of SRT-015 within the liver, with dose-proportional increase of Cmax between 40 and 320 mg, and less-than-proportional increase between 320 and 640 mg. Importantly, the predicted hepatic Cmax values were well above the efficacious exposure levels observed in preclinical efficacy models. Additionally, the model predicts efficacious exposure with IV formulated, continuous infusion SRT-015.
Conclusion: We have established a highly predictive PBPK model of SRT-015 exposure in human liver. The model indicates efficacious exposure in the liver with all oral doses tested in the phase 1 clinical trial in healthy participants and will help in the dose selection for Phase 2 trials. The model also indicates the feasibility to attain efficacious exposure via IV infusion, which could be a preferred administration route in ACLF patients with impaired consciousness or otherwise unable to swallow an oral drug.

FRI-529

Barriers for regular exercise in people with non-alcoholic fatty liver disease

Kedar Deshpande[1], Ken Nosaka[1], Oyekoya Ayonrinde[2], John Olynyk[1], Marcelle Scagliotta[2], Wendy Lam[2], Huirong Ma[2], Crystal Connelly[2]. [1]*Edith Cowan University, School of Medical and Health Sciences, Australia;* [2]*Fiona Stanley Hospital, Gastroenterology and Hepatology, Australia*
Email: kdeshpan@our.ecu.edu.au

Background and aims: Performing regular exercises is an important alternative or adjunct to pharmacotherapy for treating non-alcoholic fatty liver disease (NAFLD). While many people with NAFLD do not perform adequate physical activity and exercise, it is important to understand barriers for them to achieve an effective exercise routine. We therefore aimed to examine associations between patients' knowledge of exercise as treatment of NAFLD, their self-perceived barriers to exercise, and their stages in NAFLD.
Method: Patients with NAFLD attending an outpatient hepatology clinic were recruited. They were assessed for the severity of hepatic steatosis using controlled attenuation parameter (CAP) and fibrosis by transient elastography (TE). An online questionnaire was administered to them to ask their self-reported exercise patterns, barriers to exercise, and knowledge regarding effectiveness of different types of exercise for NAFLD. We sought associations between the questionnaire responses and liver characteristics.
Results: Forty-seven patients (29 females) with a mean age of 57.6 ± 11.7 years and body mass index (BMI) of 33.7 ± 6.3 completed the questionnaire. The mean CAP and liver stiffness measurement (LSM) values by TE were 336.2 ± 44.5 dB/m and 13.2 ± 12.6 kPa, respectively. Although the majority of patients (n = 42, 89%) considered NAFLD to be a serious health concern, 72% (n = 34) of them did not achieve recommended exercise levels of ≥150 minutes of moderate-intensity physical activity per week, and 64% (n = 30) were unsure about the role of exercise in NAFLD treatment. The most common barriers to exercise reported were health problems (64%), lack of time (36%), and lack of enjoyment in exercising (26%). There were no significant associations between CAP, LSM and exercise questionnaire responses.
Conclusion: The majority of patients were unaware of the role of exercise as a potential treatment for NAFLD and were not achieving recommended exercise levels. Inadequate time to exercise, physical and mental health problems, and lack of enjoyment in exercise were the major barriers for them to exercise. Future randomised exercise trials and behavioural research for NAFLD should focus on individualised and sustainable exercise programs to improve patients' long-term adherence to exercise to reduce the burden of NAFLD.

FRI-530

A randomized controlled trial of kalmegh supplementation on non-alcoholic fatty liver disease

Sanket Nandekar[1], Sunil Kumar[1], Devesh Yadav[2], Binay Sen[3], Pournima Gadge[4]. [1]*Institute of medical sciences, Banaras hindu university, Department of community medicine, Varanasi, India;* [2]*Institute of medical sciences, Banaras hindu university, Department of gastroenterology, Varanasi, India;* [3]*Institute of medical sciences, Banaras hindu university, Department of dravyaguna, Varanasi, India;* [4]*Apex institute of ayurvedic medicine and hospital, Department of prasuti tantra, Mirzapur, India*
Email: snktmv@bhu.ac.in

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease worldwide (prevalence 20–30%). Kalmegh (Botanical name: Andrographis-paniculata nees, Family: Acanthaceae) is an exceptional herb from classical Indian literature having comprehensive action over liver. Our aim was to assess the safety, effectiveness and cost of treatment for kalmegh supplementation in NAFLD using modern day investigations and standard procedures of randomized controlled trial.

Method: We have enrolled 91 patients of age group 18–60 years from Gastroenterology OPD of tertiary care hospital in northern India. Written and informed consent was obtained and patients were randomized to group A and group B. Patients in group A (n = 49) were given kalmegh capsules and group B (n = 42) were given placebo capsules, each having dose of 1600 mg per day. Standard lifestyle modification and dietary intervention were advised in both the groups. Patients were followed up for the period of 90 days at 30 days interval for 3 subsequent visits. Anthropometric measurements along with blood and radiological investigation were performed during each follow-up.
Ethical approval was obtained from institutional ethical committee-ECR/526/Inst/UP/2014/RR-20.
CTRI (clinical trial registry India) registration no. CTRI/2021/10/037692.
Results: Patients in both the groups has shown significant improvement in anthropometric parameters with $p < 0.05$ at all the follow-ups. In group A, serum low density lipoprotein (Sr. LDL), LDL/HDL ratio and serum triglyceride reduced significantly ($p < 0.05$) at all the subsequent follow-ups while in group B reduction was non-significant at most of the follow-up except some. Similarly in group A aspartate aminotransferase (AST) and alanine aminotransferase (ALT) reduced significantly ($p < 0.05$) at all the subsequent follow-ups while in group B reduction was non-significant in some follow-ups. In group A, liver stiffness reduced significantly ($p < 0.05$) when compared with group B.
Cost of treatment of NAFLD for 1 month with modern medicine was Rs 1394 and with kalmegh it is Rs 82.

Figure: Showing improvement in clinical and biochemical parameters in both groups at different follow-ups

		Initial Vs 1st follow up		Initial Vs 2nd follow-up		Initial Vs 3rd follow up	
Parameter	Group	Change in percentage (%)	p	Change in percentage (%)	p	Change in percentage (%)	p
Serum	A	22.32 (–)	0.000	24.22 (–)	0.001	26.63 (–)	0.016
Triglycerides	B	16.39 (–)	0.000	19.81 (–)	0.000	23.92 (–)	0.015
Serum LDL	A	6.57 (–)	0.004	13.80 (–)	0.000	13.45 (–)	0.022
	B	6.65 (–)	0.046	2.45 (–)	0.977	9.67 (–)	0.821
LDL/HDL ratio	A	5.03 (–)	0.072	15.35 (–)	0.001	10.70 (–)	0.144
	B	5.67 (–)	0.121	3.05 (–)	0.577	2.09 (–)	0.839
AST	A	14.88 (–)	0.000	26.99 (–)	0.001	21.53 (–)	0.009
	B	9.65 (–)	0.045	17.96 (–)	0.008	18.55 (–)	0.094
ALT	A	14.23 (–)	0.004	22.06 (–)	0.002	27.40 (–)	0.026
	B	11.37 (–)	0.045	22.22 (–)	0.011	19.24 (–)	0.069
Fibroscan (Kpa)	A	19.47 (–)	0.047	20.18 (–)	0.046	35.41 (–)	0.043
	B	6.20 (–)	1.000	14.97 (–)	0.482	1.05 (+)	0.285

Note: (–) reduced; (+) increased.

Conclusion: Study shows that patients taking kalmegh supplementation has shown more significant improvement in lipid profile, liver enzymes and liver stiffness when compared with patients taking placebo. No patient in both the group has shown any adverse reaction or progress of the disease pathogenesis. This supports the safety and effectiveness of kalmegh in NAFLD and also, we can conclude that treatment of NAFLD with kalmegh is 17 times more economical than that of modern medicine.

Non-invasive assessment of liver disease except NAFLD

FRI-477

Dynamics of liver stiffness measurements provide incremental prognostic information in advanced chronic liver disease

David JM Bauer[1,2,3], Zhenwei Yang[4], Fiona Köck[1], Laurenz Fritz[1], Benedikt Hofer[1,2,5], Lorenz Balcar[1,2], Lukas Hartl[1,2], Mathias Jachs[1,2], Katharina Stopfer[1], Theresa Bucsics[1,2], Benedikt Simbrunner[1,2,5], Bernhard Scheiner[1,2], Michael Trauner[1], Mattias Mandorfer[1,2], Thomas Reiberger[1,2,5], Georg Semmler[1,2]. *[1]Medical University of Vienna; Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Wien, Austria; [2]Medical University of Vienna, Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Vienna, Austria; [3]Klinik Ottakring-Wiener Gesundheitsverbund, 4. Medical Division with Gastroenterology, Hepatology, Endoscopy, Wien, Austria; [4]Erasmus University Medical Center, Department of Biostatistics, Netherlands; [5]Medical University of Vienna, Christian-Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Wien, Austria*
Email: thomas.reiberger@meduniwien.ac.at.

Background and aims: Liver stiffness measurements (LSM) allow for non-invasive assessment of the severity of chronic liver disease and identification of advanced chronic liver disease (ACLD). Yet, the clinical relevance of dynamics in LSM within ACLD are unclear. This study examines the significance of LSM dynamics as a marker of liver disease regression or progression, and as a predictor of hepatic decompensation and liver-related mortality.
Method: Patients with chronic liver disease who underwent ≥2 reliable LSM, least 6 months apart, were retrospectively included. At baseline (BL), participants were divided into three groups: non-ACLD with BL-LSM <10 kPa, and compensated ACLD (cACLD) with BL-LSM ≥10 kPa. Joint modelling (combining a linear mixed effects model with a cause-specific proportional hazard model) was used to assess the association of longitudinal changes in LSM with hepatic decompensation and liver-related mortality.
Results: 2123 patients (67% non-ACLD, 33% cACLD) were followed for a median of 65 months, during which 4 (0.3%) non-ACLD and 72

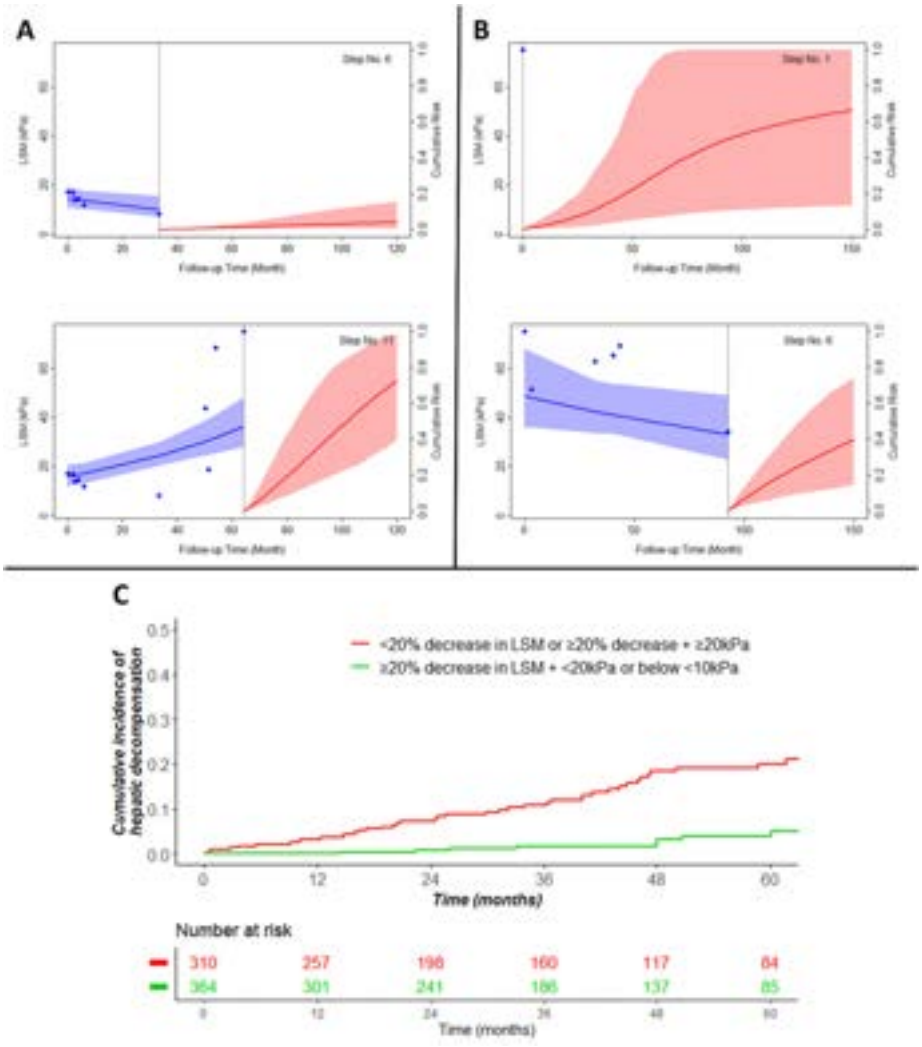

Figure: (abstract: FRI-477) Updated risk prediction of the longitudinal LSM model for (A) increasing LSM and (B) decreasing LSM (LSM values and a regression line in blue on the left side, cumulative risk of hepatic decompensation in red on the right side), and (C) Kaplan Meier curve for hepatic decompensation in cACLD patients according to the BAVENO cutoff for a clinically significant LSM decrease.

(9.9%) cACLD patients developed hepatic decompensation, while 2 (0.1%) and 41 (5.9%) died of liver-related causes. In cACLD patients, doubling of LSM at any point was linked to a significantly higher risk of hepatic decompensation (adjusted hazard ratio (aHR) per log-increase: 4.33 [95%CI: 2.74–7.06], p < 0.001) and liver-related death (aHR: 4.00 [95%CI: 2.47–6.87], p < 0.001), indicating a ~50% change in risk for every 20% change in LSM over time, in a model adjusted for age, platelet count, MELD, and albumin. Results were robust and numerically similar in subgroup analyses of hepatitis C patients, and in a model adjusted for etiological cure as a time-dependent covariable.

The accuracy of LSM dynamics (ROC: 0.847) for predicting hepatic decompensation within 2 years was higher was superior to a single BL-LSM (0.805), and dynamics in platelet count (0.754), MELD (0.722) or albumin (0.559).

The definition of a clinically significant LSM-decrease suggested by the BAVENO VII consensus, i.e., a 20% decrease in LSM to a value <20 kPa or <10 kPa was validated to identify patients with a significantly reduced risk of hepatic decompensation (HR: 0.18, 95% CI: 0.09–0.37, p < 0.001).

Conclusion: Repeated longitudinal measurements of LSM facilitate an individualized and continuously updated risk prediction for hepatic decompensation and liver-related mortality. Importantly, the prognostic value of dynamics in LSM was superior to those of other established prognostic markers.

FRI-478

Liver stiffness measurement Baveno VII rule of 5 and risk of hepatocellular carcinoma after HCV eradication in patients with cirrhosis

Binu John[1], Yangyang Deng[2], David Kaplan[3], Janice Jou[4], Tamar Taddei[5], Paul Martin[6], Dustin Bastaich[2], Hann-Hsiang Chao[7], Bassam Dahman[2]. *[1]Miami VA Health System and University of Miami, Gastroenterology and Hepatology, Miami, United States; [2]Virginia Commonwealth University, United States; [3]University of Pennsylvania, United States; [4]Portland Va and Oregon Health Sciences University, United States; [5]VA Connecticut Health System and Yale University, United States; [6]University of Miami, United States; [7]VA Richmond Health Care, United States*

Email: binu.john@gmail.com.

Background and aims: Liver stiffness (LSM) using the Baveno VII "Rule of 5" cut-offs can reliably predict risk of hepatic decompensation. Patients with cirrhosis secondary to chronic hepatitis C (HCV) are at risk for hepatocellular carcinoma (HCC) despite sustained virological response (SVR). We examined if post-SVR LSM using the Baveno VII "Rule of 5" cut-offs can be used for risk stratification to predict the annual risk of HCC.

Method: This was a retrospective cohort study of 1,605 participants from the VOCAL cohort, with HCV cirrhosis and SVR. Patients were followed from the time of post-SVR LSM until diagnosis of HCC, death, or 03/01/2022 in the VOCAL cohort for a total follow-up of 4444.06 person-years.

Results: The annual risk of HCC was 1.43% among participants with post SVR LSM <10 KPa, 2.52% in those with LSM 10–14.9 KPa (adjusted Hazard Ratio [aHR] vs. baseline 1.83, 95% CI 1.06–3.18, p = 0.03), 2.15% for LSM 15–19.9 KPa (aHR 1.56, 95% CI 0.76–3.21, p = 0.22), 3.43% among LSM 20–24.9 KPa (aHR 2.51, 95% CI 1.24–5.07, p = 0.01), and 4.14% in LSM≥25 KPa (aHR 3.20, 95% CI 1.84–5.56, p < 0.0001).

When post SVR Fib-4 was used, the annual risk of HCC was 1.47% in participants with post-SVR Fib-4 < 1.45 (baseline) and similar at 1.82% in those with Fib-4 1.45–3.25 (aHR 1.29, 95% CI 0.68–2.43, p = 0.44), but elevated at 3.96% (aHR 2.91, 95% CI 1.47–5.75 p = 0.002) in participants with Fib-4≥3.25.

Conclusion: Increase in LSM using the Baveno VII criteria "rule of 5" on liver elastography predicts higher rates of HCC in HCV cirrhosis after SVR at multiple cut-off levels, compared to dichotomous risk stratification by Fib-4, and offers a single test to predict risk of hepatic decompensation and HCC.

FRI-479

Liver stiffness can monitor disease severity and changes predict decompensation in alcohol-related liver disease

Email: katrine.holtz.thorhauge@rsyd.dk.

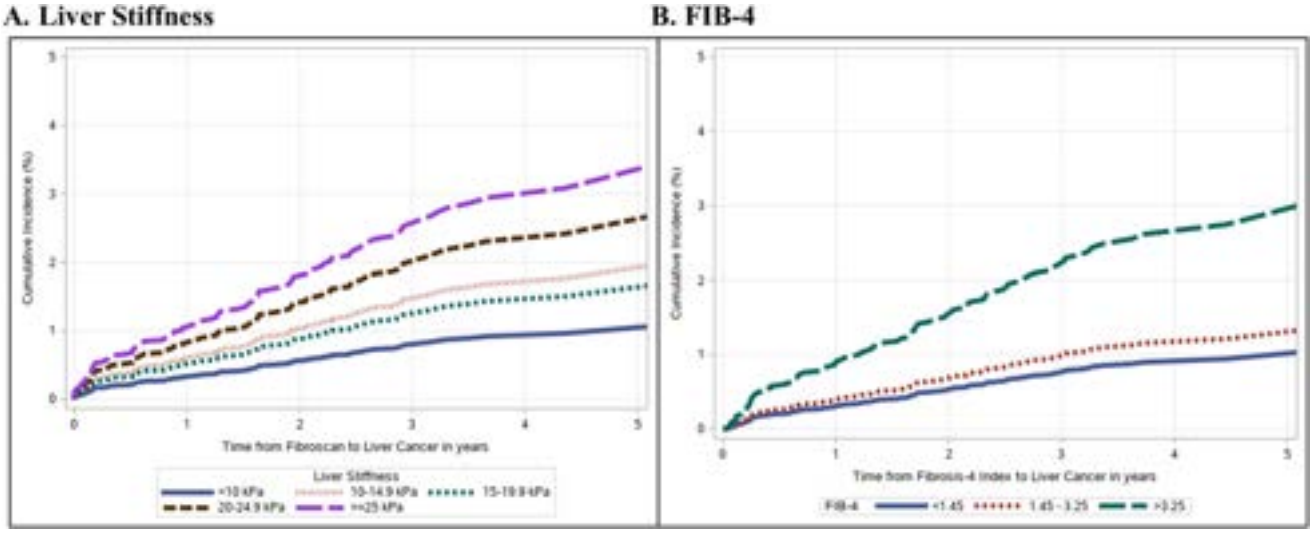

Figure: (abstract: FRI-478) Cumulative incidence frequency for adjusted hazard ratio of liver cancer by liver stiffness and FIB-4, among patients with HCV cirrhosis after SVR

Background and aims: More than 75 million people worldwide are at-risk of alcohol-related liver disease (ALD). Transient elastography (TE) is an established diagnostic and prognostic tool, but is not yet validated for disease monitoring in compensated advanced chronic liver disease (cACLD). We aimed to evaluate the value of TE for disease monitoring in ALD, as suggested by Baveno VII.
Method: Two cohorts of compensated ALD patients with long-term outcome evaluation were included. Based on repeated TE, we evaluated the risk of decompensation in cACLD (TE ≥10 kPa) stratified for changes in disease severity and compared to patients without cACLD (TE <10 kPa). According to the rule-of-five (e.g. TE: 10–15–20–25 kPa), we defined disease progression as an increase of ≥5.0 kPa, while disease regression was defined as a repeated TE <10 kPa *or* a repeated TE <20 kPa with an associated decrease of ≥20%. We calculated subdistribution hazard ratios (SHR) from competing risk analysis with death prior to decompensation as a competing event. Moreover, we report the 3-year decompensation-free survival for the full cohort.
Results: We included 537 patients (n = 440 Odense, n = 97 Vienna) with a median age of 57 years (IQR: 49–63) and baseline TE of 8.2 kPa (IQR: 5.0–21.6). 371 patients (69%) had a repeated TE after a median of 25 months (IQR: 18–38) and were followed for additionally 37 months (IQR: 25–61) during which 41 decompensated (11%) and 55 died (15%). In cACLD patients with repeated TE (n = 125/371) 10% progressed (progressors), 43% regressed (regressors), while 14% had stable non-severe disease (TE <25 kPa) and 33% had stable severe disease (TE ≥25 kPa). We found an increased risk of decompensation for patients with cACLD vs. without cACLD (SHR = 17.5, CI: 7.1–43.0, P < 0.01). Moreover, progressors (SHR = 3.6, CI: 1.2–11.1, P = 0.03) and patients with stable severe disease (SHR = 3.9, CI: 1.6–9.1, P < 0.01) had a significant higher risk of decompensation than regressors (figure).13% of patients without cACLD at baseline progressed to cACLD (n = 33/246) associated with a higher risk of decompensation, but not statistically significant (SHR = 4.6, CI: 0.8–26.0, P = 0.08). The overall 3-year decompensation-free survival was 69% in patients with cACLD at baseline (CI: 0.62–0.75) and 97% in patients without cACLD at baseline (CI: 0.95–0.99).

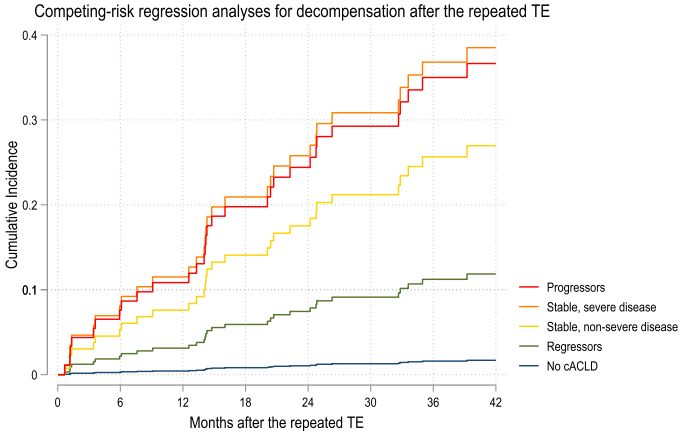

Figure:

Conclusion: Repeated TE is useful for monitoring disease severity in cACLD as defined by Baveno VII, and changes in TE accurately predicts decompensation in patients with ALD.

FRI-480

Transient elastography efficiently detects severe fibrosis in patients with chronic hepatitis D

Dominique Roulot[1], Segolene Brichler[2], Layese Richard[3], Nathalie Ganne-Carrié[1], Christiane Stern[4], Veronique Loustaud-Ratti[5], Martial Gouton[6], Françoise Roudot-Thoraval[3], Victor de Lédinghen[7]. *[1]AP-HP, hopital Avicenne, Liver Unit, Université Sorbonne Paris Nord, Bobigny, France; [2]AP-HP, hopital Avicenne, Laboratoire de microbiologie clinique, Université Sorbonne Paris Nord, Bobigny, France; [3]AP-HP, hopital Henri Mondor, Unité de recherche clinique, Université Paris-Est, Créteil, France; [4]AP-HP, hopital Beaujon, Liver Unit, Clichy, France; [5]CHU Limoges, hopital Dupuytren, Liver Unit, Limoges, France; [6]AP-HP, hopital Avicenne, Liver Unit, France; [7]CHU Bordeaux, Hopital Haut Leveque, Liver Unit, Bordeaux Pessac, France*
Email: dominique.roulot@aphp.fr.

Background and aims: Hepatitis D virus infection (HDV) is associated with accelerated progression of liver disease to cirrhosis. Identifying severe fibrosis in chronic HDV-infected patients requiring urgent treatment is crucial. Non-invasive transient elastography (TE) has transformed the management of chronic hepatitis B and C virus infection. In patients with chronic hepatits D, liver biopsy remains the gold standard procedure for fibrosis staging. The aim of this study was to evaluate the performance of TE (FibroScan) for the diagnosis of liver fibrosis in HDV-infected patients.
Method: TE was evaluated in HDV RNA-positive patients with liver biopsy (LB) included in a national cohort. LB and laboratory parameters were performed within 6 months from TE. Hepatic fibrosis was assessed using the Metavir stages (F0–4). TE diagnostic performance in identifying cirrhosis (F4), severe fibrosis (F3) and significant fibrosis (F2) was compared to that of non-invasive fibrosis tests, such as the aspartate aminotransferase to platelet ratio index (APRI), the fibrosis-4 score (FIB-4) and the Delta-4 fibrosis score (D4FS). Area under receiver operator characteristics (AUROC) and Youden indexes were used to establish new cut-offs values.
Results: Data from 192 HDV-infected patients with valid TE measurements were analyzed (66% males, median age 35 [29–43] yrs, median BMI 24.0 [21.6–27.3] kg/m^2). The prevalence of histologic fibrosis stages was 22.6% for F0F1, 25.5% for F2, 8.4% for F3 and 33.5% for F4. TE demonstrated excellent diagnostic accuracy for the detection of cirrhosis with an AUROC of 0.87, compared with that of APRI (0.72), FIB-4 (0.75) and D4FS (0.84) (p = 0.002). TE was also superior for the detection of severe fibrosis (AUROC of 0.84, compared to 0.70 for APRI and 0.74 for FIB-4 (p = 0.002). TE performance was not better, however, for the detection of significant fibrosis (AUROC of 0.78 compared to 0.73 for APRI and 0.70 for FIB-4). At the optimized cut-off value of 11 kPa for determining cirrhosis, TE showed a sensitivity of 79%, a specificity of 80%, a predictive positive value (PPV) of 67% and a negative predictive value (NPV) of 88%; 80% of the patients being correctly classified. At the optimized cut-off value of 9 kPa for determining severe fibrosis, TE had a sensitivity of 81%, a specificity of 72%, a PPV of 77% and a NPV of 77%, with 77% of correctly classified patients.

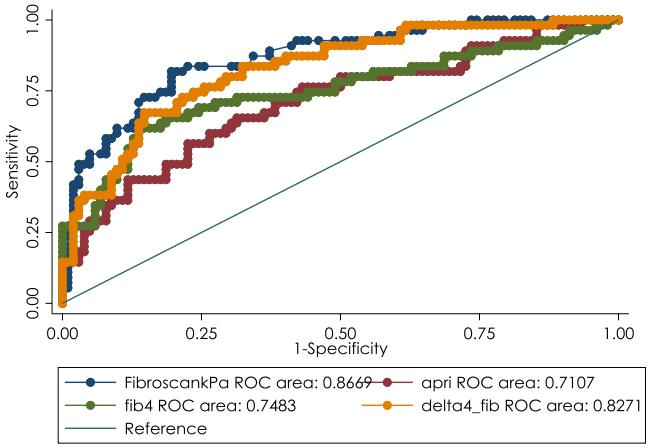

Figure: AUROC for Diagnosis of HDV cirrhosis.

Conclusion: In summary, based on these data from a large real-life cohort, TE has a good diagnostic performance for determining severe

fibrosis and cirrhosis in patients with chronic HDV infection at baseline.
The high probability of severe fibrosis or cirrhosis in patients with LSM >9 kPa necessitates rapid appropriate treatment. In case of LSM <9 kPa, a liver biopsy is recommended. Additional studies will evaluate the potential superior diagnostic performance of combining TE with biomarkers.

FRI-481

Screening for hepatic fibrosis in primary care by FIB-4 score, followed in second line f the ELF (enhanced liver fibrosis) test: what are the best thresholds?

Denis Ouzan[1,2], Guillaume Peneranda[3,4], Malik Jlaiel[5], Jeremie Corneille[6]. *[1]Instutut Arnault Tzanck, SAINT LAURENT DU Var, France; [2]RHECCA, France; [3]AlphaBio, Marseille, France; [4]BIOGROUP ALPHABIO-Laboratoire Européen, France; [5]BIOGROUP BIOESTEREL-Laboratoire Mandelieu-Passero, France; [6]BIOGROUP BIOESTEREL-Laboratoire Mougins-L'espérance, France*
Email: denis.ouzan@wanadoo.fr.

Background and aims: Screening for liver fibrosis in the general population is a public health issue. We have shown in a previous study that FIB-4 (1), can detect liver fibrosis in general practice and identify a possible cause of liver disease. But the optimal FIB-4 threshold remains to be specified. The FIB-4 thresholds usually used are: low risk if <1.30, intermediate risk between 1.3 and 2.67, and high risk if ≥2.67. Only one study (2) has proposed an age-dependent FIB-4 threshold: FIB-4 ≥1.3 for subjects younger than 65 years and ≥2 for those older than 65 years. The objective of our work was to explore different FIB-4 thresholds and in particular the threshold of >2 for all patients, which is much simpler and independent of age, by performing a second-line ELF (Enhanced Liver Fibrosis) score, after screening for liver fibrosis by FIB-4 in general practice.
Method: The FIB-4 score was performed prospectively from March to September 2022 in all consecutive patients seen by 17, outside the emergency. When the FIB-4 was ≥1.3, it was defined as positive, and a confirmatory ELF test was systematically performed. The positive FIB-4 test was confirmed when the second line ELF test was ≥9.8 (indicating an advanced fibrosis).
Results: The results are reported in the table below. Among the 3427 patients seen in general practice, 869 (25%) had a positive FIB4 score, which was confirmed by the ELF test in 59% (n = 509) of cases. 35% of them were older than 65 years. Confirmation was significantly more frequent in subjects over 65 years of age compared to those under 65 years of age: 67% vs 36%, p < .0001. For an age-dependent FIB-4 threshold (>1.3 (<65 yrs.)/>2 (>65 yrs.) which concerned 55% of the FIB-4 positive subjects (n = 481), 56% were confirmed by the ELF test (n = 271). For the FIB-4 threshold of 2, regardless of age which concerned 33% of the FIB-4 positive subjects (n = 284), 74% of the FIB-4 ≥2 subjects were confirmed by ELF testing versus 51% of those with a FIB-4 score <2 (Relative Risk (IC95) 1.88 (1.52, 2.32) p < 0.001). 80% of the subjects in the high risk zone of fibrosis (FIB-4 ≥2.67) were confirmed by ELF test. The percentage of subjects in the intermediate fibrosis risk decreases from 90% for a FIB-4 between 1.3 and 2.67, to 45% for a FIB-4 between 1.3/2and 2.67, and to 23% for a FIB-4 between 2 and 2.67.

Figure: FIB4 confirmation by ELF according to FIB4 thresholds

FIB-4 Threshold	N (%)	ELF≥9.8	% confirmation by ELF test in subjects <FIB-4 threshold
FIB-4>1.3	869 (100%)	509 (59%)	NA
FIB-4 >1.3/2	481 (55%)	271 (74%)	61%
FIB-4 ≥2	284 (33%)	210 (74%)	51%
FIB -4 ≥2.67	85 (10%)	68 (80%)	56%

Conclusion: ELF testing performed in the second line had significantly confirmed proven fibrosis in subjects with FIB-4 ≥2. The high percentage of confirmation when the FIB-4 is ≥2.67 confirms the high fibrosis risk of this aera. A threshold of 2 retains a high percentage of confirmation while reducing the size of the intermediate risk zone for fibrosis and may allow more effective screening for liver fibrosis in primary care.

Validation of cut-off values proposed by the society of radiologists in ultrasound liver elastography for diagnosis of compensated advanced chronic liver disease using 2D shear wave elastography

Ji Hun Kang[1], Yeri Lee[1], Young Seo Cho[1], Yongsoo Kim[1], Nam Hee Kim[2]. *[1]Hanyang University College of Medicine, Hanyang University Guri Hospital, Radiology, Guri, Korea, Rep. of South; [2]Sungkyunkwan University School of Medicine, Kangbuk Samsung Hospital, Division of Gastroenterology, Department of Internal Medicine, Korea, Rep. of South*
Email: jihunkang@hanyang.ac.kr

Background and aims: The Society of Radiologists in Ultrasound Liver Elastography proposed dual cut-off values of <9 and >13 kPa to rule out and rule in compensated advanced chronic liver disease (cACLD) using acoustic radiation force impulse techniques. However, the diagnostic performance of this recommendation has not been extensively validated. Therefore, this study aimed to validate the cut-off values for the diagnosis of cACLD using 2D shear wave elastography (SWE).
Method: From the database of liver stiffness (LS) measurement in a single center using an Supersonic Aixplorer ultrasound between 2018 and 2021, we included patients who performed esophagogastroduodenoscopy or liver biopsy within 1 year of their LS measurement. We selected the first examination in cases of multiple LS measurements and excluded unreliable LS measurement. cACLD was defined as varices shown on EGD or severe fibrosis or cirrhosis on liver biopsy, according to the Baveno VII consensus.
Results: In total, 1440 patients (mean age 58 ± 12 years, 61% males) were included and cACLD was confirmed in 717 (50%) patients. The cohort consisted of patients with chronic hepatitis B (n = 563, 39%), chronic hepatitis C (n = 92, 6%), alcohol-related liver disease (n = 475, 33%), non-alcoholic fatty liver disease (n = 151, 11%), and other etiologies (n = 159, 11%). Overall, 688 (48%) and 548 (38%) patients had LS <9 and >13 kPa, respectively. Using cut-off values of <9 and >13 kPa, the sensitivity and specificity for ruling-out and ruling-in cACLD were 84% and 92%, respectively. However, a more optimal dual cut-off of <7 and >12 kPa was found to have 92% sensitivity and 90% specificity for ruling-out and ruling-in cACLD (AUROC = 0.89; 95% CI = 0.87–0.91; p < 0.001).
Conclusion: Our study suggests that a dual cut-off of <7 and >12 kPa, as measured by 2D SWE, is more optimal for ruling-out and ruling-in cACLD than the previously proposed cut-off values.

Hospital discharge after percutaneous liver biopsy-less is more?

Isabel Garrido[1], Rosa Coelho[1], Guilherme Macedo[1]. [1]*Centro Hospitalar Universitário de São João, Gastroenterology Department, Portugal*
Email: isabelmng@hotmail.com

Background and aims: Liver biopsy is a technique frequently performed in clinical practice. However, the recommended surveillance period after the procedure is not established in the guidelines. The primary objective of this study was to assess the safety of hospital discharge 2 hours after a percutaneous liver biopsy. The secondary objectives were to assess the degree of patient satisfaction with early hospital discharge and to report the incidence of complications.
Method: Prospective monocentric study which included all patients who underwent percutaneous liver biopsy between December 2020 and November 2022. Individuals were discharged 2 hours after the procedure according to a protocol that was implemented in our institution. The ethical approval for this study was obtained from the Ethics Committee.
Results: A total of 200 patients were included, the majority male (52.0%), with a median age of 52 years old (IQR 40–60). There were 191 (95.5%) outpatients and 9 (4.5%) inpatients. Most procedures were made under conscious sedation with midazolam (97.0%) or under anesthesia with propofol (1.0%). A total of 88 (44.0%) US-guided biopsies were performed with the Tru-cut needle (16G or 18G) and 112 (56.0%) after US site marking with the Menghini needle. Two-needle passes were required in 33 (16.5%) cases, three-needle passes in 8 (4.0%) cases and four-needle passes in 1 (0.5%) case. In addition to a biopsy of the liver parenchyma, 6 (3.0%) patients also underwent a biopsy directed to a liver lesion/nodule. Forty-two (21.0%) individuals had complications at the time of or within 2 hours of the procedure (abdominal pain n = 29, pain radiating to the shoulder n = 11, headache n = 2). Most complications (90.4%) occurred in the first hour after the liver biopsy. Thirty-five (17.5%) patients required analgesia. Only 5 (2.5%) patients were kept under observation for 4 hours due to abdominal/shoulder pain. On the phone call made by the nurse, carried out 4 hours after the procedure, 28 (14.0%) patients reported abdominal/shoulder pain, 2 (1.0%) patients reported nausea and 1 (0.5%) patient reported headache. Only 5 of these individuals underwent analgesic therapy and all of them reported symptomatic improvement. In addition, 2 (1.0%) patients contacted the on-call physician for shoulder pain (4 days after the procedure) and nausea (3 days after the procedure). There were no serious complications and no patient required admission. The majority of individuals reported being satisfied (21.6%) or very satisfied (77.8%) and felt safe (98.9%) with this protocol.
Conclusion: This is one of the first prospective studies worldwide to prove that patients requiring percutaneous liver biopsy can be safely discharged after a short recovery time. In fact, major complications after liver biopsy are rare and manifest early. In addition, patients showed a preference for early hospital discharge and felt safe with this protocol.

Non-invasive assessment of adult bilirubin based on multispectral reconstruction technology and a smartphone platform

WenQian Geng[1], Zhiyuan Sun[2], Wanyu Li[1]. [1]*The first hospital of Jilin University, Department of hepatobiliary and pancreatic Medicine, Changchun, China;* [2]*Chinese academy of sciences, Changchun institute of optics, fine mechanics and physics, Changchun, China*
Email: liwanyu@jlu.edu.cn

Background and aims: Jaundice refers to yellow coloration of the skin and sclera caused by increased levels of serum bilirubin, which is an important indicator of liver function. The aim of this study is to evaluate jaundice in a meticulous, non-invasive and intelligent way by using multispectral reconstruction technology on the platform of smartphone.
Method: A total of 351 patients with normal or elevated total serum bilirubin (TSB) were selected. Non-invasive detection equipment was set up, and scleral images were obtained without an external light

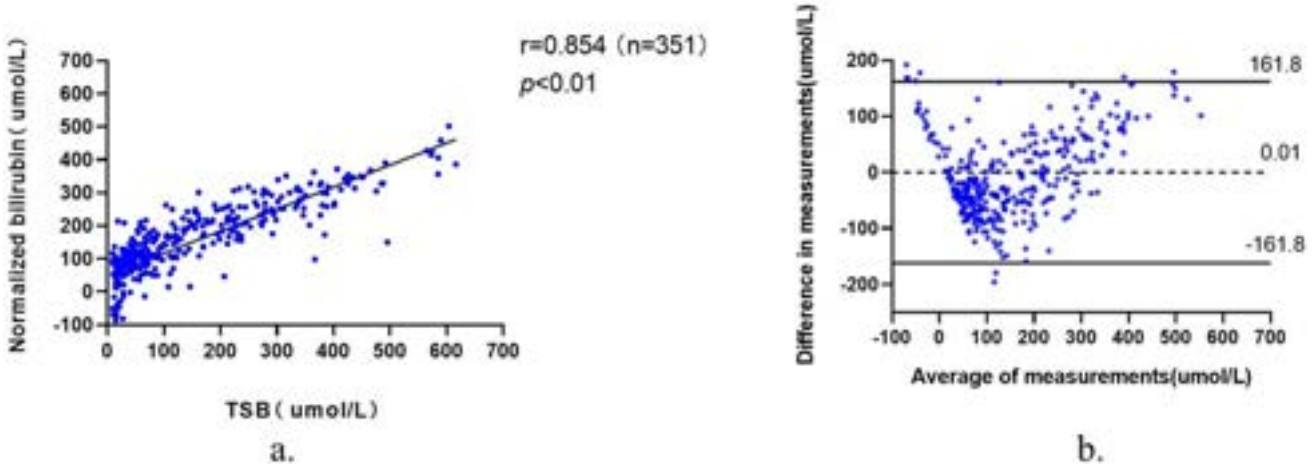

Figure: (abstract: FRI-484): **a.** Correlation between total serum bilirubin (TSB) and normalized bilirubin: r = 0.854, $p < 0.01$. TSB: Total serum bilirubin. **b.** Bland-Altman plot of TSB versus normalized bilirubin. The mean difference is zero and 97.4% of the values were within the 95% limits of agreement, i.e., ± 161.8 umol/L.

source in the room. After the scleral image was extracted, the RGB image of the sclera was reconstructed into a multispectral image to obtain the quantized bilirubin level, namely, the normalized bilirubin value.

Results: The linear correlation coefficient between the normalized bilirubin value and TSB was 0.854 (Fig. a). The Bland–Altman consistency test indicated that 97.4% of the values were within the 95% limits of agreement (LOA) (Fig. b). There were no significant differences in the normalized bilirubin values of the sclera at different orientations in the same patient. There was a high correlation between normalized bilirubin and TSB in different groups of sex, age, bilirubin grade, disease spectrum and bilirubin elevation type. The area under the receiver operating characteristic (ROC) curve was 0.90, the sensitivity was 75.0%, and the specificity was 92.0%.

Conclusion: The non-invasive bilirubin detection method we proposed has high accuracy, sensitivity and universality. Compared with the "gold standard" of bilirubin detection, this non-invasive detection method is cost-effective, easy to perform, and can reduce the discomfort of patients, suitable for long-term monitoring of bilirubin.

FRI-485

Diagnosis and treatment of patients with suspected mucinous cystic neoplasms according to the EASL-guidelines: a retrospective cohort study

Alicia Furumaya[1,2], Hannah Schulz[1,2], Joanne Verheij[1,2], Bart Takkenberg[1,2], Marc Besselink[1,2], Geert Kazemier[3,4], Joris Erdmann[1,2], Otto van Delden[1,2]. *[1]Amsterdam Umc, University of Amsterdam, Netherlands, [2]Amsterdam Gastroenterology Endocrinology Metabolism, Netherlands, [3]Amsterdam Umc, Vrije Universiteit Amsterdam, Netherlands; [4]Cancer Center Amsterdam, Netherlands<Please check the city names are missing.>*
Email: a.furumaya@amsterdamumc.nl

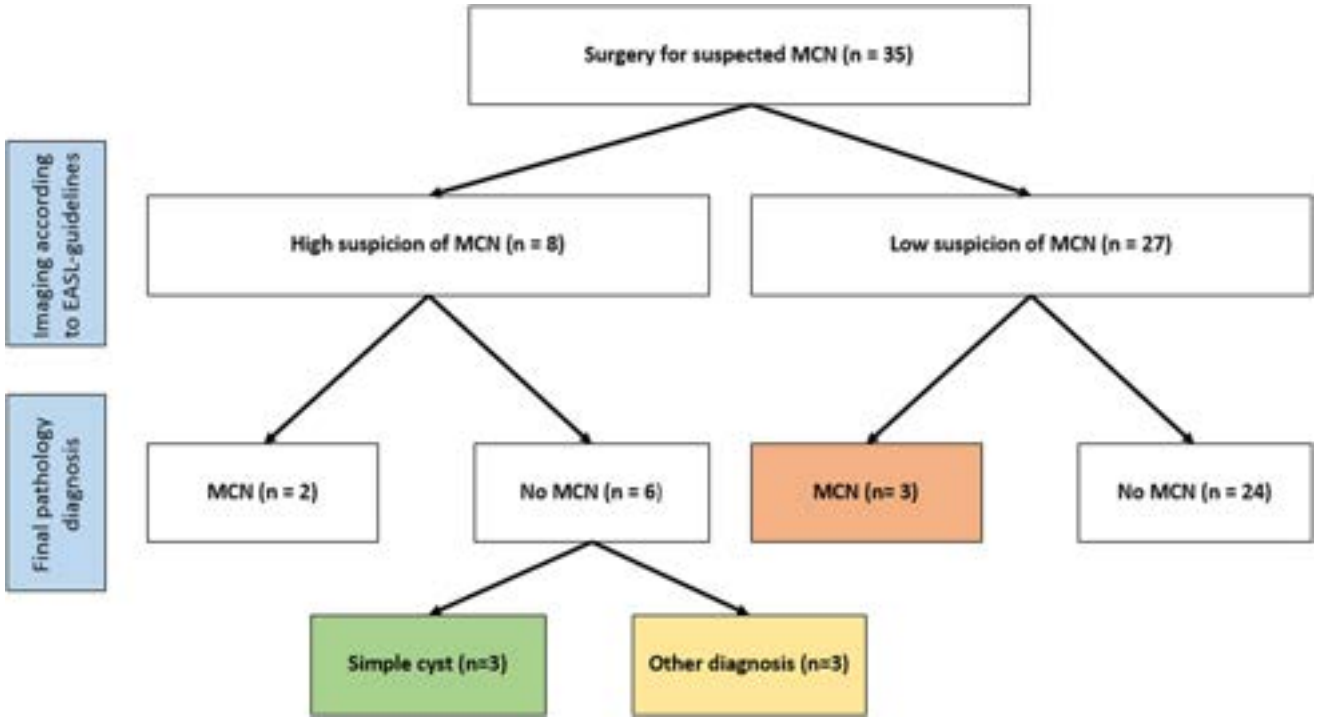

Figure: (abstract: FRI-485).

Background and aims: Mucinous cystic neoplasms (MCNs) are a rare subset of hepatic cysts with a low malignant potential. The recent European Association for the Study of the Liver (EASL) guidelines provide guidance on the imaging features and surgical management of MCNs, yet are hampered by a lack of studies adhering to the revised World Health Organization (WHO) criteria. Therefore, the current study attempted to validate the new 2022 EASL-guidelines in a retrospective cohort study of patients who underwent surgery for suspected MCN.
Method: Patients undergoing surgery for suspected MCN in a single center between 2010 and 2020 were included. Imaging features were assessed according to the EASL guidelines and were compared to final pathological diagnoses, according to the WHO criteria. Surgical outcomes were compared between deroofing and complete (minor or major) resection.
Results: In total, 35 patients were included. In three patients, there were no worrisome imaging features, yet final pathological diagnosis showed MCN. Contrarily, three patients with worrisome imaging features had simple cysts and another three patients with worrisome imaging features had an alternative diagnosis. The sensitivity of the EASL-guidelines for the diagnosis of MCN was 40% (95%CI: 5.3–85%) and the specificity was 80% (95% CI: 61–92%). More recurrences occurred after deroofing (n = 4/15) compared to complete, minor resection (n = 0/17, p = 0.038).
Conclusion: In conclusion, although the new EASL-guidelines provide some guidance, they could not reliably distinguish MCN from other cysts in our series. Thus, we should be careful in selecting surgical strategies based on these criteria.

FRI-486
Use of magnetic resonance elastography for accurate staging of liver fibrosis in children with autoimmune hepatitis

Wojciech Janczyk[1], Jędrzej Sarnecki[2], Piotr Pawliszak[2], Paulina Opyrchał[2], Kamil Janowski[3], Diana Kamińska[3], Małgorzata Woźniak[3], Wieslawa Grajkowska[4], Maciej Pronicki[4], Elżbieta Jurkiewicz[2], Piotr Socha[3]. *[1]Children's Memorial Health Institute, Gastroenterology, Hepatology, Feeding Disorders and Pediatrics, Warsaw, Poland; [2]Children's Memorial Health Institute, Radiology, Poland; [3]Children's Memorial Health Institute, Gastroenterology, Hepatology, Feeding Disorders and Pediatrics, Poland; [4]Children's Memorial Health Institute, Pathology, Poland*
Email: w.janczyk@ipczd.pl

Background and aims: Autoimmune hepatitis (AIH) may present as hepatitis, chronic or acute liver failure. Liver fibrosis may progress to cirrhosis. Pharmacological treatment is aimed to preserve liver function and induce remission. Magnetic resonance elastography (MRE) has been already applied in many chronic liver diseases for non-invasive assessment of liver fibrosis. Previously we showed an excellent diagnostic accuracy of transient elastography in assessment of advanced liver fibrosis in children with AIH. Now we aimed to evaluate the usefulness of MRE in relation to liver biopsy and selected laboratory markers of liver function in the large pediatric AIH cohort.
Method: We included 48 children (26 females) with mean age of 13.9 yrs with established AIH and 16 healthy children aged 14.4 yrs as controls. All patients with AIH underwent liver biopsy and MRE to assess liver fibrosis. Liver biopsy was performed for monitoring purposes. Histology was described semiquantitatively based on modified scoring system by Ischak. Statistical analysis was performed to assess correlation between liver fibrosis on histology, MRE and selected lab tests. The area under the curve (AUC) for the ROC and its 95% CI were calculated to determine diagnostic accuracy of MRE in estimating mild fibrosis vs advanced fibrosis. The AUC were calculated by using the logistic procedure in MedCalc v. 20.215
Results: Our patients with AIH presented with increased liver fibrosis on MRE 3 kPa (2.4; 3.8) [median (lower; upper quartile)] and various grade of fibrosis according to histological score. Fibrosis on MRE was significantly higher in AIH than in healthy control group 2.3 kPa (2.2; 2.6); p = 0.002 using Mann-Whitney U test.
For diagnosis of advanced fibrosis (=>F4) MRE showed very good diagnostic accuracy (AUROC 0, 88) and even better for = >F5 (AUROC 0, 9). Optimal cut-off point for = >F5 was 3.65 kPa with high sensitivity and specificity (see Figure below).

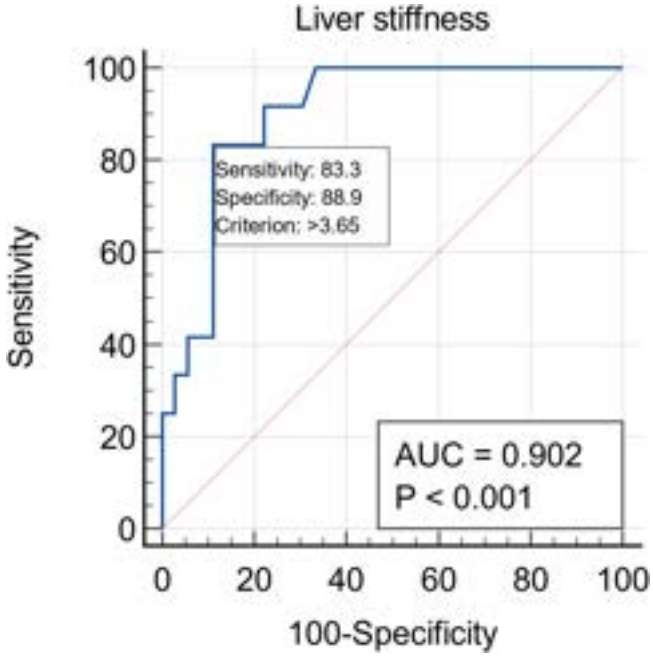

Figure:

Conclusion: MRE was highly accurate to discriminate between mild and advanced fibrosis when compared to liver biopsy.
MRE can be used in children with autoimmune hepatitis for assessment of liver fibrosis and especially to pick up those patients with advanced fibrosis.

FRI-487
Fibrosis-4 index is associated with cardiovascular risk in people living with HIV

Giulia Morsica[1], Costanza Bertoni[1,2], Daniele Ceccarelli[1], Laura Galli[1], Hamid Hasson[1], Alessia Siribelli[1,2], Riccardo Lolatto[1], Antonella Castagna[1,2], Caterina Uberti-Foppa[1,2]. *[1]San Raffaele, Scientific Institute, Dept. of Infectious Diseases, Milan, Italy; [2]Vita Salute, University, Milan, Italy*
Email: morsica.giulia@hsr.it

Background and aims: The severity of liver fibrosis dictates the risk of cardiovascular complications. We investigated the association between Fib4 and the cardiovascular risk (CVR) in patients living with HIV (PLWH) and the diagnostic performance of fibrosis4 (Fib4) index as non-invasive marker of liver fibrosis (NILF).
Method: CVR and Fib4 were calculated in 5235 PLWH using the atherosclerotic cardiovascular disease (ASCVD) score categorized as<7.5 = low risk, 7.5–20 = intermediate risk, >20 = high risk. LF by fibroscan was categorized according to manufacturer's cutoff: F0-F1 = <7 KpA;F2 = 7–9 KpA;F3-F4 >9 KpA). The diagnostic performance of Fib4 was assessed in 855 PLWH with paired fibroscan as gold standard for LF. The area-under-the-curve (AUC) and the cut-off values of Fib4, compared to LF classification (F0-F1vsF2 and F2vsF3-F4), were determined by the logistic regression and the receiver operating characteristics (ROC) curves.
Results: The AUC-ROC identified a Fib4 threshold of 1.30 for F2 vs F0-F1 and 2.35 for F3-F4 vs F2 (Fig. 1). Of 5235 PLWH, 3167 had Fib-4 < 1.30 (group1)1551 had Fib4 >1.30<2.35 (group2) and 517 had Fib4

>2.35 (group3). PLWH in group1 were younger, median age 47 years (yr) compared with group2 and 3 (median age 57 and 57 yr, respectively) P < 0.0001. PLWH in group2 and 3 had a longer duration of ART, median 17.9 and 18.5 yr, respectively, vs 10 yr in group1 with higher rate of detectable HIV-RNA (>50 copies/ml in 10% of group2 and 13% of group3) compared to group1 (7%) lower CD4, median 547 and 662 cells/mmc, respectively, vs 733 cells/mmc in group1. HBV and HCV were present in 5.0% and 16% of group1, in 7% and 31% of group2 and 10% and 50% of group3, respectively, P < 0.001; PLWH with a Fib4 >1.30–2.35 compared to those with a Fib4≤1.30 had a risk of intermediate ASCVD of 2.89 (95%CI: 2.52–3.32) and a risk of high ASCVD of 6.26 (95%CI: 4.91–7.99). PLWH with a Fib4 >2.35 compared to those with a Fib4 >1.30–2.35 had a risk of intermediate ASCVD of 1.44 (95%CI: 1.26–1.66) and a risk of a high ASCVD of 2.72 (95%CI: 2.98–3.23).

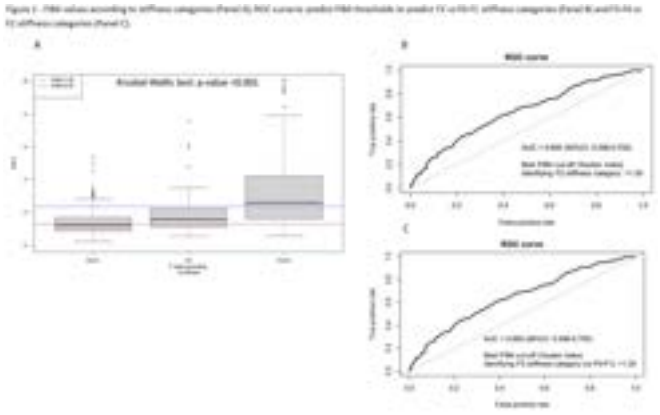

Figure:

Conclusion: We identified a Fib4 thresholds distinguishing F0-F1 vs F2 vs F3-F4 stiffness categories in PLWH. We found the correlation of Fib4 with CVR assessed by ASCVD in a large sample size of PLWH.

FRI-488

Diagnostic accuracy of magnetic resonance elastography, transient elastographyand predictive scores in cystic fibrosis related liver steatosis and fibrosis

Ana Piñar Gutiérrez[1], Carmen Lara Romero[1], Silvia García Rey[1], María C. Roque-Cuéllar[1], Javier Castell[1], Ángeles Pizarro Moreno[1], Esther Quintana Gallego[1], Pedro Pablo García-Luna[1], Manuel Romero Gomez[1]. [1]*Virgen del Rocío University Hospital, Sevilla, Spain*
Email: mromerogomez@us.es

Background and aims: Cystic fibrosis-related liver disease is a complication whose definition, etiopathogenesis, diagnostic criteria and associated factors are not well known. In this entity, liver biopsy has been shown to be inconsistent, so other diagnostic tools should be sought. In addition, it is still unclear whether liver steatosis is part of its varied clinical presentation or a separate entity. Aims were to determine the prevalence of steatosis and liver fibrosis in a cohort of adult patients performing imaging-derived proton density fat fraction (PDFF) and magnetic resonance elastography (MRE) respectively; the usefulness of non-invasive liver tests (NITs) and transient elastography (TE) in the diagnosis of this entity; as well as factors related to a higher prevalence of both entities.
Method: Cross-sectional study. Adult patients cared for in a Cystic Fibrosis Unit were included. Liver assessment was performed by TE, NITs (APRI, FIB4, HSI, NFS), PDFF and MRE. To evaluate the specificity and sensitivity of TE and NITs compared to PDFF and MRE as gold-standards, ROC curves were performed. A univariate analysis was performed to search for factors associated with both entities.
Results: N = 84. Age = 32.5 (24.75–41)years. Women = 35 (41.7%). Exocrine pancreatic insufficiency = 55 (65.5%); endocrine pancreatic insufficiency = 39 (46.4%); malnutrition = 7 (8.3%). 20.2% presented with liver steatosis in PDFF; 23.8% in TE. 10.7% presented with liver fibrosis in MRE; 10.7% in TE. The ROC curves of diagnostic accuracy of TE compared to PDFF and MRE are shown in Figure 1. None of the NITs performed had a statistically significant diagnostic accuracy. In univariate analysis, malnutrition (95% CI 0.165 (0.033–0.829); p = 0.029) and elevated alkaline phosphatase levels (95% CI 1.013 (1.003–1.029); p = 0. 015) were related to liver steatosis; and age (95% CI 0.906 (0.824–0.996); p = 0.042), endocrine pancreatic insufficiency (95% CI 11.355 (1.351–95.459); p = 0.025), elevated GOT (95% CI 6.7 (1. 487–30.189); p = 0.013), GPT (CI 95% 4.665 (1.079–20.086); p = 0.039), total bilirubin (CI 95%; 29.583 (5.14–170.277); p < 0.001) and alkaline phosphatase (CI 95% 1.025 (1.008–1.042) p = 0. 005) levels, thrombocytopenia (95% CI 21.143 (1.697–263.427); p = 0.018) and vitamin A (95% CI 0.915 (0.848–0.987); p = 0.022) and E (95% CI 0.997 (0.995–1); p = 0.03) deficiency were related to liver fibrosis.

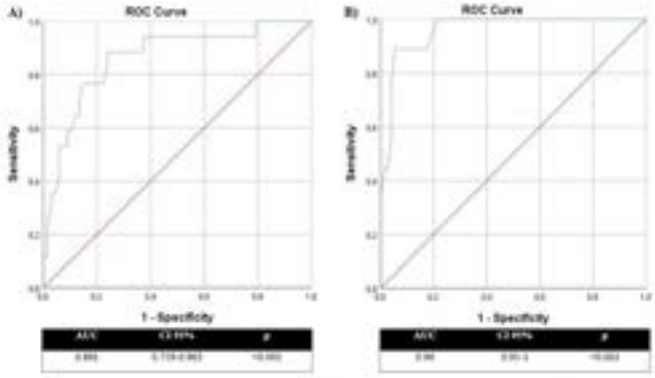

Figure:

Conclusion: One fifth of the patients presented liver steatosis and one tenth liver fibrosis. The diagnostic accuracy of TE may be comparable to that of PDFF and MRE, which is less accessible. The factors associated with both entities were mainly related to poor nutritional status and biochemical parameters related with liver dysfunction.

FRI-489

Negative and positive predictive values of utilizing a two-stage approach to non-invasive fibrosis testing in patients with hepatitis C virus infection

Rachel Epstein[1,2], Benjamin Buzzee[3], Laura F. White[4], Jordan J. Feld[5], Laurent Castera[6], Richard Sterling[7], Benjamin Linas[1], Lynn Taylor[8]. [1]*Boston University Chobanian and Avedisian School of Medicine, Medicine, Section of Infectious Diseases, United States;* [2]*Boston University Chobanian and Avedisian School of Medicine, Pediatrics, Section of Infectious Diseases, United States;* [3]*Boston Medical Center, Infectious Diseases, United States;* [4]*Boston University School of Public Health, Biostatistics, United States;* [5]*University of Toronto, Toronto Centre for Liver Disease, Toronto, Canada;* [6]*Hopital Beaujon, Assistance Publique-Hôpitaux de Paris, University of Paris, Hepatology, France;* [7]*Virginia Commonwealth University, Internal Medicine, Division of Gastroenterology, Hepatology and Nutrition, United States;* [8]*University of Rhode Island, United States*
Email: rachel.epstein@bmc.org

Background and aims: Non-invasive liver disease staging methods have supplanted liver biopsy for clinical care of most individuals with hepatitis C virus (HCV). Few data exist to compare test accuracy when using a two-test approach of an initial screening serum-based test followed by a second test with higher specificity. This study aims to estimate sensitivity, specificity, negative and positive predictive values (NPV and PPV) for detecting cirrhosis when using tests in combination.

Table: (abstract: FRI-489).

	Single Test				Staged two-test approach: Indicated test + TE for F2/F3 Only				Two-tests for all approach: Indicated test + TE for all			
Test	Sensitivity	Specificity	NPV	PPV	Sensitivity	Specificity	NPV	PPV	Sensitivity	Specificity	NPV	PPV
APRI	68.6%	79.4%	98.3%	14.3%	95.8%	81.6%	99.8%	18.6%	95.8%	81.2%	99.8%	18.2%
FIB-4	60.8%	90.1%	98.2%	27.2%	93.1%	89.3%	99.7%	27.6%	94.8%	88.7%	99.8%	26.8%
FibroTest	85.7%	71.3%	99.0%	12.3%	98.1%	72.9%	99.9%	13.6%	98.1%	72.6%	99.9%	13.5%
TE	86.7%	91.9%	99.4%	51.3%	-	-	-	-	-	-	-	-

NPV and PPV calculated using a prevalence of cirrhosis that reflects US population with chronic HCV accessing care at federally qualified health centers: 44.8% F0, 25.5% F1, 21% F2, 4.5% F3, 4.2% F4.

Method: We performed secondary data analysis on clinical trial and retrospective data from collaborators and the literature for patients with HCV with or without HIV co-infection for four major fibrosis staging methods: Fibrosis-4 (FIB-4; N = 579), AST-to-platelet ratio index (APRI; N = 580), FibroTest (N = 101), and Transient Elastography (TE; N = 282). We used a stochastic, individual-based microsimulation model (HEP-CE) to predict Metavir fibrosis stage using independent probabilities from each staging test based on this data, using liver biopsy as gold standard for true Metavir fibrosis stage. We compared two strategies: each serum test in combination with TE only for those with intermediate (F2/F3) results on the first test (staged approach) or each test in combination with TE for all individuals (two tests for all), and selected the maximum result from the two tests. We then calculated sensitivity, specificity, NPV and PPV of correctly identifying cirrhosis (F4), using Metavir fibrosis stage prevalence of a US national federally qualified health center cohort with chronic HCV.
Results: With the calculated population prevalence of cirrhosis of 4.2%, individual test NPVs for cirrhosis ranged from 98.2% for FIB-4 to 99.4% with TE (Table). PPV ranged from 12.3% (FibroTest) to 51.3% (TE). Sensitivity of detecting cirrhosis improved from 60.8–86.7% with individual tests to 93.1–98.1% with two-test approaches. However, combining serum testing strategies with TE resulted in only slightly higher NPV (range: 99.7% for FIB-4 to 99.9% for FibroTest) and PPV (range: 13.5% with FibroTest to 27.6% with FIB-4) for correctly staging F4 than serum testing alone. NPV and PPV changed minimally between using a second testing method for all vs. only for those with intermediate stages (F2/F3) on the first test.
Conclusion: We demonstrate that with low prevalence of cirrhosis, combining results from a serum staging test plus TE minimally improves NPV for detecting cirrhosis over using a serum test alone, and performing TE in all yields limited clinical benefit over the staged approach. These data can help inform clinicians practicing in various settings with different availability of testing and also decision modelers to estimate clinical and cost-effectiveness of fibrosis staging methods.

FRI-490

Repeatability of liver stiffness measurement by vibration-controlled transient elastography and controlled attenuation parameter in patients with cirrhosis

Rohit Loomba[1], Jaclyn Bergstrom[1], Maral Amangurbanova[1], Christie Hernandez[1], Egbert Madamba[1], Claude Sirlin[1], Daniel Huang[1]. [1]*University of California San Diego, United States*
Email: daniel_huang@nus.edu.sg

Background and aims: The regulatory qualification of non-invasive tests (NITs) for liver fibrosis severity assessment is a major unmet need for drug development and clinical care in cirrhosis. Ultrasound-based methods such as vibration-controlled transient elastography (VCTE) evaluate liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) as a marker for fibrosis severity and steatosis, respectively. Repeated use of VCTE has the potential to assess disease response and progression. However, this potential application has been limited by a paucity of repeatability data in the patient population at risk. The aim of this prospective study from the San Diego Cirrhosis Registry was to address this knowledge gap and contribute to the evidentiary basis needed for the qualification of ultrasound-based methods in various contexts of use in clinical trials and practice.
Method: A prospective cohort of adults with suspected or established cirrhosis underwent two FibroScan examinations (Fibroscan Expert 630, Echosens, France) on the same day performed by the same experienced operator. LSM by VCTE and CAP measurements were reported and analyzed in units of kPa and dB/m, respectively. The primary end point was the same-day/same-operator repeatability coefficient (RC), which represents the value under which the difference between repeated measurements should fall with a 95% probability. Secondary outcomes include the intra-class correlation coefficient (ICC) which represents the proportion of total variation explained by between-patient differences rather than measurement variation, and the within-case coefficient of variation (wCV), which represents the ratio of within-patient variation to overall measurement values.
Results: Repeat scans were available on 24 participants (mean age of 61 years, 58% were women, mean body mass index (BMI) was 30.4 kg/m^2). The percentage of cases due to non-alcoholic steatohepatitis (NASH), alcohol, hepatitis C virus, and hepatitis B virus were 67%, 13%, 17%, and 4%, respectively. RC was 7.4 kPa for LSM by VCTE and 82.1 dB/m for CAP, meaning that any change greater than those values has a 95% probability to reflect true change rather than measurement error. ICC was excellent for LSM (.96) and fair for CAP (.74), while wCV indicates that the within-patient variation is close to the overall measurement values for LSM and CAP (Table 1).

Table: Repeatability, intra-class correlation, and within-case coefficients for LSM by VCTE and CAP

	Mean (SD)	Repeatability Coefficient (RC)	Intra-class Correlation ICC (95% CI)	Within-case Coefficient of Variation (wCV)
LSM by VCTE (kPa)	19.9 (13.1)	7.4	.96 (.91–.98)	13.1%
CAP (dB/m)	262.5 (54.7)	82.1	.74 (.50–.88)	11.6%

Conclusion: LSM and CAP measurement by FibroScan XXX model, demonstrated good repeatability within patients with cirrhosis. These repeatability estimates are likely to inform ultrasound-based NIT qualification by defining the values that are expected to reflect a true change in the context of clinical trials or clinical care.

FRI-491

Pattern of transient elastography in Egyptian people living with HIV: predictors of hepatic steatosis and fibrosis

Naeema El Garhy[1], Lamiaa Al sehemy[1], Reham Awad Awad Ibrahem[1], Mariam I. Abdelraouf[1], Ammar Hatem[1], Aya M. Al-shari[1], Haidi Karam-Allah[2], Engy Alkhatib[1], Rahma Mohamed[1], Gamal Esmat[1], Ahmed Cordie[1]. [1]*Kasr Alainy, Egypt;* [2]*Assuit University, Egypt*
Email: naemaelgarhy92@gmail.com

Background and aims: Liver related disease contributes to 13–18% of all-cause mortality in people living with HIV (PLWHIV). Transient elastography (TE) has been validated as a non-invasive tool for assessment of liver fibrosis stage. By means of controlled attenuation parameter (CAP), TE proved to be a useful screening tool for steatosis (HS) in patients at high-risk for NAFLD. TE use in HIV mono-infected patients has not yet been validated as in patients with other liver diseases. The aim of this study was to analyze the TE data in an Egyptian cohort of PLWHIV, and determine the predictors of fibrosis and HS in them.

Method: This cross-sectional study was conducted on PLWHIV in Kasr Alainy Viral Hepatitis Centre between July-December 2022. Focused clinical interview was performed including smoking, alcohol use, hepatitis C or B (HCV or HBV) co-infection, hypertension, dyslipidaemia or diabetes mellitus (DM) and any co-morbidity suggestive of metabolic syndrome. Body mass index (BMI) was calculated, and patients were examined for signs of liver disease. Active HCV or HBV co-infection was excluded. Patients who previously received HCV treatment and achieved SVR were included in this cohort. Testing was done for liver enzymes, glycated haemoglobin (HbA1c), lipogram, HIV RNA and CD4 count. After fasting, a good quality TE was performed. Results of fibrosis were considered significant if liver stiffness (LS) >7.1 and significant HS if CAp >238 dB/m.

Results: A total of 145 patients were included; 83.4% were males, 36.25 ± 10.2 years was the mean age, 45.5% were smokers, 15.9% reported occasional alcohol intake, 13.8% had previous HCV, and 46.2% were obese. The median ALT and AST were 22 and 25, respectively. Mean HbA1c was 5.59 ± 0.7 and undetected HIV viral load in 58.6%. As indicated by TE, 11.7% had significant fibrosis, F4 in 1.4%, 32.4% had HS, significant HS in 24.8%, and 8.3% had both HS and fibrosis. HbA1c and higher cholesterol were predictors of fibrosis (OR: 7.02 and 1.04, respectively). Meanwhile, obesity and older age were predictors of HS (OR: 3.41, and 1.07**,** respectively).

	Hepatic fibrosis				Hepatic steatosis			
Items	P value	OR	95% CI Lower level	Upper level	P value	OR	95% CI Lower level	Upper level
Age	0.25	1.04	0.97	1.11	**0.01***	1.07	1.02	1.12
Sex	0.08	0.08	0.00	1.39	0.27	1.87	0.61	5.72
HCV	0.14	3.67	0.66	20.32	0.68	0.76	0.21	2.79
DM	0.89	0.86	0.09	8.53	0.88	0.88	0.17	4.54
Hypertension	0.31	4.08	0.27	62.59	0.71	0.62	0.05	7.65
Obesity	0.48	0.58	0.13	2.61	**0.01***	3.41	1.31	8.89
HIV RNA	0.42	1.88	0.41	8.67	0.67	0.81	0.32	2.08
CD4 count	0.35	0.99	0.99	1.00	0.82	1.00	0.99	1.00
Triglyceride	0.23	1.01	0.995	1.02	0.26	1.00	0.99	1.01
Cholesterol	**0.03***	1.04	1.00	1.08	0.55	0.99	0.98	1.01
HDL	0.94	0.99	0.92	1.08	0.74	0.99	0.95	1.04
HbA1c	**0.02***	7.02	1.33	36.96	0.28	1.52	0.71	3.24

Conclusion: In this first Egyptian report on PLWHIV, older age, DM, dyslipidemia, and obesity were predictors of significant fibrosis and hepatic steatosis.

FRI-492

Enhanced detection of cirrhosis and risk of advanced fibrosis with dynamic breath analysis

Giuseppe Ferrandino[1], Antonio Murgia[1], Iris Banda[1], Yusuf Ahmed[1], Menisha Manhota[1], Kelly Sweeney[1], Louise Nicholson-Scott[1], Lucinda McConville[1], Federico Ricciardi[1], Olga Gandelman[1], Max Allsworth[1], Billy Boyle[1], Agnieszka Smolinska[1,2], Carmen Alexandra Ginesta Frings[3,4], Jorge Contreras[4], Claudia Del Carmen Asenjo Lobos[5], Victor Gabrielli Rivera[3], Viviana Barrientos Parra[3], Nataly Clavo Morales[3], Angela Novoa Arce[4], Amy Riviotta[5], Melissa Javiera Jerez Pardo[6], Luis Arnaldo Mendez Alcaman[3,4]. [1]*Owlstone Medical, United Kingdom;* [2]*Department of Pharmacology and Toxicology, School for Nutrition and Translational Research in Metabolism (NUTRIM), Maastricht University Medical Center, Netherlands;* [3]*Hospital Padre Hurtado, Chile;* [4]*Clinica Alemana, Gastroenterología, Chile;* [5]*Instituto de Ciencias e Innovación en Medicina (ICIM), Las Condes, Chile;* [6]*University of the Americas, Chile*
Email: giuseppe.ferrandino@owlstone.co.uk

Background and aims: Recent calls for action and a keynote statement on EU health policy highlighted the clinical need for chronic liver disease detection before decompensation to reduce the associated burden and premature mortality. Chronic liver diseases alter the systemic bioavailability of xenobiotics undergoing phase 1 metabolism. Limonene, one of these xenobiotics, is partially excreted unchanged in the breath, where it can be non-invasively measured to assess alterations associated with chronic liver diseases. With an unprecedented study design, dynamic limonene breath analysis was evaluated for classification performance for cirrhosis, and correlations with risk of liver fibrosis and disease severity.

Method: A total of 30 subjects with cirrhosis [21 female (f), 9 males (m)] [10 non-alcoholic fatty liver disease (NAFLD), 1 alcoholic, 1 viral hepatitis, 7 autoimmune hepatitis, 11 other] [Child-Pugh: 23 A, 5 B, 2 NAs] and 29 controls without liver diseases [17 f, 12 m], were enrolled with random recruitment, and orally administered 100 mg limonene after an overnight fasting. Breath samples were collected before, and 20, 40, 60, 90, and 120 minutes after ingestion using the ReCIVA® breath sampler. Absolute limonene quantification was obtained by gas chromatography mass spectrometry. Blood tests were administered to all the subjects within 6 months from breath sampling. Logistic regression with cross-validation was used to estimate Area Under the Curve (AUC) for each timepoint. Correlation of breath limonene with risk of fibrosis and disease severity was evaluated using canonical correlation analysis (CCA).

Results: Subjects with cirrhosis with a Median (M) age of 59 years (y) and IQR (54.3–66.8 y) showed significant difference in age compared to controls (M = 43 y, IQR = 38–57y) (p value <0.01). All tested timepoints, showed higher levels of breath limonene in subjects with cirrhosis compared to controls (p <0.01). At baseline limonene discriminated subjects with cirrhosis from controls with an AUC (SD) of 0.87 (0.11). Limonene administration induced a spike on breath of >100 folds with a peak (Cmax) after 20 or 40 minutes (Tmax) in more than 90% of the subjects. AUCs (sd) at post administration timepoints were respectively: 0.89 (0.10); 0.93 (0.06) (Fig. 1A); 0.91 (0.08); 0.92 (0.07); 0.94 (0.06).

In subjects with cirrhosis, breath limonene levels at Cmax showed a collective correlation with liver fibrosis risk estimated with FIB4 and APRI, and disease severity estimated with MELD score [R^2 = 0.76, p = 3e-5] (Fig. 1B). No correlations were observed in the control group.

Conclusion: The dynamic limonene breath analysis demonstrates excellent performance to discriminate cirrhosis. It may also serve to identify fibrosis and have a prognostic role in patients with liver disease. This premise should be evaluated with/against Fibroscan in patients with various stages and etiologies.

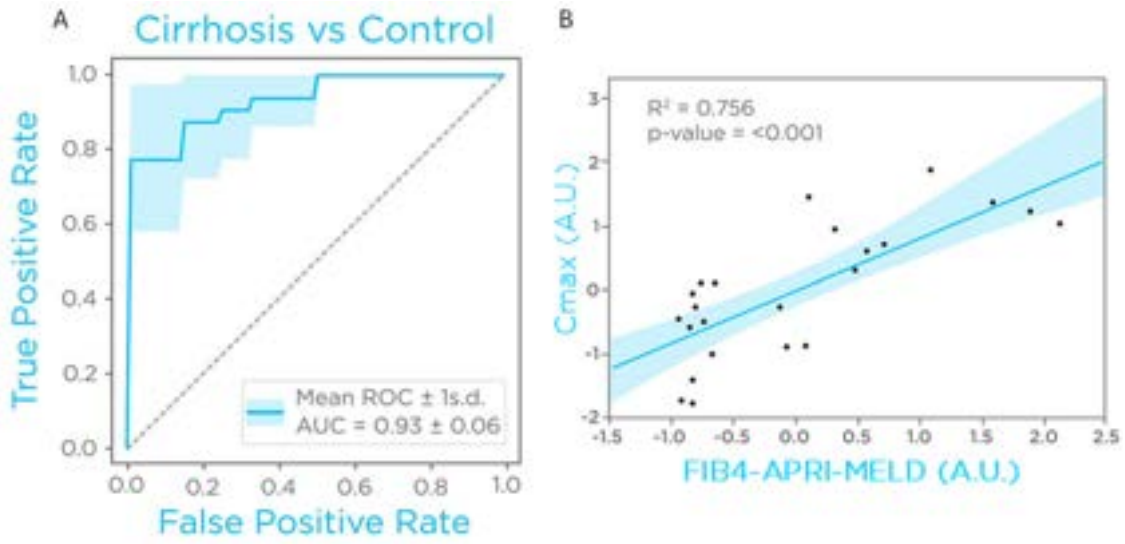

Figure:

FRI-493

Safety and signal intensity of a novel liver-specific MRI contrast agent, Orviglance® (manganese chloride tetrahydrate), in adult subjects with mild, moderate, or severe hepatic impairment

Nadilka Hettiarachchige[1], Andreas Norlin[1], Hanna Persson Hedman[1], Eric Lawitz[2]. [1]*Ascelia Pharma Ab, Sweden;* [2]*The Texas Liver Institute, United States*
Email: nadilka.h@ascelia.com

Background and aims: Orviglance is a novel oral magnetic resonance imaging (MRI) contrast agent developed for visualization of focal liver lesions. In this study, we investigated safety and change in MRI signal intensity (SI) in the liver over time after a single dose of Orviglance in adult subjects with hepatic impairment.
Method: Subjects with mild (n = 9), moderate (n = 6) or severe (n = 7) hepatic impairment as defined by the Child-Pugh score and matched controls with normal hepatic function (n = 13) were given a single dose of Orviglance. Safety was evaluated until 72 hours post-dose. Absolute change in liver SI was assessed pre-dose and at 1, 4, 8 and 24 hours post-dose.
Results: 10 (28.6%) of the 35 subjects reported adverse events. All adverse events were gastrointestinal disorders of mild to moderate severity, with no differences across stages of hepatic impairment. No safety findings were observed for ECG, vital signs or laboratory parameters. Mean liver SI enhancement peaked at 4 hours post-dose and was 53.2, 31.7 and 26.3 compared to pre-dose levels in subjects with mild, moderate and severe hepatic impairment, respectively. Corresponding SI enhancement for subjects with normal hepatic function was 79.0.
Conclusion: Orviglance was safe and well tolerated in subjects with varying degrees of hepatic impairment. Consistently with previous studies, highest liver SI enhancement was observed at 4 hours after administration independently of hepatic impairment severity. A consistent reduction in liver SI enhancement was observed with increasing severity of hepatic impairment.
The safety profile suggests that Orviglance can be used in patients with any degree of hepatic impairment.

FRI-494

Soluble CD163 as a biomarker of liver fibrosis in liver transplant recipients

Emilie Høegholm Ernst Lauridsen[1], Rasmus Hvidbjerg Gantzel[1], Allan Rasmussen[2], Henning Grønbæk[1], Susanne Dam Nielsen[3], Gerda Villadsen[1]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark;* [2]*Copenhagen University, Department of Surgical Gastroenterology, Copenhagen, Denmark;* [3]*Copenhagen University, Department of Infectious Diseases, Copenhagen, Denmark*
Email: emllur@rm.dk

Background and aims: Soluble CD163 (sCD163) is a marker of liver inflammation and fibrosis in acute and chronic inflammatory liver diseases. However, it remains unknown whether the plasma sCD163 level reflects liver fibrosis in patients following liver transplantation. This study aims to investigate the associations between the non-invasive inflammation and fibrosis marker plasma sCD163, the FIB-4 score, and liver stiffness (FibroScan) in liver transplant recipients.
Method: This project is a sub-study of the Danish Comorbidity in Liver Transplant Recipients (DACOLT) study and consists of 110 liver transplant recipients recruited from Aarhus University Hospital. FibroScan stiffness is considered as the non-invasive golden standard for liver fibrosis.
Results: The included patients had a median age of 51 years (range: 21–76), 51 (46.4%) patients were male and the median time from transplantation to inclusion was 6 years (range: 0.4–31). Autoimmune diseases were the most common causes of transplantation with primary sclerosing cholangitis as the predominant etiology (26%). The median sCD163 was 2.64 mg/L (IQR: 2.02–3.54) and 19 patients (17%) had sCD163 levels above the normal range (>3.86 mg/L). The patients with a liver stiffness >8 kPa (n = 16) had significantly higher sCD163 than patients with a liver stiffness <8 kPa (3.84 mg/L (IQR: 3.13–5.01) vs. 2.57 mg/L (IQR: 1.95–3.06), p < 0.001). We observed a significant correlation between sCD163 and liver stiffness (rho = 0.38, p < 0.001). Patients with a FIB4 score >1.45 (n = 51) had higher median sCD163 than patients with a FIB4 score <1.45 (2.86 mg/L (IQR: 2.23–3.77) vs. 2.48 mg/L (IQR: 1.99–3.14), p = 0.07). However, there was no correlation between sCD163 and the FIB-4 score. In addition, we observed no correlation between the FIB-4 score and FibroScan liver stiffness (rho = 0.13, p = 0.20).
Conclusion: In liver transplant recipients, plasma sCD163 correlated with liver stiffness but not with the FIB-4 score. There was no correlation between the FIB-4 score and liver stiffness, questioning

the FIB-4 score as a marker of liver fibrosis in liver transplant recipients. In contrast, our data suggest that sCD163 is a clinically relevant biomarker for detection of liver fibrosis in liver transplant recipients.

FRI-495

Does methotrexate therapy harm the liver in psoriatic patients?

Isabel Bessa[1], Ana Correia-Sá[2], Letícia Marques Leite[1], Hugo Oliveira[3], Margarida Gonçalo[3,4], Arsénio Santos[1,5], Armando Carvalho[1,5], Adelia Simao[1,5]. [1]*Centro Hospitalar e Universitário de Coimbra, Internal Medicine, Coimbra, Portugal;* [2]*Centro Hospitalar e Universitário de Coimbra, Internal Medicine, Coimbra, Portugal;* [3]*Centro Hospitalar e Universitário de Coimbra, Dermatology, Coimbra, Portugal;* [4]*University of Coimbra, Faculty of Medicine, Dermatology, Coimbra, Portugal;* [5]*University of Coimbra, Faculty of Medicine, Internal Medicine, Coimbra, Portugal*
Email: aspcarvalho@gmail.com

Background and aims: Psoriasis is associated with a greater risk of hepatic damage, including steatosis and fibrosis. A popular and crucial medication for the treatment of psoriasis is methotrexate (MTX), that is known to cause transaminasemia, but it isn't clear yet how this affects liver fibrosis or steatosis. Patients with psoriasis who also suffer from obesity, diabetes or metabolic syndrome have a greater risk of developing liver fibrosis, and there is evidence that MTX can act synergistically, contributing to the liver damage in these patients. Transient elastography (TE) and controlled attenuation parameter (CAP) are non-invasive methods to assess liver fibrosis and steatosis, respectively. The aim of our study is to assess if psoriatic patients treated with MTX have higher degrees of fibrosis and steatosis that those not treated with MTX.
Method: A case-control prospective study was undertaken on 85 patients (45 males, 40 females) with psoriasis, 65 of them treated (study group) and 20 not treated with MTX (control group). Epidemiological and clinical data were collected, and TE and CAP (Fibroscan) were performed on all patients. Data were analysed using the SPSS Statistics* platform.
Results: Both groups appear to be similar, with no statistically significant difference regarding sex, BMI, duration of disease, other comorbidities (dyslipidaemia, type 2 diabetes *mellitus* and hypertension), and alcohol consumption, but with a significant difference in mean age (60 years for treated patients and 52 years for those not treated with MTX). The mean elasticity in treated patients was 7.38 (+– 5.60) kPa and in the control group was 5.97 (+– 3.03) kPa (p = 0.160). The mean CAP was 270.66 (+– 70.14) dB/m in teated patients and 250.85 dB/m (+– 64.70) dB/m in non-treated (p = 0.170). We did not found a statistically significant correlation between the duration of the disease, or the cumulative MTX dose (less or more than 2 g) and the grade of steatosis or the stage of fibrosis. There was a statistically significant difference concerning steatosis in obese versus non-obese patients (p = 0.012)-including those treated with MTX (p = 0.001)-but not for fibrosis. There was no statistically significant difference for fibrosis or steatosis in the presence versus absence of type 2 diabetes *mellitus*, dyslipidaemia, or alcohol consumption in our psoriatic patients.
Conclusion: In our psoriatic patients, MTX has no significant effect in the stage of fibrosis or grade of steatosis. Obesity has a significant correlation with steatosis, but not with fibrosis, independently of MTX therapy. Type 2 diabetes *mellitus* and dyslipidaemia and alcohol consumption have no correlation with fibrosis or steatosis in all the patients. Studies with more patients and follow-up are needed to better clarify the impact of MTX therapy in the liver of psoriatic patients.

FRI-496

Performance of the scores diagnosis of autoimmune hepatitis in Moroccan patients

Sara Chbourk[1], Mohamed Borahma[1], Imane Benelbarhdadi[1], Fatima Zahrae Ajana[1]. [1]*Mohamed V university, Ibn Sina hospital, department of gastroenterology C, Rabat, Morocco*
Email: docteurchbourk@gmail.com

Background and aims: Autoimmune hepatitis (AIH) is a chronic liver disease whose diagnosis use diagnostic scores that were established by the international autoimmune hepatitis group in 1993 with a revision in 1999. Since 2008, a simplified score is more commonly used taking into account 4 histo-biological parameters. The aim of this study is to compare the performance of these 2 scores in the diagnosis of autoimmune hepatitis in the Moroccan population.
Method: In this mono-center retrospective study, the 2 diagnostic scores were used in 31 patients followed for autoimmune hepatitis and in 32 patients followed for other chronic liver diseases (porto-sinusoidal vascular disease = 16, non-alcoholic fatty liver disease = 13, primary sclerosing cholangitis = 3). The sensitivity and specificity of each score were calculated using Jamovi software.
Results: The mean age in our study was 42 years with extremes between 15 and 74 years, a clear female predominance was noted with a sex ratio of 0.14. Using the simplified autoimmune hepatitis score, the sensitivity and specificity for the detection of probable autoimmune hepatitis (scores≥6) were 45% and 100%, with a positive and negative predictive value of 100% and 65%, respectively. For the diagnosis of definite AIH (scores ≥7), the sensitivity and specificity were 6.45% and 100%, with a positive and negative predictive value of 100% and 52%, respectively. On the other hand using the Revised International Autoimmune Hepatitis Group Scoring System the sensitivity and specificity for the detection of probable autoimmune hepatitis were 96% and 62% respectively with a positive predictive value of 71% and a negative predictive value of 95%.
Conclusion: Our statistical study shows that both scores are efficient tools for the diagnosis of AIH, the simplified score which is a practical and easily applied in the clinical setting presents a better specificity while the Revised International Autoimmune Hepatitis Group Scoring System is more sensitive for the detection of autoimmune hepatitis.

FRI-497

Assessment of international normalized ratio to albumin ratio in predicting mortality in decompensated liver disease at a resource limited medical centre

Marium Fatima Waqar[1], Madiha Qadir[1], Zeeshan Junejo[1], Syed Masroor Ahmed[1], Shabnam Naveed[1]. [1]*Jinnah Postgraduate Medical Centre, Medical unit III, ward 7, Karachi, Pakistan*
Email: mariumwaqar5@gmail.com

Background and aims: Decompensated liver disease (DCLD) has a high mortality and morbidity irrespective of its etiology. It is characterized by reduced liver reserves resulting in reduced synthesis of albumin and deranged international normalized ratio (INR). Prothrombin time- INR and serum albumin both reflect the functional capacity of the liver. Abnormalities in their levels can frequently lead to a poor prognosis in liver cirrhosis.
Our study aims to evaluate Prothrombin time- INR and serum albumin ratio (PTAR) as a prognostic score for predicting 30 day mortality and its association with Model for End Stage Liver Disease Sodium (MELD Na) in patients with DCLD presenting at tertiary care hospital in a resource limited country.
Method: This prospective study was conducted at a medical unit of a tertiary care centre Jinnah Postgraduate Medical Centre. The baseline characteristics and laboratory parameters were recorded. The Child-Turcotte-Pugh (CTP) and the MELD Na scores were calculated to assess the severity of liver disease. The PTAR was calculated as INR divided by serum albumin in g/dl of the enrolled patients.

Data was stored and analyzed using IBM-SPSS version 25.0. Receiver operating characteristic curve (ROC) analysis was performed on PTAR and Meld Na scores to identify the cutoff of these parameters. The sensitivity and specificity were also estimated using ROC curve. After obtaining cutoff value for PTAR using ROC, all quantitative and qualitative parameters were assessed using Mann Whitney U test and Fisher's exact test. The p value less than 0.05 was considered statistically significant.

Results: Out of a total 307 DCLD patients enrolled, male patients outnumbered female patients, 54.7% (n = 168) versus 45.3% (n = 139). The median age of the patients was 54 (45–61) years. Total number of deceased patients was 61 (19.9%). The ROC curve analysis showed the area under the curve for PTAR was 58%, with 95% confidence interval l (0.51–0.66) and for Meld Na score it was 65% with 95% confidence interval (0.58–0.72). Both were found statistically significant with p <0.05. The cutoff value of PTAR suggested by the ROC curve was 0.25 for mortality. The sensitivity and specificity for PTAR was 95.1% and 3.7%. Upon further analysis, ROC curve showed that as the sensitivity increases, the value of 1-specificity also increase and the cut off value of PTAR for mortality decreases.

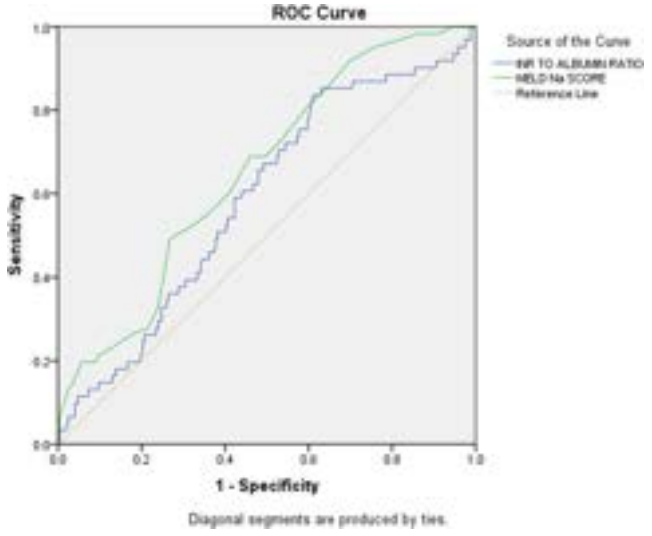

Figure:

Conclusion: In our study PTAR showed significant positive correlation with MELD Na and high sensitivity in predicting mortality of DCLD patients. The PTAR is easily calculated through commonly available laboratory investigations. It can serve as a prognostic tool and can facilitate health care professionals to make early decisions regarding admission of these patients into high dependency units in a resource constraint medical centre. However, multicentric studies at larger scale need to be conducted to validate the results.

FRI-498

Moving toward a more perfect liver function test: the next generation of HepQuant tests

Michael McRae[1], Steve Helmke[2], Greg Everson[2]. [1]*Custom Diagnostic Solutions, LLC, United States;* [2]*HepQuant, LLC, United States*
Email: michaelpmcrae@gmail.com

Background and aims: The HepQuant SHUNT Test (V1.0) uses stable isotopes of cholate administered both intravenously (13C-CA) and orally (d4-CA) to quantify liver function and physiology. The Test has been used in over 26 clinical trials and studies, encompassing a broad range of etiologies and stages of liver disease, where it has compared favorably to other liver diagnostic tests. However, the Test is sensitive to variability in the timing of collection of the 5-minute blood sample and difficulty in maintaining intravenous access. The aim of this study was to enhance the Test and its performance by simplifying the sampling procedure and shortening the time of testing. Herein we evaluate two new versions of the Test: V1.1 and V2.0.

Method: In V1.0, the volume of distribution (Vd) is calculated from ln-linear regression of 5- and 20-minute 13C-CA concentrations versus time. V1.1 estimates Vd based on body weight and height (Lemmens et al. 2006), eliminating the requirement for the 5-minute blood sample. V2.0 is based on our published compartmental analysis (McRae et al. 2022) and further simplifies sampling requirements to 2 timepoints at 20 and 60 minutes. To compare reproducibility, coefficients of variation (CV) and intraclass correlation coefficients (ICC) with one-sided test for lower acceptable limit of 0.7 were analyzed in a study of 16 controls, 16 NASH patients, and 16 HCV patients, each with 3 replicate tests conducted on 3 separate days (Burton et al. 2021). We assessed differences in areas under the receiver operator characteristic curve (AUROC) for predicting large esophageal varices (LEVs) in hepatitis C (HCV) subjects from the HALT-C study (N = 217) (Everson et al. 2012) by the DeLong method. Test outputs include a Disease Severity Index (DSI) and portal-systemic shunting (SHUNT%).

Results: For the measurement of DSI, V1.1 and V2.0 demonstrated similar ICCs but improved CVs relative to the V1.0 method. For the measurement of SHUNT%, the V1.1 and V2.0 test versions demonstrated improved reproducibility based on both ICC and CV%. Diagnostic performance based on AUROCs for V1.1 and V2.0 was equivalent to V1.0 in most cases and improved in V1.1 for SHUNT%.

Figure:

	Reproducibility (N = 48 Control, NASH, HCV)			Diagnostic performance of in the prediction of LEVs (N = 217)	
Test Parameter and Method	CV (%)	ICC	p value	AUROC	p value
Disease Severity Index (DSI)					
V1.0	11.17%	0.94	**<0.001**	0.81 (0.72–0.89)	-
V1.1	8.48%	0.95	**<0.001**	0.82 (0.71–0.89)	0.5795
V2.0	8.98%	0.94	**<0.001**	0.84 (0.77–0.90)	0.1218
Portal-systemic Shunt (SHUNT%)					
V1.0	15.11%	0.73	0.3209	0.80 (0.66–0.88)	-
V1.1	11.88%	0.85	**<0.001**	0.83 (0.74–0.90)	**0.0321**
V2.0	12.57%	0.84	**0.0012**	0.83 (0.73–0.90)	0.1019

Conclusion: The next generation of HepQuant SHUNT tests V1.1 and V2.0 simplify the test administration by eliminating the 5-minute sample (V1.1), reducing the total samples required to 2 (V2.0), and shortening the time from 90 minutes to 60 minutes (V2.0). These improvements should enhance operator performance, resource utilization, and patient acceptance of the HepQuant testing procedure, allowing for greater utilization of HepQuant for measuring liver function and physiology.

FRI-499

Liver elastography is a useful technique to assess the severity of liver congestion in patients with Budd-Chiari syndrome

Marcos Andres Thompson[1], Oana Nicoara-Farcau[1], Ernest Belmonte[1], Maria Ángeles García-Criado[1], Anna Darnell[1], Valeria Perez[1], Lara Orts[1], Pamela Vizcarra[1], M Àngels Falgà[1], Joana Codina Jane[1], Fanny Turon[1], Anna Baiges[1], Pol Olivas[1], Marta Magaz[1], Giuseppe Grassi[1], Sarah Shalaby[1], Virginia Hernandez-Gea[1], Juan Carlos Garcia Pagan[1]. [1]*Hospital Clinic Barcelona, Hepatic Hemodynamic Laboratory, Liver Unit, Hospital Clínic, Barcelona, Spain*
Email: thompsonmarcos86@gmail.com

Background and aims: In Budd-Chiari syndrome (BCS), hepatic congestion is the main cause of portal hypertension development. Liver congestion is a recognized cause of increase in liver stiffness (LS). Recent publications suggest that LS could be useful in assessing on congestion and the response to treatment in BCS. Our study aimed

to assess this issue and the LSM as a tool to asses on BCS follow-up in a large cohort of BCS patients.
Method: Observational retrospective study including patients with BCS with at least 2 LS measurements (LSM) by Fibroscan® (Echosens, Paris, France). LSM were performed at different stages of the disease: clinical stability or instability under medical and/or interventional radiological treatment (IR: TIPS or hepatic vein stent-HVS).
Results: We included 51 patients with BCS. 15 patients were clinically stable while on anticoagulation treatment (ACO) and remained compensated throughout the whole follow-up (median of 2 years: 4 months-11 years). These patients had 82 LSMs (median 4/patient; range 2–11) with 79 LSMs (96%) of these <25 kPa; the remaining 3 LSMs (in 2 patients) were between 25–30 kPa. Twelve patients had LSMs while decompensated. Once under ACO, only one of those achieved compensation with: LSM pre-ACO-64 kPa; 32 kPa at 3 months and 20 kPa at 6 months of ACO. The 11 patients that remained decompensated had 80 LSMs (median 8/patient; range 3–12); median follow-up of 8 months (2 months-13 years): 76 (95%) LSMs were >25 kPa with 67 (84%) being >30 kPa.
IR was performed in 29 decompensate patients (28 TIPS and 1 angioplasty/HVS). LSM pre and post IR were available in 10 patients. Median LSM pre-IR: 59 kPa (IQR 45.1–75) decreasing to 33.6 kPa (IQR 26.75–41.5) at 24 h; to 25 kPa (IQR 21.8–29.4) at 1 month; 22 kPa (IQR 21–24) at 3 months; and 23.6 kPa (IQR 22–25) at 6–12 months post IR. 18 IR treated patients had 105 LSMs while clinically stable (13 patients throughout the whole follow-up and 5 during long periods of clinical stability between periods of IR dysfunction) (median 5 LSMs/patient, range 2–13) during a median follow-up of 3.5 years (2 months-12 years). 101 LSMs (96%) were <25 kPa and 4 between 25 and 30 kPa which decreased <25 kPa when repeated. 16 patients had 97 LSMs while presenting IR dysfunction (median 6/patient; range 2–14); 84were >30 kPa and 13 between 25–30 kPa, all above 25 kPa.
Conclusion: In patients with BCS, LSM values <25 kPa suggest an adequate hepatic decongestion under medical or IR treatment. LSM values >30 kPa are highly suggestive of persistent hepatic congestion due to medical treatment inefficacy or TIPS/stent dysfunction. Values between 25–30 kPa represent a grey zone and if possible, should be repeated shortly during follow-up to assess whether there is a LSM increase/decrease.

FRI-500
Fibrosis-4 score less than 2.67 and normal gamma-glutamyl transferase levels are associated with high negative predictive value for high-risk of liver stiffness in patients with primary biliary cholangitis

Alan Bonder[1], Vilas Patwardhan[1], Joanna MacEwan[2], Anran Shao Shao[2], Leona Bessonova[3], Erik Ness[3], Tracy Mayne[3], Darren Wheeler[3], Radhika Nair[3], Jing Li[3], Shari Orbach[3]. *[1]Division of Gastroenterology, Beth Israel Deaconess Medical Center, Boston, United States; [2]Genesis Research, Hoboken, United States; [3]Intercept Pharmaceuticals Inc, Morristown, United States*
Email: erik.ness@interceptpharma.com

Background and aims: Transient elastography (TE), an imaging test for liver stiffness and fibrosis, is a non-invasive alternative to liver biopsy that is predictive of liver outcomes in individuals living with primary biliary cholangitis (PBC). Here, we assess the sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of biochemical markers and commonly used composite liver fibrosis scores versus liver stiffness measured by TE in people living with PBC.
Method: Liver biochemistries, commonly used fibrosis scores, and TE stiffness measurements were obtained from electronic health records of people living with PBC followed at Beth Israel Deaconess Medical Center through October 2022. The agreement between liver biochemistries/fibrosis scores and liver stiffness (TE >10 kPa) was evaluated by sensitivity, specificity, PPV, and NPV. Normal limits for biochemistries and commonly used thresholds for fibrosis scores were assessed.
Results: Data were analyzed from 74 patients (mean 54 years of age, 96% female). Mean ALP was 1.6 × ULN (±1.2; ULN = 120 U/L) and mean total bilirubin was 0.6 × ULN (±0.3; ULN = 1 mg/dL). The PPV of liver biochemistries and composite fibrosis scores ranged from 22% to 69%; the NPV for all individual labs and composite labs was >75% (Table).

Table: Agreement between liver biomarkers/composite fibrosis scores and liver stiffness assessed by transient elastography (TE) in patients with primary biliary cholangitis

	Threshold	TE Data Pairs[a] n	Sensitivity	Specificity	PPV[b]	NPV[c]
Albumin	≤4 g/dL	85	0.409	0.937	0.692	0.819
Gamma glutamyl transferase	≥40 U/L	51	0.900	0.390	0.265	0.941
Immunoglobulin G	≥1600 mg/dL	48	0.154	0.943	0.500	0.750
Immunoglobulin M	≥250 mg/dL	50	0.846	0.622	0.440	0.920
Alkaline phosphatase	≥120 U/L	109	0.846	0.374	0.297	0.886
Total bilirubin	≥1 mg/dL	109	0.192	0.952	0.556	0.790
Aspartate transaminase	Female, ≥30 U/L Male, ≥35 U/L	109	0.731	0.566	0.346	0.870
Alanine transaminase	≥40 U/L	109	0.385	0.735	0.313	0.792
Platelet count	≤150 × 10^9/L	106	0.083	0.915	0.222	0.773
FIB-4 score[d]	≥2.67	106	0.208	0.927	0.455	0.800
APRI score[e]	≥0.5	106	0.458	0.768	0.367	0.829

[a]TE scores and liver biomarkers/fibrosis scores assessed within ± 60 days of each other.
[b]Probability of a positive TE test (liver stiffness ≥10 kPa).
[c]Probability of a negative TE test (liver stiffness ≤10 kPa).
[d]Composite of age, AST, ALT, and platelet count.
[e]Ratio of AST as a multiple of ULN to platelet count.

Conclusion: These findings indicate that these readily available liver biochemistries and commonly used fibrosis scores are excellent predictors of a low-risk liver stiffness value (TE <10 kPa) in people living with PBC. When TE testing is not available, healthcare providers can use standard liver biochemistries to further assess overall liver health.

FRI-501
Suitability of Fibroscan, APRI and FIB-4 indexes compared with liver biopsy in the evaluation of liver fibrosis: a single-centre retrospective study

Benjamin Polo Lorduy[1], Alvaro Yagüe[1], Andres Castañeda[1], Rocio Calvo Hernandez[1], Juan Carlos Porres Cubero[1]. *[1]Hospital Universitario Fundación Jiménez Diaz, Spain*
Email: bpolo@fjd.es

Background and aims: The prognosis and management of liver diseases largely depend on the amount and progression of liver fibrosis and the possibility of developing cirrhosis. Liver biopsy has traditionally been considered the gold standard for the diagnosis of cirrhosis and staging of fibrosis. However, it is and invasive and inaccurate technique with many drawbacks. In order to overcome the limitations of liver biopsy, a number of non-invasive markers have been developed over the past decade for the evaluation of liver fibrosis. The aim of this study is to evaluate the ability of FibroScan, APRI and FIB-4 indexes to predict liver fibrosis using liver biopsy as the reference standard.
Method: The case records of 204 patients who underwent liver biopsy from March 2019 until November 2022 were retrospectively reviewed. Those patients who had undergone FibroScan measurements and blood samples simultaneously or with a maximum difference of one month from liver biopsy were included in the study,

with a final number of 188 patients. Liver fibrosis stage was determined using the METAVIR system.
Results: 188 patients with a mean age of 51.8 ± 13.3 years were examined, being women the majority of them (72.9%). FibroScan liver stiffness results ranged from 4.50 to 8.30 kPa (median: 5.9 kPa), while serological marker values ranged from 0.85 to 2.01 (median: 1.34) for FIB-4 and from 0.36 to 1.11 (median: 0.54) for APRI. In liver biopsy, 81.4% of the patients presented F0–1, while mild fibrosis (F≥2) was found in the remaining 18.6%. For the detection of F≥2, FibroScan showed a sensitivity of 77% and a specificity of 80% with a positive predictive value of 47% and a negative predictive value of 94%. Its degree of concordance with the biopsy was moderate (kappa index: 0.45). Regarding FIB4 and APRI, both showed high sensitivity (91% for FIB4 and 86% for APRI) and low specificity (63% for FIB4 and 50% for APRI), with a kappa index of 0.35 and 0.20, respectively.

Variable	Media ± DT Mediana (Q1, Q3)	Rango
Edad	51.8 ± 13.3	(20.0, 81.0)
CAP	242 ± 70.5	(117, 400)
FibroScan	5.90 (4.50, 8.30)	(2.50, 45.0)
% ESTEATOSIS	0.00 (0.00, 15.0)	(0.00, 95.0)
FIB 4	1.34 (0.85, 2.01)	(0.29, 9.36)
APRI	0.54 (0.36, 1.11)	(0.13, 18.1)

Biopsia	FibroScan	
	F0-1	F2-4
F0-1	122	31
F2-4	8	27

Biopsia	FIB4	
	F0-1	F2-4
F0-1	97	56
F2-4	3	32

Biopsia	APRI	
	F0-1	F2-4
F0-1	76	77
F2-4	5	30

Figure:

Conclusion: FIB-4 and APRI indexes had an acceptable ability to detect the presence or absence of mild fibrosis; this capacity is due for their high negative predictive values. However, the weak degree of agreement and the lack of specificity shown by these non-invasive methods indicates that liver biopsy is still necessary for the diagnosis of liver fibrosis stage. In the other hand, FibroScan is more accurate and comparable to liver biopsy with a moderate degree of agreement, but it also needs a specific device and a trained health practitioner that might not be available in some cases.

FRI-502
Hepatobiliary manifestations in pediatric COVID-19
Tetiana Stoieva[1], Olga Dzhagiashvili[1], Vira Dovzhyk[2]. [1]*Odessa National Medical University, Department of Pediatrics №2, Odessa, Ukraine;* [2]*Odessa National Medical University, Faculty of Medicine №1, Odessa, Ukraine*
Email: olga.dzhagiashvili@onmedu.edu.ua

Background and aims: Mechanisms of digestive damage in COVID-2019 are important. Possible factors include virus-induced influence, systemic inflammation, hypoxia, hypovolemia, drug-induced hepatotoxicity, etc. The aim of this study is analysing the digestive system and hepatobiliary tract in children who had COVID-19.
Method: We examined 27 children aged 11 to 16 who had COVID-19 and signs of digestive damage.
Results: The mean age of the examined patients was (13.8 ± 1.6) years, with no gender differences. It was found that (71.4 ± 8.7)% children had a history of functional disorders: the cyclic vomiting syndrome- (4.8 ± 4.1)%, the overlap syndrome- (19.0 ± 7.5)%, functional disorders of the gallbladder and sphincter of Oddi- (47.6 ± 9.6)%. Gastroesophageal reflux disease- (28.5 ± 8.7)% and chronic gastroduodenitis- (14.3 ± 6.7)% occurred among organic diseases. The infection was manifested by an increase in temperature from subfebrile (37.0 ± 9.3)% to febrile (63.0 ± 9.3)% with a severe disease course and such respiratory symptoms as dry cough, nasal congestion, rhinorrhea, hyperemia of the posterior pharyngeal wall. Gastrointestinal symptoms in children with a history of digestive diseases appeared on the 2nd-3rd days, in other children a little later- by the 4–5th and were characterized by the following symptoms: abdominal pain- (70.4 ± 8.8)%, nausea- (40.7 ± 9.5)%, vomiting- (25.9 ± 8.4)%, diarrhea- (33.3 ± 9.1)%. Along with gastrointestinal symptoms, some children (22.2 ± 8.0)% had changes in taste and eating behavior. Hepatobiliary symptoms were as follows: heaviness in the right hypochondrium (51.9 ± 9.6)%, bitter taste in the mouth (29.6 ± 8.8)%, stool acholia (40.7 ± 9.5)%, which were accompanied by dyspeptic disorders. The laboratory data revealed: a slight increase of transaminases (25.9 ± 8.4)%, an increase in alkaline phosphatase (7.4 ± 5.0)%, the presence of neutral fat in the coprogram (18.5 ± 7.5)% of children. Ultrasound revealed enlarged gallbladder (37.0 ± 9.3)%, thickening of its wall (22.2 ± 8.0)%, a moderate enlargement of the liver (14.8 ± 6.8)%, microliths and gallbladder sludge (29.6 ± 8.8)%. Gastrointestinal manifestations proceeded 10–32 days. A dynamic ultrasound revealed progression of gallbladder sludge in (18.5 ± 7.5)% children, which required administration of ursodeoxycholic acid preparations.
Conclusion: Among the digestive disorders, the hepatobiliary pathology often occurs in children with COVID-19. Liver damage takes place because of several mechanisms combination, and is characterized mainly by signs of cholestasis. Treatment should include hepatoprotectors and choleretic therapy along with antiviral therapy.

Health-related quality of life in a population at-risk of NAFLD or ArLD
Helle Lindholm Schnefeld[1], Katrine Prier Lindvig[1,2], Anita Arslanow[3], Isabel Graupera[3], Maria Kjærgaard[1,2], Katrine Thorhauge[1,2], Johanne Kragh Hansen[1,2], Camilla Dalby Hansen[1,2], Stine Johansen[1,2], Mads Israelsen[1,2], Peter Andersen[1], Nikolaj Torp[1,2], Katrine Bech[1], Sönke Detlefsen[2,4], Núria Fabrellas[3], Pere Ginès[3], Aleksander Krag[1,5], Maja Thiele[1,2]. [1]*Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense c, Denmark;* [2]*Department of Clinical Research, University of Southern Denmark, Odense C, Denmark;* [3]*Liver Unit, Hospital Clinic of Barcelona, Barcelona, Spain;* [4]*Department of Pathology, Odense University Hospital, Odense c, Denmark;* [5]*Department of Clinical Research, University of Southern Denmark, Odense C, Denmark*
Email: helle.lindholm.hansen@rsyd.dk

Background and aims: Patients with decompensated cirrhosis exhibit poor health-related quality of life (HRQoL). However, little is known about HRQoL in people at risk of non-alcoholic fatty liver disease (NAFLD) and alcohol-related liver disease (ArLD). Stigmatization, physical symptoms, and increased morbidity may impair HRQoL. We aimed to investigate the correlation between HRQoL and alcohol overuse, metabolic syndrome (MetS), obesity, and type 2 diabetes (T2D), in a population screened for liver fibrosis, and whether fibrosis stage correlated with HRQoL in a liver-biopsied subgroup.
Method: We screened individuals from the general population and individuals at-risk of liver fibrosis with no established diagnosis of chronic liver disease, using transient elastography. We referred those with liver stiffness ≥8 kPa for a biopsy to stage fibrosis. We assessed HRQoL by the Short-Form-36 questionnaire (SF36; range 0–100), consisting of eight domains; physical health, limitations due to physical health, emotional well-being, limitations due to emotional problems, energy, social functioning, pain, and general health. We compared HRQoL based on: alcohol overuse, MetS, obesity, and T2D

to those with no risk factors. We performed multivariable regression on age, gender, risk factors, predisposing illnesses, and social economic parameters.

Results: The cohort consisted of 6,444 individuals, with a median age of 57 (IQR 52–63), 52% female. The prevalence of behavioral risk factors for fibrosis was 1,852 (29%) alcohol overuse, 2,551 (40%) obesity, 621 (10%) T2D, and 3456 (54%) MetS. 2,850 participants had two or more risk factors, 2,000 only had one risk factor and 1,594 had no risk factors. We performed biopsies on 203 individuals with elevated liver stiffness (165 Kleiner fibrosis stage F0-F2, 38 F3-F4). Obesity was the strongest predictor of poor HRQoL overall. Individuals with obesity reported lower physical health and energy, whilst having more pain than other groups. Individuals with alcohol overuse or obesity had lower emotional and social well-being. Individuals with MetS reported the highest HRQoL overall, only surpassed by the group with no risks. We found no significant differences in HRQoL between groups with fibrosis or cirrhosis on any of the domains. Obesity was the only risk factor significantly negatively associated with all eight domains after multivariable regression e.g. general health −4.78 (95%CI −6.02 to −3.54). Alcohol overuse was more negatively associated in domains concerning emotional and social well-being, compared to no risks, emotional −4.25 (95%CI −5.31 to −3.19) vs. no risks (.01 95%Ci −1.38 to 1.40).

Conclusion: Individuals with obesity report lower HRQoL than any other group at risk of liver fibrosis. This is independent of the fibrosis stage and the presence of other risk factors. Alcohol overuse correlates with lower emotional and social well-being.

WED-477

Effectiveness of vaccine education on vaccine awareness and vaccine uptake in patients with cirrhosis of liver of a tertiary care center in South India

K L Ajee[1], Arun Valsan[2], A Athira[1], Devika Menon[1], S Devika[1], Aswin Shaji[1], K T Moly[3], Priya Nair[2]. [1]*Amrita College of Nursing, Foundations of Nursing, Ernakulam, India;* [2]*Amrita Hospital, Kochi, Gastroenterology, Kochi, India;* [3]*Amrita College of Nursing, Principal, Ernakulam, India*
Email: capt.ajee@gmail.com

Background and aims: Patients with cirrhosis of the liver are prone to bacterial or viral infections that can lead to increased morbidity and mortality. Many of these infections are vaccine preventable and the Centers for Disease Control (CDC) currently recommends vaccination for all susceptible chronic liver disease patients. It is observed that vaccination status of patients with liver disease is poor and currently there are no guidelines available in India for vaccination of patients with cirrhosis. Hence, we aimed to study the effectiveness of vaccine education on vaccine awareness and vaccine uptake in patients with cirrhosis of liver.

Method: A pilot study was undertaken among100 adult patients with cirrhosis of liver who were vaccine naive except for Covid-19 from October 2022 to Dec 2022. We used one group pre-test post-test design with a total enumerative sampling technique. A validated questionnaire with a Cronbach's alpha of 0.81 was used to measure the level of vaccination awareness. The awareness questionnaire had twenty closed ended questions with maximum score of 60. The awareness level was categorized as lack of awareness (≤15), low level awareness (16–30), medium-level awareness (31–45) and high-level awareness (>45). After collecting information on vaccination status and state of awareness of adult vaccination from the eligible sample presenting at outpatient services using a direct interview technique, information about adult vaccination was given one-on-one basis by a trained nurse. After 7days, a post-test (interview) was done to assess awareness, thereafter within 45 days after the first interaction, the immunization record was reviewed. Statistical analysis was done with SPSS 29.0. The study was approved by the institutional ethics committee ECASM-AIMS-2022-158 dated 11October 2022.

Results: The mean age of the study population was 60 years with predominantly males (81%). All were vaccinated against Covid-19. About 65% had comorbidities like Diabetes (34%) and hypertension (31%). Seventy-six percentage of patients had low-level awareness about vaccination. After the vaccine education module was administered, post-test interview revealed significant ($p < 0.00$) improvement in level of awareness from low to high (97%). Also, this led to significant vaccine uptake within day 45. The uptake of vaccination status improved from non-vaccinated to vaccinated in hepatitis B (95%), hepatitis A (76%), influenza (49%) and pneumococcal (40%). This is of significance considering the fact that nearly half (49%) of them were diagnosed to have cirrhosis with a median diagnosis time of 3 years. About 5% of patients did not take hepatitis B vaccine due to increased bilirubin or CRP level by their treating physician's advice. The most important reason for lesser vaccine uptake of hepatitis A, influenza and pneumococcal vaccine was cost (88%), lack of insurance coverage for preventive vaccinations (61%), accessibility (42%), lack of care-giver support (32%), fear or anxiety related to vaccination (18%).

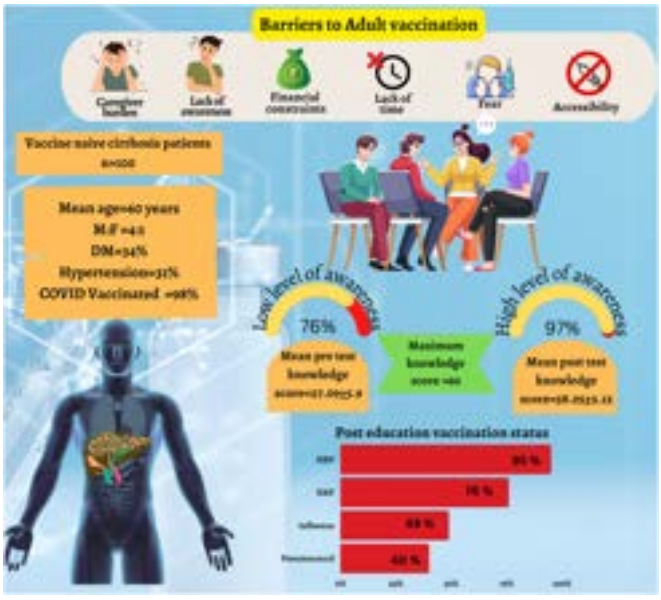

Figure:

Conclusion: Despite robust literature to support administration of vaccines in cirrhosis, the level of vaccine awareness and uptake is low in India. A structured nurse-led awareness campaign led to significant increase in vaccine knowledge and uptake. The lack of insurance coverage low awareness was the prime reasons for low vaccination status in our cohort.

WED-478

Better strategies are needed to increase engagement of patients with cirrhosis with allied health and community services

Elizabeth Powell[1], Katherine Stuart[1], Simon Finnigan[1], Jan Hinson[2], Christina Bernardes[3], Gunter Hartel[3], Patricia Valery[3]. [1]*Princess Alexandra Hospital, Woolloongabba, Australia;* [2]*Australian Catholic University, Brisbane Campus, Banyo, Australia;* [3]*QIMR Berghofer Medical Research Institute, Herston, Australia*
Email: patricia.valery@qimrberghofer.edu.au

Background and aims: Psychosocial care needs are not routinely attended to during outpatient hepatology management, and relatively little is known about the category and effectiveness of support services accessed by patients with cirrhosis. We quantified the type

and self-reported use of community and allied health services and whether patients were satisfied with the support received.
Method: Adults attending hepatology/gastroenterology clinics with a diagnosis of cirrhosis were enrolled in the CirCare study (n = 562). Health service use for support with their liver disease was assessed via interview and via linkage to the Australian Medicare Benefits Schedule (MBS). Patient needs were assessed using the Supportive Needs Assessment tool for Cirrhosis (SNAC),1 and clinical data obtained from medical records.
Results: Although most patients (85.9%) used at least one community or allied health service for support with their liver disease, many patients reported requiring additional help with psychosocial (67.4%), lifestyle (34.3%) or practical needs (21.9%) that were not met by available services, or patients did not access services. In the 12 months prior to recruitment, a multidisciplinary care plan or case conference was accessed by 48% of patients and 56.2% self-reported the use of a GP for support with liver disease. The allied health clinician most commonly accessed by patients was a dietician (45.9%). Only a minority of patients reported accessing an exercise physiologist (4.4%) or physiotherapist (11.6%). Despite the high prevalence of ongoing psychosocial needs, there was relatively limited use of mental health and social work services. Only 14.1% of patients self-reported the use of a psychologist, confirmed by a low prevalence of use of mental health services (17.7%) in the linked MBS data. When comparing patients' psychosocial needs with use of and satisfaction with self-reported consultation with relevant psychosocial health professionals, overall, 483 patients (85.9%) reported at least one psychosocial need. As displayed in Figure and out of 562 patients, the need for *additional* help with at least one area of psychosocial challenge was reported by 125 (22.2%) patients who reported accessing relevant services and 254 (45.2%) patients who did not access relevant services. All psychosocial needs were met for 104 patients (18.5%), and 16 (2.9% of 562) patients reported accessing relevant services.

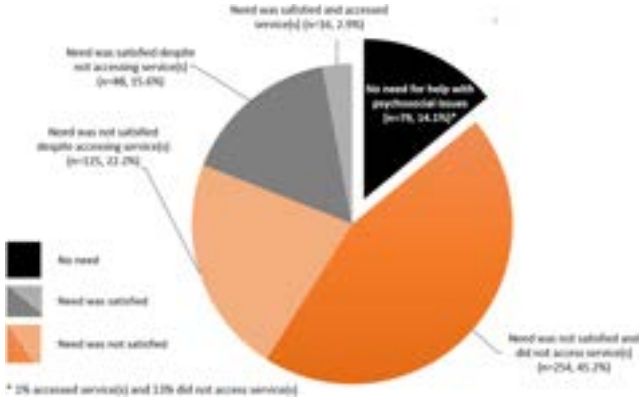

Figure: Need for help with psychosocial issues and self-reported consultation with a psychologist, psychiatrist, social worker or mental health team professionals and patient's satisfaction with care

Conclusion: Better strategies to increase engagement of patients with cirrhosis who have unmet complex physical and psychosocial needs with allied health and community services are needed.

Who's testing whom? Healthcare professional and patient knowledge of hepatitis delta virus and appropriate testing in an East Midlands hospital

Rachel Ryder[1], Kathryn Jack[1], William Irving[2]. [1]*Nottingham University Hospitals NHS Trust, Research and Innovation, Nottingham, United Kingdom;* [2]*University of Nottingham, Clinical Virology, Nottingham, United Kingdom*
Email: rachel.ryder2@nuh.nhs.uk

Background and aims: The World Health Organisation (WHO) aims to eliminate viral hepatitis as a public health threat by 2030. This includes Hepatitis Delta virus (HDV), a satellite virus which infects approximately 5–6% of HBV patients. Little is known about the true prevalence of HDV in the United Kingdom; testing and follow-up vary from region to region. This proof of concept study provides a snapshot of the acceptability and approaches to HDV testing of healthcare professionals and knowledge of HDV among HBV patients in a large teaching hospital in the East Midlands.
Method: The attitudes of healthcare professionals towards the acceptability of HDV testing were surveyed utilizing the eight constructs of the "Theoretical Framework of Acceptability" (Sekhon *et al*, 2017; 2022). Over a four month period, 39 hepatology healthcare professionals (31 doctors, 8 nurses) were recruited by opportunistic and snowball sampling, via UK and European specialist groups. Each participant completed an anonymous online survey, with questions including knowledge of National Institute for Health and Care Excellence (NICE) and European Association for the Study for the Liver (EASL) guidelines on HDV testing, acceptability of testing, barriers and facilitators to testing and long-term patient follow-up. 70 HBV surface antigen positive patients were recruited from routine clinics and were surveyed by telephone, answering questions about their primary language, knowledge of HDV and their own HDV testing status. Medical records were used to provide retrospective data on their HDV testing status.
Results: The results showed that in healthcare professionals there was a communication failure between professional bodies producing testing guidelines (NICE/EASL) and clinicians as to which patients should be tested for HDV. Only 66.6% of clinicians surveyed were able to correctly cite EASL testing guidelines, and only 53.8% were able to correctly cite NICE guidelines on appropriate HDV testing. However, there was a high level of belief that HDV testing was an acceptable intervention to perform against all eight of Sekhon *et al*'s constructs, with 97.5% of clinicians surveyed stating that HDV testing was either completely acceptable, or acceptable to them. There was a similar communication failure between clinicians and patients in explaining what HDV is, how it may affect HBV patients and why HDV testing is important, with 77.1% on HBV patients stating that they were unaware of HDV and that it had never been discussed by their healthcare professional. In contrast, 95.7% of HBV patients sampled had been tested for HDV, indicating that testing was being performed, but communication to patients was lacking. The data also showed a huge diversity of patient backgrounds within the cohort, reflecting the linguistic and cultural challenge faced by clinicians when treating HBV patients and provides some explanation for this communication failure.
Conclusion: This study shows that HDV testing is acceptable to healthcare professionals, but that many clinicians lack familiarity with recommendations laid down in clinical guidelines. Similarly in patients surveyed, a lack of knowledge and communication from healthcare professionals left them uncertain as to the nature of HDV and their own HDV testing status. A diversity of patient languages and cultures may be one cause of this, but communication need to be sharpened if the WHO objective of eliminating viral hepatitis as a public health threat by 2030 is to be met.

WED-480

First hepatitis C mass-testing in a category A prison in the United Kingdom

Alison West[1], Harriet Deverell[1], Ambrose Brown[2], Lisa Noble[3], Suzanne Ingram[3], Tara McKevitt[3], Lee Christensen[2], Nicholas Easom[1,4]. [1]*Hull University Teaching Hospitals NHS Trust, Department of Infection, Cottingham, United Kingdom;* [2]*Hepatitis C Trust, United Kingdom;* [3]*Spectrum Community Health CIC, HMP Full Sutton, United Kingdom;* [4]*University of Hull, Hull York Medical School, Hull, United Kingdom*
Email: nicholas.easom@nhs.net

Background and aims: As part of ongoing efforts to eliminate Hepatitis C in England and Wales, we undertook mass-testing of the inmates of HMP Full Sutton, a Category A prison in the East Riding of Yorkshire, UK. Micro-elimination in prisons through a combination of Hepatitis Intensive Test and Treat (HITT) events and high-uptake reception testing is an important arm of the elimination programme. However this had not previously been attempted in a Category A prison.

Method: A multiprofessional team was assembled comprising staff from the Humber and North Yorkshire Operational Delivery Network (ODN), The Hepatitis C Trust, Full Sutton prison healthcare staff, NHS England, and Spectrum Community Health. Regular planning meetings were established to coordinate between services. Prison peer-mentors were trained leading up to the event, who disseminated information to other prisoners. Two teams, each consisting of an ODN nurse, prison healthcare lead nurse, Spectrum member and a prison officer, offered testing throughout the prison across two days. Oral hepatitis C virus (HCV) antibody swabs were used to screen for HCV antibodies, sero-positive individuals received follow-up HCV RNA testing with results available same-day. HCV RNA-positive individuals were offered treatment with pangenotypic oral antiviral therapy.

Results: In total, 584 prisoners were offered HCV testing and 514 (88%) accepted a test, in addition to 161 prison staff, 15 prisoners and 1 staff member were HCV antibody positive. On HCV RNA testing, 3 prisoners were positive and 0 staff members. All three HCV RNA-positive individuals commenced oral antiviral therapy within one week of the test results.

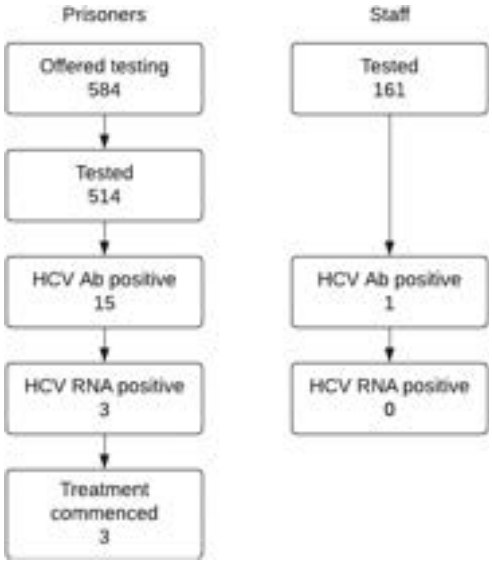

Figure:

Conclusion: Although the micro-elimination target of 95% testing uptake was not met, it was possible to test a high proportion of the prison population through a coordinated, multi-professional approach. Reasons for declining testing were related to concerns about the potential for DNA sampling or a belief that the individual did not want or deserve to be treated for this infection. Despite this, high uptake was achieved by early engagement with the prison population through peer-mentors, active participation of prison officers, and the existing good relationship between prison health-care staff and inmates. Learning has been disseminated to other ODNs for use in future Category A prison testing events.

WED-481

A prospective study to assess medication adherence to systemic therapy among patients with hepatocellular carcinoma

Suja Kumari[1], Ajee Kurunjipadath Lakshmanan[2], Arun Valsan[3], Nipun Verma[4], Priya Nair[5], Shine Sadasivan[5], K Pavithran[5], S Sudhindran[5], Merin Babu[6,7], Vaishnavy S Vinod[5], S Krishnapriya[5], Manjima P Nair[5], Ms Arunima[8]. [1]*Amrita College of Nursing, Foundations of Nursing, Kochi, India;* [2]*Amrita College of Nursing, Foundations of Nursing, India;* [3]*Amrita Institute of Medical Sciences, Dept of Gastroenterology, Kochi, India;* [4]*Postgraduate Institute of Medical Education and Research, Hepatology, India;* [5]*Amrita Institute of Medical Sciences, Dept of Gastroenterology, India;* [6]*Amrita Institute of Medical Sciences, Dept Of Oncology, India;* [7]*Amrita Hospital, Kochi, Medical Oncology, Kochi, India;* [8]*Amrita School of Pharmacy, India*
Email: arunvalsan@aims.amrita.edu

Background and aims: Hepatocellular carcinoma (HCC) represent fifth most common malignancy and the third leading cause of death due to cancer worldwide. Recent data suggest that orally administered systemic therapy (ST) can improve quality of life and survival amongst patients with advanced HCC. Real-world adherence and tolerance to ST are currently unknown outside the clinical trial settings. This study aimed to assess medication adherence, perceived barriers to adherence, and reasons for non-compliance among patients with advanced hepatocellular carcinoma.

Method: A prospective observational study was conducted among advanced hepatocellular carcinoma patients receiving systemic therapy with either lenvatinib or sorafenib. The institutional ethics committee approved the study (ECASM-AIMS-2022-111, 01 July 2022). Patients' socio-demographic and clinic-laboratory data were recorded. A modified Moriski medication adherence tool with a reliability of 0.94 was used to measure adherence to the medication, and perceived barriers to compliance with medication were assessed by a self-structured tool with a reliability of 0.86.

Results: Of the 150 patients interviewed, 118 (79%) were males with a mean age of 65 ± 5 years, with the predominant aetiology of cirrhosis being alcohol (78%) and NASH (22%). Twenty-two patients (14.6%) had permanently discontinued the drug, whereas 73 (49%) patients discontinued the drug temporarily, with a mean drug intake of 2.5 months. The study population was divided into three adherence groups based on the Moriski scale: high (n = 66), moderate (n = 18), and low (n = 66). The mean adherence score was 5.44. There was significant association between non-adherence and body mass index, potassium level, albumin and cost of medications. The common reasons cited for non-adherence were fear of side effects (98%), forgetfulness (90%), perceived worsening of the clinical condition (45%), lack of accessibility to health information (21.3%), and lack of social support (14.6%) and Lenvatinib therapy (31%).

Figure:

Conclusion: According to the study's findings, several perceived obstacles, including side effects, cost concerns, and a lack of motivation and support, deter patients from taking their medications as prescribed. Our findings highlight the necessity of modifying the perceived barriers and enhancing adherence in a population at risk by implementing prompt interventions.

WED-482

Advanced practice nurses' scope of practice in liver care: evaluation of two different Swiss settings

Patrizia Kuenzler[1,2,3], Barbara Schoop[2], David Semela[1], Beat Müllhaupt[4], Andreas E Kremer[4], Sonja Beckmann[3,5]. *[1]Cantonal Hospital St.Gallen, Division of Gastroenterology and Hepatology, St. Gallen, Switzerland; [2]Cantonal Hospital St.Gallen, Departement of Nursing, St. Gallen, Switzerland; [3]University of Basel, Institute of Nursing Science, Basel, Switzerland; [4]University Hospital Zurich, Department of Gastroenterology and Hepatology, Zürich, Switzerland; [5]University Hospital Zurich, Center of Clinical Nursing Science, Zürich, Switzerland*
Email: patrizia.kuenzler-heule@kssg.ch

Background and aims: Advanced Practice Nurses (APN) have an increasing role in Switzerland to meet the needs of patients with liver diseases and their caregivers related to their physical, psychosocial and practical problems. Although holding a master or PhD, their scope of practice is limited as e.g., by law, nurses are not allowed to prescribe or perform interventions (e.g., paracentesis). In Switzerland, two APNs at the Cantonal Hospital St.Gallen (KSSG) and University Hospital Zurich (USZ) provide in- and outpatient care within a liver transplant setting. Their roles were developed and implemented independently, depending on the clinical context and patients' needs. The APN at the KSSG provides outpatient therapies (HCV/HCC), counsels inpatients and performs, for example, hepatic encephalopathy (HE) assessments. The USZ implemented the APN role with a dedicated focus on case management in complex inpatient situations. We aimed to describe and compare the APNs' scope of practice.
Method: The APNs prospectively collected data from August-December 2022. The dataset included: patient data (e.g., characteristics, diagnosis, transplant status), process variables (e.g., type of contact, referral, setting), assessment (e.g., clinical, psychosocial, behavior) and interventions (e.g., counseling, self-management support, coordination of care). Data were descriptively analyzed on organizational level.
Results: Both APNs provided 294 consultations in 123 patients. *KSSG:* The APN performed 168 consultations in 80 patients, mainly in the outpatient setting (68%). Patients' mean age was 59 years, 20% had HCC, 66% had liver cirrhosis with a mean MELD score of 12.6, 9% were pre-, and 9% post-transplant. *USZ:* The APN performed 126 consultations in 45 patients, mainly in the inpatient setting (80%). Patients' mean age was 57 years, 11% had HCC, 93% had liver cirrhosis with a mean MELD score of 18.5, 17% were pre-, and 9% post-transplant. *Scope of practice:* Both APNs equally supported patients in symptom management (36% vs 32%) and provided education (24% vs 29%, Figure). At the KSSG, the APN interventions mostly addressed patients alone (73%) with self-management support (50%), psychosocial care (40%), decision-making (32%), outpatient medical treatment (24%), and HE assessment (18%). At the USZ, the APN interventions mostly addressed patients (65%) or caregivers alone (20%) with care coordination (44%), discharge planning (33%) and advanced care planning (22%).

Figure: APN's scope of practice at the KSSG (green) and USZ (blue) in percentages

Conclusion: Our results highlight the diverse scope of APN activity in relation to their main clinical context (in- or outpatient setting), thereby reflecting the divergent patient needs along the care continuum. Other clinics may use our findings to develop APN roles according to their specific context and available resources.

WED-483

Value based healthcare: patient perception of the liver cancer advanced practice nurse care at the Barcelona clinic liver cancer

Neus Llarch[1,2,3,4], Eva Palou[5], Jessica Farre[5], Gemma Iserte[1,2,3], Núria Granel[1,6], Marta Campos Gomez[1,2], Joan Escarrabill[5], María Reig[1,2,4,7]. *[1]BCLC group, Fundació Clínic per a la Recerca Biomèdica-IDIBAPS., Barcelona, Spain; [2]CIBERehd, Madrid, Spain; [3]Liver Oncology Unit. Institut de Malalties Digestives i Metbòliques, Hospital Clínic de Barcelona, Barcelona, Spain; [4]University of Barcelona (UB), Barcelona, Spain; [5]Patient Experience Unit. Hospital Clínic de Barcelona, Barcelona, Spain; [6]Institut de Malalties Digestives i Metabòliques. Hospital Clínic de Barcelona, Barcelona, Spain; [7]Liver Oncology Unit. Liver Unit. Hospital Clínic de Barcelona, Barcelona, Spain*
Email: mreig1@clinic.cat

Background and aims: Management of hepatocellular carcinoma (HCC) was traditionally based on the treatment's safety and efficacy. However, patient experience, which is the third pillar of the quality of Health Care was less evaluated. This study assesses the patient valued-heath care areas and experience of the liver cancer patients in the outpatient clinic at the BCLC. The interview was based on the patients' experience with the Advanced Practice Nurse (APN) program at BCLC.
Method: Liver cancer patients included in APN-led-educational programs were recruited and were purposefully selected based on gender, age and disease stage. Individual interviews were conducted between September and October 2020. From September to October, a qualitative study through interview techniques were carried out. The interviews, which lasted on average 22.4 minutes, (Range 13–50) were audio-recorded and transcribed verbatim and analyzed by MAXQDA software. Patients were divided into two groups according to their knowledge of the APN program (with and without knowledge).
Results: Twenty-one interviews were performed. From the transcription analysis, 306 considerations were obtained which were

grouped into 34 categories and 8 meta-categories (Figure 1). Although 'Nurses' duties and 'humanely' were the main themes in all patients, other different topics were in the top-third category in each group: 'Expectations' in patients without knowledge and 'emotions' in patients who were already familiar with the APN program. Under 'emotions' some patients mentioned that nurses bring peace of mind, reassurance, others nervousness, fear and some patients commented that they felt alone during admission. Regarding 'expectations', the patients mentioned that what they expected from the nurses is to be treated well and professionalism, which was the case. Surprisingly, punctuality (4% and 5% in patients with and without previous contact with BCLC-APN; respectively) and administrative support (6% in both groups) were less mentioned than the nurses expected.

Figure:

Conclusion: In qualitative studies results are not generalizable to all patients. Their needs/priorities can be interpreted as areas of the BCLC-APN program which need to be covered or the reflection of patients' needs according to their knowledge of the program. These results are the rationale for developing a Value Based-APN program which includes the patients' perceptions.

WED-484

Hepatitis C education and training for community pharmacists in Ireland

Miriam Coghlan[1], Nessa Quinn[1], Declan Bradley[2], James Kee[2], Jennifer McCartan[2], Clare Fitzell[3], Aiden McCormick[4], Bernard Carr[1], Gail Melanophy[1]. *[1]St. James's Hospital, Pharmacy Department, Dublin, Ireland; [2]Health Service Executive, Primary Care Reimbursement Service, Ireland; [3]Irish Pharmacy Union, Ireland; [4]National Hepatitis C Treatment Programme, Ireland*
Email: coghlanm@tcd.ie

Background and aims: The availability of highly effective direct acting antivirals (DAAs) has made the elimination of Hepatitis C (HCV) a realistic goal. Simplified and devolved models of HCV care are needed to reach patients most in need of treatment. In 2019, the National Hepatitis C Treatment programme (NHCTP) in Ireland initiated a pilot programme for treatment in the community by general practitioners (GPs). DAAs prescribed could then be dispensed via a patient's local community pharmacy. Community pharmacists are well positioned to participate in the HCV treatment process. To provide community pharmacists with the right tools to enable them to successfully participate in the HCV treatment process we needed to devolve the knowledge gained in the hospital setting in an innovative and accessible way.
Method: An online training module was developed by a hospital HCV specialist pharmacist in collaboration with the NHCTP, the Irish Pharmacy Union (IPU) and the Primary Care Reimbursement Service (PCRS). This module was hosted on the IPU website. The online module delivery was complimented by a virtual question and answer session between community pharmacists and the above stakeholders prior to patients initiating treatment. Module evaluation and feedback was captured electronically at the end of the online module. Rates of uptake and completion of the module were captured. Data on the number of patients started on HCV treatment via the community pathway was obtained from the PCRS.
Results: Since initiation of the pilot in July 2019, 110 pharmacists working across 87 pharmacies have completed the community pharmacist training module. Treatment has been commenced by 98 patients to date in the community setting. Among pharmacists who completed the online training module, 99% agreed that the training made them more competent in the area of Hepatitis C patient care with 99% agreeing that they will use the knowledge they gained to develop new workplace practices or services. Participants identified that the training increased their confidence in engaging and working with GPs and hospital-based colleagues to treat patients with HCV infection in their communities.
Conclusion: The online module has facilitated the involvement of community pharmacists in the processes of medication reconciliation, drug-drug interaction review, dispensing new medication and adherence counselling as related to DAAs in a patient's local community setting. The online module has allowed specialist HCV pharmacists to disseminate knowledge and learnings to community pharmacists in a standardised way. This training model has also supported greater inter-professional working among GPs and pharmacists across primary and secondary care settings.

WED-485

Quality improvement project: improving early identification of liver disease in diabetic patients in a district general hospital with opportunistic FibroScan®

Amy Thatcher[1], Catherine Mitchell[2], Vijay Grover[2]. *[1]Hillingdon Hospital, United Kingdom; [2]The Hillingdon Hospital, United Kingdom*
Email: amy.thatcher@nhs.net

Background and aims: The vast majority of liver disease is preventable, early detection is imperative to manage the disease and prevent complications. Despite diabetes being well recognised as a risk factor for fatty liver disease, diabetic patients are not routinely screened for liver fibrosis. The aim of this quality improvement project (QI) is to improve early identification of liver disease in patients with diabetes in both in and out patient district general hospital setting using FibroScan.
Method: Inpatients admitted to hospital and out-patients attending the diabetic clinic with type 1 and 2 diabetes were offered a FibroScan by the Hepatology Clinical Nurse Specialist (CNS). Patients were provided with information prior to the FibroScan and those who consented were scanned. If the FibroScan was suggestive of liver fibrosis (>8 kPa), the Hepatology CNS provided health promotion, requested a non-invasive liver screen and booked appropriate follow-up. The Hepatology CNS collected data on patients Alanine Transaminase (ALT), Liver Stiffness Measurement (LSM), Controlled Attenuation Parameter (CAP), Body Mass Index (BMI) and Metabolic Risk Factors (MRF) (Hypertension and Dyslipidaemia). Patients were excluded if they were known to have liver fibrosis, acute hepatitis, alcohol excess (>14 units per week) or raised inflammatory markers.
Results: 40 patients were offered a FibroScan, 21 outpatients and 9 inpatients, 10 outpatients declined. 30 patients accepted a FibroScan, of which 14 had Type 1 Diabetes Mellitus (T1DM) (age range 26–65) and 16 Type 2 Diabetes Mellitus (T2DM) (age range 30–86). 14% of T1DM had fibrosis with 7% CAP score of >Steatosis grade 1 (S1). 78% BMI >25, 35% had one or more MRF with an average ALT of 19.
56% with T2DM had fibrosis with 50% CAP score of >S1, 62% BMI >25, 81% one or more MRF with an average ALT of 29. 19% of T2DM had newly diagnosed cirrhosis.

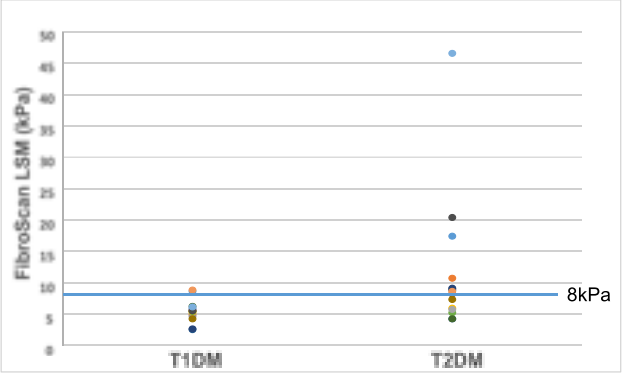

Figure:

Conclusion: This opportunistic screening QI project identified a significant number of T2DM patients with previously undiagnosed liver fibrosis, with majority having unremarkable liver enzymes. This has demonstrated the importance for this cohort of patients to be screened for liver fibrosis to prevent the complications of advanced liver disease.

WED-486

Changes in frailty as a predictor of readmission risk in patients with liver cirrhosis. Preliminary results

Martina Perez[1,2], Marta Cervera[2,3], Marta Carol[2,3], Ana Belén Rubio[2], Ruth Nadal[3], Jordi Gratacos[1,3], Anna Soria[1,3], Anita Arslanow[3], Adria Juanola[1,3], Elisa Pose[1,2,3], Isabel Graupera[1,2,3], Pere Ginès[1,2,3], Núria Fabrellas[2,3]. *[1]Liver Unit, Hospital Clínic de Barcelona, Spain; [2]University of Barcelona, Spain; [3]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Spain*
Email: maperezgu@clinic.cat

Background and aims: In addition to the complications of cirrhosis, the decompensated phase of the disease is characterized by the presence of sarcopenia, physical deterioration and/or malnutrition, all of which are associated with the concept of frailty. Recent studies have shown that frailty is a poor prognostic factor in patients with liver cirrhosis. Elevated frailty is also associated with an increase in unplanned hospitalizations, regardless of the severity of liver disease. The most frequently used tool to assess frailty is the Liver Frailty Index (LFI), designed specifically for patients with cirrhosis. Most published studies have assessed frailty at a single point; however, decompensated cirrhosis is a dynamic disease and patients' status can vary over a short period of time. The evolution of LFI changes in this population could be of interest as a tool to predict disease prognosis. The aim of this study is to investigate the relationship between changes in frailty and disease progression in patients with decompensated cirrhosis after hospital discharge.
Method: Prospective observational study in patients with decompensated cirrhosis who had been discharged after admission for a complication of cirrhosis. Frailty was measured by LFI at two points: at hospital discharge and at 7 days, and correlated with hospital readmissions within 28 days after inclusion. The cohort was divided into two groups, patients who had been readmitted within 28 days after inclusion and those who had not. The delta value of the LFI was calculated (taking into account the baseline and day 7 values) and the patients were classified into two groups, those who had improved and those who had remained the same or worsened.
Results: A total of 52 patients have been included so far, 38 of whom have completed a follow-up of 28 days. The baseline characteristics of the cohort are: mean age 62 years, mean 7 days of admission, 52% of the patients were alcoholic, and the most frequent complication was ascites, present in 63% of the patients. Considering a 28-day period, 8 patients were readmitted and 30 were not. The association between the readmission group and the LFI delta value was calculated. Of the group of patients who were readmitted, 5 patients (62% of the total of this group) had worsened LFI and 3 (38%) had improved LFI. Of the group of patients who were not readmitted, 11 (37%) had worse LFI and 19 (63%) had better LFI.
Conclusion: Although the N of this study does not allow affirmation, the analysis provides crucial evidence to suggest that the delta value of the LFI may be a useful tool to predict the risk of readmission in patients with decompensated cirrhosis. Another added value of these data lies in demonstrating the importance of improving frailty status in this population.

WED-487

Mental health, quality of life, and stigmatization in Danish patients with liver disease

Nadja Østberg[1], Birgitte Jacobsen[1], Mette Lauridsen[1], Lea Ladegaard Grønkjær[1]. *[1]University Hospital of Southern Denmark, Department of Gastroenterology and Hepatology, 6700 Esbjerg, Denmark*
Email: ns_@live.dk

Background and aims: Understanding the patient perspective is pivotal in the achievement of concordance with care and treatment. However, the mental health of patients with liver diseases is often overlooked when assessing their overall health and planning liver care, although the presence of mental health disorders are associated with poor patient outcomes, including symptom progression, increased hospitalization burden, and mortality. Thus, the aim of this study was to assess anxiety, depression, hopelessness, quality of life, and the perception of stigmatization in a large cohort of patients with chronic liver disease of different aetiologies and severity, as well as identify predictors associated with mental health disorders.
Method: A total of 340 patients completed a survey assessing mental health using the Beck Anxiety Inventory, the Beck Hopelessness Scale, and the Major Depression Inventory. Quality of life was measured with the Chronic Liver Disease Questionnaire and the European Quality-of-Life visual analogue scale. To assess stigmatization, eight validated questions from the Danish nationwide survey of patient experiences were used. Predictors associated with anxiety, hopelessness, and depression were analysed using univariable and multivariable logistic regression analyses.
Results: Fifteen percent of the patients had moderate or severe anxiety, 3% had moderate or pronounced hopelessness, and 8% had moderate or severe depression. The prevalence of all three was highest in patients with cirrhosis and was associated with a low quality of life. More patients with cirrhosis had experience stigmatization compared to patients with liver disease without cirrhosis, and more than one third of the patients, regardless of aetiology and severity, refrained from telling others about their liver disease.
Conclusion: Mental health disorders were present and associated with low quality of life in patients with liver disease and worst in patients with fully developed cirrhosis. In addition, patients experienced stigmatization. Our results emphasize the need for increased focus on mental health problems, development of intervention studies to explore the effect of therapy on quality of life and disease outcomes, and awareness on preventing discrimination and stigmatization of patients with liver disease.

WED-488

Clinical interdisciplinary development of a home-based enteral nutrition initiation and refeeding monitoring model of care for patients with chronic liver disease

Erin Russell[1], Suong Le[2,3,4], Patricia Anderson[2], Anita Figredo[5], Sheree Phillips[1], Sally Bell[2,4], Thomas Worland[2]. [1]*Monash Health, Nutrition and Dietetics Department, Australia;* [2]*Monash Health, Gastroenterology Department, Australia;* [3]*Monash Digital Therapeutics and Innovation Laboratory (MoTILa), Australia;* [4]*Monash University, School of Clinical Sciences, Australia;* [5]*Monash Health, Hospital in the home, Australia*
Email: russell.ee@hotmail.com

Background and aims: Malnutrition and sarcopenia are prevalent in 20 to 70% of adults with chronic liver disease (CLD) and are independently associated with increased mortality. Enteral nutrition (EN) can promote muscle mass restoration and improve objective liver function markers including Child-Pugh score. Malnourished CLD patients, and those with alcohol abuse, are at risk of refeeding syndrome on commencing EN. Inpatient capacity for EN initiation and monitoring was reduced during the COVID-19 pandemic. We developed an interdisciplinary home-based model of care to safely commence EN and monitor for complications in CLD patients.
Method: Monash Health is the second largest Australian tertiary healthcare network. Between February and June 2022, an interdisciplinary team of dietitians, gastroenterologists, general physicians, pharmacists, and nurses developed a home-based model of care. The protocol was derived from existing internal protocols and international guidelines for enteral feeding and refeeding management. Key elements include initiating, progressing, monitoring, escalation and ceasing enteral nutrition.
Results: We created an organisation-wide framework for supportive and collaborative patient care between multiple hospital departments (Hepatology, Hospital in the Home [HITH] and Dietetics). Our protocol includes roles and responsibilities, escalation pathways, instructions for initiating enteral feeding, precautions for refeeding management and a checklist for HITH nurses. Training for monitoring of these patients was completed at regular intervals to optimise stakeholder engagement. Communication pathways were developed to streamline inter-disciplinary collaboration. Our measures of success for this model of care include preventing hospital admissions, adverse events (including severe electrolyte requiring IV replacement or tube displacement), patient tolerance, weight restoration and improvement in Child-Pugh score. Two CLD patients successfully completed the feeding program without requiring inpatient admission. There was one tube dislodgement and one IV electrolyte replacement, successfully managed as outpatients.
Conclusion: We have developed and piloted a new model of care for home-based EN initiation program within a large tertiary healthcare network. This provided safe and effective EN therapy to a vulnerable group without requiring hospitalisation. The safety, efficacy, acceptability, and cost effectiveness of this model of care compared to traditional inpatient management will be evaluated as part of our feasibility study.

WED-489

Hepatology nursing consultation in a tertiary hospital without liver transplantation: initial experience

Alia Martín[1], Sandra Borrego[1], Sandra Díez[1], Irene Latras[1], Isabel González[1], Víctor Blázquez[1], Carolina Broco[1], Verónica Patiño[1], Raisa Quiñones[1], Ruben Díez[1], Francisco Jorquera[1], Pilar Moreno[1], Yolanda Méndez[1]. [1]*University Hospital of León, León, Spain*
Email: amartiniz@saludcastillayleon.es

Background and aims: Patients with chronic liver disease require continuous monitoring in order to detect complications or decompensations of their pathology. It is in this context that hepatology units, and therefore their patients, benefit from having an advanced practice nurse. The proposal was to set up a nursing practice to carry out intermediate follow-ups of patients with compensated chronic liver disease who are being followed up according to specific protocols for each disease. The objective was to analyse the activity of the hepatology nursing practice at the beginning of its activity in a tertiary care centre without liver transplantation.
Method: We retrospectively analysed the activity data of the nursing consultation at Complejo Asistencial Universitario de León from 1st January 2022 to 28th November 2022. The patient's express approval was required for referral to this care modality.
Results: Data from 211 patients assessed in the nursing consultation were analysed. Mean age was 63 years (SD 13.1) and 60% of patients were male. 98.6% (208/211) of the appointments were scheduled and 77.3% were on-site (163/211). After the nursing consultation it was necessary to consult a hepatologist on 13 occasions (6.2%). The main reasons for consultation were: control of B-blockers 49 (23.2%), follow-up of HBV infection (without previous liver disease) 41 (19.4%), chronic liver disease due to HCV 28 (13.3%), alcohol 22 (10.4%) and MAFLD 10 (4.7%) and follow-up of PBC without liver disease 17 (8.1%). The nurse performed a total of 299 interventions in the consultation. She provided advice on diet, exercise and lifestyle modification guidelines 134 times, adjusted medication 74 times, gave test results to 145 patients and referred 5 patients to the doctor's office. During the consultation the following tests were requested: blood tests in 176 patients, serology in 9, abdominal ultrasound in 110, MRI in 4, Fibroscan in 19 and gastroscopy in one patient. Thirty-four patients (16.1%) did not have any tests ordered.
Conclusion: The consultation of a hepatology nurse allows efficient follow-up of the patient with chronic liver disease, emerging as a key figure in bringing the hepatology unit closer to the patient.

WED-490

Development of a web-based mobile health application (ReLiver-N App) for patient activation, self-efficacy, and quality of life in patients with liver cirrhosis

Ferya Celik[1], Hicran Bektas[1]. [1]*Akdeniz University, Internal Medicine Nursing, Turkey*
Email: feryacelik@gmail.com

Background and aims: Liver cirrhosis is an important health problem that increases morbidity and mortality. Utilizing accessible and sustainable mobile health applications could help provide patient education and enhance activation. When the level of patient activation gets higher, patients' self-efficacy and quality of life get higher. Achieving this can be contributed to hepatic rehabilitation. To develop a web-based mobile health application (ReLiver-N App) led by a nurse for patient activation, self-efficacy, and quality of life support in patients with liver cirrhosis.
Method: This study was the first stage of our randomized controlled trial registered in clinical trials (ClinicalTrials.gov Identifier: NCT05658393). The development process included creating the content and designing the ReLiver-N App. We developed the ReLiver-N App-based ADDIE which is an instructional design framework and created its contents of it. After preparing the content, 10 experts evaluated the quality of the contents through "Evaluation of the Written Materials Appropriateness," and "Teaching Materials Evaluation Form." We evaluated the readability of the contents through Atesman Readability Formula. After that, we conducted a feasibility test with three patients to assess the usability of the ReLiver-N App. The patients evaluated ReLiver-N App through the "System Usability Scale" and "Rate Us" tabs.
Results: Our content included patient education information about liver cirrhosis and patient activity tasks and measurement questionnaires. Patient education information topics included "healthy lifestyle, let's learn about liver cirrhosis, complications of liver cirrhosis, diagnosis, and treatment methods." Patient activity tasks are divided into two groups, "daily activity tasks," and "weekly activity tasks." Daily activity tasks included "weight measurement, edema evaluation, fluid balance, bleeding check, and taking

medications." Weekly activity tasks included "taking blood pressure, heart rate, and body temperature." Patients can access the contents at this website "https://kcsiroz.com/." The score obtained from the experts was high (20.20 ± 3.01). The high score indicated that the readability level of the ReLiver-N App was easy. In line with expert opinions, the content of the ReLiver-N App was found to be reliable (Cronbach's alpha score: 0.83). According to the experts' opinions, we also did some changes to the content. The score obtained from the patients was 67 points. This score indicated the usability of the ReLiver-N App was acceptable. The patients rated the ReLiver-N App three out of five points.
Conclusion: We created a reliable web-based mobile health application for free. We estimate that the ReLiver-N App could help patients with liver cirrhosis to enhance their patient activation level, self-efficacy, and quality of life, and have healthier life at their homes.

WED-491
Analysis of health-related quality of life in the liver transplant patient conducted more than 10 years ago, statewide study
Sara Román Serrano[1], Fernando García Pérez[1]. [1]*Spanish Federation of Liver Patients and Transplants (FNETH), Spain*
Email: innovacion.social@fneth.org

Background and aims: To determine the health-related quality of life of patients who have undergone liver transplantation more than 10 years ago.
Method: Quantitative pilot study, in the form of an online survey, which was distributed through the website and social networks of the Spanish Federation of Liver Patients and Transplants (FNETH), and with the dissemination of our federated associations distributed throughout the national territory, after approval of the questionnaire by the Spanish Society of Liver Transplantation (SETH). To determine the health-related quality of life of patients who underwent liver transplantation more than 10 years ago. 1.0 questionnaire was used as the basis for the cross-cultural adaptation of the specific quality of life questionnaire for chronic liver diseases for use in the Spanish population. Statistical analysis of the data was performed with the Statistical Package for Social Sciences program (SPSS, version 28.0).
Results: The survey was open between 1 January 2021 and 31 October 2021, receiving a total of 114 surveys, of which 68 were finally valid for analysis. Socio-demographic characteristics: 58.8% of the participants were men and 41.2% were women, the age of the participants ranged from 27 to 79 years, and the average age was 58 years. The study showed a wide national demographic variety in terms of the place of origin of the participants. Immunosuppressant: 88.2% of respondents said they had all the information they needed to know about their immunosuppressant treatment, while 11.8% said they did not. Mainly the information about all aspects related to immunosuppressant is given by the doctor in 86.8%, in 7.4% of the cases the information has been provided by the nursing staff and it is striking that 5.9% say that they have to find out this information themselves. Psychological aspects: It is worth noting the low percentage of people who have received psychological help at some point (26.5%), compared to a large majority of participants who have never sought this type of support (73.5%). 82.3% of respondents consider psychological help to be quite or very important for the recovery of a transplant patient effect of the Covid-19 health crisis on health-related quality of life: These data are quite relevant since, without knowing the reasons for this, 35.3% of the total sample in the survey do not consider psychological support to be necessary to help them improve a psychological state which they claim to have been notably affected by the pandemic. It should be noted that of the 50 people who said they had never received psychological support, there were five participants who did feel they needed such support after the start of the pandemic.

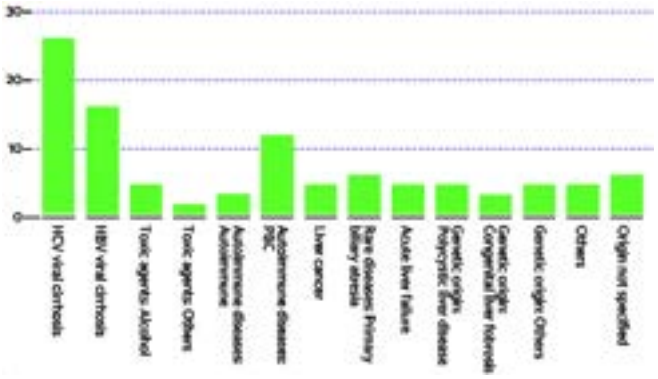

Figure: Causes of transplant

Conclusion: There is a need to provide more training and information to patients by healthcare staff on immunosuppressive treatments. It could be promoted with this type of professionals in order to resolve these doubts and acquire all the necessary information on immunosuppressive treatments. The fact that people who have been receiving treatment for more than 10 years now say that they lack information and knowledge about it has made us realize that this is an area that needs to be covered and improved. COVID-19 has increase in the number of people who have needed psychological support. However, we have seen that the majority of participants do not end up seeing a psychological professional.

WED-492
Fellowship for hepathology nurses-a new exchange program at Karolinska university hospital
Pia Loqvist[1]. [1]*Karolinska university Hospital, Dept Of Upper Intestinal Diseases, Stockholm, Sweden*
Email: pia.loqvist@regionstockholm.se

Background and aims: When patient transferred from other Swedish hospitals, nurses have noticed a variance regarding nursing care, especially in patients with diagnosis and conditions leading to hospitalization at Karolinska University Hospital. To give the patients with chronic liver diseases the most optimal, equal care and sense of security regardless of treating hospital, it is important that all have the same knowledge and follow the same guidelines. One way of reaching this goal is by well-planned and organized Fellow ship programs. As Karolinska University Hospital is accredited as a Cancer Comprehensive Center it follows a responsibility to share our specific knowledge in nursing care of the hepatology patient. The aim with a Fellow ship program is to encourage national and international network together with competence exchange with the purpose to give all patient equal nursing care regardless of treating hospital.
Method: The planned Fellowship program includes a two week period at the Hepatology clinic at Karolinska University Hospital. The period will be based on an individual planning with focus of the Fellows experiences and medical interests. Mandatory elements such as follow the livertransplant coordinator, follow the patient through specific treatments like SIRT and TACE, and get an idea in how our excellent Dieticians works will be included. The participant will during those two weeks get an opportunity to receive increased practical and theoretical knowledge regarding nursing care and medical treatment.
Results: The planned Fellowship program includes a two week period at the Hepatology clinic at Karolinska University Hospital. The period will be based on an individual planning with focus of the Fellows experiences and medical interests. Mandatory elements such as follow the livertransplant coordinator, follow the patient through specific treatments like SIRT and TACE, and get an idea in how our excellent Dieticians works will be included. The participant will during those two weeks get an opportunity to receive increased

practical and theoretical knowledge regarding nursing care and medical treatment.
Conclusion: Increased awareness through Fellowship for nurses in hepatology in combination with sharing expertise and networking should potentially lead to equal nursing care for the patient suffering of liver diseases.

Public Health Except viral hepatitis

Global, regional, and national burdens of cirrhosis in children and adolescents aged under 19 years from 1990 to 2019: a systematic analysis based on the global burden of disease study 2019
Chi Zhang[1], Yiqi Liu[1], Hong Zhao[1], Gui-Qiang Wang[1]. [1]*Peking University First Hospital, Department of Infectious Disease, Center for Liver Disease, China*
Email: john131212@126.com

Background and aims: Cirrhosis and other chronic liver diseases (collectively referred to as cirrhosis) were the leading cause of morbidity and mortality in adults, but data on the burden and trends were sparse in children and adolescents. We aimed to assess the trends in 204 countries and territories over the past 30 years in children and adolescents aged 0–19 years
Method: Data on cirrhosis was collected by the Global Burden of Disease (GBD) 2019 database from 1990 to 2019. We reported on the number, rates, and average annual percentage changes (AAPCs) of incidence and disability-adjusted life-years (DALYs) of cirrhosis at global, regional, and national level. Joinpoint regressions were used to calculate the AAPC of cirrhosis.
Results: Globally, the incident numbers of cirrhosis in children and adolescents increased from 204767 in 1990 to 241364 in 2019, an increase of 17.9%, with an AAPC 0.13 (0.10 to 0.16). Substantial change in incidence of cirrhosis in 1996, 2006, 2009, and 2017. Prevalence (AAPC = –2.27[–2.39 to –2.15]), mortality (AAPC = –1.68 [–1.86 to –1.5]), and DALYs rate (AAPC = –1.72[–1.88 to –1.56]) of cirrhosis have decreased significantly. Cirrhosis incident rates varied between sex and age groups. Rates of cirrhosis caused by alcohol use (AAPC = 1 [0.8 to 1.1]; incidence cases increased most obvious 48%), hepatitis C (AAPC = 0.4[0.4 to 0.5]), NAFLD (AAPC = 0.5 [0.3 to 0.6]) have been increasing, while only hepatitis B (–0.3[–0.4 to –0.2]) decreasing. Incidence cases of cirrhosis were increased in low (101.6%) and low-middle sociodemographic index (SDI 21.1%) areas, while decreasing in middle and above SDI areas. At the regional level, the largest increases count was observed in Sub-Saharan Africa.
Conclusion: Global incidence rate of cirrhosis has been increasing, while the DALYs rate has been decreasing in children and adolescents. Morbidity of cirrhosis caused by hepatitis B declined, while hepatitis C, NAFLD, and alcohol use increased. We appealed for that in low SDI regions and countries, promoting the widespread vaccination of hepatitis B vaccine and reducing HCV infection were prominent; in middle and high SDI regions and countries, reducing cirrhosis caused by NAFLD and alcohol use were urgent.

A systematic review of interventions for alcohol use disorder in patients with cirrhosis or alcohol-related hepatitis
Christopher Oldroyd[1,2], Olivia Greenham[1], Graham Martin[3], Michael Allison[1,2], Caitlin Notley[4]. [1]*Liver Unit, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom;* [2]*NIHR Biomedical Research Centre, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom;* [3]*THIS Institute, University of Cambridge, Cambridge, United Kingdom;* [4]*Faculty of Medicine and Health Sciences, Norwich Medical School, University of East Anglia, Norwich, United Kingdom*
Email: christopher.oldroyd@nhs.net

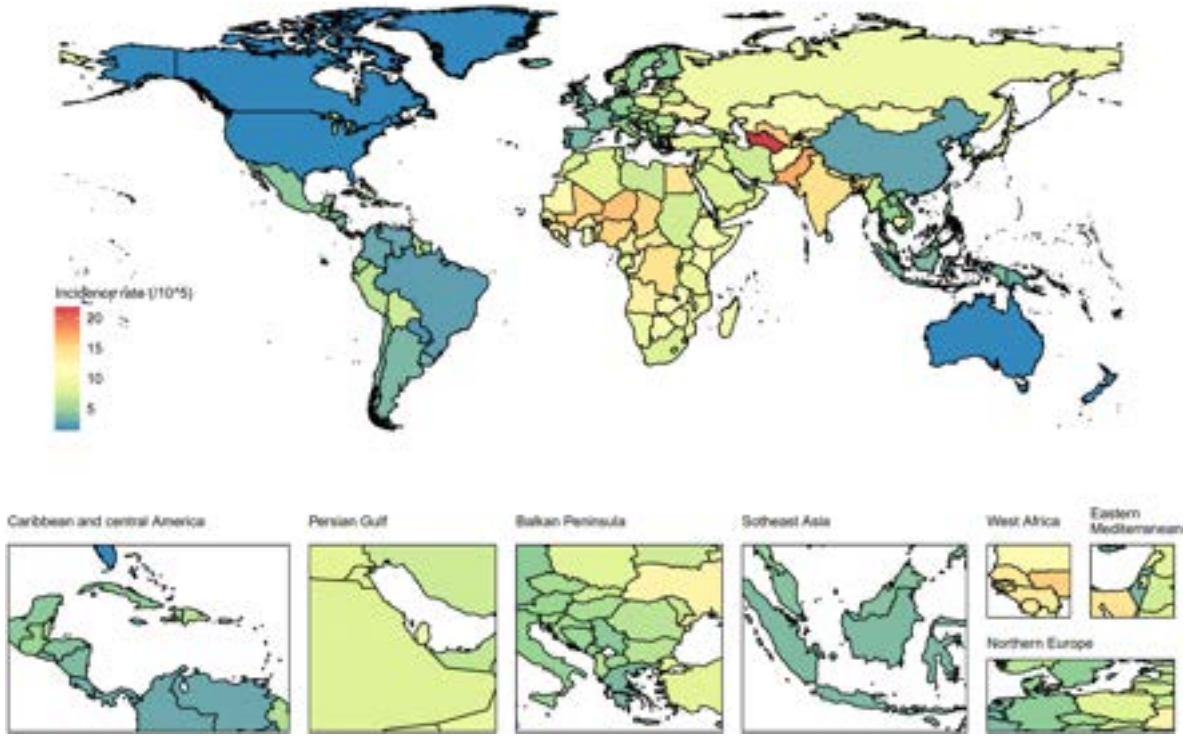

Figure: (abstract: TOP-094) The incidence rate of cirrhosis in children and adolescents at countries and regions level in 2019

Background and aims: Continued alcohol use is the most important factor in determining the prognosis of patients with alcohol-related cirrhosis and alcohol-related hepatitis. Previous systematic reviews of interventions for alcohol use disorder (AUD) have not been specifically targeted at patients with cirrhosis or alcohol related hepatitis. This review addresses this evidence gap.
Method: We followed the PRISMA guidelines for systematic reviews. Five databases were searched (MEDLINE, Web of Science, Embase, CINAHL and PSYCinfo) between inception of the database until November 2022. We included randomised trials and cohort studies which assessed the impact of an intervention to reduce alcohol intake with and without an active comparator. Only studies which included data specific to patients with cirrhosis or alcohol related hepatitis were included. We present a narrative synthesis of the results.
Results: 23 studies were included in the final analysis. The study population was dominated by two, large, retrospective, database-derived cohorts which included 101,745 patients with cirrhosis. The remaining 21 studies included 2574 patients, including 7 randomised controlled trials (RCTs) with 293 patients (Table 1). The most frequently assessed intervention was attendance at addiction therapy or alcohol rehabilitation (7 studies). Other interventions were pharmacological (baclofen, acamprosate, naltrexone, faecal transplant), psychological (motivational therapy, educational sessions) and attendance at specialist clinics. Two studies looked generically at the impact of any intervention for AUD. One retrospective cohort examined the impact of using low alcohol drinks. Studies variably reported outcomes related to liver disease (decompensation of cirrhosis, mortality and hospital admissions (n = 6)), alcohol use only (n = 10) or both outcome categories (n = 6). All of the studies which recorded alcohol outcomes reported that the intervention was beneficial in reducing intake or preventing relapse. In studies with control groups which reported on mortality, addiction treatment, attendance at outpatient clinics and (in a large database derived cohort) any AUD treatment had a statistically significant beneficial effect ($p < 0.05$). Three studies with control groups examined readmissions with only one finding a statistically significant reduction, this being associated with addiction therapy. Seven studies looked at new episodes of hepatic decompensation or change in MELD score. Of these, five of the interventions were found to have a statistically significant beneficial effect.

Figure: RCTs in the review

Reference	Country	Age (Mean or **Median**)	Males	n	Intervention	Outcomes	Follow-up
Sussman 2005	USA	44	75%	25	Educational sessions	Alcohol only	3 months
Addolorato 2007	Italy	**56**	64%	84	Baclofen	Alcohol only	90 days
Bajaj 2021	USA	65	100%	20	Faecal Transplant	Alcohol and Liver Disease	6 months
DeMartini 2018	USA	50.8	73%	15	Text message-based alcohol intervention	Alcohol only	8 weeks
Proeschold-Bell 2020	USA	54.9	71.3%	58	Alcohol Treatment	Alcohol only	12 months
Weinrieb 2011	USA	49.2	84%	91	Motivational Therapy	Alcohol only	24 months

Conclusion: Interventions for alcohol use disorder can be effective in improving clinical outcomes of patients with cirrhosis and alcohol related hepatitis. The evidence base is dominated by large database derived cohorts and the interventions are not well defined, indicating the need for further research in this area.

Socioeconomic disparities and survival in patients with primary liver cancer by subtype: a french population-based study

Thi Thu Nga Nguyen[1,2], Olivier Dejardin[3], Jean Baptiste Nousbaum[4,5], Anne-Marie Bouvier[6], Joséphine Gardy[3], Guy Launoy[3], Veronique Bouvier[3,7], Isabelle Ollivier-Hourmand[2]. [1]*Normandie University UNICAEN, France;* [2]*Caen University Hospital, Hepatogastroenterology, Caen, France;* [3]*'ANTICIPE' U1086 INSERM-UCN, Normandie University UNICAEN, Caen, France;* [4]*Brest University Hospital, Hepatogastroenterology, Brest, France;* [5]*Registry of Digestif Cancers of Finistère, EA 7479 SPURBO, Université de Bretagne Occidentale, Brest, France;* [6]*Registry of Digestif Cancers, INSERM UMR 1231, UFR Santé de Bourgogne, Dijon, France;* [7]*Registry of Digestif Cancers of Calvados, Caen, France*
Email: nguyen.nga@live.com

Background and aims: Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCCA) are the two most common histological subtypes of primary liver cancer (PLC). These two subtypes are recorded under distinct topological codes by the French Network of Cancer Registries (FRANCIM). There is no solid study evaluating distinctly prognosis of these two cancers as well as the influence of socioeconomic inequalities. We aim to assess the influence of socioeconomic disparities on net survival in patients with HCC and iCCA using population-based data.
Method: All patients diagnosed between 2013 and 2015, recorded under the topological code C22.0 (HCC) and C22.1 (iCCA) by the French Network of Cancer Registries FRANCIM were included with a follow-up until Juin 2018. Social environment was assessed by the European Deprivation Index (EDI). Flexible parametric analyses with multidimensional penalized splines were used to model excess mortality hazard and estimate the effect of EDI on net survival.
Results: A total of 6528 patients were included comprising 5271 patients diagnosed with HCC and 1257 with iCCA. Median age was 69.67 years in HCC patients and 72.42 years in iCCA patients. Male gender was predominant in both cancers (85% in HCC and 60% in iCCA). Net survival was higher in HCC patients than those with iCCA at any time of follow-up, regardless of sex (5-year survival: 19.07%, 19.84%, 10.67% and 9.58% in HCC men, HCC women, iCCA men and iCCA women, respectively). Net survival was significantly shorter in HCC men and iCCA women living in a more deprived environment compared to those living in a less deprived one. Excess mortality hazard was up to 14% higher and 20% higher among HCC men and iCCA women living in the most deprived areas compared to the least deprived ones, respectively (HR = 1.14, CI95% 1.139–1.142 in HCC men and HR = 1.209, CI95% 1.207–1.212 in iCCA women). EDI had no significant effect on net survival in HCC women nor in iCCA men.

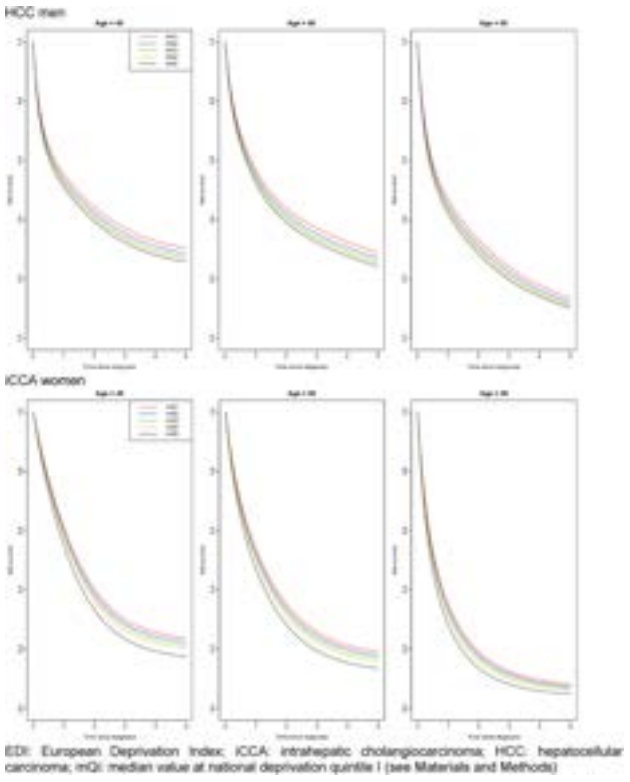

Figure: Net survival over time since diagnosis by level of deprivation for each cancer site and sex for which EDI effect was significant, predicted by selected model for 40-, 60- and 80- year-old.

Conclusion: In conclusion, our study provides an original and distinct survival analysis in HCC and iCCA patients, showing a higher mortality in iCCA. It also highlights a social gradient in survival which differs according to sex and cancer site. Our findings suggest the implementation of targeted actions especially among men at risk of HCC living in disadvantaged environment.

TOP-099

Higher ultra-processed food intake positively associated with non-alcoholic fatty liver disease in both adolescents and adults

Longgang Zhao[1], Xinyuan Zhang[2], Chun-Han Lo[3], Euridice Martinez[4], Fang Fang Zhang[5], Xuehong Zhang[2,6,7]. *[1]University of South Carolina, Columbia, United States; [2]Brigham and Women's Hospital, Boston, United States; [3]Kirk Kerkorian School of Medicine at UNLV, Las Vegas, United States; [4]University of São Paulo, Brazil; [5]The Gerald J. and Dorothy R. Friedman School of Nutrition Science and Policy, Boston, United States; [6]Harvard Medical School, United States; [7]Harvard T.H. Chan School of Public Health, United States*
Email: poxue@channing.harvard.edu

Background and aims: The influence of consumption of ultra-processed foods (UPF) on non-alcoholic fatty liver diseases (NAFLD) remains poorly understood. Related evidence for adult NAFLD is limited and no study has yet evaluated NAFLD in adolescence.
Method: We conducted a study among 806 adolescents and 2,734 adults who participated in the National Health and Nutrition Examination Survey (2017–2018). UPF intake was estimated using the dietary data collected by two 24-hour dietary recalls. NAFLD was defined by transient elastography in the absence of other causes of chronic liver disease. Logistic regression was used to estimate the multivariable odds ratio (OR) and 95% confidence intervals (CI) for associations between UPF consumption and NAFLD with survey weight adjustments.
Results: The mean consumption of UPF was 810 grams/day for adolescents and 823 grams/day for adults. A total of 12.4% (n = 111) among adolescents and 35.6% of the participants (n = 1,053) among adults had NAFLD. Higher UPF intake was associated with higher odds of NAFLD in both adolescents ($OR_{Quintile\ 5\ vs\ Quartile\ 1}$ = 2.34, 95% CI = 1.01–5.41, P_{trend} = 0.15) and adults ($OR_{Quintile\ 5\ vs\ Quintile\ 1}$ = 1.78, 95% CI = 1.04–3.03, P_{trend} = 0.002). In adults, about 68% and 71% of the association between UPF intake and NAFLD was mediated by BMI and waist circumference (all P values <0.001), respectively. We also found higher UPF intake was positively associated with serum levels of albumin and C-reactive protein in adults. Results were similar for adolescents though not statistically significant.
Conclusion: Higher UPF intake was associated with higher odds of having NAFLD among both adolescents and adults. These associations are largely mediated by elevated body fatness. Further prospective studies are needed to confirm our findings. If confirmed, reducing UPF intake might help prevent NAFLD in both adolescents and adults.

SAT-114

An explainable artificial intelligence model for prediction of high-risk non-alcoholic steatohepatitis

Basile Njei[1], Eri Osta[2], Nelvis Njei[3], Joseph Lim[1]. *[1]Yale University, United States; [2]The University of Texas Health Science Center at San Antonio, United States; [3]Centers for Medicare and Medicaid Services, United States*
Email: basile.njei@yale.edu

Background and aims: High-risk Non-alcoholic Steatohepatitis (NASH) is defined by non-alcoholic fatty liver disease (NAFLD) activity score ≥4 and fibrosis stage ≥2 on liver biopsy. The FibroScan-AST (FAST) score, calculated using liver stiffness measurement and controlled attenuation parameter values from FibroScan and aspartate aminotransferase levels, is a validated algorithm to identify individuals with high-risk NASH. However, liver biopsy and FibroScan are not always available in resource-limited settings. Early identification of high-risk NASH can offer patients access to novel therapeutic options and potentially decrease the risk of progression to cirrhosis. We used explainable artificial intelligence (XAI) to develop an algorithm integrating demographic, clinical, and laboratory data for predicting high-risk NASH.
Method: Data were derived from the National Health and Nutrition Examination Surveys (NHANES) 2017-March 2020. We used FAST score ≥0.35, to identify individuals with high-risk NASH. Three machine learning models, extreme gradient boosting (XGBoost), random forest (RF), and logistic regression (LR), were used to establish the prediction. The training set contained 50% of included patients. The optimized model was then validated by the independent holdout test set, on the remaining 50%. We illustrated the clinical feature's importance and provided visualized interpretation using SHapley Additive exPlanations (SHAP) and local interpretable model-agnostic explanations (LIME). To identify high-risk NASH subphenotypes, an unsupervised distance-based clustering method was used.
Results: There was a total of 5281 subjects meeting the inclusion criteria. The mean age was 53 (range 18–80 years), and 2602 (49%) were women. Subjects with high-risk NASH comprised 6.5% and 7.5% of training and test set, respectively. Figure 1 shows the areas under our models' receiver operating characteristic curve (AUC) for predicting high-risk NASH. The optimized XGBoost model demonstrated a superior ability to predict high-risk NASH vs. FIB-4, BARD, and NAFLD fibrosis scores (AUC of 0.97 vs. 0.75, 0.81 and 0.72, respectively, all p < 0.001). To explain the high performance of the XGBoost model, we found that the top 5 predictors of high-risk NASH were ALT, AST, waist circumference, BMI, and glycohemoglobin. Using cluster analysis, 4 novel subphenotypes of high-risk NASH were identified: (1) women with low ALT; (2) young patients with low waist circumference; (3) Mexican Americans and Non-Hispanic Black

Americans with high platelets; and (4) patients with prediabetes/diabetes and low ALT.

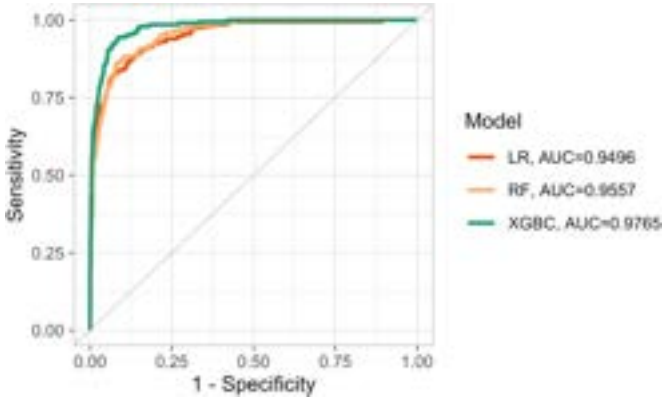

Figure 1: Areas under the receiver operating characteristic curve (AUC) plot of our models for predicting high-risk NASH

Conclusion: We used an XAI approach to develop a clinically applicable model that outperforms commonly used clinical risk indices and could increase the identification of high-risk NASH patients in resource-limited settings.

SAT-115

Healthcare resource use and costs among patients with primary sclerosing cholangitis in Sweden-a retrospective population-based cohort study

Annika Bergquist[1,2], Nandita Kachru[3], Martina Aldvén[4], Oskar Ström[4], Douglas Knutsson[5], Emilie Toresson Grip[2,4], Hannes Hagström[1,2]. *[1]Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden; [2]Division of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden; [3]Gilead Sciences Inc., Foster City, United States; [4]Quantify Research AB, Sweden; [5]Quantify Research AB, Sweden*
Email: Nandita.Kachru@gilead.com

Background and aims: Primary sclerosing cholangitis (PSC) is a rare, chronic, cholestatic liver disease characterized by biliary inflammation and fibrosis of both small and large bile ducts, that can potentially lead to cholestasis and cirrhosis. This study characterized the baseline comorbidities, healthcare resource utilization (HRU) and costs among PSC patients in Sweden.

Method: Using the Swedish National Patient Register which captures all hospitalizations and outpatient hospital visits, PSC patients (≥18 years) were identified via ICD-10 codes from 01/01/2002 to 12/31/2020 using diagnosis of PSC (K83.0A) and/or combination of cholangitis (K83.0) and inflammatory bowel disease (IBD) (K50 or K51). Those with prior diagnosis of biliary atresia, cystic fibrosis, human immunodeficiency virus or primary biliary cholangitis were excluded. First date of PSC diagnosis within this period defined the index date. Patients were required to have ≥360 days look-back (baseline) period and ≥30 days of follow-up. Incident patients (with no PSC diagnosis 1 year prior to index date) were followed from the index date to death, emigration, or end of study. Annualized mean all-cause HRU and costs, reported as 2021 Euros, were calculated during the baseline and follow-up period.

Results: After applying inclusion/exclusion criteria, 4,819 PSC patients were included in the study. Of these, 4,213 (mean age 48.4 years, 56.8% male) were identified as incident. During the follow-up period (mean 6.7 years; range 0.1–19.0; 28,283 person-years), 935 (22%) patients died. PSC patients reported liver complications during baseline (4.6% had compensated or decompensated cirrhosis, 4.7% had hepatobiliary or pancreatic malignancy and 1.0% had been transplanted). 73% patients had IBD and 16.4% showed use of ursodeoxycholic acid. The mean length of inpatient stay, number of hospitalizations and outpatient visits were found to significantly increase from baseline to follow-up period (5.1 ± 12.9 vs. 15.5 ± 43.1, 0.9 ± 1.7 vs 1.8 ± 3.8, 4.9 ± 7.5 vs 6.6 ± 9.6 respectively; $p < 0.0001$). Similarly, total all-cause healthcare costs reported a significant increase by 117% (from € 9424.4 to € 20,487.2; $p < 0.0001$), hospitalization costs were the primary driver (Figure).

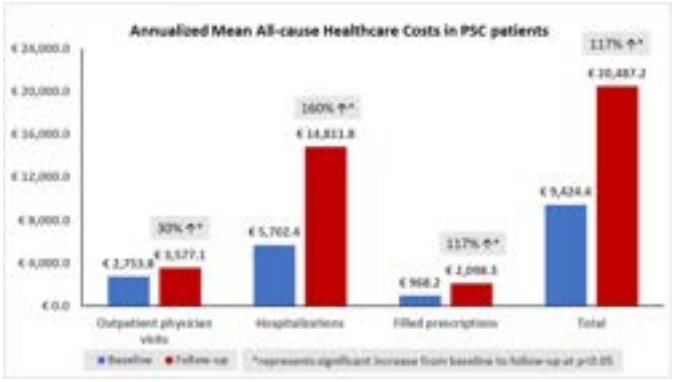

Figure:

Conclusion: Although PSC is considered a rare disease, the impact on HRU and costs are reported to be substantial. Early identification and effective therapies are needed to reduce the risk of disease progression and subsequent healthcare costs.

SAT-116

Health economics of the enhanced liver fibrosis test in the detection of advanced liver fibrosis in patients with non-alcoholic fatty liver disease in the UK

Zobair Younossi[1,2,3], Maria Stepanova[4], James Paik[2,3], Fatema Nader[4], Linda Henry[4], Richard Pollock[5]. *[1]Inova Health System, Medicine Service Line, United States; [2]Beatty Liver and Obesity Research Program, Inova Health System, United States; [3]Inova Health System, Department of Medicine, Center for Liver Diseases, United States; [4]Center for Outcomes Research in Liver Disease, United States; [5]Covalence Research Ltd, Harpenden, United Kingdom*
Email: zobair.younossi@inova.org

Background and aims: The enhanced liver fibrosis (ELF) test is a non-invasive blood test to assess the risk of advanced fibrosis in patients with non-alcoholic fatty liver disease (NAFLD). The aim of the present study was to evaluate the cost-effectiveness of a diagnostic pathway including the Fibrosis-4 (FIB-4) index plus ELF for patients with an indeterminate FIB-4 index (1.30–2.67), compared versus FIB-4 alone, FIB-4 plus Transient Elastography (TE), and standard of care (SoC), in the detection of advanced fibrosis in patients with NAFLD from the perspective of a UK healthcare payer.

Method: A cost-utility model was developed with two modules: a diagnostic pathway module which distributes patients between true and false positive and negative diagnoses of advanced fibrosis, and then a long-term extrapolation based on a Markov model. The performance of the FIB-4/ELF, FIB-4/TE and FIB-4 alone pathways was based on published literature. UK standard of care was based on Srivastava et al. (J Hepatol 2019). The long-term Markov model captured transitions through fibrosis stages, cirrhosis, decompensated cirrhosis, hepatocellular carcinoma, liver transplant, and death. UK-specific cost data were obtained from the literature and utility values were derived from patients with NAFLD using EQ5D or equivalent instrument. Future cost and effectiveness outcomes were discounted at 3.5% per annum and the long-term model was run over a 20-year time horizon.

Results: The decision tree reported that, with FIB-4/ELF, 5.6% of patients with NAFLD had a false positive diagnosis of advanced fibrosis versus 6.0% with FIB-4/TE, 22.1% with FIB-4 alone, and 29.8% with SoC. The model showed that the costs of a FIB-4/ELF pathway

would be the lowest of the four options; the higher initial cost of the FIB-4/ELF diagnostic pathway was more than offset by a reduction in resource utilisation arising from false positive diagnoses. The long-term extrapolation showed that FIB-4/ELF would be dominant versus SoC, reducing costs while increasing quality-adjusted life-years gained.

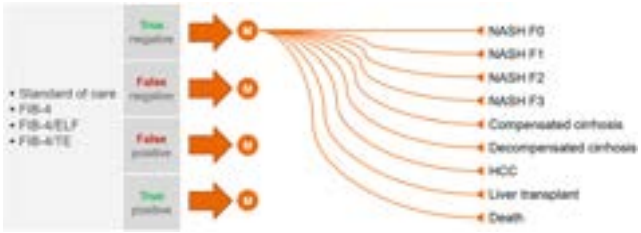

Figure:

Conclusion: A pathway combining FIB-4/ELF to detect advanced fibrosis in patients with NALFD in the UK would be cost saving relative to SoC, FIB-4/TE and FIB-4 alone. FIB-4/ELF would also dominate SoC over a 20-year extrapolation and would therefore be considered a cost-effective use of UK healthcare resources.

SAT-117

Influence of the COVID-19 pandemic on liver cancer-related mortality in the United States

Zhu Zhan[1], Dan Shi[2], Chengchen Zhang[3], Yujing Shi[1], Na Wu[1], Hong-Gang Ren[1], Hong Ren[1]. *[1]Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, Department of Infectious Diseases, the Second Affiliated Hospital of Chongqing Medical University, China; [2]Department of Nutrition and Food Hygiene, School of Public Health, Chongqing Medical University, China; [3]Center of Clinical Research, Shanghai Children's Medical Center Affiliated with Shanghai Jiaotong University School of Medicine, China*
Email: renhong0531@cqmu.edu.cn

Background and aims: The COVID-19 pandemic has caused a diverse and extensive impact on the public health system. This study attempted to examine the influence of the pandemic on liver cancer (LC)-related mortality in the United States (U.S.).
Method: We reviewed data from the National Vital Statistic System from the Center for Disease Control and Prevention Wide-Ranging Online Data for Epidemiologic Research (CDC WONDER) platform and ICD-10 codes, and screened for LC-related deaths. We also analyzed the actual event versus estimated mortality rate for 2020–2021, according to the patterns from 2010 to 2019 using joinpoint and prediction modelling analysis.
Results: We identified 322,698 LC-related deaths in the U.S. from 2010 to 2022. Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (ICC) are the most prominent LC types, accounting for 61% and 38% of all cases, respectively. The HCC age-standardized mortality rate (ASMR, per 100,000) revealed an overall upward trend from 2010 to 2019, with a mean annual percentage change (APC) of 3.7%. However, the HCC ASMR remained unchanged in 2020, and showed a sharp increase since January 2021, with a peak in December 2021, compared to the levels predicted from pre-pandemic trend (ASMR of 4.36 vs. 4.35 in 2020, 6.45 vs. 4.48 in 2021). This delayed rise in mortality during the COVID-19 pandemic was also found in ICC and other LC types. Although the older population (≥65 years) contributed to over half of the deaths among people with LC, the younger population (25–44 years) revealed the highest APC for HCC (11.6%) and ICC (6.4%) during the COVID-19 pandemic. In addition, female, American Indian/Alaska Native (AI/AN), Asian, and Pacific Islanders (API) were more susceptible to the COVID-19 pandemic, compared to their counterparts.

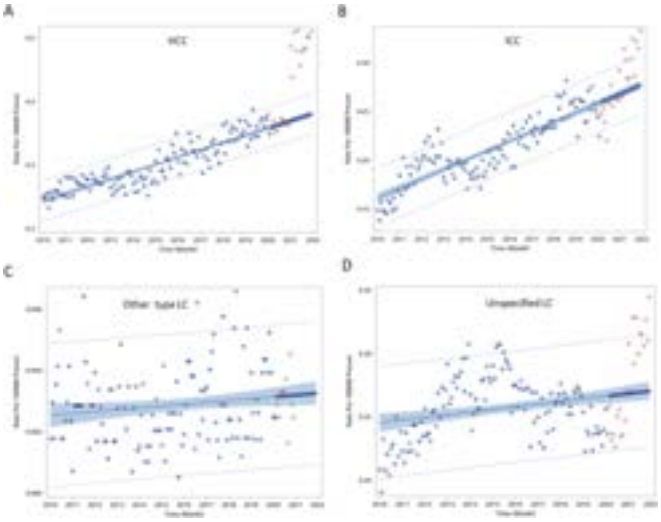

Figure:

Conclusion: We observed a delayed rise in LC-related mortality during the COVID-19 pandemic, and young, female, AI/AN, and API populations were most at risk.

SAT-118

Acceptability and feasibility of a multimodal early detection pilot study for liver disease in high risk groups: "Alright My Liver?"

Ann Archer[1,2], Sally Tilden[1], Tom May[2,3], Jo Kesten[2,3,4], Jane Gitahi[1], Lucy Yardley[2,3,4,5,6], Matthew Hickman[2,3], Kushala Abeysekera[1,2], Fiona Gordon[1]. *[1]University Hospitals Bristol and Weston NHS Foundation Trust, Bristol, UK, Liver Medicine, Bristol, United Kingdom; [2]Bristol Medical School, University of Bristol, Bristol, UK, Population Health Science, Bristol, United Kingdom; [3]University of Bristol, NIHR Health Protection Research Unit (HPRU) in Behavioural Science and Evaluation, Bristol, United Kingdom; [4]University Hospitals Bristol and Weston NHS Foundation Trust, UK, NIHR Applied Research Collaboration West (NIHR ARC West), Bristol, United Kingdom; [5]University of Bristol, School of Psychological Science, Bristol, United Kingdom; [6]University of Bristol, Centre for Academic Primary Care, Bristol, United Kingdom*
Email: ann.archer@uhbw.nhs.uk

Background and aims: 75% of people with cirrhosis are diagnosed during an emergency admission to hospital, at which point mortality is 1 in 6. Cirrhosis prevalence is <1% in the general population, making a targeted approach to case finding desirable. In 2022, NHS England funded the Bristol and Severn hepatitis C operational delivery network to broaden its existing outreach work as part of the "Piloting Community Liver Health Checks" scheme. The aim of this study is to report disease detection and acceptability outcomes of the "Alright My Liver?" service, developed in collaboration with service users, to screen and detect advanced liver fibrosis from alcohol, viral hepatitis and metabolic syndrome in those deemed high risk.
Method: Liver health screening events were co-located with existing services that serve vulnerable and high risk groups. These included drug and alcohol services, primary care services in areas with a high index of deprivation and with Caafi Health, an organization providing health outreach to black and ethnic minority communities in the region. A health history, transient elastography (TE) using FibroScan® and capillary blood borne virus testing if indicated were collected. All patients received personalized advice including brief alcohol reduction interventions and cessation service signposting if indicated. To encompass multiple aetiologies of liver disease, commissioners advocated a liver stiffness measurement (LSM) by TE of ≥11.5 kPa for advanced fibrosis, 8.5–11.4 kPa for moderate fibrosis and <8 kPa normal. Clients identified with advanced fibrosis were booked directly into hepatology clinic with an offer of funded transport and telephone reminders. Semi-structured interviews were conducted with service

users and providers to which the agile co-production and evaluation (ACE) framework is being applied to optimize the service.
Results: 622 people were assessed at outreach events between July and Dec 2022. Median age 46 years (IQR 16), median BMI 26.1 kg/m^2 (IQR 7.1 kg/m^2), 49% female (n = 308/622). 18.9% (n = 118/622) had experienced homelessness. The population screened had an ethnicity case of mix of 40% white British/12% Black African/4% South Asian. Median LSM 5.1 kPa (IQR 2.7 kPa), median IQR/M 17% (IQR 13%). Inpatient and outpatient addiction settings were highest yield, with 14% (n = 6/43) and 9.5% (n = 10/135) respectively of clients identified as having advanced fibrosis. Five patients were identified as having active hepatitis C infection, of whom four have now started treatment. One case of chronic hepatitis B infection was identified. Attendance rate at hepatology clinic appointment was 78% (n = 18/23) and attendance rate for ultrasound was 85% (n = 32/37). Semi-structured interviews with service users returned overwhelmingly positive feedback, suggesting that the service is acceptable to its target group.

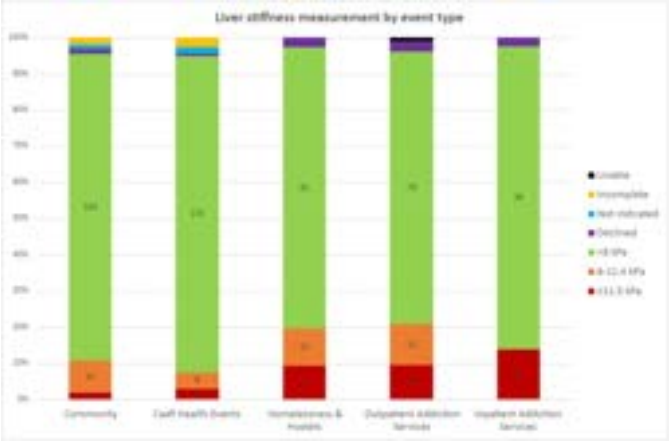

Figure:

Conclusion: Early detection of advanced fibrosis in high risk groups within the community setting is achievable and acceptable to patients. The drug and alcohol services setting provides the highest yield for advanced fibrosis. Longer term follow-up will clarify how well patients engage with liver services and treatment to impact clinical outcomes.

SAT-119

Lifestyle-related population-attributable risk for non-alcoholic fatty liver disease in adolescents and youth

Vanessa Garcia-Larsen[1], Hani Tamim[2], Saad Alghamdi[3], Mohammad Ali Shagrani[4], Faisal Abaalkhail[5], Walled Alhamoudil[6], Faisal Sanai[7], Saleh Alqahtani[8,9]. *[1]Bloomberg School of Public Health, The Johns Hopkins University, International Health, United States; [2]Alfaisal University, College of Medicine, Saudi Arabia; [3]King Faisal Specialist Hospital and Research Centre, Liver and Small Bowel Transplant and Hepatology Surgical, Riyadh, Saudi Arabia; [4]King Faisal Specialist Hospital and Research Centre, Liver and Small Bowel Transplant and Hepatology Surgical Department, Saudi Arabia; [5]King Faisal Specialist Hospital and Research Centre, Department of Medicine, Gastroenterology Section, Saudi Arabia; [6]King Faisal Specialist Hospital and Research Centre, Liver and Small Bowel Transplant and Hepatology Surgical, Saudi Arabia; [7]King Abdulaziz Medical City, Gastroenterology Unit, Department of Medicine, Jeddah, Saudi Arabia; [8]King Faisal Specialist Hospital and Research Centre, Liver Transplant Centre, Saudi Arabia; [9]Johns Hopkins University, Division of Gastroenterology and Hepatology, Baltimore, United States*
Email: vgla@jhu.edu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) affects an estimated 15–25% of the adult population worldwide. Obesity and metabolic syndrome are among the most important risk factors for the disease, but evidence in children and youth has been less examined. This study aimed to quantify the population-attributable risk (PAR) for NAFLD due to lifestyle-related factors in youth.
Method: We included data from the 2017–2018 U.S. National Health and Nutrition Examination Survey (NHANES) cycle on youth aged 12 to <21 years who underwent vibration-controlled transient elastography with controlled attenuation parameter (CAP). Liver steatosis (NAFLD) was defined as a CAP score of ≥248 dB/m. PAR (%), i.e., the prevalence of NAFLD attributed to each factor under study, was investigated for exposures previously shown to be independently associated with liver steatosis in adolescents, namely body mass index (BMI), systolic blood pressure, waist-to-height ratio (WHR), and the homeostatic model assessment for insulin resistance (HOMA-IR). The Dietary Approaches to Stop Hypertension (DASH; higher scores = higher adherence) and the Alternative Healthy Eating Index (AHEI; 0 = low adherence, 110 = highest adherence) were also included as measures of diet quality, a domain seldom studied in relation to NAFLD in this age group. Survey-weighted, z-transformed PARs were calculated (adjusting for age, sex, ethnicity, BMI [when applicable], total energy intake, household income, and education) by comparing an unhealthier vs. healthier scenario for each factor (namely, having a BMI ≥30 vs. a BMI <25; having a BMI ≥25 <30 vs. a BMI <25; no physical activity vs. practicing physical activity for at least 60 minutes during the week/vigorous recreational activities during the week; highest vs. lowest quartile of WHR; highest vs. lowest quartile of HOMA-IR; and lowest vs. highest quartile of diet quality adherence).
Results: A total of 972 participants (mean age 15.7 ± 2.4; male 51.0%) with complete data were included in this study. The prevalence of liver steatosis was 28.3%. The adjusted risks of liver steatosis attributable to overweight and obesity were 3.3% (95% confidence interval [CI]: 2.1, 4.7) and 10.1% (CI: 7.9, 12.4), respectively. The PAR associated with NAFLD was 7.2% for higher systolic blood pressure (CI: 3.9, 10.6), and 4.4% for lower DASH adherence (CI: 0.2, 8.5). The risks attributable to a higher WHR, lack of physical activity and low AHEI adherence were not statistically significant.
Conclusion: NAFLD in adolescents and youth from the U.S. is highly prevalent. Obesity, overweight, systolic blood pressure, and diet quality are important contributors to the disease among youth. As the DASH diet has a recognized benefit in the control of overweight and hypertension, improving its adherence during adolescence may contribute to reducing the burden of NAFLD.

Email: stylianos.tzedakis@aphp.fr

Background and aims: Meta-analyses showed that the Coronavirus Disease 2019 (COVID-19) pandemic reduced cancer screening and treatment. However, most studies were inconclusive for primary liver cancer.
Method: We analyzed the French, nationwide, cohort of all newly recorded adult inpatients with primary liver cancer between January 1, 2018, and September 30, 2022. The primary exposure was the period of first diagnosis: Pre-pandemic (January 1, 2018 to December 31, 2019), COVID-19 Pandemic (January 1, 2020 to June 30, 2021), and COVID-19 Post-pandemic (July 1, 2021, to September 30, 2022) periods. The outcomes were access to a curative treatment (defined as liver resection, liver transplantation and/or percutaneous ablation) and mortality. Independent associations were analyzed in multivariate logistic and Cox models.
Results: Out of 51,572 patients [median (IQR) age, 71 (63.0; 78.0) years; 74% men], 13,873 (27%) had a curative treatment. The incidence of primary liver cancer [median (IQR), 907 (857; 946) new cases per trimester] remained stable ($p = 0.08$). Compared with [Pre-pandemic] patients, and adjusted for age, sex, malnutrition, cancer stage, decompensated cirrhosis, severe comorbidities, and deprivation, the odds ratios (95% CI) for access to a curative treatment were 0.90 (0.86–0.95, $p < 0.001$) and 0.69 (0.66–0.73, $p < 0.001$) for [Pandemic] and [Post-pandemic] patients, respectively. Probabilities of 6-month survival for [Pandemic] and [Post-pandemic] patients were 60.3% (59.5–61.1; $p = 0.91$) and 55.5% (54.5–56.5; $p < 0.001$), respectively. The corresponding adjusted hazard ratios for mortality were 1.02 (0.99–1.05; $p = 0.2$) and 1.22 (1.18–1.26; $p < 0.001$), respectively. The results remained stable in a 1:1 propensity-matched sample of 28,232 [Pre-pandemic] and [Post-pandemic] patients.

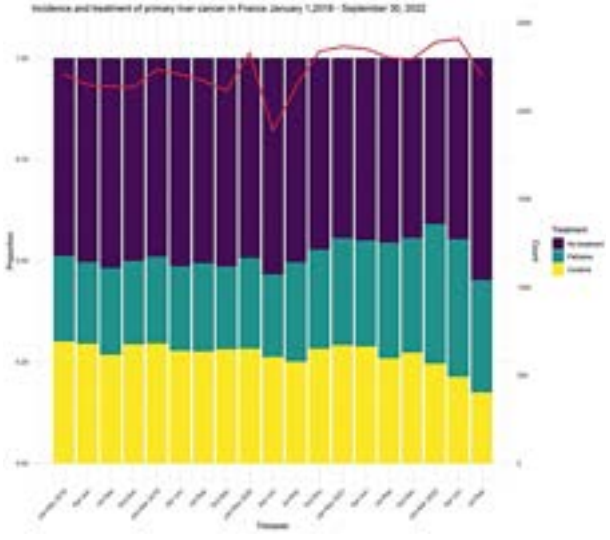

Figure:

Conclusion: COVID-19 crisis decreased access to curative treatment for primary liver cancer. The risk of dying without a curative treatment was highest in the [Post-pandemic] period.

SAT-121

Identify, screen and treat via electronic pathway (I-STEP): an innovative approach to wait list management for general liver hospital outpatient referrals

Eliza Flanagan[1,2], Stephen Pianko[1,2], Julianne Grant[1], Edward Saxby[1], Sally Bell[1,2], Suong Le[1,2]. *[1]Monash Medical Centre, Gastroenterology, Clayton, Australia; [2]Monash University Clayton Campus, Department of Medicine, Clayton, Australia*
Email: elizaflanagan2@gmail.com

Background and aims: Wait times for hospital specialist outpatient clinics are long, with patients often triaged incorrectly due to incomplete clinical information. We developed a multifaceted intervention to semi-automatically prioritise patients with untreated hepatitis C virus (HCV) and or advanced liver disease, awaiting an initial liver appointment at Monash Health (MH), an Australian tertiary hospital network.
Method: Our novel triage intervention consisted of 1) semi-automated electronic re-triage of patients based on new pathology results, 2) reflexive HCV polymerase chain reaction (PCR) testing in those with positive antibodies, and 3) a liver care guide (LCG) to augment patient uptake.
We excluded patients who were deceased, non-residents (due to additional costs), and those without mobile phone numbers. Eligible patients received a short message service (SMS) that explained the initiative (with a website link for further information) and were invited to participate by completing a blood test. The LCG conducted a follow-up phone call to answer questions. Our pathology panel included a full blood count, urea, electrolytes and creatinine, liver function tests, international normalised ratio, HCV antibody testing, and if positive, reflexive PCR testing. An AST to Platelet Ratio Index (APRI) and Fibrosis-4 (FIB4) score was auto-calculated. Patients with an APRI ≥1, FIB4 ≥3.25, or positive HCV PCR were flagged and re-triaged for urgent review.
Results: In May 2022, MH had 1026 adult patients on the waitlist for an initial liver clinic appointment. 20 patients were excluded due to no mobile phone (n = 9), non-residents (n = 6) and deceased (n = 5). The median historical waitlist time for eligible patients was 283 days (IQR 183–450.25). The median age was 51 years (IQR: 40–61) and 527 (52.29%) were male. 690 patients (68.59%) responded 'Yes' to the SMS; 387 (56.09%) required a prompting call from the LCG before responding. 51 patients (5.07%) responded 'No', and 265 patients (26.34%) did not respond. 490 patients (71.01%) completed pathology testing and 40 (8.16%) were re-triaged based on APRI/FIB4/HCV PCR results (table 1). 26/40 of the re-triaged patients underwent a fibroscan with a median stiffness of 15.4 kilopascals (IQR 7.5–26.55). Sub analysis of 120 patients demonstrated increased engagement through implementation of the LCG. Over a two-week period, 60 patients received a text followed by phone call, whilst the other 60 only received a SMS. There was a higher uptake of pathology testing in those who had LCG and SMS compared to those who received SMS only (42 (70%) vs 27 (45%), p value 0.03).

Table 1:

RETRIAGED	
APRI ≥1 only	14
APRI ≥1 + FIB4 ≥3 .25	14
APRI ≥1 + HCV PCR+ve	1
APRI ≥1 + HCV PCR+ve + FIB4 ≥3 .25	2
FIB4 ≥3 .25 only	7
HCV PCR+ve only	2
Total	40

Conclusion: We successfully piloted a novel semi-automated method for identifying patients with advanced liver disease and/or active HCV awaiting a general liver clinic appointment. There were high levels of engagement with this approach augmented by the LCG,

which may be scaled to other clinics or repeated longitudinally to screen for and proactively manage high risk liver patients.

SAT-122

Socio-economic disparities drive the prevalence of non-alcoholic Fatty Liver Disease (NAFLD) among teenagers in the United States

Zobair Younossi[1,2,3], James Paik[1,2,4], Shira Zelber-Sagi[5], Jeffrey Lazarus[6], Pegah Golabi[1,2,7,8,8], Leyla Deavila[9], Jillian Price[9], Janus Ong[10], Saleh Alqahtani[11], Linda Henry[1,2,3,8]. *[1]Inova Health System, Betty and Guy Beatty Center for Integrated Research, Falls Church, United States; [2]Inova Health System, Inova Medicine, Falls Church, United States; [3]The Global NASH Council, Wahington, United States; [4]The Global NASH Council, Falls Church, United States; [5]University of Haifa, School of Public Health, Haifa, Israel; [6]University of Barcelona, Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [7]The Global NASH Council, Washington, United States; [8]Inova Fairfax Medical Campus, Center for Liver Disease, Department of Medicine, Falls Church, United States; [9]Inova Health System, Beatty Liver and Obesity Research Program, Inova Medicine, Falls Church, United States; [10]University of the Philippines, College of Medicine, Manila, Philippines; [11]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia*
Email: zobair.younossi@inova.org

Background and aims: Socio-economic factors and obesity have driven NAFLD to become the most common cause of liver disease among adults. Given the increasing rate of obesity in younger population, we assessed the prevalence of NAFLD among teenagers.
Method: National Health and Nutrition Examination Survey (2017–2018) data was used. NAFLD and Significant Fibrosis (SF) were defined by transient elastography (TE) as controlled attenuation parameter (CAP) of ≥285 dB/m and stiffness of >8.0 kPa without other causes of liver disease. Obesity was defined as age-sex-specific body mass index (BMI)≥95th percentile. Central obesity was defined by age-sex-specific waist circumference. Low-income household was defined as household income ≤138% federal poverty level. Low household education was defined as the head of the household without college education.
Results: 712 teenagers (age 13–18) were included [mean age 15.3 ± 1.6; 53.0% male; 50.0% white, 13.9% Black, 16.4% Mexican American, 6.9% Hispanic and 5.2% Asian; 22.2% obesity; 45.8% central obesity; 1.0% diabetes]. The prevalence of NAFLD and SF were 11.5% (95% confidence interval [CI]: 8.2–14.8%) and 2.8% (0.8–4.9%), respectively. There were disparities according to sex, race/ethnicity, household income and education. The prevalence of NAFLD was higher among teenage boys (13.7% vs. 9.1%); Mexican Americans (21.9% vs. 7.1% whites); living in low income (17.1% vs. 8.6%) and low education (14.0% vs. 4.4%) households (all p values <0.03). The prevalence of NAFLD was higher in those with obesity (according to BMI 42.2% vs. 2.9% and waist circumference 24.3% vs. 1.1%). SF was more common in Black Americans (7.2% vs. 1.9% white); those with low household education (2.8% vs. 0.5%); and those with obesity (7.1% vs. 1.3%). After adjustment for demographic factors, living in a low-income (odds ratio [OR] = 2.05, 95% CI: 1.16–3.62) and low education (OR = 3.14, 1.40–7.04) households were associated with a higher risk of NAFLD. However, the addition of obesity to the model made this risk no longer significant. On the other hand, low household education remained a significant predictor of SF (OR = 4.67, 2.15–10.15) even after adjustment for demographics and obesity.
Conclusion: NAFLD and SF were found to be more common among teenagers living in low income/education households. Targeting obesity prevention interventions to such settings should become an important aspect of all policies that address the burden of fatty liver disease.

SAT-123

Non-alcoholic fatty liver disease prevalence has increased in Australia, particularly amongst women

Karl Vaz[1,2], William Kemp[1,2], Ammar Majeed[1,2], John Lubel[1,2], Dianna Magliano[3], Kristen Glenister[4], Lisa Bourke[4], David Simmons[4,5], Stuart Roberts[1,2]. *[1]Alfred Health, Gastroenterology and Hepatology, Melbourne, Australia; [2]Monash University, Central Clinical School, Australia; [3]Baker Heart and Diabetes Institute, Diabetes and Population Health, Australia; [4]University of Melbourne, Department of Rural Health, Australia; [5]Western Sydney University, Macarthur Clinical School, Australia*
Email: karlpvaz@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent liver condition globally. Despite Australia having one of the highest rates of obesity worldwide, epidemiological data on NAFLD is scant. The aim of this study was to evaluate the change in age- and sex-standardised prevalence of NAFLD in regional Australia over a 15-year period and explore the underlying factors associated with differences over time.
Method: Repeat cross-sectional studies with equivalent methodology conducted in regional Victoria, Australia between 2001 and 2003 and 2016–2018 (CrossRoads I and II [CR-1 and CR-2] respectively). Households were randomly selected from residential address lists from local government organisations, with a single adult member of each household randomly selected to undertake a clinic sub-study. Detailed information collected included baseline demographics, anthropometric, and health-related clinical and laboratory data including alcohol use. NAFLD was defined by Fatty Liver Index (FLI) ≥ 60 in absence of excess alcohol consumption and viral hepatitis.
Results: In total, 1048 and 747 participants enrolled into CR-1 and CR-2, respectively, with sufficient data evaluable for FLI in n = 1040 (99%) and n = 721 (97%), respectively. Crude and age-/sex-standardized prevalence for NAFLD significantly increased from 32.7% and 32.4% (95% confidence interval [CI] 29.5–35.4) to 38.8% and 35.4% (95% CI 31.3–39.5) (p = 009 and p < 001), respectively, over the 15-year study period (Figure 1). Crude and age-standardized NAFLD prevalence remained stable for men (crude: 41.7% to 43.3%, p = 0.66; standardized: 38.2% [95% CI 33.9–42.4] to 38.4% [95% CI 31.9–44.8], p = 0.52) but significantly rose for women (crude: 25.5% to 35.1%, p = 001; standardized: 27.2% [95% CI 23.1–31.4] to 33.0% [95% CI 28.0–38.1], p < 001) (Figure 1). There was also a rise in prevalence of obesity (crude: 27.8% to 35.5%, p < 0.01; standardized: 29.9% [95% CI 27.1–32.7] to 33.5% [95% CI 29.4–37.6, p < 0.01), elevated waist circumference (crude: 48.2% to 60.1%, p < 0.01; standardized: 50.3% [47.3–53.4] to 54.8% [50.9–58.7], p < 0.01) and consumption of takeaway food one or

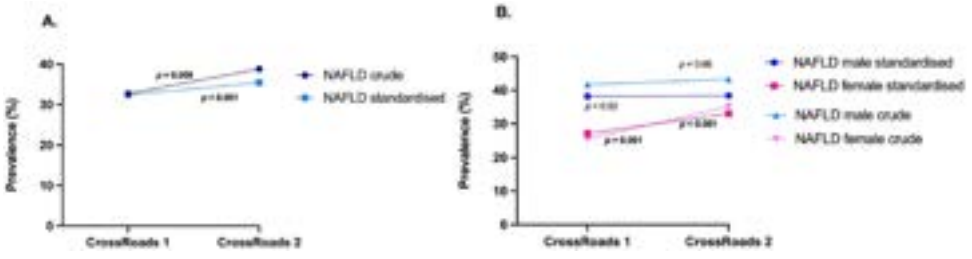

Figure: (abstract: SAT-123) Changes in NAFLD prevalence; A-entire cohort; B-according to gender

more times per week (crude: 26.1% to 30.7%, p = 0.04; standardized: 24.6% [95% CI 22.1–27.2] to 39.1% [34.9–43.3], p < 0.01).
Conclusion: Prevalence of NAFLD has risen significantly over a 15-year period in a regional part of Australia, paralleling rising obesity prevalence and most significantly in women. Public health programs to curb this trend are urgently required.

SAT-124

Multiple vitamin co-exposure and mortality risk in metabolic dysfunction-associated fatty liver disease

Wang Zilong[1], Linxiang Huang[1], Xiaoxiao Wang[1], Rui Jin[1], Baiyi Liu[1], Feng Liu[1], Huiying Rao[2]. [1]*Peking University People's Hospital, Peking University Hepatology Institute, China;* [2]*Peking University People's Hospital, China*
Email: rao.huiying@163.com

Background and aims: Metabolic-associated fatty liver disease (MAFLD) has emerged as a growing health burden worldwide. Existing studies have explored the associations between individual vitamin effects and disease progression in patients with NAFLD, and controversial findings were obtained. However, the effect of multiple vitamin co-exposure on MAFLD has not been fully elucidated. This study aims to elucidate the associations of multiple circulating vitamin co-exposure with mortality risks in MAFLD.
Method: The National Health and Nutrition Examination Survey (NHANES) III from 1988 to 1994 and NHANES III-linked mortality data through 2019 were used. MAFLD was defined as ultrasonically diagnosed hepatic steatosis in combination with metabolic dysfunction. We prospectively evaluated the concentrations of four kinds of vitamins (A, C, D, and E) in serum with mortality risk among U.S. adults. An unsupervised K-means clustering was used to cluster the participants into several vitamin co-exposure patterns. The logistical and cox proportional hazard model were used for statistical analysis.
Results: Three co-exposure patterns were generated based on the vitamins (A, C, D, and E), as follows: low-level exposure (cluster 1), vitamin D exposure (cluster 2), and vitamin A/C/E exposure (cluster 3) (Figure A, B). Compared with those in cluster 1, participants in cluster 2 and 3 had a lower risk of MAFLD (p < 0.01). In MAFLD patients, participants in cluster 2 have lower all-cause mortality risks, with hazard ratios (95% confidence intervals [CIs]) of 0.73 (0.58, 0.92), while cluster 3 was not associated with a decreased risk of all-cause mortality, with hazard ratios (95% confidence intervals [CIs]) of 0.87 (0.70, 1.09). Going one step further, we then performed a specific analysis for the 4 kinds of vitamins. Vitamin A and D at moderate levels have lower all-cause mortality risks, with hazard ratios (95% confidence intervals [CIs]) of 0.63 (0.47, 0.83) and 0.63 (0.48, 0.81). Vitamin D at moderate levels has lower cardiovascular mortality risks, with hazard ratios (95% confidence intervals [CIs]) of 0.52 (0.31, 0.87) (Figure C). Furthermore, a J-shaped nonlinear exposure-response relationship was observed between all studied vitamins and all-cause mortality risk (except for vitamin D) (Figure D).
Conclusion: Our findings indicated that high levels of circulating vitamin D levels have a lower risk of illness and death in MAFLD. Thus, the detection of Vitamin D levels may have a prognostic value in MAFLD patients.

Background and aims: Pruritus is an important but under-appreciated symptom of chronic liver diseases. We assessed factors associated with pruritus among patients with NAFLD.

Method: Patients with NAFLD seen in real-world clinical practices were prospectively enrolled in the Global NAFLD/NASH Registry (GNR)™. Clinical parameters and patient reported outcomes (PROs; FACIT-F, CLDQ-NASH, WPAI) were collected. Clinically significant pruritus was defined as score ≤4 in the respective item of CLDQ-NASH (range 1–7; lower score indicates more severe pruritus).

Results: We included 4203 NAFLD subjects from 17 countries: age 52 ± 13 years, 48% male, 48% employed, 23% advanced fibrosis and 14% cirrhosis (by biopsy or non-invasive FIB-4), 44% type 2 diabetes (T2D), 21% history of depression and 45% clinically overt fatigue. Furthermore, 78% of those with a biopsy had NASH. The prevalence of clinically significant pruritus among NAFLD was 28%. The highest prevalence of significant pruritus was in patients enrolled in Middle East/North Africa and Latin America (36–39%), the lowest in South Asia (7%). NAFLD patients with pruritus were less commonly employed (42% vs. 51%), more commonly female (61% vs. 49%) and obese (69% vs 63%). Also, they more commonly had T2D (51% vs 41%), advanced fibrosis (27% vs. 22%), anxiety (47% vs. 31%), depression (30% vs 18%), fatigue (58% vs. 40%), abdominal pain (37% vs. 20%), and sleep apnea (27% vs 21%) (all $p < 0.01$) than those without pruritus, despite similar age ($p > 0.05$). NAFLD patients with pruritus experienced significantly lower PRO scores (FACIT-F, CLDQ-NASH, and WPAI) ranging from −4% to −19% of a PRO score range (all $p < 0.0001$) All CLDQ-NASH domain scores were lower in NAFLD patients with pruritus as compared to those without (Figure). In multivariate analysis adjusted for the regions of enrollment, independent predictors of an increased risk of pruritus included female sex, T2D, depression, clinically overt fatigue, abdominal pain, and the lack of regular (≥3/times week; ≥30 min/time) exercise (odds ratios range 1.30 to 1.96, all $p < 0.01$). Among patients with 1-year follow-up, lower pruritus scores and higher prevalence of clinically significant pruritus were still observed in patients who had experienced pruritus at baseline: mean pruritus score increased from 3.1 to 4.6 in those with baseline pruritus vs. decreased from 6.4 to 6.0 in those without baseline pruritus while the prevalence of clinically significant pruritus at 1-year follow-up was 52% vs 19%, respectively (all $p < 0.0001$).

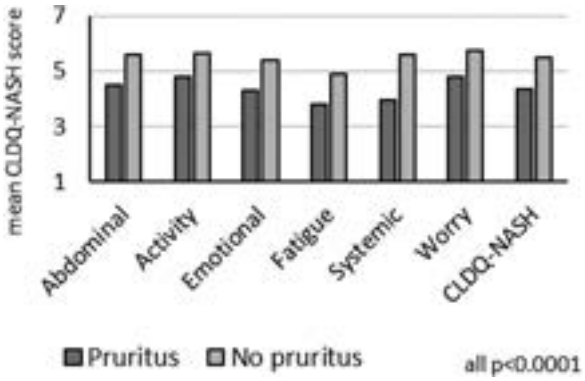

Figure:

Conclusion: Pruritus is a common and persistent symptom among patients with NAFLD, especially those with T2D and female subjects. Presence of pruritus negatively affects all PRO scores and is impacted by non-hepatic comorbidities.

SAT-126

Relationships between education and non-alcoholic fatty liver disease

Florian Koutny[1], Bernhard Paulweber[2], Elmar Aigner[2], Christian Datz[3], Sophie Gensluckner[2], Andreas Maieron[1], Stefano Novati[4], Bernhard Iglseder[5], Patrik Langthaler[6], Vanessa Frey[6], Eugen Trinka[6], Bernhard Wernly[3]. *[1]University Hospital St. Pölten, Department for Gastroenterology, Hepatology and Rheumatology, Sankt Pölten, Austria; [2]Gemeinnützige Salzburger Landeskliniken Betriebsges.mbH, First Department of Medicine, Salzburg, Austria; [3]Gerneral Hospital Oberndorf, Teaching Hospital of the Paracelsus Medical University, Department of Internal Medicine, Austria; [4]Bolzano Regional Hospital, Gastroenterology, Italy; [5]Christian-Doppler-Klinik, Department of Geriatric Medicine, Austria; [6]Christian-Doppler-Klinik, Department of Neurology, Austria*
Email: bernhard.wernly@pmu.ac.at

Background and aims: Low socioeconomic status (SES) is associated with associated with adverse health outcomes, including metabolic syndrome and NAFLD. However, it has remained enigmatic whether the association of NAFLD with SES is independent of age, sex and

metabolic syndrome. Therefore, the aim of this study was to investigate an independent relationship between NAFLD and degree of education as measured by the International Standard Classification of Education (ISCED) as a surrogate marker for SES.
Method: This study evaluated 8,315 participants from the Paracelsus 10,000 study. Anthropomorphic, clinical and laboratory parameters were collected from all participating subjects. To assess the association between NAFLD and ISCED, multivariable logistic regression models and multivariable linear regression were calculated. The primary end points were an increased fatty liver index (FLI) score (≥30) as a surrogate marker for NAFLD and liver fibrosis as indicated by an elevated fibrosis-4 index (FIB-4) score (≥1.3) as a surrogate marker. In a subgroup analysis of 789 participants the end point NAFLD was specified by liver stiffness measurement data. Trichotomized ISCED categories (low, middle and high) were chosen as an independent fixed variable with a lower ISCED as the reference category. MetS was defined according to the National Cholesterol Education Program (NCEP) Adult Treatment Panel III.
Results: Participants with a high education level had a significantly lower odds ratio (FLI score ≥30, odds ratio 0.41, 95% CI 0.34–0.50, $p < 0.01$) for liver steatosis compared to those in the low-ISCED group independent of age, sex, MetS and alcohol consumption (g/d). Univariate linear regression analysis showed that liver fibrosis defined by the FIB-4 Score was also associated with a lower ISCED. Further subgroup analysis has shown that participants in the high-ISCED group exhibited lower rates of liver stiffness compared to those in the low-ISCED group (r: −1.73 [−3.06 to −0.40]; $p < 0.01$). The same applied for patients in the intermediate-ISCED group compared to participants with the lowest education levels (r: −1.44 [−2.66 to −0.22]; $p < 0.01$). Significance of the linear regression coefficient remained after forcing sex, age MetS and daily alcohol consumption into the system.
Conclusion: Results of our study suggests that a low ISCED is associated with a higher risk for liver steatosis and fibrosis. These liver parenchymal damages have a significant impact on morbidity and may even lead to hepatocellular carcinoma. Thus, the outcome of the current study is of importance in clinical practice and highlights the need for considering socioeconomic factors in the prevention and management of NAFLD. We therefore advocate prevention strategies tailored to socioeconomic groups. Further studies are needed to evaluate the impact of socioeconomic interventions on NAFLD.

SAT-127
A pilot study to improve the uptake of hepatocellular carcinoma surveillance

Maria Qurashi[1], Nina Stafford[2], Laith Al-Rubaiy[2], Shahid Khan[1], Rohini Sharma[1]. [1]*Imperial College London, United Kingdom;* [2]*London North West University NHS Trust, United Kingdom*
Email: maria.qurashi09@imperial.ac.uk

Background and aims: Ninety percent of HCC cases arise on a background of liver cirrhosis (1). EASL and other international guidelines recommend six-monthly ultrasound surveillance for patients with cirrhosis, advanced fibrosis or high risk hepatitis B (2). Surveillance for HCC has been shown to lead to earlier diagnosis and improved survival (3). However, surveillance uptake is less than 25% internationally; a US study suggests the most common reason for this is a failure to order surveillance in those who are eligible (4). We aimed to improve surveillance uptake by implementing an automated system to issue reminders to healthcare professionals about which patients were due surveillance imaging.
Method: We created a database of patients at three district general hospitals in London who are regularly seen in specialist hepatology clinics and eligible for HCC surveillance. We implemented an automated "call-recall" system which notified clinicians about which of their patients required surveillance imaging booking.
Results: 243 patients eligible for surveillance were included. Baseline characteristics were: 69% male; median age 58 years; 60% alcohol related liver disease (ArLD), 26% viral hepatitis, 10% NAFLD.
In July 2022, prior to the automated recall system being activated, 19% (45 patients) were up-to-date with their HCC surveillance. The automated "call-recall" system was initiated in August 2022. Two months later (September 2022), 38% (93 patients) were up-to-date with their HCC surveillance.
Conclusion: HCC surveillance uptake is low. An automated "call-recall" system aims to flag to clinicians when individual patients need surveillance imaging. In a pilot study, this system doubled HCC surveillance attendance in three district general hospitals in London. Further work will look at the long-term efficacy of an automated recall system on surveillance rates, HCC diagnosis and clinically relevant outcomes, as well as exploring patient-related barriers to HCC surveillance.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease in Korea. Health check-up examinations are extensively conducted in Korea, almost all adults (esp, >40 years) receive health examinations, but systematic management of NAFLD is not effective. This study conducted to investigate the hurdles of the NAFLD treatment cascade through a nationwide survey in Korea.
Method: This cross-sectional study was conducted using an online survey. A total of 1,000 panels was finally selected according to distribution of sex, age group, and residential area in Korean adult. The survey consisted of a 3-domain and 18-item questionnaires. Content validity of questionnaire was measured by a total of 14 experts including medical doctors, nutritionists, and a methodologist who did not participate in the development of the questionnaire. Content validity index (CVI) for each item was rated above 0.80.
Results: A total of 27.2% responded that they had never heard of NAFLD terminology. Approximately half of responders (60.2%) heard of NAFLD through media (TV, newspaper, and radio), only 24.8% of people had heard of NAFLD through medical staff. A total 42.9% of the respondents recognized that liver cirrhosis, and hepatocellular carcinoma can be developed in NAFLD. Only 25.7% of the respondents

recognized that angina pectoris, myocardial infarction, ischemic stroke associated with NAFLD. Only 40.2% who diagnosed with NAFLD visited clinic for the further evaluation and management of NAFLD. The most common reason for not visiting the medical facility after diagnosis of NAFLD was 'I could manage the disease on my own' (50.6%), followed by 'never been told from my physician that I need disease management' (32.9%). The most common response by gender was 'lack of time to visit the hospital' in men (84.6%) and 'I could manage the disease on my own' in women (45.0%). Most 20s-40 s thought they could manage the disease on my own, and fatty liver was not regarded as a serious disease' in 50s-60 s.

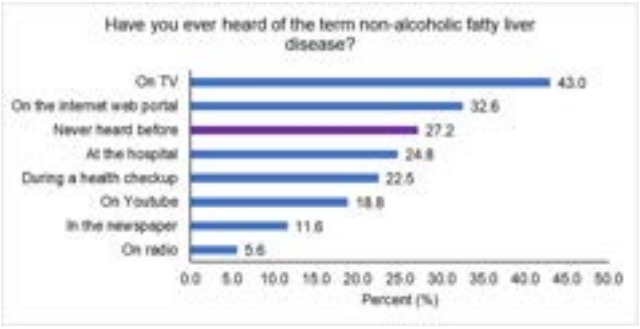

Figure:

Conclusion: Only 40% visited the clinic after diagnosis with NAFLD. Reasons for not visiting the clinic after diagnosis of NAFLD differed significantly according to gender and age.

Email: jparab@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is the third most common cause of cancer-related deaths worldwide. The aims of the study were to explore HCC-related population-wide public health policies (PHP) in terms of prevention, treatments availability, epidemiological surveillance, and awareness campaigns worldwide.
Method: We conducted a 43-item survey about HCC: policies and civil society (18 questions), clinical guidelines (5 questions), epidemiology (7 questions), and care management (13 questions). We invited 249 gastroenterologists, hepatologists, oncologists, surgeons, radiation therapists, and public health experts from 74 countries/territories. The survey was administered using an electronic form between May 14, 2022, and January 24, 2023. Data were collected in a spreadsheet, revised by two independent reviewers, and verified with governmental institutions, regulatory agencies, scientific societies, and scientific publications.
Results: We obtained 132 responses from 66 countries/territories (Africa N = 16, the Americas N = 18, Asia N = 10, Europe N = 21, and Oceania N = 1). A total of 46 (69.7%) countries had a written national cancer strategy or action plan (including solid and haematological neoplasms). However, only 5 (7.6%) had a specific written national strategy or action plan on HCC (Figure). Thirty-two (48.5%) countries had national clinical practice guidelines on HCC, mainly focused on prevention (84.4%), screening (93.8%), diagnosis (93.8%), treatment (93.8%), and palliative care (68.8%). Fifty-four (81.8%) countries had a national disease registry that included HCC. Several providers are involved in management of HCC: oncologists (83.3%), gastroenterologists (75.8%), hepatologists (74.2%), surgeons (60.6%), and palliative medicine specialists (33.3%). The most common strategies for staging of HCC were Barcelona Clinic Liver Cancer (BCLC) (85%) and TNM classification (10%). The survey reflects important differences in the availability of treatments, including surgery (98.4%), tyrosine kinase inhibitors (95.1%), chemoembolization (85.2%), radiofrequency or alcohol ablation (82%), immunotherapy plus anti-VEGF (82%), liver transplant (74.2%), stereotactic body radiation therapy (42.6%), and radioembolization (36.4%).
Conclusion: Existence of PHP on HCC is insufficient worldwide. The most common strategy for staging is BCLC, but there are important differences on treatment availability across countries, especially regarding curative therapies.

SAT-130

Exploring attitudes towards non-invasive liver fibrosis tests in secondary care pathways: comparing national surveys between 2014 and 2021

Kushala Abeysekera[1,2], Ankur Srivastava[3], Ian Rowe[4], Helen Jarvis[5], Stephen Ryder[6], Andrew Yeoman[7], John Dillon[8], William Rosenberg[9]. *[1]University of Bristol, United Kingdom; [2]University Hospitals Bristol and Weston NHS Foundation Trust, Department of Liver Medicine, United Kingdom; [3]North Bristol NHS Trust, United Kingdom; [4]University of Leeds, United Kingdom; [5]University of Newcastle, United Kingdom; [6]University of Nottingham, United Kingdom; [7]Anuerin Bevan University Health Board, United Kingdom; [8]University of Dundee, United Kingdom; [9]University College London, United Kingdom*
Email: k.abeysekera@bristol.ac.uk

Background and aims: Increasing availability of non-invasive liver tests (NITs) has created the opportunity to apply them to improving early detection and risk stratification of advanced liver disease. This study aimed to determine changes in attitudes and practices of secondary care specialists involved in managing liver disease in the UK, focusing primarily on attitudes to fibrosis assessment and the use of NITs. Secondary aims included exploring knowledge of NITs, use of designated early detection and risk stratification pathways, and barriers to implementing NITs in practice.
Method: Specialists managing patients with liver disease were invited to complete web-based surveys between 1st Oct 2014 to 1st Oct 2015 (Survey 1), and again between 1st Nov and 24th Dec 2021 (Survey 2) in the UK via the British Society of Gastroenterology, the British Association for the Study of the Liver, and using Twitter®. The second survey was closed early due to national clinical pressures from the COVID19 Omicron wave.
Results: Two hundred and fifteen healthcare professionals (HCPs) completed Survey 1 (49.5% hepatologists). The repeat survey was completed by 112 HCPs (64.3% hepatologists). Respondents represented 71 acute services in Survey 1 compared to 60 in 2021. Between the surveys the proportion of HCPs performing fibrosis assessment in all or nearly all cases rose by almost two-thirds from 45.1% to 74.1% ($x^2 = 25.01$; $p < 0.0001$). The proportion of respondents who considered FIB-4 to be useful in fibrosis assessment doubled from 40.7% (n = 87/215) 83.0% (n = 93/112; $x^2 = 53.93$; $p < 0.0001$). In 2014 87.0% (n = 187/215) considered transient elastography useful for fibrosis assessment, rising to almost all respondents (95.5%; n = 107/112; $x^2 = 5.96$, $p = 0.148$). Enhanced Liver Fibrosis (ELF) test was more favourably viewed amongst respondents for fibrosis assessment, increasing from 25.3% (n = 54/215) to 43.7% (n = 49/112; $x^2 = 11.85$; $p = 0.0006$) usage in 2021. A further 49.1% of respondents considered ELF useful but did not use it in their practice in 2021. Of the acute services represented by respondents, 46.5% (n = 33/71) respondents in acute services reported the use of NITs in clinical pathways, rising to 70.0% (n = 42/60) in Survey 2 ($x^2 = 7.35$; $p = 0.007$). Availability of tests has increased but is not universal. The proportion reporting availability as a barrier to uptake has fallen from 57.2% of responses in Survey 1 to 38.4% in 2021 ($x^2 = 11.01$; $p = 0.0009$).

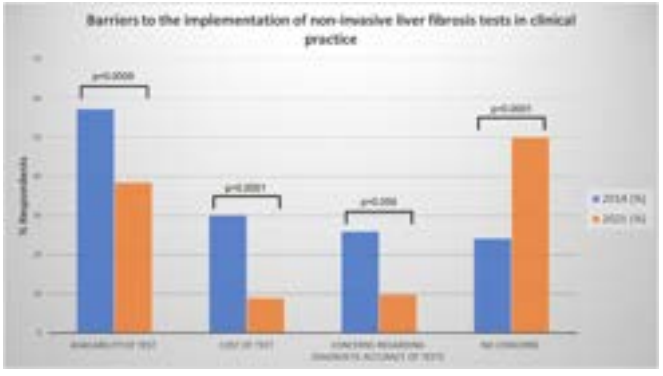

Figure:

Conclusion: Between 2014 and 2021, there has been a substantial increase in the use of NITs for fibrosis assessment accompanied by their use in clinical pathways to guide the management of people at risk or with liver disease. Poor access to NITs remains the predominant barrier. There is a pressing need for a simple, coordinated national strategy for testing individuals at risk of cirrhosis in primary care to ensure that cases can be identified and provided with prompt specialist care.

SAT-131

Evidence of significant alcohol-associated mortality in a large population cohort in Uganda

Cori Campbell[1], Joseph Mugisha[2], Elizabeth Waddilove[3], Ronald Makanga[2], Tingyan Wang[1], Beatrice Kimono[2], Florence Nambaziira Muzaale[2], Philippa Matthews[3], Eleanor Barnes[1]. *[1]University of Oxford, Nuffield Department of Medicine, United Kingdom; [2]Medical Research Council/Uganda Virus Research Institute/ London School of Hygiene and Tropical Medicine (MRC/UVRI/LSHTM) Uganda Research Unit, Entebbe, Uganda, Uganda; [3]The Francis Crick Institute, 1 Midland Way, London, UK, United Kingdom*
Email: cori.campbell@ndm.ox.ac.uk

Background and aims: Liver function tests (LFTs) can be used as prognostic biomarkers of all-cause mortality, however few investigations have been undertaken in African populations despite a high burden of liver disease in these settings. Previous analysis of the General Population Cohort (GPC) in Uganda suggested high prevalence of alcohol-related liver disease, HIV infection, HBV and associated primary liver cancer. We aimed to investigate how LFTs associated with risk of all-cause mortality in the GPC.

Method: The prospective GPC was established in 1989 in Kalungu District in rural south-western Uganda. In the 22nd survey round (years 2010/11), selected participants underwent measurement of biophysical and blood parameters to investigate disease risk factors and outcomes. Outcomes were ascertained via presentation to health clinic. Descriptive statistics were used to summarise parameters and compare correlations between LFTs, blood lipids (including low density lipoprotein, LDL), AST:ALT ratio (values >2 indicate alcoholic hepatitis), Haemoglobin A1C (HbA1c). We investigated characteristics/biomarkers associated with hazards of death via Cox proportional hazards modelling.

Results: In 7896 individuals with median age 30 years (IQR 17–46), 43.8% were male (n = 3455). Minorities of individuals had confirmed chronic hepatitis B virus (HBV) (n = 216, 2.7%) or human immunodeficiency virus (HIV) (n = 582, 7.4%) infections throughout follow-up. Over 6.30 mean years (SD 3.26) of follow-up, 629 (7.8%) individuals died from any cause. Fisk factors for all-cause mortality included increasing age, male sex, HIV positivity (Figure 1). Nearly a quarter (23.3%, n = 147) of participants who died had an AST:ALT value >2, as compared to 9.8% (n = 710) of individuals who survived. A one-unit increase in AST:ALT ratio was associated with 17% higher hazards of death, and a 10 unit increase in gamma-glutamyl transferase (GGT) with a 1% increase in hazards. Other cardiometabolic factors associated with death included HbA1c and LDL.

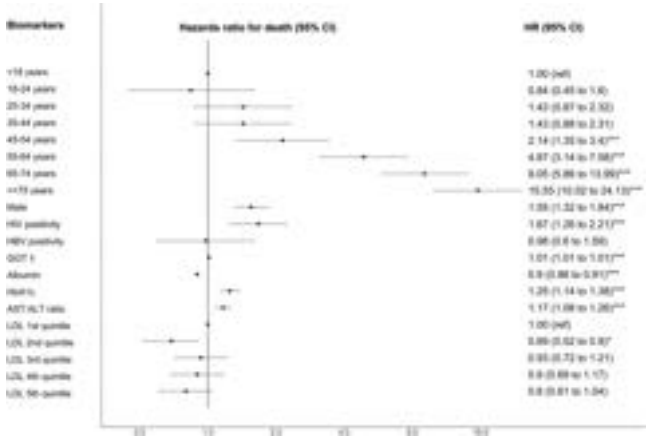

Figure: Forest plot for factors associated with all-cause mortality in Ugandan General Population Cohort (GPC). † Per 10-unit increase in GGT

Conclusion: Understanding of liver disease in the WHO Africa region must urgently improve. Using AST:ALT ratio cutoff (established in Western populations) suggests an association of alcoholic hepatitis with mortality, which is substantiated by elevated GGT. Clinical and public health programmes should be informed by data suggesting high alcohol consumption is a significant contributor to mortality.

SAT-132

Detection of potential subjects at risk of liver fibrosis in general population in Spain

María Del Barrio Azaceta[1], Paula Iruzubieta[1], Armando Raúl Guerra Ruiz[1], Marta Alonso-Peña[1], María Teresa Arias Loste[1], Aitor Odriozola[1], Ángela Antón[1], Sara Alonso[1], Bernardo Alio Lavin[2], Javier Crespo[1]. *[1]Gastroenterology and Hepatology Department, Marqués de Valdecilla University Hospital, Clinical and Translational Digestive Research Group, IDIVAL, Santander, Spain, Spain; [2]Análisis Clínicos y Bioquímica. Hospital Universitario Marques de Valdecilla, Santander, Spain*
Email: javiercrespo1991@gmail.com

Background and aims: A two-step assessment with fibrosis index-4 (FIB-4) and transient elastography has been established as an appropriate screening strategy for liver fibrosis in >50 years old with metabolic risk factors. However, a screening program needs to guarantee the greatest accessibility for the population at risk. Our aim was to determine the prevalence of high risk of advance fibrosis (AdF) by FIB-4 in the general population and, therefore, subjects susceptible to undergo a second fibrosis assessment.

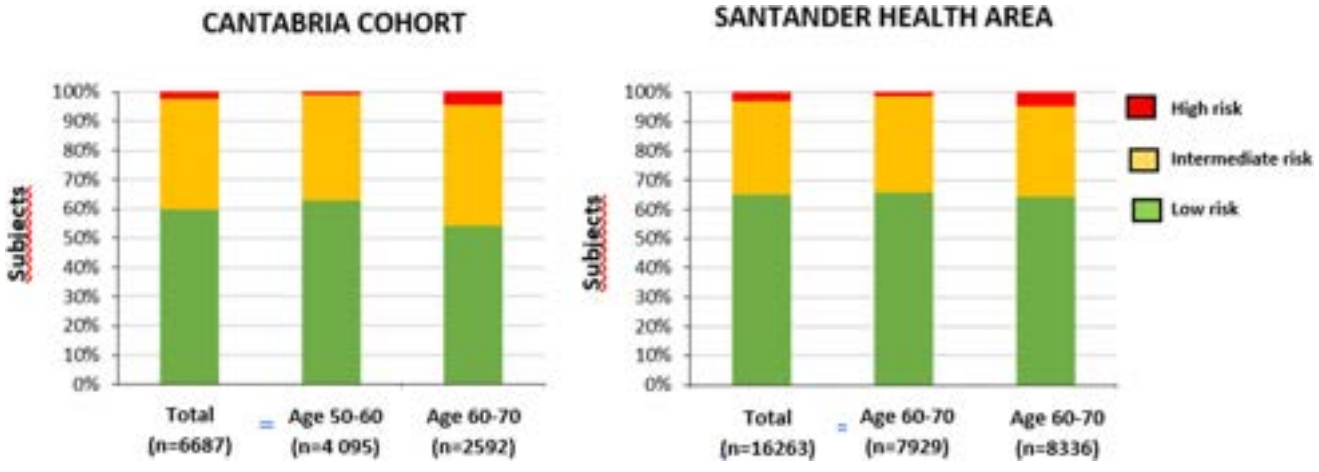

Figure: (abstract: SAT-132).

Method: Cross-sectional study in Spain based on general population that included subjects aged 50–70 from: A) Cantabria Cohort (volunteers and random sampling of the entire population of Cantabria –585,222 inhabitants-) enrolled from October 2021 to April 2022; B) Santander health area (315, 000 inhabitants) who had an analysis from Primary Care between August-October 2021. The risk of AdF was determined using FIB-4: low risk (FIB-4 <1.3/<2.0 in >65 years), intermediate risk (1.3–2.67/2.0–2.67 in >65 years) and high risk (>2.67).
Results: From Cantabria cohort, 6,687 subjects were included (mean age 58.7 ± 5.8; 41.0% men; 23.6% obese). 2,545 subjects (38.1%) had an intermediate risk, and 155 subjects (2.3%) had a high risk. No differences were found in the prevalence of high risk of AdF between obese and non-obese subjects (2.0% vs. 2.3%; p = 0.4). FIB-4 could be calculated in 16,263 of the subjects in the Santander health area (mean age 60.4 ± 6.0; 41.7% men). Intermediate risk was observed in 5,185 cases (31.9%) and high risk in 498 (3.1%), similar to the general population cohort (Fig).
Conclusion: In a health area of 315,000 inhabitants, a two-step fibrosis screening strategy in subjects aged 50–70 years, without considering metabolic factors, would entail the application of a second test in approximately 1500 subjects/month and, therefore, this implies that approximately 150 subjects/month need to be referred to a specialized consultation; which is a number of patients that can be assumed by the Hepatology unit service of a tertiary referral hospital.

SAT-133
Comparison of the opt in vs opt out policy and its impact on the donation rate of liver transplantation in the Colombian healthcare system
Andres Gomez Aldana[1,2], Diana Carolina Gomez[3]. [1]*Fundación Santa Fe de Bogota, Bogota, Colombia;* [2]*McMaster University, Canada;* [3]*Sanitas EPS, Colombia*
Email: andresgomezmd@hotmail.com

Background and aims: The organ donation process around the world is supported by two systems denominated opt-in (the patient agrees to be a donor) and opt-out (it is presumed that the person consents to the donation unless they have registered their contrary decision); This last policy was pursuing to bolster donations rate. Given the lack of potential donors and our low donor rate (8 per million inhabitants), Colombia promulgated some laws (823 in 2015 and 714 in 2016), seeking to expand the legal presumption of donation of anatomical components for transplant purposes or other therapeutic uses, designing a legal framework to increase the donation rate to all those people who had not expressed the refusal to do so while alive.
Method: This is a retrospective study comparing two years before and two years after the establishment of this new law in terms of the number of liver transplants.
Results: The absolute number of organ donations in Colombia (This organ donation and distribution in 6 different geographical regions across the country), was assessed during the period of 2015–2016. Therefore, this time will be known as the opt-in period. Moreover, the period 2017–2018 was covered during the opt-out policy period. Overall, the national donation rate increases reach up to 11.6%. Otherwise, the refusal rate of family members, before and after the enacted legislation, shows a decrease of 61%, which suggests a favorable outcome. Moreover, the liver transplant rate during the opt-in period (2015–2016), showed a slight increase in the number of transplants, reaching 3.44% in the absolute number. By contrast, during the period 2017–2018, a decrease of 17% is observed in the number of transplants compared.
Conclusion: In summary, the new legislation switching to the "opt-out" policy has been a favorable strategy for transplants of different solid organs. Unfortunately, the liver transplant rate has shown an unfavorable trend with this intervention, which would make it necessary to carry out more studies to identify which other causes are inducing this negative impact on this population. Otherwise, there is still more research required to assess the impact of COVID-19 on this policy.

SAT-134
Global burden of common cancers attributable to metabolic risks from 1990 to 2019
Qing-Qing Xing[1], Jing-Mao Li[2], Chen Chen Zhi-Jian[1], Xiaoyun Lin[1], You You Yan-Ying[3], Mei-Zhu Hong[4], Shangeng Weng[5], Jin-Shui Pan[1]. [1]*First Affiliated Hospital of Fujian Medical University, Department of Hepatology, Fuzhou, China;* [2]*Xiamen University, Department of Statistics, School of Economics, Xiamen, China;* [3]*First Affiliated Hospital of Fujian Medical University, Department of Hepatology, Fuzhou, China;* [4]*Mengchao Hepatobiliary Hospital of Fujian Medical University, Department of Traditional Chinese Medicine, Fuzhou, China;* [5]*First Affiliated Hospital of Fujian Medical University, Hepatopancreatobiliary Surgery Department, Fuzhou, China*
Email: 363111396@qq.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is usually accompanied by metabolic syndrome, which is associated with increased risk of cancer. To inform a tailored cancer screen in patients at higher risks, we estimated the global burden of cancer attributable to metabolic risks.
Method: Data of common metabolism-related neoplasms (MRNs) were derived from the Global Burden of Disease (GBD) 2019 database. Age-standardized, disability-adjusted life year (DALY) rates and death rates of patients with MRNs were extracted from the GBD 2019 database and stratified by metabolic risk, sex, age, and level of socio-demographic index (SDI). The annual percentage changes of age-standardized DALYs and death rates were calculated.
Results: Metabolic risks, consisting high body-mass index and fasting plasma glucose, contributed substantially to the burden of neoplasms, including colorectal cancer (CRC), tracheal, bronchus, and lung cancer (TBLC), etc. Globally, in 2019, there was an estimated age-standardized DALYs rate (ASDR) of 234.0 (95% CI 124.0–376.0) per 100,000 person-years for neoplasms attributable to metabolic risks. ASDRs of MRNs were higher for CRC, TBLC, men, patients aged ≥50 years, and patients with high or high-middle SDI.
Conclusion: These findings further underpin the correlation between NAFLD and intrahepatic and extrahepatic cancers and highlight the possibility of tailored cancer screening for the NAFLD population at higher risks.

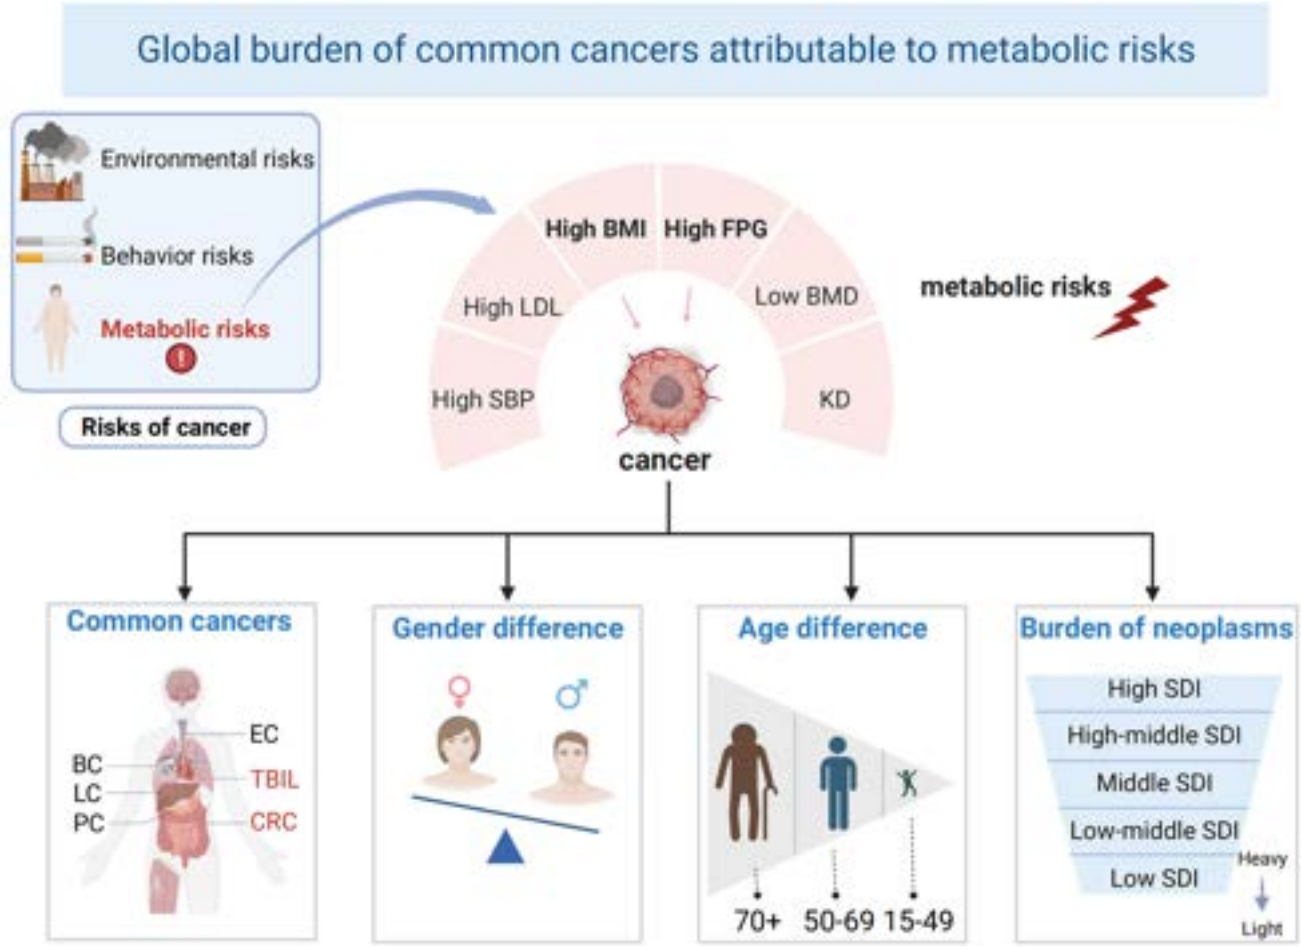

Figure: (abstract: SAT-134).

Impact of coronavirus disease pandemic on hospitalizations due to chronic liver disease in Belgrade, Serbia

Ivana Pantic[1], Nina Rajovic[2], Sofija Lugonja[3], Svetlana Miltenovic[4], Tamara Milovanovic[1,5]. *[1]Clinic of gastroenterology and hepatology, University clinical center of Serbia, Belgrade, Serbia; [2]Institute for medical statistics and informatics, Faculty of medicine, Univeristy of Belgrade, Belgrade, Serbia; [3]General hospital "Djordje Joanovic", Serbia; [4]Institute of publich health of Belgrade, Serbia; [5]Faculty of medicine, University of Belgrade, Serbia*
Email: tamara.alempijevic@med.bg.ac.rs

Background and aims: The consequences of severe and worldwide health-care disruption as a result of coronavirus disease (COVID-19) pandemic still have to be dealt with. Besides the decreased availability of health-care services during the lockdown, it is also hypothesized that patients detained themselves from seeking help. Additionally, an increase in alcohol consumption during that period is well documented. The aforementioned mechanisms contributed to higher morbidity and mortality of patients suffering from all chronic diseases-including the chronic diseases of the liver. The aim of our study was to evaluate whether there are any differences in hospital admissions due to chronic liver disease (CLD) and outcomes during the pandemic in Belgrade, Serbia, compared to the previous years.
Method: Hospital admissions due to alcohol-related, viral, autoimmune, and overlapping liver disease were identified using primary and secondary discharge diagnosis codes, based on the 10th revision of the International Statistical Classification of Diseases and Related Health Problems. All hospitalization reports (including re-hospitalizations) which included adult subjects on the territory of Belgrade, between 2016 and 2021, and contained pre-defined principal discharge codes were selected. We compared the period of pandemic (2020 and 2021) with previous years (2016–2019).
Results: A total of 6789 hospitalizations due to CLD were noted during the study period. The mean age of patients was 52.5 ± 15.9 years, and majority were male (65.5%). Median hospital stay of the patients was 4 days (25th-75th percentile: 1–12). Number of hospitalizations due to CLD per year from 2016 to 2021 was as follows: 1395 (20.5%), 1259 (18.5%), 1268 (18.7%), 1533 (22.6%), 800 (11.8%), and 534 (7.9%), respectively. Average number hospitalizations per year before COVID-19 pandemic was 1364 ± 129, while during COVID-19 pandemic, average number of hospitalizations per year was 667 ± 188 ($p = 0.005$). During COVID-19 pandemic hospitalized patients were more often female ($p < 0.001$), younger ($p = 0.006$), and more often had autoimmune liver disease than patients admitted due to CLD before COVID-19 pandemic ($p < 0.001$). During COVID-19 pandemic, shorter hospital stay (4 days vs. 1 day; $p < 0.001$) was reported, while mortality rate increased (7.6% vs. 8.8%; $p = 0.048$) compared to patients admitted for CLD is before COVID-19 pandemic. Before COVID-19 pandemic, patients with alcohol-related/overlapping liver disease had the highest mortality rate (15.1%; $p < 0.001$). During COVID-19 pandemic, mortality rate for alcohol-related/overlapping liver disease increased to 21.2% ($p < 0.001$). In both groups (before and after COVID-19 pandemic), male ($p < 0.001$) and older ($p < 0.001$) patients were at increased risk for overall mortality ($p < 0.001$ and $p < 0.001$, respectively).
Conclusion: During COVID-19 pandemic less hospital admissions due to CLD was noted. Overall length of stay was shorter, overall mortality increased, while a significant increase in mortality was

noted in hospitalizations due to alcohol-related/overlapping liver disease. During the pandemic, hospitalized patients were younger and more often female, and patients were more commonly admitted due to autoimmune liver disease.

SAT-136

SIRIUS project: sensing probe exploring liver fibrosis in Slovakia

Lubomir Skladany[1], Daniel Jan Havaj[1], Svetlana Adamcova Selcanova[1], Janka Vnencakova[1], Natalia Bystrianska[1], Daniela Žilinčanová[1], Karolina Sulejova[1], Beata Skvarkova[1], Marek Rac[2], Sylvia Dražilová[3], Martin Janičko[3], Peter Jarcuska[3], Tomáš Koller[4]. *[1]F. D. Roosevelt University Hospital in Banská Bystrica, Slovakia; [2]Faculty Hospital Nitra, Nitra, Slovakia; [3]Louis Pasteur University Hospital Kosice, Slovakia; [4]Faculty of Medicine (University of Comenius), Bratislava, Slovakia*
Email: lubomir.skladany@gmail.com

Background and aims: In Slovakia, liver cirrhosis is the most prevalent of all the countries in the world and, it is the number-one cause of death in young adults (25–45 y/o). One of the responses on the side of the professional liver community was the launch of country-wide screening project SIRIUS. SIRIUS Project was aimed primarily at detecting liver fibrosis in general population and to try to find its associations with the most common risk factors for chronic liver diseases. This is the first interim analysis, aimed at the prevalence of liver fibrosis as detected by transient elastography (TE) with the treshold for increased stifness as proposed by the LiverScreen project.
Method: In this community-outreach project, SIRIUS teams composed of physicians, nurses, volunteers and liver patient organization members travelled to pre-selected sociomes of six types from cities to remote villages and roma communities in all the regions of the country and recorded: brief medical history, demography, anthropometry, capillary blood chemistry, TE and, in a subset of participants gut microbiome samples. Liver stifness was considered increased if the result of standardized TE (FibroScan^{R}) measurement was above 8 kPa. We included only consenting adult community dwellers without known (ICD registered) liver disease apart from trivial NAFLD, and without active/unstable/life-threatening extrahepatic comorbidity. In the case TE, or laboratory parameters suggested liver disease, recall policy was two-pronged: 1) patients were offered on-site consultation by a physician from the liver unit and they were issued 2) Green Card with SIRIUS personal identifier serving as a passport for the subsequent in-depth examination in the respective regional liver outpatient clinic. In the case local show-up exceeded the capacity of SIRIUS day, unserved interested persons were issued Orange Card with SIRIUS personal identifier allowing for the SIRIUS exam in the future. SIRIUS has been granted Institutional Ethics committe approval and NCT registration number.
Results: Between August 23, 2022 and January 31, 2023, SIRIUS team visited nineteen sites and completed the data collection in 1 663 adult participants. Issued were 560 Green Cards and 332 Orange Cards, respectively. We detected liver stifness >8 kPa in 243 participants (15%).
Conclusion: In this country-wide endeavour, the prevalence of increased liver stifness was considerably higher than in other regions of Europe. Before we claim the prevalence is concordant with staggering prevalence of end-stage liver disease in Slovakia, we have to exclude self-selecion bias by continuing enrollment until tsunami of interest to be screened levels off.

SAT-137

Anti-hepatitis B surface antigen negativity can be a risk factor for SARS-CoV-2 infection in SARS-CoV-2 vaccinated healthcare workers

Tomohide Kurahashi, Atsuishi Hosui[1], Naoki Hiramatsu[1]. *[1]Osaka-Rosai Hospital, Department of Gastroenterology and Hepatology, Sakai, Japan*
Email: tkurahashi@osakah.johas.go.jp

Background and aims: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection has raged around the world. It is important for health care institutions providing SARS-CoV-2 medical care to understand the risk factors of infection among health care workers. Vaccination has been used as an effective method for health care workers fighting SARS-CoV-2, however, nevertheless, infection can often occur after vaccination. In this study, we investigated the factors involved in SARS-CoV-2 infection in health care workers after vaccination.
Method: We registered 1133 healthcare workers (826 women, 307 men) who received first SARS-CoV-2 vaccination between February and April 2021 in our hospital. The BNT162b2 vaccines (Pfizer/BioNTech) were inoculated three times according to the pharmaceutical reference. Self-reported questionnaires and medical checkup were used to collect medical histories and demographic characteristics. The alinity SARS-CoV-2 IgG II quant (Abbott) quantitative IgG spike protein serology assay were examined in a group of participants who have passed 1, 4, 6 months after the second vaccination and 1 month after the third vaccination of the BNT162b vaccine. Lower antibody (Ab) titers were defined under median at each time step. The risk factors of SARS-CoV-2 infection to persons who received vaccination three times were analyzed. The log-rank test was used as the analysis method.
Results: The mean observation period was 16.1 ± 2.0 months (mean ± standerd deviation) after first vaccination. The median titers at 1, 4, 6 months after the second vaccination were 9293 U/ml (interquartile range [IQR], 5840–14392 U/ml), 1658 U/ml (IQR, 999–2676) and 832 U/ml (IQR, 523–1300), respectively. The median titers at 1 month after the third vaccination was 13780 U/ml (IQR, 9085-22722). SARS-CoV-2 infected 40.1% of the enrolled healthcare workers during the observation period. In univariate analysis, the risk factors for SARS-CoV-2 infection were hepatitis B surface antibody (HBsAb) negative ($p = 0.011$, OR = 1.613) and high γGTP ($p = 1.768$, OR = 0.032) participants. The participants with underlying disease was marginally significant ($p = 0.072$, OR = 1.407). No significant association was found between SARS-CoV-2 infection and Ab titer at the time of our measurement. Multivariate analysis showed that HBsAb negative was the only significant factor for SARS-CoV-2 infection ($p = 0.021$, OR = 1.595). The 1-year cumulative infection rates of SARS-CoV-2 infection in HBsAb negative and positive people were 5.2% and 3.7%, respectively ($p = 0.007$). Next, 238 participants who had previously vaccinated against hepatitis B in this cohort were examined in order to investigate the relationship in detail between HBsAb status and SARS-CoV-2 infection. Of these participants, 129 were responders who acquired HBsAb from the vaccine and 109 were vaccine refractory (non-responders). HBV vaccine non-responders were more susceptible to SARS-CoV-2 infection compared to responders (non-responders 4.6% vs responders 0.8%, $p = 0.042$, OR = 1.51).
Conclusion: HBsAb negativity can become a factor indicating susceptibility to SARS-CoV-2 infection. Recently, three segments in the hepatitis B protein have been reported to have antigenic properties that can induce protective effect against SARS-CoV-2 infection (Haddad-Boubaker et al. BMC Bioinfomatics, 2021). Our results can suggest a protective effect of HBsAb against SARS-CoV-2 infection clinically.

Public Health Viral hepatitis

WEDNESDAY 21 TO SATURDAY 24 JUNE

Trends in hepatitis B and hepatitis C related hepatocellular carcinoma, 2015 to 2030

Devin Razavi-Shearer[1], Sarah Blach[1], Ivane Gamkrelidze[1], Kathryn Razavi-Shearer[1], Alexis Voeller[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: drazavishearer@cdafound.org

Background and aims: Hepatocellular carcinoma (HCC) secondary to hepatitis B (HBV) and/or hepatitis C (HCV) virus infection is an important cause of morbidity and mortality. We aimed to estimate the change in incident HCC cases from 2015 through 2030 under the current HBV and HCV treatment paradigms.
Method: To estimate the number of HCC cases attributed to HBV or HCV, first the annual number of incident liver cancers cases was collected (by country for all available years) from national cancer registries. If registry data were unavailable, estimates from local hospitals or clinics were collected and extrapolated to the country level in consultation with local experts. Next, incident liver cancer cases were adjusted for type (HCC), etiology (HBV or HCV) and underreporting (if indicated by local experts). Proportions used to adjust for type, etiology, and underreporting were retrieved from published literature, local databases, or expert input.
In parallel, country-specific models for HBV (PRoGReSs Model) and HCV (Bright Model) were developed using epidemiological data and expert input. These estimated the natural history (from 1950 to 2050) of HBV or HCV disease and future burden, including HCC. After calibration, model calculated incident HCC cases were validated against reported cases, where available.
Finally, the modeled numbers of HBV- or HCV-related incident HCC cases from 2015 to 2030 were retrieved by country. If country-specific data were not available, regional averages were used. Country data were summed, by disease, to estimate the global number of incident HBV- or HCV-related HCC. Finally, the number of viral hepatitis-related HCC cases was calculated by summing HBV-related and HCV-related cases. Incidence rates were calculated per 100,000 population (adults 18+).
Results: At the country level, the incidence of viral hepatitis-related HCC in 2022 was generally correlated with viral hepatitis prevalence in the same year. Given current prophylaxes and treatment trends, the global number of incident viral hepatitis-related HCC cases would increase from 860,000 (16.9 per 100,000) in 2015 to 1.08 million (17.5 per 100,000) by 2030. HCV-related incident HCC cases would increase 3% (from 210,000 in 2015 to 216,000 in 2030), while the incidence rate would decrease 15% (from 4.1 to 3.5 per 100,000). Meanwhile, HBV-related incident HCC would increase (33% for cases, 10% for rate), from 652,000 (12.8 per 100,000) in 2015 to 864,000 (14.0 per 100,000) by 2030. Due to the changing trends by disease area, the proportion of viral hepatitis-related HCC cases attributed to HBV would increase from 76% in 2015 to 80% in 2030.
Conclusion: HBV-related HCC was the major driver of increasing trends in incident HCC cases. Prevention and treatment of HBV and HCV should be pursued not only for the elimination of viral hepatitis, but also as a strategy for cancer prevention.

Engagement of patients with viral hepatitis diagnosed by opt-out universal emergency department testing

Amy Teague[1], Jingwei Zeng[2], Tanzina Haque[2], Douglas Macdonald[1,3], Kathleen Bryce[1,4]. [1]*Department of Hepatology, Royal Free London NHS Foundation Trust, London, United Kingdom;* [2]*Department of Virology, Royal Free London NHS Foundation Trust, London, United Kingdom;* [3]*Institute of Liver and Digestive Health, University College London, London, United Kingdom;* [4]*Institute for Global Health, University College London, London, United Kingdom*
Email: kathleenbryce@doctors.org.uk

Background and aims: We report on the engagement and assessment outcomes of adults diagnosed with viral hepatitis through a recently implemented universal opt-out blood-borne virus testing program across two emergency departments (ED) in London.
Method: Opt-out blood-borne virus (BBV) testing (HCV Ab, HBsAg and HIV) commenced for all adults attending ED at the Royal Free London NHS Trust from 15th April 2022. Reflex testing of HCV RNA and HBV DNA were performed in positive HCV Ab and HBsAg samples. Patient engagement was nurse-led and managed by a bespoke patient management system from which data was extracted to 24th January 2023. Patients were initially contacted by phone and then by letter if this was unsuccessful after two separate attempts. All patients contacted were offered assessment in a hospital outpatient setting.
Results: A total of 52 new hepatitis C and 195 new hepatitis B diagnoses were made during the study period. The subsequent engagement and treatment cascade is shown in Table 1. The proportion of those not under care that have since been assessed are the same for both groups (56%) but the non-attendance rate of

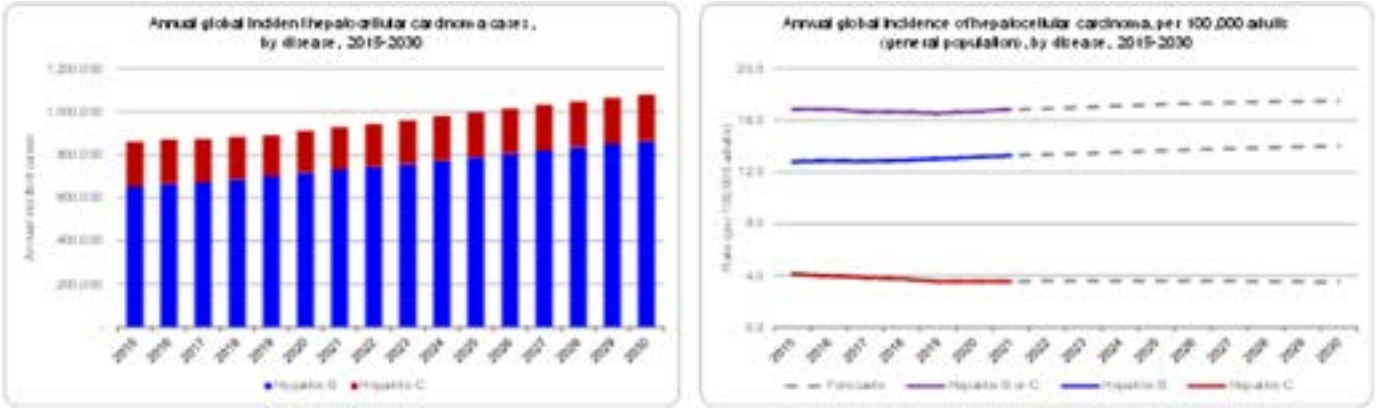

Figure: (abstract: TOP-096).

patients after successful contact was higher in those with hepatitis B than those with hepatitis C (21% vs 9%). 13% of those with hepatitis B spoke English as a first language compared with 65% of those with hepatitis C (p < 0.0001, Fisher's exact test). Of those assessed in clinic with hepatitis B, 15.8% had an HBV DNA >2000 and 13.9% had F2 or greater fibrosis. 14% (n = 16) have been commenced on nucleotide therapy. 2 new HCC diagnoses were made at baseline imaging. Of those assessed with hepatitis C, 22% had F3 or greater fibrosis and 62.5% (n = 20) had been commenced on treatment by the censor date. A further 5 patients with hepatitis C who were not contactable or disengaged after assessment have been successfully engaged and treated by a mobile Find-and-Treat service.

Conclusion: We have shown that opt-out ED BBV testing is feasible at scale and can identify large numbers of new cases of viral hepatitis, particularly hepatitis B. However, subsequent engagement presents challenges which differ between hepatitis B and C cohorts. In implementation of opt-out ED testing appropriate resource allocation to subsequent engagement, assessment and treatment is essential if patients are to benefit from diagnosis.

Table 1:

	HCV RNA+	HBsAg+
Total tests	54509	54398
Total positives (% of all tests)	64 (0.117%)	253 (0.465%)
– New diagnoses (% of all positives)	52 (81%)	195 (77%)
– Lost to follow-up (% of all positives)	8 (13%)	32 (13%)
– Already under follow-up (% of all positives)	4 (6%)	26 (10%)
Total requiring assessment (% of all positives)	57 (89%)	204 (81%)
– Contacted (% of total requiring assessment)	42 (74%)	177 (87%)
– Attended (% of all appointments booked before censor date)	32 (89%)	115 (76%)
Commenced on treatment (% of all attended)	20 (62.5%)	16 (13.9%)

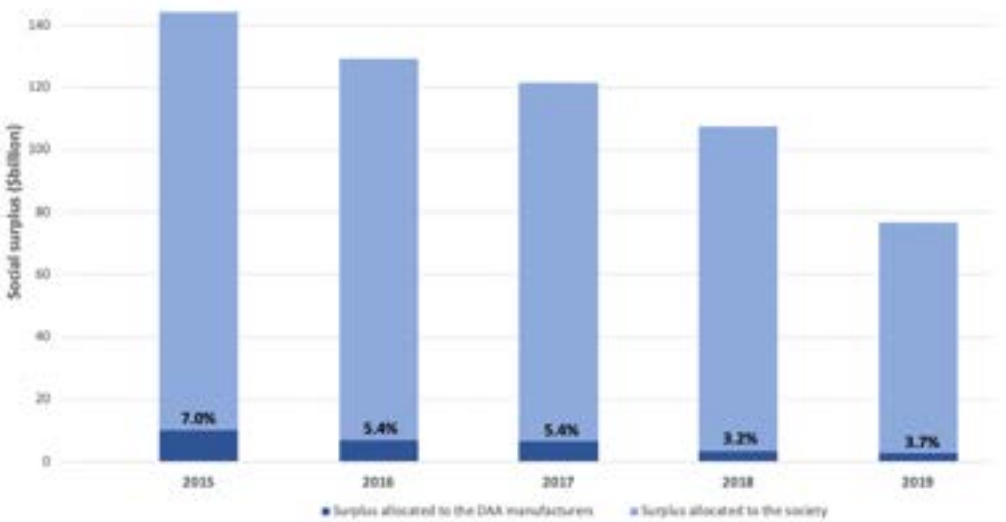
Estimating the economic value allocation of the social surplus generated by the utilization of second-generation direct-acting antivirals for hepatitis C in the United States, 2015–2019

Louis Garrison[1,2], Boshen Jiao[1,3], Zizi Elsisi[1,2], Alon Yehoshua[4], Roy Koruth[4], Bruce Kreter[4], Jens Grueger[2,5]. *[1]University of Washington, United States; [2]VeriTech Corporation, Mercer Island, United States; [3]Harvard School of Public Health, United States; [4]Gilead Sciences, Inc., United States; [5]Boston Consulting Group, United States*
Email: jens.grueger@t-online.de

Background and aims: While the rising costs for innovative medicines are discussed widely, they are rarely put in context of the total social surplus that is generated for health systems and society. Between 2014 and 2019, several innovative direct-acting antiviral therapies (DAAs) were introduced with the potential to cure patients with hepatitis C (HCV). They generate surplus in the form of the value of the health gains for patients as well as the cost-savings for health systems. As an incentive for innovation, manufacturers of patent-protected medicines are rewarded with a share of this social surplus in the form of the revenues that they accrue over the life cycle of a product—from initial launch through eventual patent expiry and perhaps beyond. This analysis focuses on the U.S. during this period and addresses the question: what share of the aggregate economic value generated by DAA utilization from 2015 to 2019 was allocated to manufacturers versus the rest of society?.

Method: This analysis took a national healthcare system perspective. We projected the impact of DAAs on health outcomes and costs compared with the counterfactual scenario using the pre-DAA standard of care (SOC). Analyses are based on CDAF-Polaris database on the utilization of HCV treatments from 2011 to 2019. Projections



Number of patients treated with a DAA who would have been treated with prior SOC	34,627	34,879	35,100	35,285	60,268
Number of patients treated with a DAA who would not have been treated	221,373	196,121	173,900	153,715	134,732
Total number of patients	256,000	231,000	209,000	189,000	195,000
Total sales ($billion)	10.1	6.9	6.5	3.5	2.8
Total surplus ($billion)	144.4	129.3	121.5	107.3	76.8
Share of surplus (%)	7.0%	5.4%	5.4%	3.2%	3.7%

Figure: (abstract: FRI-113).

of the expected patient lifetime quality-adjusted life-years (QALYs) gained and expected patient lifetime medical costs avoided were made using a standard HCV disease progression model of DAA treatment versus the prior SOC as well as versus no treatment. The underlying model has nine health states based on degree of fibrosis and cirrhosis as well as hepatocellular cancer and liver transplantation. The model generated estimates of expected lifetime discounted QALYs and non-DAA costs for a typical (55-year-old) HCV patient. The counterfactual was constructed by extrapolating treatment rates from the period 2008–2011 prior to the adoption of DAAs. Annual QALY gains were valued at $114 k (2× per-capita U.S. GDP in 2015$). All outcomes and costs were discounted at 3%. Estimates for manufacturer revenues for DAAs were based on IQVIA sales data in 2015$.

Results: Of the estimated 1,080,000 patients who received DAAs in 2015–19, the estimated share who would not have been treated (pre-DAA) is 81.5%. They are projected, on average, to gain 4.4 QALYs and save $104,400 in lifetime costs while those who would have been treated gain 1.7 QALYs and save $41,500 in lifetime costs. in the aggregate, those who would not have been treated generate the larger social surplus of $531.8 billion, vs. $47.4 billion for those who would have been treated.

Conclusion: The uptake of DAAs in the US from 2015 to 2019 generated substantial aggregate social surplus, valued at $579.3 billion. Manufacturers had $29.9 billion in sales (2015$) in this period, implying that they were allocated 5.2% of the economic value generated for these cohorts.

FRI-114

Late diagnosis of hepatitis C in Quebec, Canada, 1990–2018: a population-based study

Ana Maria Passos-Castilho[1,2], Donald Murphy[3], Karine Blouin[4], Marina B. Klein[5], Julie Bruneau[6], Andrea Benedetti[7], Jeff Kwong[8], Beate Sander[9,10], Naveed Janjua[11], Christina Greenaway[1,2,12]. *[1]Lady Davis Institute, Jewish General Hospital, Centre for Clinical Epidemiology, Canada; [2]McGill University, Department of Medicine, Canada; [3]Institut National de Santé Publique du Québec, Laboratoire de Santé Publique du Québec, Canada; [4]Institut National de Santé Publique du Québec, Unité sur les Infections Transmissibles Sexuellement et par le Sang, Canada; [5]Research Institute of the McGill University Health Center, Canada; [6]Research Center, Centre Hospitalier de l'Université de Montréal, Canada; [7]School of Population and Global Health, McGill University, Department of Epidemiology, Biostatistics and Occupational Health, Canada; [8]Dalla Lana School of Public Health, University of Toronto, Canada; [9]Toronto General Hospital Research Institute, University Health Network, Canada; [10]Institute of Health Policy, Management and Evaluation, University of Toronto, Canada; [11]BC Centre for Disease Control, Canada; [12]Division of Infectious Diseases, Jewish General Hospital, Canada*
Email: anampassos@gmail.com

Background and aims: Timely diagnosis and treatment of all individuals infected with HCV is needed to prevent poor outcomes such as decompensated cirrhosis (DC), hepatocellular carcinoma (HCC), and liver-related deaths. We estimated annual rates and predictors of late HCV diagnosis in Quebec, Canada.

Method: A population-based cohort of all reported HCV cases in Quebec (1990–2018) were linked to several health administrative databases including the landed immigrant database (1980–2018). People who inject drugs (PWID) and liver related outcomes (DC/HCC) were defined using published algorithms. Missing data were addressed with multiple imputation by chained equations. Late diagnosis was defined as the occurrence of DC or HCC any time before up until 2 years after HCV diagnosis. Annual crude rates of late diagnosis per 100 HCV diagnoses were estimated until 2016 to avoid truncation bias. Rate ratios (RR), yearly percent change, and 95% confidence intervals (CI) were estimated using Poisson regression. Predictors of late diagnosis were analyzed using multiple logistic regression adjusting for demographics, social/material deprivation and comorbidities. Results are shown as adjusted odds ratio (aOR), 95% CI, and p value.

Results: Among 40,667 individuals diagnosed with HCV from 1990 to 2016, 67% were male, with a mean age of 44.2 years (standard deviation 14.9); 56% were born in 1945–1965, 46% were PWID, and 13% immigrants. Overall, 17% of all HCV diagnoses were late, with an increase of 4.5%/year (95% CI, 2.2–6.7, p < 0.001) between 1998 and 2004, 9.0%/year (7.3–10.7, p < 0.001) between 2005 and 2012, and then with a decrease of −9.3%/year (−15.5–3.1, p = 0.001) between 2013 and 2016. The rate of late diagnosis/100 HCV cases was higher among immigrants compared to non-immigrants (20.9 vs. 16.3; RR 1.28, 95% CI 1.18–1.40, p < 0.001) with highest rates among those from Sub-Saharan Africa (25.8; 1.58, 1.22–2.04, p = 0.001). Overall predictors of higher risk of late diagnosis in adjusted analysis included alcohol use disorder (aOR 1.40, 95% CI 1.32–1.47, p < 0.001), being born <1945 compared to >1965 (1.38, 1.29–1.47, p < 0.001), social deprivation (1.12, 1.03–1.23, p = 0.012), male sex (1.11, 1.07–1.14, p < 0.001), and immigrant status (1.10, 1.05–1.16, p < 0.001). Factors associated with a lower risk of late diagnosis included PWID status (0.78, 0.75–0.81, p < 0.001), mental health diagnosis (0.93, 0.89–0.96, p < 0.001), being born in 1945–1965 compared to >1965 (0.94, 0.90–0.98, p = 0.007), and rural residence (0.95, 0.92–0.99, p < 0.008). Among immigrants, those from Sub-Saharan Africa compared to High Income regions (1.40, 1.03–1.92, p = 0.034) and women (1.10, 1.01–1.19, p = 0.023) were at higher risk of late diagnosis.

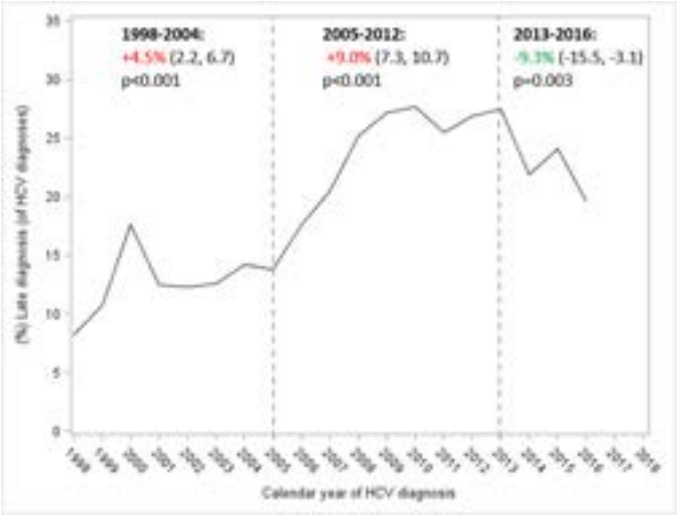


Figure: Prevalence of late diagnosis of hepatitis C in Quebec, Canada, 1990–2018 (yearly change in rate of late diagnosis shown per period as percent with 95% confidence interval and p value).

Conclusion: Older individuals, those with comorbidities, alcohol use disorder, and immigrants should be targeted for HCV screening and treatment to prevent liver-related sequelae.

FRI-115

An international coalition to eliminate hepatitis B virus (ICE-HBV) survey confirms inadequate HBV/HDV screening and diagnosis diminishing elimination targets in resource limited settings

Daryl Lau[1], Anna Kramvis[2], Camila Picchio[3], Kathy Jackson[4], Alice Lee[5], Gail Matthews[6], Jess Howell[7], Carla Coffin[8], Maud Lemoine[9], Peter Revill[10], Mark Sonderup[11,12], Fatou Fall[13], Vonthanak Saphonn[14], Margaret Hellard[15], David Anderson[16], Wendy Spearman[11], Massimo Levrero[17], Capucine Penicaud[18], Manal Hamdy El-Sayed[19]. *[1]Liver Center, Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, United States; [2]Hepatitis Virus Diversity Research Unit, Department of Internal Medicine, University of the Witwatersrand, South Africa; [3]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Spain; [4]Section of Molecular Microbiology, Doherty Institute, Australia; [5]World Gastroenterology Organization, Australia; [6]The Kirby Institute, University of New South Wales, Australia; [7]Department of Gastroeneterology, Burnet Institute, Australia; [8]Cumming School of Medicine, University of Calgary, Canada; [9]Division of Digestive Diseases, Department of Metabolism, Digestion, and Reproduction, Imperial College London, United Kingdom; [10]Department of Microbiology and Immunology, Doherty Institute, Australia; [11]Faculty of Health Sciences, University of Cape Town, South Africa; [12]University of Cape Town Faculty of Health Sciences, Division of Hepatology, Cape Town, South Africa; [13]Dakar University Hospital, Senegal; [14]University of Health Sciences (UHS), Cambodia; [15]Burnet Institute, Australia; [16]Global Health Diagnostics Laboratory, Burnet Institute, Australia; [17]Université Claude Bernard Lyon, Hospital de la Croix-Rousse, France; [18]The Hepatitis Fund, Switzerland; [19]Department of Pediatrics, Ain Shams University, Egypt*
Email: dlau@bidmc.harvard.edu

Background and aims: The availability of diagnostic tools and technologies in resource limited settings (RLS) is critical to achieve the WHO 2030 goal to eliminate hepatitis B virus (HBV) as a public health challenge. HBV/hepatitis Delta virus (HDV) coinfection is associated with rapid liver disease progression and is under-diagnosed. Our objective was to assess the perceived priorities for HBV elimination among healthcare providers and to evaluate the availability of diagnostic tests for HBV and HDV in RLS.

Method: Between Jan–Dec 2022, ICE-HBV launched a global online survey in three languages (English, French, Spanish) to better understand the challenges in delivering HBV care in RLS. The survey had 53 items addressing the priorities to reach the goal for HBV elimination, and the accessibility to diagnostic tests and therapies.

Results: Among the 178 health care worker (HCWs) survey respondents, specialists made up 50%; hepatologists (33%), gastro-enterologists (6.9%), and infectious disease physicians (12.2%). The majority of the respondents worked in sub-Saharan Africa (sSA) (37%), South/South East Asia (SEA) (22%), and Europe (EU) (15%). Increasing HBV screening, diagnosis, and optimizing strategies to prevent mother-to-child-transmission (MTCT) were considered the highest priorities in achieving HBV elimination by 80% of responders. Universal HBV screening of pregnant women at antenatal visit were only routinely practiced in 59% of sSA and 66% of SEA settings. HBsAg ELISA testing was reported to be available in all regions, but in only 45% of sSA settings. Unlike HBsAg ELISA, HBsAg rapid diagnostic tests (RDT) were accessible in >90% of sSA regions. Similarly, HBV-DNA quantification with PCR were available in >80% of SEA and EU regions but only in 54% of sSA settings. More than 55% of all responders strongly agreed that an affordable point-of-care (POC) HBV DNA test is necessary in their locations if HBV DNA is in the treatment algorithm. HDV serological (36%) and molecular (34%) testing were the least frequently available diagnostic tests and were particularly low in sSA (Figure). Only 20% of all the respondents reported routine screening for anti-HDV among HBsAg-positive persons and the rates were even lower in sSA (3%) and SEA (12%). HDV-RNA PCR testing was least available in sSA (13%), SEA (20%), and South America (30%). Seventy-one (45%) of respondents reported inadequate training and resources available to HCWs for hepatitis B management in their settings.

Conclusion: Increased HBV screening and optimizing strategies to prevent MTCT were considered the highest priorities in achieving the WHO 2030 goal for HBV elimination. sSA has high HBV prevalence

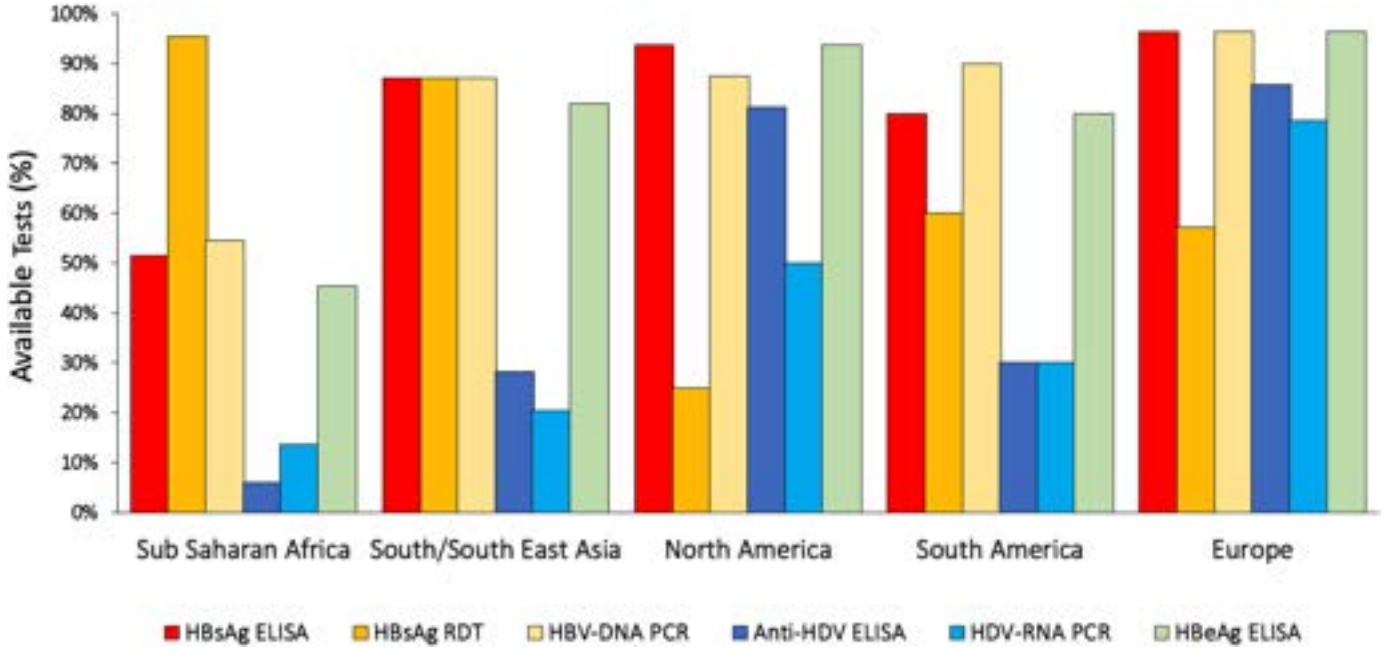

Figure: (abstract: FRI-115): Reported available HBV and HDV diagnostic tools in resource limited settings by regions.

but least access to essential HBV screening assays. While effective HDV therapies are becoming available, RLS are not equipped to appropriately screen and diagnose HBV/HDV coinfection, particularly in regions where HDV infection is prevalent. Improved HBV and HDV screening strategies, resources to increase antenatal HBV screening of pregnant women and training for HCWs are urgently needed in RLS to accelerate progress towards the WHO elimination targets.

FRI-116

Population adjusted prevalence of hepatitis delta virus in 21 countries and territories

Devin Razavi-Shearer[1], Kathryn Razavi-Shearer[1], Homie Razavi[1].
[1]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: drazavishearer@cdafound.org

Background and aims: The hepatitis delta virus (HDV), a satellite RNA virus, requires the hepatitis B virus (HBV) for assembly and propagation. Individuals co-infected with HDV progress to advanced liver disease at a faster rate than HBV mono-infected. Recent studies have estimated the global prevalence of anti-HDV among the HBV-infected population at 5–15%. This study aimed to better understand HDV prevalence at the population level in 21 countries and territories.
Method: A comprehensive literature review was conducted for anti-HDV and HDV-RNA-positive prevalence for all countries/territories. Virtual meetings were held with experts from each setting to discuss the literature search findings, collect unpublished data/reports, and weight data for patient segments and regional heterogeneity to estimate the adjusted prevalence in the HBV-infected population. The findings were then combined with The Polaris Observatory HBV data to estimate the overall anti-HDV and HDV-RNA prevalence in each country/territory at the population level.
Results: After adjusting for geographical distribution, disease stage and special populations, the anti-HDV prevalence among the HBsAg+ population changed from the literature estimate in all but three countries. The highest anti-HDV prevalence was in Israel at 6.8% (Table 1). However, once adjusted for HBV+ population and HDV-RNA+, China had the highest absolute number of HDV-RNA+ cases.
Conclusion: We found significantly lower HDV prevalence than previously reported as prior meta-analyses primary focused on studies conducted in groups/regions that have a higher probability of being positive. When available data were weighted appropriately, the anti-HDV prevalence decreased by >50% in many countries. The implementation of reflex testing would result in more accurate estimates while allowing earlier linkage to care for HDV-RNA+ individuals. The burden of reflex testing would be limited as it would only screen HBV+ cases. Cost effectiveness studies of reflex testing will be needed in East Asia where the hepatitis B prevalence is high and HDV prevalence is relatively low.

FRI-117

Prevalence and incidence of delta hepatitis in HIV-HBV coinfected patients in the Dat'AIDS cohort

Figure: (abstract: FRI-116).

incidence and risk factors in a large cohort of people living with HIV (PLWH).

Method: A retrospective analysis was performed in the DatAIDS cohort, a nationwide cohort representing roughly half of PLWH in-care in France. Demographics, HBV, HDV and HCV serology and individual risk factors were collected. HDV prevalence was determined in patients with chronic hepatitis B infection (CHB) and a known HDV serology result. HDV incidence was determined in patients with at least one consecutive serology following a first negative one.

Results: HBV serology was available in 62473 of 74550 PLWH (83.8%), among whom 3737 had CHB (6.0%). HDV serology was available in 2406 patients with CHB (64.4%), of whom 376 had a positive HDV serology (HDV prevalence rate 15.6%). Among HIV-HBV coinfected patients, HDV prevalence rate reached 56.5% in IV drug users (IVDU), 38.2% in patients from Eastern Europe and 42.4% in patients coinfected with HCV. Among HDV-infected patients, blood contact was reported more frequently in patients born outside Africa than in patients from Africa (70.8% vs 10.0%, $p < 0.001$). In a multivariable analysis, male gender (OR 1.5, $p = 0.02$), HIV risk factor IVDU (OR 7.0, $p < 001$) or heterosexual sex (OR 1.8, $p = 0.02$), country of origin in Eastern Europe (OR 3.2, $p = 0.002$) or in Africa (OR 2.8, $p < 0.001$) and HCV coinfection (OR 2.9, $p < 0.001$) were positively associated with HDV infection. Conversely, age at HBV diagnosis (OR 0.96/year, $p < 0.001$) and duration of HBV infection (OR 0.84/year, $p < 0.001$) were negatively associated with HDV infection. HDV serology was positive at first determination in 349 patients (prevalent HDV 92.8%) while 27 patients acquired HDV during follow-up (incident HDV 7.2%). Repeated HDV serology results were available in 1827 patients for a total follow-up of 21006 patient-years (PY). HDV incidence rate was 0.12/100 PY (95%CI 0.08–0.18)-see Figure. For incident HDV infections, the median time separating HBV and HDV diagnoses was 11.4 years and these patients had similar demographics and characteristics than patients with prevalent HDV apart from older age at HDV diagnosis (48.0 years vs 37.3 years, $p < 0.001$).

Conclusion: HDV coinfection is common in HIV-HBV coinfected patients in France. Most HDV infections are prevalent infections, but some incident infections occurred during follow-up indicating that HDV transmission is still present in this population. Patients born in Africa or in Eastern Europe, IVDU and HBV-HCV coinfected patients are high-risk populations for HDV infection and should be targeted for systematic screening.

FRI-118

Patients with persistently abnormal liver biochemistry are under-investigated and can be rapidly identified using a novel case-finding database

Almuthana Mohamed[1], Christina Owen[1], Sarah Gormley[1], Waqas Khan[1], Emma Wesley[1], Timothy Jobson[1]. [1]*Musgrove Park Hospital, Somerset NHS Foundation Trust, Gastroenterology, Taunton, United Kingdom*
Email: almuthana700@gmail.com

Background and aims: Chronic liver disease (CLD) continues to increase in prevalence. However, it remains underdiagnosed, with many patients missing opportunities for treatment. Guidelines state that patients with persistently abnormal liver chemistry should have a non-invasive liver screen (NILS) to identify potentially treatable causes of CLD. Unfortunately, in practice, these guidelines are often

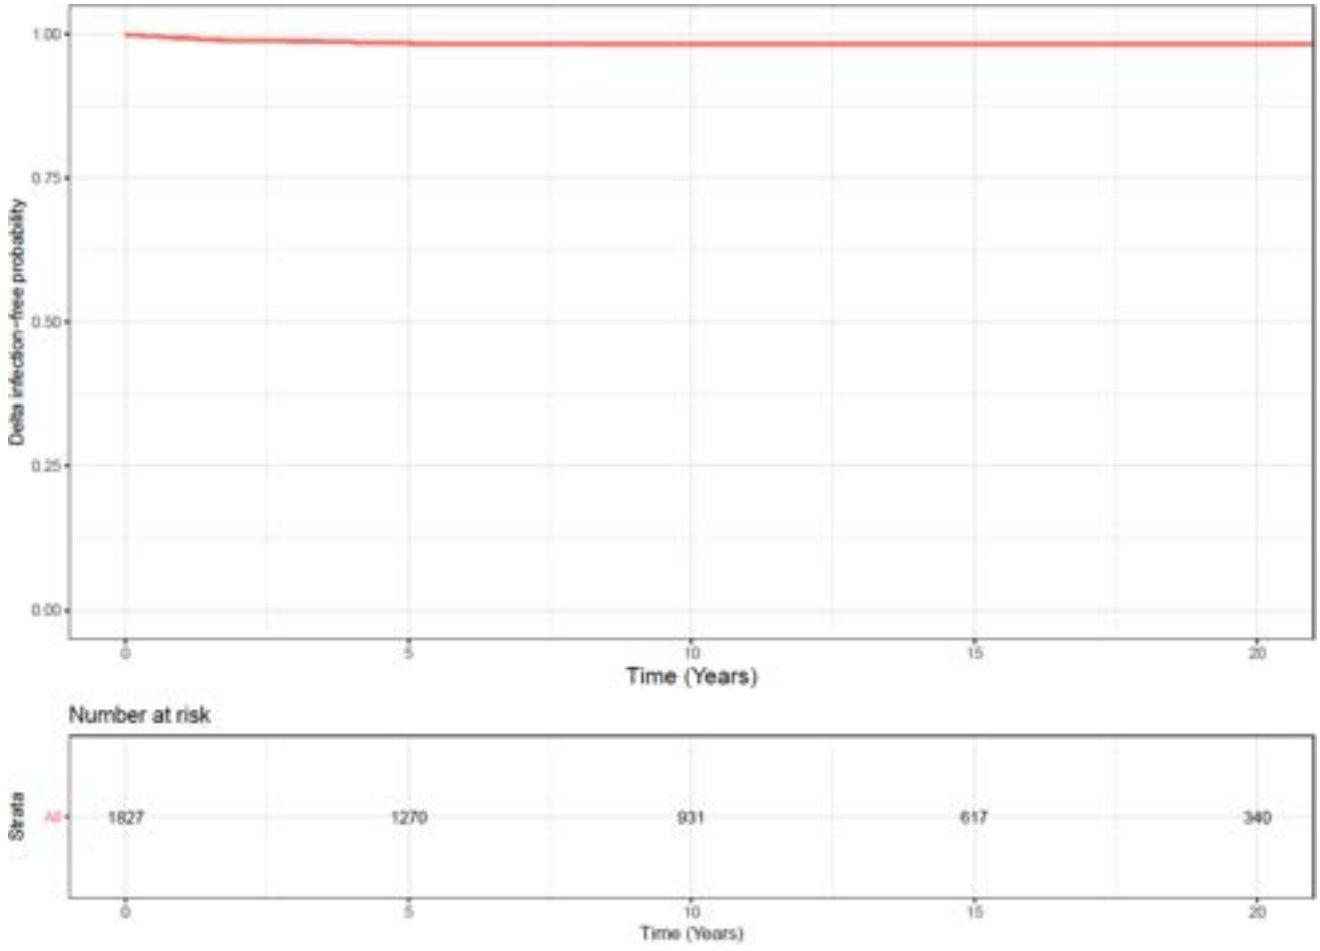

Figure: (abstract: FRI-117).

not followed. We have developed a novel case-finding database in Somerset, UK, currently with data on 560,000 individuals. We used this system to identify patients with persistently abnormal liver chemistry and quantify the completeness of subsequent investigation.

Method: Using data up to 31/12/2020, the case finding database was configured to identify patients between the ages of 30 and 75 with persistently abnormal liver chemistry (last ALT >40 IU/L and abnormal for at least the preceding 90 days). Within that cohort we further risk stratified to identify those with more concerning results (ALT >80; ALP >90; ALP >130; both ALT >80 and ALP >130). The number of patients in each group with a complete 'basic' NILS (defined as viral hepatitis B, C; autoimmune screen; ferritin; AST) was determined. The screen was considered complete if these tests were found within a six-month period (based on ferritin date as the commonest test). A sample of cases was reviewed manually to confirm the accuracy of the results. We also assessed which age cohorts were more likely to have persistently abnormal liver chemistry and if there was any difference in age and likelihood of having had the 'basic' NILS.

Results: 8224 males and 2537 females were identified as having persistently elevated liver biochemistry. Only 11% of males and 16% of females had a complete 'basic' NILS using our definition. 5% of men and 6% of women were deceased, with no difference in the investigation rate. Persistently abnormal LFTs were most likely to be identified in the age 50–59 cohort for both men and women. There was no significant difference in the likelihood of having a NILS when different age groups were compared. In the higher risk group (abnormal tests at least 90 days, last ALT >80, last ALP >130), there were a total of 547 patients identified, of whom 442 had never had a NILS (81%). The slight trend towards improved investigation in higher-risk groups was not statistically significant (Figure 1).

Conclusion: Our data confirm that patients with persistently abnormal liver chemistry are frequently not investigated, with a high likelihood of missed opportunities for treatment. Our novel case-finding database can rapidly identify in seconds nearly 9000 individuals who may benefit from further investigation. Furthermore, the system can be used to easily risk stratify these patients for more targeted interventions. Further work is needed to implement processes to identify those needing specialist treatment.

FRI-119

Care cascade for children with hepatitis C virus exposure in the United States and implications of early ribonucleic acid testing

Megan Curtis[1,2,3,4], Benjamin Buzzee[5], Benjamin Linas[4,5], Andrea Ciaranello[1,3], Rachel Epstein[4,5]. *[1]Massachusetts General Hospital, Boston, United States; [2]Brigham and Women's Hospital, United States; [3]Harvard Medical School, Boston, United States; [4]Boston University School of Medicine, United States; [5]Boston Medical Center, United States*

Email: meg.rose.curtis@gmail.com

Background and aims: An estimated 3.26 million children and adolescents are living with hepatitis C virus (HCV) globally. The World Health Organization (WHO) recommends simplification of HCV care pathways to overcome low rates of detection and linkage among children with HCV. The United States (US) Centers for Disease Control and Prevention (CDC) has proposed simplified draft recommendations for ribonucleic acid (RNA) testing at ≥2–6 months for infants who are perinatally exposed to HCV. Current US guidelines for perinatally exposed infants recommend antibody testing at age 18 months. However, this approach is associated with high rates of loss to follow-up. Our objective was to characterize infant HCV testing patterns, linkage to care, and possible impact of the CDC draft recommendations.

Method: From TriNetX, a network of electronic health record data with approximately 90 million individuals from US healthcare organizations, we identified a cohort of children born 2010–2020 with an International Classification of Diseases (ICD) code for exposure to viral hepatitis (Z20.5). We defined presumed HCV exposure by excluding children with only hepatitis B virus testing. We calculated the number of children with any testing, complete testing, HCV infection, and HCV treatment. Testing was considered complete if one of the following criteria were met: negative antibody test at any age, positive antibody test at 18 months or greater followed by at least 1 RNA test, two positive RNA tests, or two negative RNA tests.

Results: Our cohort included 8517 children with presumed HCV exposure. Of those, 3899 (46%) had any HCV testing: 2041 (52%) had antibody testing, 980 (25%) had RNA testing, and 878 (23%) had both. Among those with complete testing, 125 (4%) children were identified with HCV infection, of whom 9 (7%) were linked to treatment. Of those with incomplete testing, 51 children had one positive RNA test

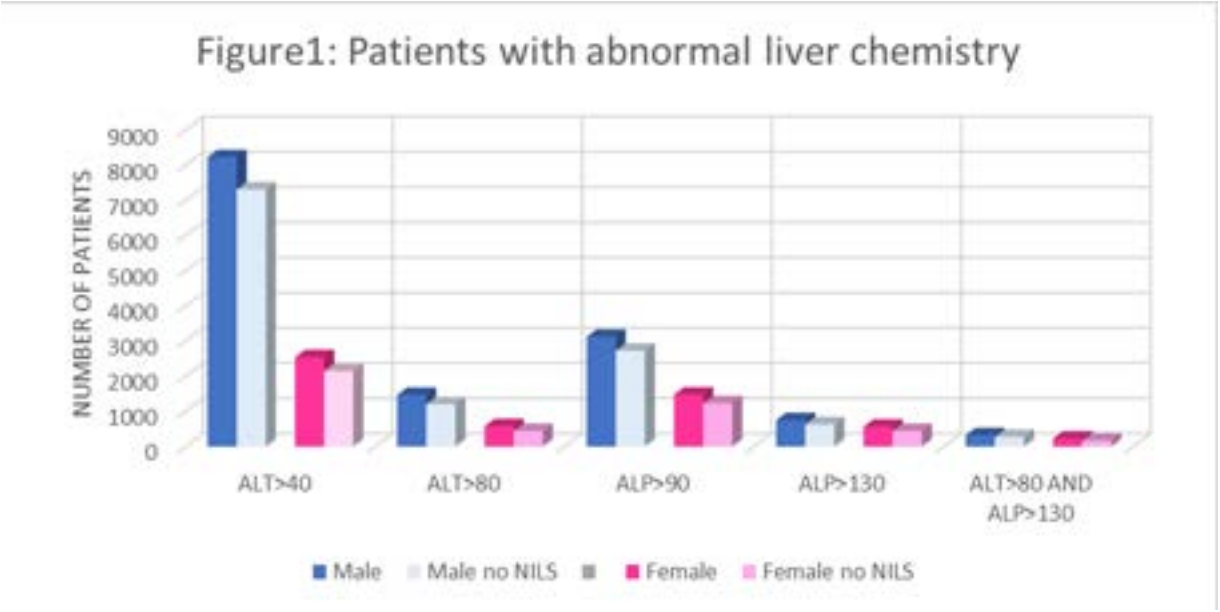

Figure: (abstract: FRI-118).

with no follow-up testing. These children would have been identified for early linkage by CDC draft recommendations but were lost to follow-up under current guidelines for antibody testing at 18 months.

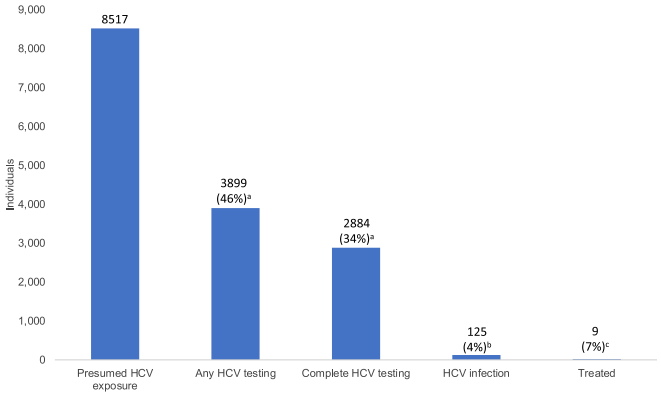

Figure: Current testing and treatment rates for children with presumed HCV exposure in the United States.
Percentage of total with HCV exposure.
Percentage of those with complete HCV testing.
Percentage of those with HCV infection.

Conclusion: Fewer than half of children identified with ICD codes for presumed HCV exposure in this cohort were tested, and very few children with HCV were treated. This analysis shows that some physicians are already offering early HCV RNA testing in exposed infants, and that this could capture more cases when compared to waiting until 18 months to complete antibody testing per current guidelines. The CDC's draft recommendation for RNA testing could improve identification of perinatal HCV and advance efforts towards HCV elimination in alignment with WHO goals.

FRI-120

Opt-out testing for hepatitis B and C infections in adults attending the emergency department of a London Hospital

Jingwei Zeng[1,2], Douglas Macdonald[3], Russell Durkin[4], Dianne Irish[1], Jennifer Hart[1], Tanzina Haque[1]. *[1]Royal Free Hospital, Department of Virology, London, United Kingdom; [2]Royal Free London NHS Foundation Trust, Department of Virology, London, United Kingdom; [3]Royal Free Hospital, Department of Hepatology, London, United Kingdom; [4]Royal Free Hospital, Emergency Department, London, United Kingdom*
Email: thaque@nhs.net

Background and aims: The National Health Service in England commissioned opt-out testing in all London emergency departments (ED) to allow early identification and management of hepatitis B (HBV) and hepatitis C virus (HCV) infection in patients unaware of their HBV or HCV status. This retrospective study evaluates the effectiveness of this new ED hepatitis virus screening programme at the Royal Free Hospital in northwest London.
Method: All adults over the age of 16 undergoing blood tests in the ED at the Royal Free Hospital were tested for HBV surface antigen (HBsAg) and anti-HCV IgG antibody unless they opted out. A streamlined screening protocol was developed with input from ED, Virology and Hepatology departments to ensure follow-up of patients with positive results. Data was collected from the 12th of April 2022 to the 22nd of August 2022.
Results: Of 11,215 patients tested for HCV, 164 patients were found to be anti-HCV IgG positive (Table 1), giving a seroprevalence rate of 1.46%. 69% of HCV seropositive patients were male and 31% were female (Odds ratio (OR) 2.54; 95% confidence interval (CI) 1.82–3.54). 52 of the HCV IgG positive patients did not have previous HCV serology results on our system. In total, 23 of the HCV IgG positive patients were HCV RNA positive (RNA seroprevalence 0.2%), and 17 of those were new diagnoses of HCV viraemia. The most common HCV genotype was genotype 1a (39%), followed by genotype 3a (30%) and genotype 1b (13%); genotypes 4a and 4v constituted 4% each. At the time of this study, 14 patients (82%) with new diagnosis of HCV were contacted by the Hepatology team; median time to the first recorded attempted contact was 4 days (range 2 to 43 days) and 5 patients have been started on treatment. For HBV screening, 82 out of 11,192 patients tested were found to be HBsAg positive (prevalence 0.73%; male 55% and female 45%; OR 1.38; 95% CI 0.89–2.13), including one patient who presented acutely with a positive HBV core IgM. 39 of the HBsAg positive patients were previously unknown to us; of these, 9 had an HBV viral load of >2000 IU/ml, including 3 patients with

	Anti-HCV IgG	HCV RNA	HBsAg	HBeAg	Anti-HBe IgG	HBV DNA	Anti-HDV Antibody
Patients Tested	11, 215	161	11, 192	82	82	40	39
Positive	164	23	82	4	78	37	1
Sex							
Male	113	15	45	3	42	18	0
Female	51	8	37	1	36	19	1
Age							
16-35	11	3	10	0	10	4	0
36-55	61	9	34	1	33	19	0

Table: (abstract: FRI-120).

positive HBV e antigen (HBeAg) and one patient with hepatitis D virus (HDV) co-infection (Table 1). 38 (97%) of these new patients were contacted by the Hepatology team during the study period.
Conclusion: Opt-out screening of HBV and HCV in ED is effective at detecting previously unknown cases of infection and helps to identify patients who needed a link to care. HCV RNA prevalence was lower in our study at 0.21%, compared with RNA prevalence of 0.93% in a similar study conducted at our hospital in 2015 (Cieply et al., 2019), despite a similar HCV IgG seroprevalence (1.46% vs 1.63%).

FRI-121

Estimation of prevalence of chronic HCV infection in EU/EEA countries using multiparameter evidence synthesis

Ilias Gountas[1], Christos Thomadakis[1], Erika Duffell[2], Konstantinos Gountas[1], Benjamin Bluemel[2], Thomas Seyler[3], Filippo Pericoli[3], Dominique Van Beckhoven[4], Els Plettinckx[4], Thomas Vanwolleghem[5,6], Tonka Varleva[7], Diana Nonkovic[8], Mirjana Lana Kosanovic Licina[9], Tatjana Nemeth-Blazic[10], Fani Theophanous[11], Peer Brehm Christensen[12], Susan Cowan[13], Kristi Rüütel[14], Cécile Brouard[15], Ruth Zimmermann[16], Sandra Dudareva[16], Georgia Nikolopoulou[17], Zsuzsanna Molnár[18], Emese Kozma[18], Magnús Gottfredsson[19,20], Niamh Murphy[21], Renate Putnina[22], Ligita Jancoriene[23], Carole Devaux[24], Tanya Melillo[25], Marc van der Valk[26], Eline Op de Coul[27], Hilde Klovstad[28], Robert Neil Whittaker[28], Małgorzata Stępień[29], Magda Rosinka[29], Odette Popovici[30], Maria Avdicova[31], Jana Kerlik[31], Mojca Maticic[32], Asuncion Diaz[33], Julia del Amo[34], Georgios Nikolopoulos[1]. *[1]University of Cyprus, Medical School, Cyprus; [2]European Centre for Disease Prevention and Control, Sweden; [3]European Monitoring Centre for Drugs and Drug Addiction, Portugal; [4]Sciensano, Department of Epidemiology and Public Health, Belgium; [5]University of Antwerp, Viral Hepatitis Research Group, Laboratory of Experimental Medicine and Pediatrics, Belgium; [6]University Hospital Antwerp, Department of Gastroenterology and Hepatology, Belgium; [7]Medical University, Pleven, Bulgaria; [8]Teaching Institute of Public Health Split and Dalmatia County, University of Split, Department of Health Studies, Croatia; [9]Andrija Stampar Teaching Institute of Public Health, Communicable Disease Epidemiology Department, Croatia; [10]Croatian Institute of Public Health, Croatia; [11]Ministry of Health, Cyprus, Cyprus; [12]Odense University Hospital, Department of Infectious Disease, Denmark; [13]Statens Serum Institut, Department of Infectious Disease Epidemiology and Prevention, Denmark; [14]National Institute of Health Development, Estonia, Infectious Diseases and Drug Monitoring Department, Estonia; [15]Santé Publique France, Infectious Diseases Direction, HIV, Hepatitis B/C, STI Unit, France; [16]Robert Koch Institute, Germany; [17]Hellenic National Public Health Association, Greece; [18]National Public Health Center, Hungary, Hungary; [19]University of Iceland, Faculty of Medicine, School of Health Sciences, Iceland; [20]Landspitali University Hospital, Iceland; [21]Health Protection Surveillance Centre, Ireland, Ireland; [22]Center for Disease Control and Prevention, Latvia, Latvia; [23]Vilnius University, Clinic of Infectious Diseases and Dermatovenerology, Institute of Clinical Medicine, Medical Faculty, Lithuania; [24]Luxembourg Institute of Health, Department of Infection and Immunity, Luxembourg; [25]Ministry for Health, Health Promotion and Disease Prevention, Malta, Department for Health Regulation, Malta; [26]University of Amsterdam, Department of Infectious Diseases, Amsterdam Infection and Immunity Institute (AIandII), Amsterdam UMC, Netherlands; [27]National Institute for Public Health and the Environment (RIVM), Netherlands; [28]Norwegian Institute of Public Health, Section for Respiratory, Blood-Borne and Sexually Transmitted Infections, Department of Infection Control and Vaccines, Norway; [29]National Institute of Public Health NIH-National Research Institute, Poland, Department of Infectious Diseases Epidemiology and Surveillance, Poland; [30]National Institute of Public Health Romania, National Centre for Surveillance and Control of Communicable Diseases, Romania; [31]Regional Authority of Public Health Banska Bystrica, Slovakia, Slovakia; [32]University of Ljubljana, Clinic for Infectious Diseases, University Medical Centre Ljubljana and Faculty of Medicine, Slovenia; [33]National Centre of Epidemiology, Carlos III Health Institute, CIBER in Infectious Diseases (CIBERINFEC), Spain; [34]Ministry of Health, Spain, Division for HIV, STI, Viral Hepatitis and Tuberculosis Control, Spain*
Email: nikolopoulos.georgios@ucy.ac.cy

Background and aims: In Europe, hepatitis C virus (HCV) infection affects both the general population and specific groups, including people who inject drugs (PWID). Although countries have HCV prevalence estimates in the general population and/or specific population groups, those alone cannot be directly used to obtain a national estimate. Our aim was to estimate the national prevalence of chronic HCV infection (CHCV) and the contribution of injection drug use in the European Union (EU)/European Economic Area (EEA) countries in 2019.
Method: Multi-parameter evidence synthesis (MPES) is an approach that combines simultaneous information to derive an overall estimate. MPES was applied to each country to obtain national estimates. The overall CHCV prevalence (π) in the population was defined as: $\pi = \pi_{rec}\rho_{rec} + \pi_{ex}\rho_{ex} + \pi_{non}\rho_{non}$. The parameters π_{rec}, π_{ex} and π_{non} represent CHCV prevalence among recent PWID (injecting behavior in the last 12 months), ex-PWID, and non-PWID, respectively, while the parameters ρ_{rec}, ρ_{ex} and ρ_{non} represent the proportion of recent, ex-PWID, and non-PWID in the overall population. π_{rec} was provided by the ECDC (European Centre for Disease Prevention and Control) hepatitis national focal points (NFP), the EMCDDA (European Monitoring Centre for Drugs and Drug Addiction) databases or the published literature. CHCV prevalence among ever PWID was needed to indirectly calculate π_{ex} and was obtained through the EMCDDA databases or the NFP. π_{non} was obtained from an ECDC review or by the NFPs. A multi-state Markov model was used to estimate the number of recent and ex-PWID. Adjustment for treatment with direct-acting antivirals (DAAs) was made when appropriate. The national estimates were combined to obtain regional estimates. NFPs from 26 EU/EEA countries provided feedback.
Results: The overall CHCV (HCV RNA positive) prevalence in EU/EEA countries at the end of 2019 was 0.54% (95% credible interval-CrI: 0.50%, 0.59%). The highest and lowest CHCV prevalence were observed in the East (0.89%; 95% CrI: 0.82%, 0.96%) and the West (0.26%; 95% CrI: 0.20%, 0.35%) of EU/EEA. On country level, the Netherlands (0.04%), Slovenia (0.07%), and Iceland (0.1%) had the lowest CHCV prevalence. The highest CHCV prevalence was estimated in Romania (2.26%) and Estonia (1.71%). Still, the majority of the EU/EEA countries have a CHCV prevalence in 2019 of less than 1%. The model estimates that 37.6% (95% CrI: 35.1%, 40.3%) of the 2019 CHCV prevalence in EU/EEA countries is associated with injection drug use.
Conclusion: The overall CHCV prevalence among EU/EEA is relatively low but substantial part of the CHCV burden is due to injection drug use. Countries in the east of the EU have the highest CHCV prevalence. Further efforts to monitor, prevent, and control CHCV, especially in this region and among PWID, are needed.

FRI-122

One step closer to the goal: mobile InfoHep centre offering detection, protection, prevention and treatment/linkage-to care services in Croatian penalty institutions

Tatjana Reic[1], Magda Pletikosa Pavic[2], Diana Nonkovic[2], Ana Visic[1], Anna Mrzljak[3]. *[1]Croatian Society for the Liver Diseases "Hepatos", Croatia; [2]Teaching Institute for Public Health Split-Dalmatia County, Croatia; [3]University Hospital Center Zagreb, Croatia*
Email: tatjana@hepatos.hr

Background and aims: In Croatia, during the COVID-19 pandemic, activities related to the prevention, testing, and treatment of viral hepatitis in penalty institutions were significantly limited. Given the high HCV prevalence in incarcerated settings, screening and planning further treatments is highly important. Aiming to provide linkage-to-

care services, NGO Hepatos implemented an HCV pilot project within Croatian penalty institutions.

Method: Hepatos has been providing services within the penalty system since 2009 as the only organization in the Western Balkans with a FibroScan® device as part of the Mobile InfoHep Center (MIHC) clinic. In cooperation with the Croatian Gastroenterological Society and Public Health Institute Split-Dalmatia County, an 18-month (Jun 2021–Dec 2022) project was implemented offering services to the 7 Croatian penalty institutions. Services included: screening, HCV and/or HIV testing, on-spot liver examination by FibroScan®, consultation, and referral of HCV+ prisoners to local specialists for the diagnostic workup necessary for the DAA approval by the Croatian Health Insurance Fund. The Ministry of Justice of the Republic of Croatia granted consent for the project.

Results: Linkage-to-care services were offered to 368 prisoners (287 male and 81 female). The response rate was 85%, with 313 prisoners (251 male and 62 female). Personal issues were the main reasons for the drop-out. 847 MIHC services included 313 hepatitis counseling, 130 HCV and 69 HIV testing, 299 on-site liver exams by FibroScan®, and 36 referrals to further diagnostic workup. In total, 2.2% of prisoners reported previous/current HCV infection. Out of the tested, 19 (14.6%) prisoners were HCV positive, and all were HIV negative. The mean liver stiffness measurement (LMS) and controlled attenuation parameter (CAP) were 6.15 ± 3.97 kPa and 264.99 ± 57.1 dB/m. Most prisoners (55.9%) had no fibrosis, whereas stage F1 to F4 was detected in 24.7%, 12%, 5%, and 2.3% of prisoners, respectively. FibroScan® was performed in 17 out of 19 HCV+ prisoners. Among HCV+ prisoners, fibrosis stage distribution (F1-4) was 35.3%, 29.4%, 17.6%, and 11.8%, respectively. The LMS was significantly higher in HCV+ than in HCV- prisoners (10.97 ± 11.07 kPa vs. 6.27 ± 3.41 kPa, p = 0.001), whereas CAP did not differ. All HCV+ prisoners and HCV- prisoners (n = 17) with advanced fibrosis were referred to liver specialists.

Conclusion: The referral of prisoners to treating physicians represents a humble but vital contribution to the WHO's goal of HCV elimination. NGOs, medical experts and governmental bodies included in multi stakeholder's approach, through the Force of Four services (detection, protection, prevention, and treatment) within penalty institutions, may add one step closer. This linkage-to-care model brings change to HCV+ prisoners as it ensures that no one is left behind on our road to HCV elimination.

FRI-123

Late presentation of chronic hepatitis C for care in Georgia: data from the national hepatitis C elimination program, 2016–2021

Tengiz Tsertsvadze[1,2], Nikoloz Chkhartishvili[1], Shaun Shadaker[3], Akaki Abutidze[1,2], Lali Sharvadze[2,4], Amiran Gamkrelidze[5], Irina Tskhomelidze[6], Senad Handanagic[3], Tamar Gabunia[7]. [1]*Infectious Diseases, AIDS and Clinical Immunology Research Center, Georgia;* [2]*Ivane Javakhishvili Tbilisi State University, Georgia;* [3]*Centers for Disease Control and Prevention, Division of Viral Hepatitis, National Center for HIV, Hepatitis, STDandTB Prevention, Atlanta, United States;* [4]*Hepatology Clinic HEPA, Georgia;* [5]*National Center for Disease Control and Public Health, Georgia;* [6]*The Task Force for Global Health, Georgia;* [7]*Ministry of IDPs from the Occupied Territories, Labour, Health and Social Affairs of Georgia, Georgia*

Email: tt@aidscenter.ge

Background and aims: Timely diagnosis and treatment of hepatitis C reduces liver-related morbidity and mortality as well as prevents onward transmission of the virus. We aimed to assess trends in late presentation for hepatitis C care in Georgia since the launch of the national hepatitis C elimination program.

Method: Data were extracted from the national hepatitis C elimination program database. Analysis included treatment-naïve persons with chronic hepatitis C enrolling in the elimination program during January 1, 2016 to December 31, 2021. Late presentation was defined as significant fibrosis assessed by either FIB-4 score >3.25 or transient elastography >9.5 kPa. Trends were assessed using Kendall Tau-B test. Comparisons between population characteristics for patients with and without late presentation were tested using Pearson's Chi-square test.

Results: Among 72,187 persons who enrolled in the elimination program during the study period, 55,822 (77.3%) were men and 41,057 (56.9%) were in the age category of 40–59 years. A total of 19,842 (27.5%) met criteria for late presentation. The rate of late presentation declined from 30.6% in 2016 to 24.3% in 2020 and then increased to 29.0% in 2021 (p for trend <0.0001). Rates of late presentation increased with age, from a low of 2.7% in those aged 18–29 years to a high of 50.2% among people aged ≥60 years (p < 0.0001). Women had a higher percentage of late presentation 28.8% vs. 27.1%, p < 0.0001. Women were the only population sub-group with no statistically significant changes in late presentation over the study period (from 29.9% in 2016 to 31.2% in 2021, p for trend = 0.41). Higher percentages of late presentation were observed among: alcohol consumers (32.2% vs. 23.1%, p < 0.0001), people with BMI ≥25 (29.8% vs. 19.4%, p < 0.0001), and those with diabetes mellitus (48.1%

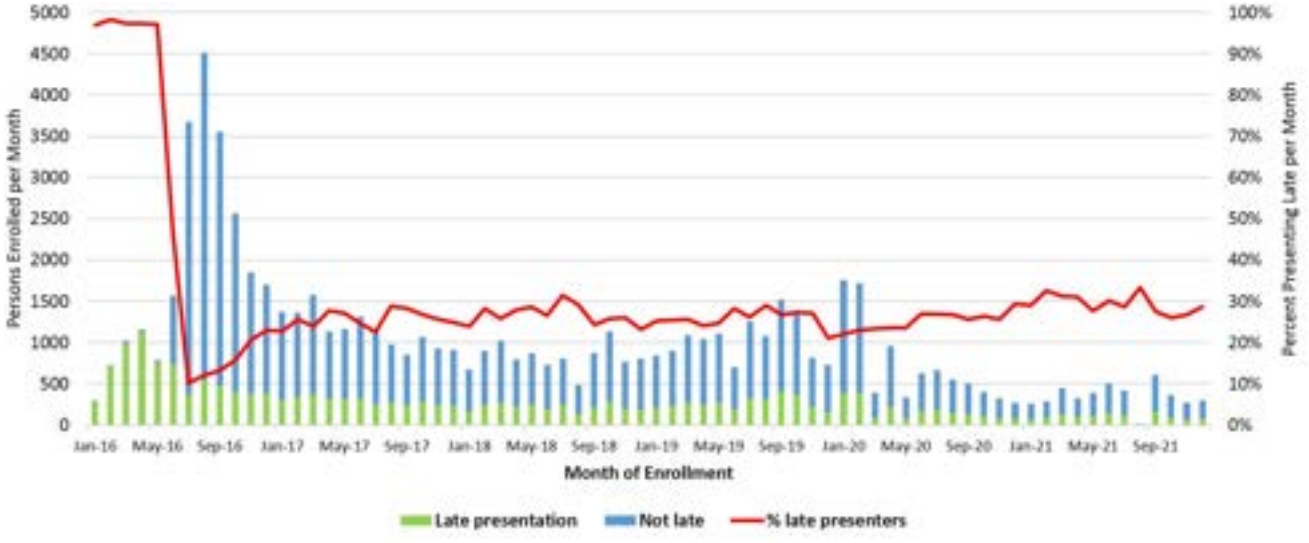

Figure: (abstract: FRI-123): Trends in late presentation by month of enrolment, Jan 2016–Dec 2021.

vs. 24.7%, p < 0.0001). Incarcerated persons had a lower percentage of late presentation (18.0% vs. 27.0%, p < 0.0001). No statistically significant differences were found among those reactive for hepatitis B surface antigen (24.5% vs. 25.7%, p = 0.28).

Conclusion: Despite statistically significant changes in percentages among sub-groups and trend over time, late presentation for hepatitis C care remains a significant problem emphasizing a need for improving testing and linkage to care. Targeted interventions among women, older people, alcohol consumers and those with metabolic disorders can reduce late presentation.

FRI-124

The impact of hepatitis D virus infection on health-related quality of life and fatigue in patients untreated for HDV: descriptive results from a cross-sectional study across Italy, Germany, Spain and the US

Pietro Lampertico[1,2], Robert G. Gish[3], Nancy S. Reau[4], Heiner Wedemeyer[5], Maria Buti[6], Ankita Kaushik[7], Laura Mirams[8], Hilary Ellis[8], Teresa Taylor-Whiteley[8], Alon Yehoshua[7]. *[1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Division of Gastroenterology and Hepatology, Milan, Italy; [2]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, Milan, Italy; [3]Hepatitis B Foundation, Doylestown,*

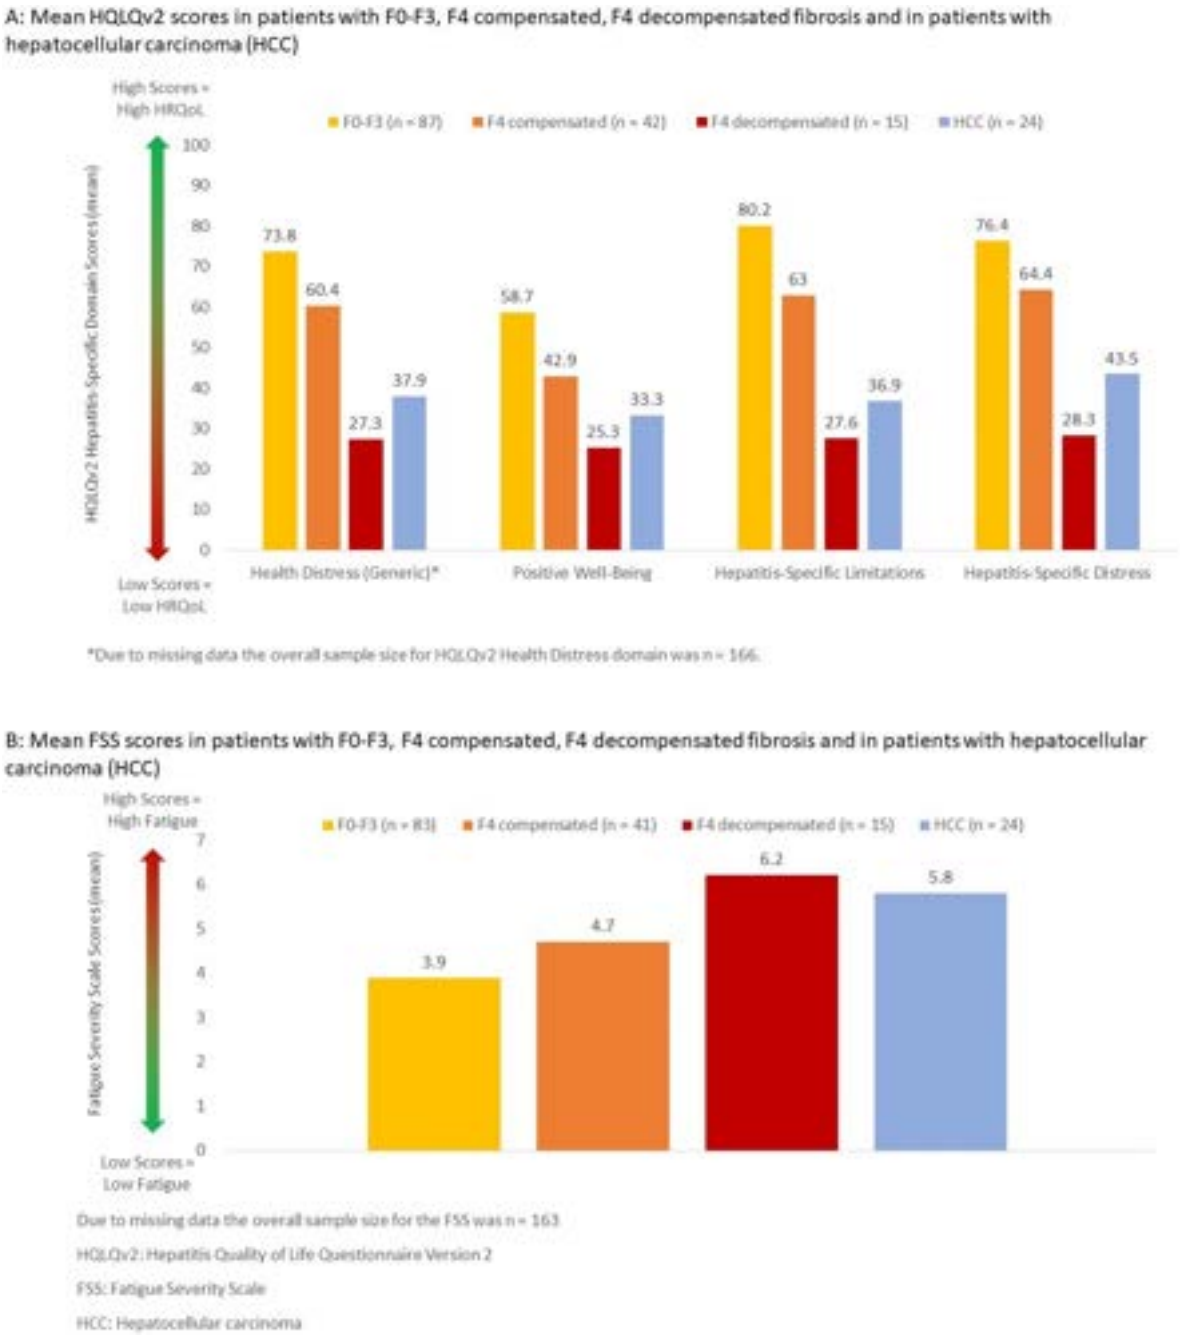

Figure: (abstract: FRI-124).

United States; [4]Rush Medical College, Department of Internal Medicine, Division of Digestive Diseases and Nutrition, Chicago, United States; [5]Hannover Medical School, Department of Gastroenterology, Hepatology, and Endocrinology, Hannover, Germany; [6]Hospital Universitario Valle Hebron and Ciber-ehd del Instituto Carlos III, Liver Unit, Barcelona, Spain; [7]Gilead Sciences, California, United States; [8]Adelphi Real World, Macclesfield, United Kingdom
Email: laura.mirams@adelphigroup.com

Background and aims: Hepatitis D virus (HDV) is associated with accelerated progression to advanced liver disease compared to mono-infection with hepatitis B (Fattovich, et al. 2000). Poorer overall prognosis may result in reduced health-related quality of life (HRQoL) relative to the general population and other hepatitis infections (Buti et al., 2021), however there is limited evidence regarding the effect of HDV on HRQoL. This study aimed to understand the impact of HDV infection at various stages of fibrosis by investigating HRQoL among untreated patients living with chronic HDV.
Method: A cross-sectional survey including the Hepatitis Quality of Life Questionnaire (HQLQv2) and the Fatigue Severity Scale (FSS) was completed by adults with a physician confirmed diagnosis of chronic HDV infection in Italy, Germany, Spain, and the US between July-November 2022. Patients who were heavily immunocompromised, received interferon (IFN)/peg-IFN in the past six months, were diagnosed with human immunodeficiency virus or hepatitis C, or had received an organ transplant were not included. Patients receiving any licensed HDV treatment were also excluded for this analysis.
Results: Descriptive results from a group of 168 patients (74% male, mean age = 52.8) who were not receiving treatment indicated for HDV are presented. This group included patients across all fibrosis stages, F0-F3 (52%), F4 compensated (F4C, 25%), F4 decompensated (F4D, 9%) and 24 (14%) patients with concomitant hepatocellular carcinoma (HCC). The majority of patients (81%) had been diagnosed with HDV between 0 and 5 years. HQLQv2 scores were lowest in patients with F4C and F4D cirrhosis across all domains (Figure 1), suggesting that HRQoL worsens as the disease progresses. All HDV patients regardless of fibrosis stage suffered from fatigue, which was severe in F4C (4.7), F4D (6.2), and HCC (5.8) patients, as defined by a mean FSS score of ≥4 (Rossi *et al.* 2017) and also seemed to have worsened with higher disease severity.
Conclusion: This study demonstrates that HRQoL and fatigue scores were detrimentally impacted by HDV regardless of fibrosis stage, but the impact is greater in later stages and in those with a concomitant HCC diagnosis. Newer treatment interventions which slow down disease progression could be considered to lower the impact of HDV on HRQOL and fatigue.

FRI-125

The impact of Covid-19 on hepatocellular carcinoma screening in British Columbia

Makuza Jean Damascene[1,2], Stanley Wong[3], Mawuena Binka[4], Maryam Darvishian[5], Dahn Jeong[1,6], Prince Adu[6], Georgine Cua[2], Amanda Yu[3], Hector Velasquez[1,2], Maria Alvarez[7], Sofia Bartlett[3], Eric Yoshida[8], Alnoor Ramji[8], Mel Krajden[3], Naveed Janjua[1,3,9]. *[1]The University of British Columbia, School of Population and Public Health, Vancouver, Canada; [2]BC Centre for Disease Control, Clinical Prevention Services, Vancouver, Canada; [3]BC Centre for Disease Control, Clinical Prevention Services, Vancouver, Canada; [4]BC Centre for Disease Control, Clinical Prevention Services, Vancouver, Canada; [5]BC Cancer Research Centre, Vancouver, Canada; [6]BC Centre for Disease Control, Vancouver, Canada; [7]BC Centre for Disease Control, Vancouver, Canada; [8]The University of British Columbia, Division of Gastroenterology, Vancouver, Canada; [9]St. Paul's Hospital, Centre for Health Evaluation and Outcome Sciences, Vancouver, Canada*
Email: makorofr@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) has the second highest incidence among all cancers in Canada. Individuals with HCV who have cirrhosis should be screened twice yearly for HCC in Canada. Coronavirus disease 2019 (COVID-19) has disrupted many health services globally since 2020, including HCC screening among eligible individuals. We assessed the impact of the COVID-19 pandemic on HCC screening using surveillance data from the BC-Hepatitis Testing cohort (BC-HTC).
Method: We performed a retrospective cohort study using data from the BC-HTC, which includes about 1.7 million individuals tested for HCV or HIV or reported as a case of HCV, HIV, or HBV from January 1990 to December 31, 2015. Our primary outcome was HCC screening among individuals with HCV and cirrhosis according to Canadian guidelines. In our dataset, HCC screening was flagged by the first HCC-related medical screening following the initial cirrhosis diagnosis with liver or abdomen ultrasound and CT scan if the ultrasound is unclear among individuals with HCV. We summarized the number of individuals screened each month between March 2018 and December 2020. We included interruption on March 2020 when the BC government implemented COVID-19 restriction measures. We conducted interrupted time-series (ITS) analysis using a segmented linear regression model to assess the impact of COVID-19 and included first-order auto-correlation terms to control for data correlation.
Results: Overall, 7809 HCC screenings were performed among 1641 individuals living with HCV and cirrhosis. Among these screenings, 6168 (78.98%) were conducted from March 2018 to December 31, 2020 and 1,476 (23.84%) during the COVID-19 period (March 2020-December 2020). During the study period, the average monthly number of individuals screened was 181. Number of individuals screened dropped to 138 in March 2020 and 54 in April 2020 (72% drop from April 2019), the lowest point during pandemic, then started to recover with 129 screening in May 2020. The ITS also showed an immediate decline in March 2020 and a sharp decline in April 2020, with some recovery afterward. The decline was not shown in individuals non-treated for HCV and those under 45 years of age.
Conclusion: There was a sharp decline in the number of individuals with HCV with cirrhosis screened for HCC immediately after implementing public health measures, with recovery later in 2020.

FRI-126

HCV screening automation at hospitals level based on extrahepatic manifestations and risk profile. Preliminary results from the Hospitals without_ C programme (hospitales sin C)

Antonio Garcia Herola[1], Sonia Pascual[2,3], Rubén Cuesta[4], Mármol Aguilar Carlos Josué[5], Ana Bejarano[6], Antonio Diaz Sanchez[7], Marina Eliana Millan Lorenzo[8], Marinela Mendez[9], Raquel Domínguez-Hernández[10]. *[1]Hospital Marina Baixa de Villajoyosa (Alicante), Digestive Medicine Section, Spain; [2]Hospital General Universitario de Alicante, Hepatic Unit, Gastroenterology Service, Spain; [3]Center for Biomedical Research in Liver and Digestive Diseases Network (CIBERehd), Alicante, Spain; [4]Hospital de Sagunto (Valencia), Digestive Diseases Section. Email: rdominguez@porib.com

Background and aims: Hepatitis C virus (HCV) infection is associated with risk factors and highly prevalent extrahepatic manifestations, whose identification could help to find HCV-infected patients. The objective of Hospitals without_C program is to raise awareness of hepatitis C in different hospital services, set protocol for HCV screening, and protocol automation in these settings.
Method: The Hospitals without_C program consisted of training sessions to healthcare professionals to promote education on the

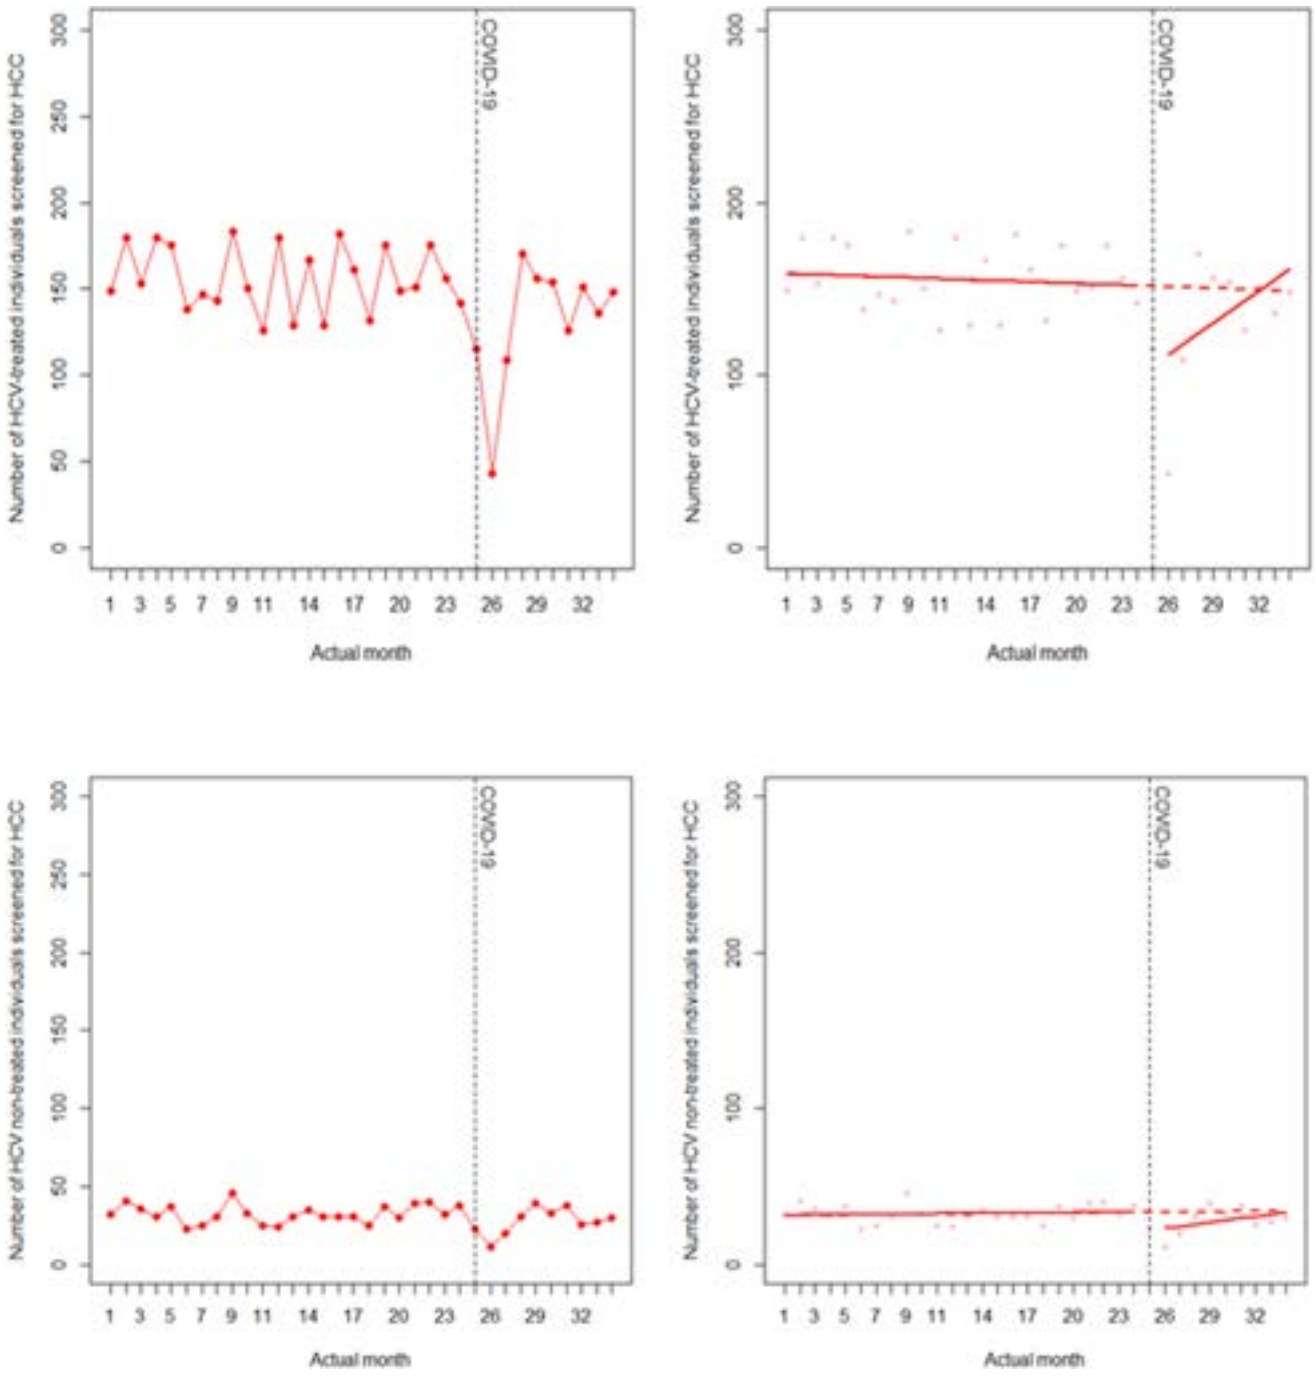

Figure: (abstract: FRI-125): Evolution of monthly HCC screening among individuals living with HCV with cirrhosis treated and non-treated for HCV in BC from March 2018 to December 2020 (left: observed plot, right: model plot).

relevance of hepatitis C diagnosis in different hospital services. The selection of services was carried out considering those treating patients with extrahepatic manifestations related to HCV and where a high number of anti-HCV serologies are requested. The services in which the sessions were held included Psychiatry, Emergency, Internal Medicine, Gynaecology/Obstetrician, and Haematology, among others. The training sessions were conducted by hepatologists, infectious diseases specialists, internal medicine specialists and microbiologists. After the sessions, a follow-up was carried out every 6–12 months to collect information about the number of: i) updated protocols to introduce HCV screening in each service; ii) protocols automated; iii) patients' identification and referral, including those of new diagnosis or lost to follow-up i.e diagnosed but untreated patients (DBU); iv) implementation of an alert between Microbiology lab and HCV specialist to notify RNA-HCV positive cases.

Results: 54 hospitals participated until Oct 2022, with 207 training sessions conducted in different services; with an average of 3.8 sessions per hospital and a maximum value of 12 sessions. After the sessions, almost half of the services (101 services, 49%) had an updated, but non-automated protocol, whereas 26 services (12.5%) of 9 hospitals had an updated and automated protocol. After the sessions, 246 HCV patients were identified. HCV-positive viremia alerts to HCV-specialist allowed patient journey simplification,

allowing direct linkage to care for disease management, helping to avoid loss to follow-up of DBU patients through the care cascade.
Conclusion: Hospitals without_C program has proven to be a key strategy for raising awareness of the infection among professionals in different hospital services managing patients with HCV-associated extrahepatic manifestations. Moreover, the program favours the setup, updating and automation of protocols to find HCV patients of new diagnose and lost to follow-up in the health system.

FRI-127
Policy and implementation needs for hepatitis B birth dose in the WHO African region: a survey of national program managers
Henry Njuguna[1], Lindsey Hiebert[1], Neil Gupta[1], John Ward[1]. [1]*Coalition for Global Hepatitis Elimination, Decatur, United States*
Email: hnjuguna@taskforce.org

Background and aims: Two thirds of the 1.5 M new chronic hepatitis B virus (HBV) infections globally occur in Africa. Most new infections are preventable with HepB vaccination beginning with a timely birth dose (BD) for new-borns. However less than one in five new-borns in Africa receive timely HepB BD vaccination. Due to COVID 19 pandemic, Gavi, the Vaccine Alliance, paused plans to support HepB BD implementation. To understand the status of HepB BD vaccination in Africa, CGHE conducted a survey with three objectives: assess development of national policies, the impact of COVID-19 pandemic, and operational challenges and resource needs for introduction or scale-up of HepB BD vaccination.
Method: CGHE developed an electronic 23-question survey. Respondents were solicited via targeted emails among Expanded Program on Immunization (EPI) managers and hepatitis focal persons in 36 countries in WHO Africa region.
Results: From October 11, 2022, to January 10, 2023, one respondent from each of 24 countries participated in the survey. Of countries represented, 21 (88%) were eligible for Gavi support, 13 (54%) had no policies for HepB BD vaccination, 9 (38%) and 2 (8%) had policies for universal or targeted HepB BD vaccination, respectively. Of 13 countries without policies for HepB BD vaccination, 7 (54%) National Immunization and Technical Advisory Groups (NITAGs) had recommended routine HepB BD vaccination, 4 (31%) NITAGs were considering a recommendation and 2 (15%) were not. Respondents from only 3 (23%) countries reported their NITAGs focus on COVID-19 vaccination impacted their country's introduction plans for HepB BD vaccination. In contrast, respondents from 19 (79%) of 24 countries reported that immediate availability of Gavi funds was of high (n = 16) or moderate (n = 3) importance in decisions to introduce or scale-up HepB BD vaccination; 18 (75%) reported that Gavi's funding would increase their priority for HepB BD introduction or scale-up. The most frequently reported challenges for HepB BD introduction or scale-up were out-of-facility births (n = 17), training health care workers (n = 16), and political and civil society awareness (n = 16). The most frequent recommendations for the priorities for Gavi funding included health care worker training (n = 23), HepB BD demand creation (n = 19) and vaccination of neonates born outside health facilities (n = 19).
Conclusion: Many countries in Africa are planning or beginning introduction or scale-up of HepB BD vaccination. Compared to the resource demands for pandemic response, the lack of Gavi support is the major factor influencing national decisions to implement HepB vaccination of newborns. Unpausing GAVI's support for HepB BD is urgently needed to substantially increase coverage of this critical intervention to eliminate mother to child transmission of HBV in Africa.

FRI-128
Influence of language barrier and cultural differences in hepatitis B disease knowledge in the chinese community of Barcelona
Anna Pocurull[1], Laura Tapias[1], Tao Wang[1], Maria Jose Moreta[1], Anna Miralpeix[1], Cristina Collazos[1], Sabela Lens[1], Zoe Mariño[1], Xavier Forns[1]. [1]*Liver Unit, Hospital Clínic de Barcelona, University of Barcelona, IDIBAPS and CIBEREHD, Barcelona, Spain*
Email: apocurull@gmail.com

Background and aims: Hepatitis B is prevalent in patients of Asian origin. Due to language barriers and cultural differences, it is not always straightforward to evaluate disease knowledge in the liver clinics. We aimed to assess the current awareness on HBV infection and its mechanisms of transmission in HBV-infected Chinese patients and their household contacts.

Table 1: Differences in knowledge on the mechanisms of HBV transmission between Chinese and non Chinese patients.

Patients	All patients N = 182	Chinese N = 85	Non Chinese N = 97	P
Spanish understanding				<0.01
No	26 (14%)	25 (29%)	1 (1%)	
Limited	47 (26%)	43 (51%)	4 (4%)	
Good	109 (60%)	17 (20%)	92 (95%)	
Knowledge on horizontal transmission				0.045
No	12 (6%)	9 (10%)	3 (3%)	
Yes	170 (94%)	76 (90%)	94 (97%)	
Knowledge on sexual transmission				0.054
No	14 (8%)	10 (11%)	4 (4%)	
Yes	168 (92%)	75 (88%)	93 (96%)	
Knowledge on vertical transmission				<0.01
No	36 (20%)	5 (6%)	31 (32%)	
Yes	146 (80%)	80 (94%)	66 (68%)	
Prevention measures (horizontal transmission)				<0.01
No	31 (17%)	6 (7%)	25 (26%)	
Yes	148 (83%)	76 (93%)	72 (74%)	
No answer	3 (1%)	3 (4%)	0	
Prevention measures (sexual transmission)				0.138
No	73 (40%)	29 (34%)	44 (45%)	
Yes	108 (60%)	55 (66%)	53 (55%)	
No answer	1 (1%)	1 (1%)	0	

Method: HBV-infected Chinese patients and their household contacts were interviewed by a nurse (Chinese or native) about their knowledge on hepatitis B transmission mechanisms, use of preventive measures and vaccination status. Non-Chinese HBV-infected patients were defined as a control group.
Results: A total of 182 patients and 398 relatives/household contacts participated in the study. Eighty-five (48%) patients and 240 (60%) of household contacts were from China. Language barrier was documented in 80% of Chinese patients and 44% of their household contacts. Knowledge on horizontal and sexual HBV transmission was high (90%) in both groups of patients. However, Chinese patients were significantly more aware of vertical transmission (94% vs 68%, $p < 0.01$) and were more forewarned in the use of horizontal transmission measures (93% vs 74%; $p < 0.01$). No differences in preventive sexual measures were detected. Chinese household contacts were

less knowledgeable on horizontal and sexual HBV transmission compared to controls (86% vs 96% for horizontal; 81% vs 95% for sexual, $p < 0.01$). However, Chinese household contacts used preventive measures more frequently than controls (79% vs 65% for horizontal transmission, $p < 0.01$). Differences in vaccination coverage between Chinese (78%) and control (86%) household contacts did not reach statistical significance.
Conclusion: Despite relevant language barriers, Chinese HBV-infected patients are well informed on the mechanisms of HBV transmission, particularly on the vertical route. Cultural differences may explain a higher use of preventive measures among the Chinese population. HBV vaccination of household contacts should be reinforced in both groups of individuals.

FRI-129
Health outcomes of hepatitis C direct-acting antivirals: beyond real life sustained viral response data
Carmen Alonso Martin[1], Irene Peñas Herrero[1], Carolina Almohalla Alvarez[1], Félix García Pajares[1], Nieves Martín Sobrino[2], Laura Isusi Lomas[2], Albero Rodriguez Palomo[2], Gloria Sánchez Antolín[1]. *[1]Hospital Universitario Rio Hortega, Valladolid, Spain; [2]Dirección Técnica de Farmacia, Gerencia Regional de Salud, Consejería Sanidad, Spain*
Email: calonsoma@saludcastillayleon.es

Background and aims: Hepatitis C (HCV) infection was the leading cause of liver transplantation worldwide, causing significant mortality associated with end-stage liver disease. The appearance in 2015 of HCV direct-acting antivirals (DAAs) for the treatment of Hepatitis C with an efficacy close to 100% has changed the natural history of hepatitis C. Its economic impact conditioned the prioritization of its use, initially in more severe patients. Health results of DAA treatment have been described, such as reducing the liver transplant waiting list, but there are no studies on the impact of DAAs on the activity of health systems. The aim of our study is to find out if new DAA-based treatments for hepatitis C have had an impact on the outcomes of a healthcare system. We analyzed the evolution of hospital discharges of patients with a primary diagnosis of hepatitis C, hospital discharges for hepatocellular carcinoma, and hospital discharges for other causes with an additional diagnosis of hepatitis C.
Method: The number of hospital discharges from 2012 to 2020 was analyzed, selecting patients with hepatitis C as primary or secondary diagnosis. The information of the admitted patients was obtained from the minimum basic set of hospital discharge data. We also analyzed the average number of discharges due to hepatocellular carcinoma or bile duct neoplasm in the same period and compared the average number of discharges for the period 2012–2015 with the average for 2016–2020.
Results: Hospital discharges associated with HCV infection decreased progressively from 2015 to 2022. The average number of discharges in the period 2012–2015 was significantly higher than that of 2016–2020 for patients admitted for any reason with a diagnosis of hepatitis C associated (2327.5 vs. 1505.2, $p < 0.005$). The mean number of discharges due to hepatocarcinoma and cholangiocarcinoma was also significantly higher in the first period (95.5 vs. 72.8, $p < 0.05$). The % variation of hospital discharges compared to 2012 was −32.74% in 2015, −40.93% in 2016, −44.84 in 2017, −55.52% in 2018, −53.38 in 2019 and −61.57% in 2020. The average age ranged from 54 years old in the 2012–2015 period to 57 in the 2016–2020 period.
Conclusion: The introduction of direct-acting antivirals (DAAs) for the treatment of chronic hepatitis C infection (HCC) has led to a significant decrease in the number of hospital discharges for hepatitis C-related diseases.The variation in hospital discharges since 2012 represents a drop of up to 60% in 2020.A progressive decrease in the number of discharges due to hepatocellular carcinoma and other causes with an additional diagnosis of HCV was also demonstrated. Most of the hospital discharges of patients with HCV due to other causes were classified in ICD10 group 9: diseases of the digestive system, followed by group 1: infectious and parasitic diseases, and group 2: neoplasms. Our study demonstrates the efficacy of DAAs on health outcomes.

FRI-130
Low HBV treatment uptake among Rwandan people with HIV and HCV co-infections: a cohort study from 2016 to 2019
Makuza Jean Damascene[1,2,3], Dahn Jeong[1,3], Phymar Soe[3], Prince Adu[1], Mawuena Binka[1], Hector Velasquez[1,3], Marie Paul Nisingizwe[3], Albert Tuyishime[2], Caren Rose[4], Alnoor Ramji[5], Naveed Janjua[1,3,6]. *[1]BC Centre for Disease Control, Clinical Prevention Services, Vancouver, Canada; [2]Rwanda Biomedical Center (RBC), IHDPC, Kigali, Rwanda; [3]The University of British Columbia, School of Population and Public Health, Vancouver, Canada; [4]BC Centre for Disease Control, Vancouver, Canada; [5]The University of British Columbia, Division of Gastroenterology, Vancouver, Canada; [6]St. Paul's Hospital, Centre for Health Evaluation and Outcome Sciences, Vancouver, Canada*
Email: makorofr@gmail.com

Background and aims: Treatment of chronic hepatitis B virus (HBV) infection is associated with prevention of complications such as cirrhosis, hepatocellular carcinoma, and overall improved survival. In Sub-Saharan Africa, data on HBV treatment uptake is limited overall and among people living with HIV. We assessed the HBV treatment uptake and associated factors among people diagnosed with HBV mono-infection, HBV/HCV co-infection, and HBV/HIV co-infection in Rwanda during 2016–2019.
Method: We used data from the District Health Information System 2, which included data on 915,800 individuals screened for HBV in Rwanda, from January 2016 to December 2019. Individuals were included if they were >2 years old, had information on HBV treatment eligibility criteria according to Rwanda's national HBV prevention and treatment guidelines: HIV co-infection, HBV DNA ≥ 20,000 copies/ml, cirrhosis, abnormal ALT on 3 consecutive tests, and aspartate aminotransferase to platelet ratio index (APRI)-score ≥1.5. HBV treatment uptake is the study primary outcome defined as the proportion of individuals who received HBV treatment among those who met the HBV treatment eligibility criteria. We estimated the proportions of treatment uptake, and assessed factors associated with HBV treatment uptake to account for confounders through multivariable logistic regression.
Results: Among 22,570 individuals with HBV infection, 3,750 (1,986 with HBV mono-infection, 1,764 with co-infection HBV/HIV, 14 with co-infected HBV/HCV, and 5 with HBV/HCV/HIV triple infection) were eligible for HBV treatment during the study period. The majority were males (n = 1,972, 52.6%), between 35 and 54 years old (n = 1,545, 48.5%, median age = 41 years). Among all individuals, 246 with HBV mono-infection (12.3%) and 31 (1.8%) with HIV/HBV co-infection, had cirrhosis. Among 1,332 people with data on HBV DNA, 1,076 (80.8%) had ≥20,000 copies of HBV DNA per ml. Among 1,521 people with data on ALT, 562 (36.9%) had ≥45 IU per ml. Among 1,215 with information on APRI scores, 175 (14.4%) had ≥1.5. During the study period, 2,584 (68.9%) individuals started HBV treatment. People with HBV mono-infection had a greater proportion of treatment uptake compared to those with HBV/HIV co-infection [1,601 (80.6%) vs. 983

(55.7%)]. In the multivariable model, HIV coinfection (adjusted odd ratio [aOR]: 0.46; 95%CI: 0.32–0.66), and living in provinces other than Kigali city: East (aOR: 0.11; 95%CI: 0.04–0.28), North (aOR: 0.17; 95%CI: 0.06–0.47), West (aOR: 0.15; 95%CI: 0.06–0.37), and South (aOR: 0.29; 95%CI: 0.11–0.74) were associated with a lower likelihood of HBV treatment uptake. Follow-up at provincial and referral hospitals (aOR: 6.09; 95% CI: 2.50–14.83) compared to follow-up at district hospitals, and having health insurance for public and private employees compared to having community-based health insurance

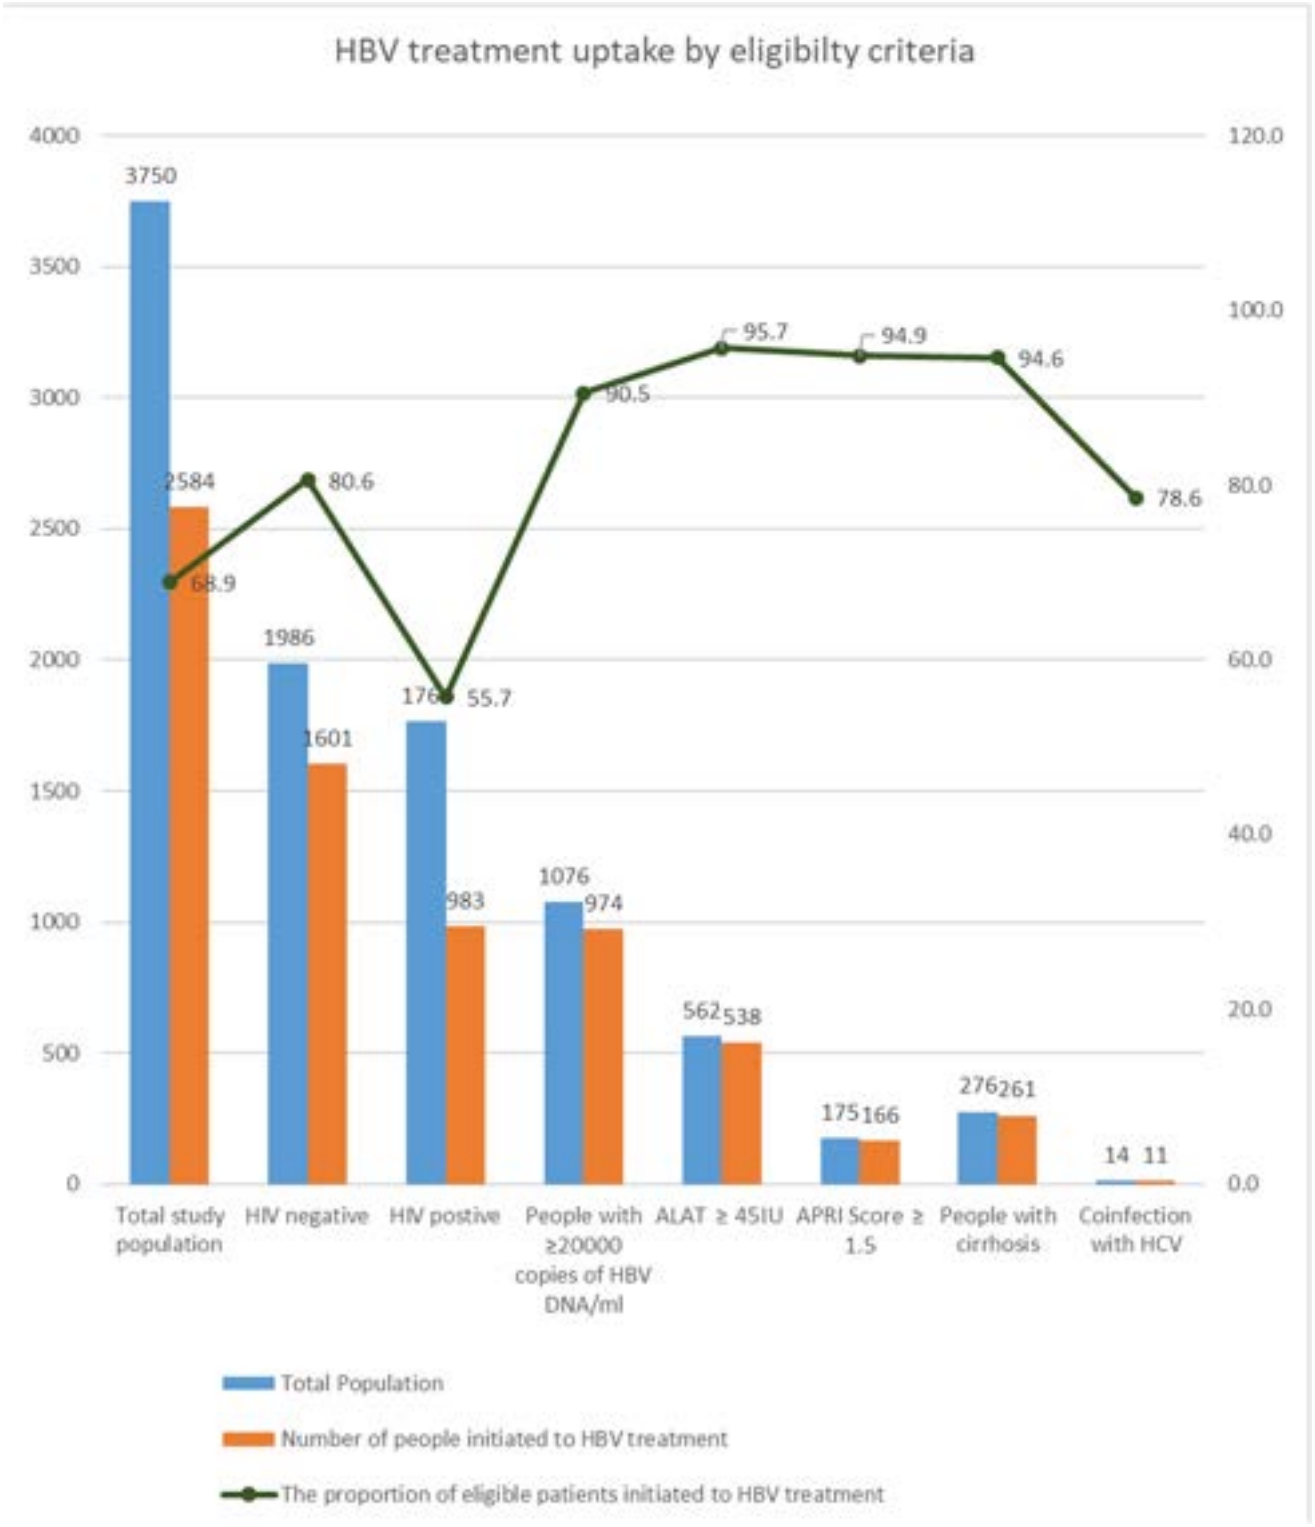

Figure: (abstract: FRI-130).

(aOR: 2.53; 95%CI: 1.03–6.26) were associated with higher treatment uptake.
Conclusion: This study found that during the study period, the treatment initiation was low overall, especially among people with HBV/HIV and HBV/HCV co-infections. These findings highlight the need for scale-up of HBV care and treatment, especially in people with HIV and HCV co-infection.

FRI-131
Prevalence of chronic hepatitis C on the Swiss organ transplantation list from 2009 to 2019
Philip Bruggmann[1,2], Simone Temperli[3], Luis Falcato[1], Franz Immer[3].
[1]*Arud Centre for Addiction Medicine, Internal Medicine, Zurich, Switzerland;* [2]*Institute of Primary Care, University and University Hospital of Zurich, Zurich, Switzerland;* [3]*Swisstransplant, Bern, Switzerland*
Email: p.bruggmann@arud.ch

Background and aims: The prevalence of chronic hepatitis C (CHC) is high on the organ transplant waiting list compared to the general population. This is mainly due to HCV-induced liver damage and increased risk of infection by hemodialysis in patients with advanced renal failure. Since 2013, HCV can be cured, and sequelae prevented by timely therapy with directly acting antivirals (DAA's). The aim of this study is to analyze the time trends of the number of HCV-RNA positive patients (RNA+) on the organ transplantation waiting list in Switzerland from 2009 to 2019 and examine the effects of DAA's.
Method: The study is a retrospective secondary analysis of aggregated data on the subsample of RNA+ on the Swiss organ transplantation list. The yearly numbers of listed patients, grouped by requested organ (liver, kidney, any organ), and of delisted patients, grouped by reason (transplanted, deceased) were analyzed. Besides descriptive and visual evaluation of the respective time series, linear regression models (y = constant + b * x) were calculated, using above variables as dependent (y), and the transformed calendar years (2010 = 0; increment = 1) as predictor (x). Parameter estimate, significance, and model fit were assessed.
Results: In 2009, there were 36 RNA+ on the total, 33 on the liver and 3 on the kidney waiting list. For the total and the liver list this number peaked in 2013 with 50 resp. 42 patients, while the peak on the kidney list was in 2012 with 6 patients. In 2019 there were 9, 8 resp 1 RNA+ on the total, liver resp kidney list. In 2009 27 RNA+ were transplanted, 4 died. The number of transplants peaked in 2012 with 28 patients, the number of deaths in 2012 with 8 deaths. In 2019 6 RNA+ were transplanted and none died. inear regression showed significant yearly decreases in cases waiting for any organ (b = .4.1, p = 0.002), liver (b = –3.6, p = 0.001) and kidney (b = –0.5, p = 0.041), and decrease for transplantation (b = –2.3, p = 0.001) and death (b = –0.8, p = 0.001) as delisting reasons.

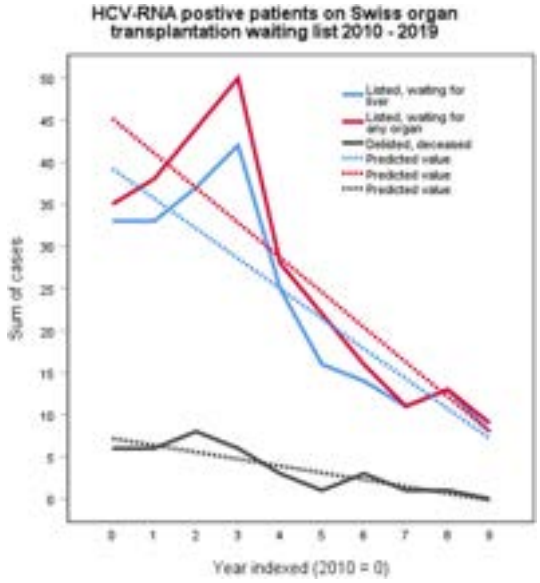

Figure:

Conclusion: Since the introduction of DAAs, few more patients with CHC died on the organ transplant waiting list and the number of individuals with CHC decreased significantly. However, in 2019, 6 years after the first availability of DAAs, CHC patients were still listed for organ transplantation. Every single one of these cases should be considered a failure of the care system, in a country with such a high standard of healthcare as Switzerland.

FRI-132
The impact of removing all hepatitis B virus (HBV) testing and treatment restrictions
Homie Razavi[1], Erkin Musabaev[2], Shakhlo Sadirova[3], Kathryn Razavi-Shearer[1], Shokhista Bakieva[2], Krestina Brigida[2].
[1]*Center for Disease Analysis Foundation, Lafayette, United States;* [2]*Research Institute of Virology, Tashkent, Uzbekistan;* [3]*Center For Disease Analysis Foundation, Tashkent, Uzbekistan*
Email: hrazavi@cdafound.org

Background and aims: Simplifying HBV testing and treatment guidelines has been a topic of debate with proponents arguing for a higher linkage to care and opponents arguing for potential over-treatment.
Method: In 2020, 62,975 individuals vising polyclinics in Tashkent, Uzbekistan were tested for HBV using rapid tests with 30,727 tested before the COVID-19 shut-down, and the remaining tested post-COVID. All positive individuals were tested with HIV and creatinine rapid tests in an adjoining room. Pre-COVID, they were referred to specialists at the Virology Institute and post-COVID to trained General Practitioners (GPs) in the same polyclinic.
Results: 1,509 individuals were newly diagnosed. The cascade of care is shown below with 29% of all diagnosed cases initiating treatment in our program and the private sector. A survey of those who did not seek treatment found that 42% did not know HBV infection can lead to cancer. A separate analysis of GPs prescription and treatment initiation found treatment initiation rates between 12%-84% of their patients even though all GPs received the same training.
Conclusion: Our study suggests that significant difficulties remain even if all testing and treatment barriers are removed due to a very low level of awareness of HBV and the corresponding disease burden in the general population. It also highlights the importance of

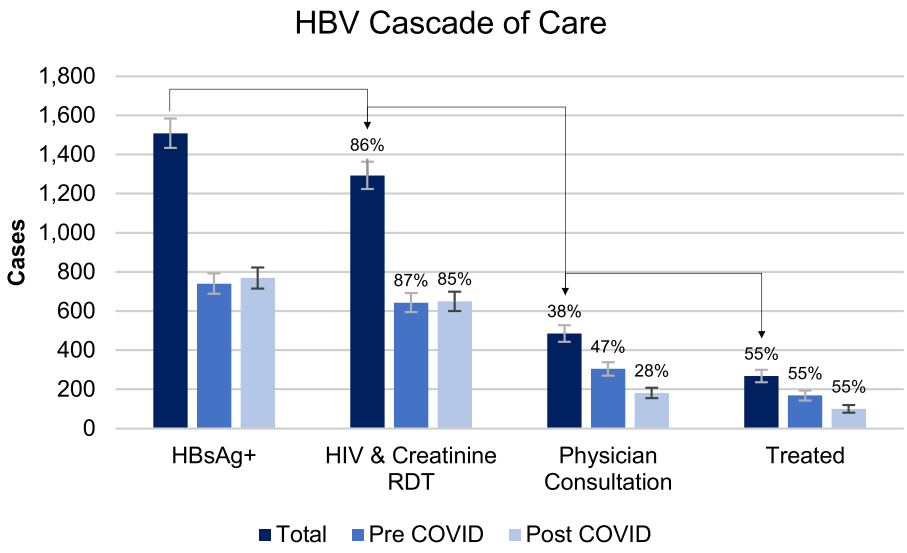

Figure: (abstract: FRI-132).

training and retraining GPs as they are typically the first medical experts who explain the implications of the positive HBV test. Finally, the private sector cannot be ignored as it accounted for 38% of all treated patients.

FRI-133

Spontaneous clearance of hepatitis C virus infection in the country of Georgia, 2015–2021

George Kamkamidze[1], Maia Butsashvili[1], Davit Baliashvili[2], Shaun Shadaker[3], Maia Kajaia[1], Mamuka Zakalashvili[4], Tengiz Tsertsvadze[5], Lali Sharvadze[6], Maia Tsreteli[7], Senad Handanagic[3]. *[1]Health Research Union and Clinic NeoLab, Tbilisi, Georgia; [2]The Task Force for Global Health, Georgia; [3]Centers for Disease Control and Prevention, United States; [4]Medical Center Mrcheveli, Georgia; [5]Infectious Diseases, AIDS and Clinical Immunology Research Center, Georgia; [6]Clinic Hepa, Georgia; [7]National Center for Disease Control and Public Health Georgia, Georgia*
Email: georgekamkamidze@gmail.com

Background and aims: The majority of hepatitis C virus (HCV) infections persist, while approximately 15–30% of infections clear spontaneously and do not progress to chronic hepatitis C. Epidemiological, viral, and host factors have been associated with HCV clearance in previous studies, showing that a strong virus-specific host immune response favors viral clearance. Female sex, younger age at infection, lower HCV RNA levels, co-infection with hepatitis B virus, and specific polymorphisms of IL28 gene were positively associated with spontaneous clearance, while alcohol consumption showed a negative correlation. The aim of our study was to evaluate HCV spontaneous clearance among persons tested for HCV infection within the national HCV elimination program in the country of Georgia and association with sex, age, and the specific population subgroups.

Method: Spontaneous clearance was defined as a reactive HCV-antibody test followed by no detection of HCV RNA or core antigen, with no HCV treatment history. Data were extracted from Georgia's screening registry and HCV elimination program database, which contain all hepatitis C testing and treatment data nationally. Chi-square tests and logistic regression were used for statistical analysis of the data.

Results: Data for 137,981 persons tested for HCV infection during 2015–2021 were analysed. Overall, 20.7% of persons tested for viremia had spontaneously cleared the virus. Spontaneous clearance of HCV infection increased each year during 2015–2021 (table). Overall spontaneous clearance was higher among women than men (27.1% vs. 18.5%, respectively; prevalence ratio [PR] = 1.47 and 95% confidence interval [CI] = 1.43–1.49). Clearance was lowest among those aged 40–49 years (17.9%) and highest among children aged <18 years (58.2%). Compared to the general population, lower spontaneous clearance was documented for people living with HIV infection (PR = 0.50; 95% CI: 0.32–0.79) and persons in penitentiary settings (PR = 0.57; 95% CI: 0.38–0.59).

Year	Anti-HCV positive N	Tested for HCV RNA or Core Antigen N (%)	HCV spontaneous Clearance N (%)	Prevalence Ratio (PR)	PR 95% CI
2021	8098	5460 (67.4)	1712 (31.4)	Reference	Reference
2020	10755	8070 (75.0)	2445 (30.3)	0.97	0.92—1.02
2019	21210	17533 (82.7)	4489 (25.6)	0.82	0.78—0.86
2018	23697	20103 (84.8)	4724 (23.5)	0.75	0.72—0.79
2017	29619	23022 (77.7)	4143 (18.0)	0.57	0.55—0.60
2016	25432	22726 (89.4)	3924 (17.3)	0.55	0.52—0.58
2015	19170	18125 (94.5)	2419 (13.3)	0.43	0.40—0.45

Figure: Spontaneous clearance of HCV by year, Georgia.

Conclusion: Substantial increases in HCV spontaneous clearance over time may be considered as an indirect outcome of a positive impact of the HCV elimination program on the structure of HCV infections in the population of Georgia. Updated estimates of HCV clearance are important for the strategic planning of further activities towards HCV elimination.

FRI-134

Automation of hepatitis C screening through electronic health record algorithm

Vítor Magno Pereira[1], Madalena Pestana[1], Elisa Xavier[2], Luís Jasmins[1], Nuno Ladeira[1], Ana Reis[3], Nancy Faria[3], José Bruno Freitas[2], Nuno Canhoto[2], Alba Carrodeguas[4], Diogo Medina[4]. *[1]Hospital Dr. Nélio Mendonça, Gastroenterology and Hepatology, Funchal, Portugal; [2]Hospital Dr. Nélio Mendonça, Funchal, Portugal; [3]Hospital dos Marmeleiros, Funchal, Portugal; [4]Gilead Sciences Inc, Madrid, Spain*
Email: magnovitorp@gmail.com

Background and aims: The high proportion of people living with hepatitis B and C who are undiagnosed is a key finding of ECDC recent

report on the elimination of viral hepatitis. World Health's Organization (WHO) 2030 goals for the elimination of viral hepatitis are still therefore unreachable by many of these countries.In January 2020, we embraced the mission to achieve these goals through the implementation of a universal program for Hepatitis C virus screening (HCV), a systemic policy defended by all players in our region.

Method: The initiative consists of an opportunistic HCV screening with HCV antibody in patients aged 18–70, without prior records of HCV antibody or HCV RNA, who required blood work for any purpose across all public health facilities (primary care, emergency department, hospital clinics and wards).

Electronic health record (EHR) algorithms were developed in order to determine eligibility and oral opt-out consent was obtained. Whenever a positive antibody test is found, a reflex confirmatory test is automatically generated on the same sample.

Results: From January 2020 until December 2022, we screened 32418 patients (average of 900 tests/month) and found 155 positive antibody (0.47%) and 51 viremic patients (0.16%). Linkage to care was achieved at 94% of viremic patients. Usage of intravenous drugs and and other patients' social issues are the major barriers in complying with healthcare. An analysis of fibrosis staging at screening using non-invasive scores was performed for all viremic patients. Fibrosis-4 (FIB-4) Index for Liver Fibrosis was calculated with the following Results: 20 patients low risk (FIB-4 <1.3), 13 patients indeterminate risk (FIB-4 1.3–2.67) and 16 patients high risk (FIB-4 >2.67).

For patients with SVR available (15), there were no treatment failures (SVR of 100%).

Conclusion: This automated screening strategy permitted the diagnosis of 51 previously undiagnosed HCV viremic patients, including a third with advanced liver fibrosis. The authors report a global HCV antibody prevalence of 0.47% and 0.16% HCV RNA in this general screening population. This kind of strategy is an important measure to ensure a reduction in the significant number of undiagnosed patients with chronic viral hepatitis.

FRI-135

Hepatitis C seroconversion rates among individuals with repeated testing-Georgia, 2017–2021

Davit Baliashvili[1], Shaun Shadaker[2], Nathan Furukawa[2], Maia Tsereteli[3], Vladimer Getia[3], Paige A. Armstrong[2], Senad Handanagic[2]. [1]*The Task Force for Global Health, Georgia;* [2]*Centers for Disease Control and Prevention, United States;* [3]*National Center for Disease Control and Public Health, Georgia*
Email: dato.baliashvili@gmail.com

Background and aims: As Georgia moves closer to achieving hepatitis C virus (HCV) elimination, demonstrating the program's impact on the ongoing transmission of hepatitis C becomes a priority. One way to monitor reduction in incidence is to observe temporal trends of seroconversion and new viremic cases among repeatedly tested persons. Using nationwide programmatic data, we aimed to estimate annual rates of seroconversion and new viremic infections among persons repeatedly tested in Georgia.

Method: We used data from 2017 to 2021 and identified a subset of adults with at least two anti-HCV tests ≥14 days apart and nonreactive results for the first anti-HCV test. Seroconversion was defined as nonreactive anti-HCV test followed by a reactive. The seroconversion rate was calculated by dividing number of seroconversions by total person-time within the given calendar year and expressed per 100,000 person-years (PY). Person-time was calculated as the number of days from the first anti-HCV test to either the last nonreactive test (for consistently nonreactive individuals) or the first reactive test (for individuals who seroconverted). We estimated the seroconversion rate by year and sex. Among those with seroconversion, we identified persons with subsequent HCV RNA or HCV core antigen testing and calculated the rate of new viremic infection with the same methodology as above. Rate ratios and 95% confidence intervals (CI) were calculated to compare rates between different years.

Results: We identified 942,030 individuals with more than one anti-HCV test with an initial nonreactive result. After a median follow-up time of 654 days (IQR: 334–1012), 13,022 (1.4%) individuals seroconverted. The seroconversion rate per 100,000 PY decreased

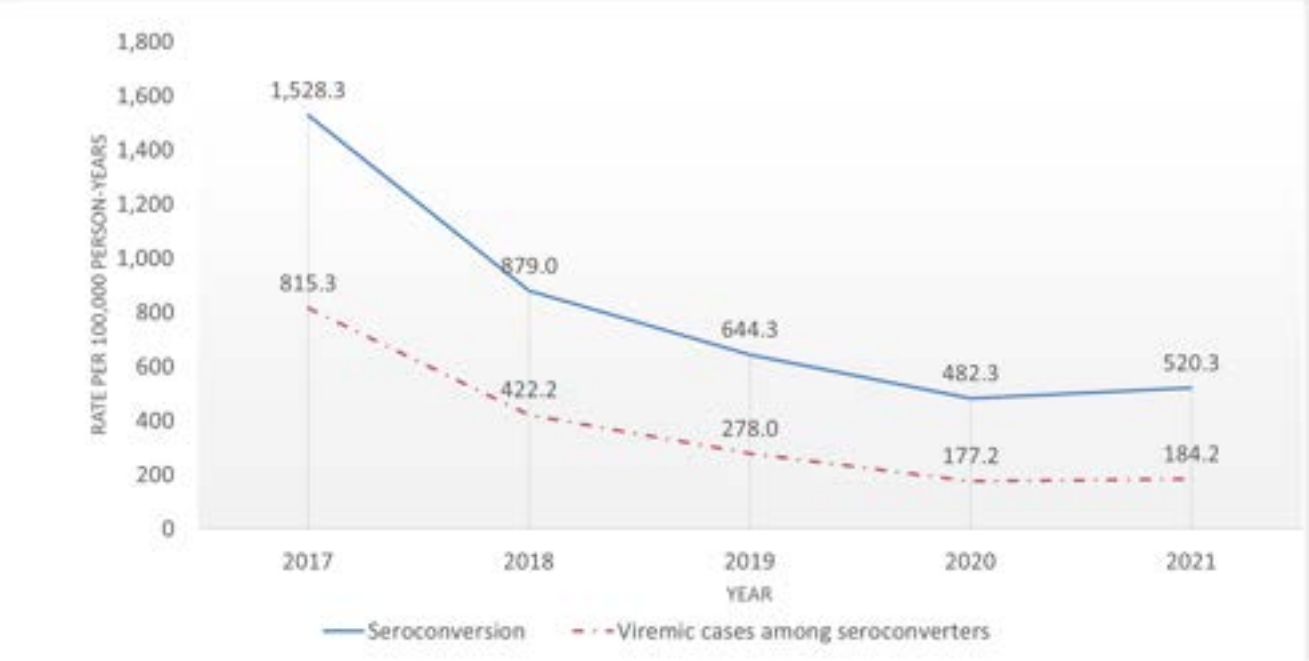

Figure: (abstract: FRI-135): Rate of new hepatitis C cases per 100, 000 person-years among repeat testers- Georgia, 2017–2021.

by 66% over five years, from 1,528 in 2017 to 520 in 2021 (rate ratio = 0.34, 95% CI: 0.32, 0.37). Incidence was lowest in 2020 (482 per 100,000 PY), followed by an increase in 2021. Overall, the seroconversion rate was more than twice as high among males than females, but rate of decrease was similar in both sexes. Among those with seroconversion, 10,159 (78%) were tested for viremia, and 5,824 (57%) were detectable. The annual rate of new viremic cases per 100,000 PY decreased by 77%, from 815 in 2017 to 184 in 2021 (rate ratio = 0.23, 95%CI: 0.20, 0.25) (figure).

Conclusion: The seroconversion rate in Georgia decreased approximately three-fold during 2017–2021. A slight reversal of the trend in 2021 could be explained by the potential negative impact of the COVID-19 pandemic on preventive programs and infection prevention and control practices. During a similar period (2015–2021), prevalence of hepatitis C decreased by 67% in Georgia, suggesting use of seroconversion rates may provide a valuable tool for monitoring progress towards elimination. Continued progress toward elimination will require further scale-up of both treatment and preventive programs.

FRI-136

Characterization of recent HCV infections and re-infections among the high-risk population from Georgia using global hepatitis outbreak and surveillance technology

Adam Kotorashvili[1], Amiran Gamkrelidze[2], Tamar Gabunia[2], Nato Kotaria[2], Maia Tsereteli[2], Ana Papkiauri[2], Ketevan Galdavadze[2], Maia Alkhazashvili[2], Paata Imnadze[2], Tinatin Kuchuloria[3,4], Lilia Ganova-Raeva[5], Sumathi Ramachandran[5], Shaun Shadaker[5], Saleem Kamili[5], Paige A. Armstrong[5], Yury Khudyakov[5]. *[1]National Center for Disease Control and Public Health, Genome Center, Tbilisi, Georgia; [2]National Center for Disease Control and Public Health, Tbilisi, Georgia; [3]The Task Force for Global Health, United States; [4]The Task Force for Global Health, Tbilisi, Georgia; [5]Centers for Disease Control and Prevention, Atlanta, United States*
Email: adam.kotorashvili@gmail.com

Background and aims: Global Hepatitis Outbreak and Surveillance Technology (GHOST), developed at the Centers for Disease Control and Prevention, is a novel technology that identifies any transmission links among individuals infected with hepatitis C virus (HCV), generating a user-friendly graphic display. The National Center for Disease Control and Public Health (NCDC) of Georgia became the first international GHOST-implemented regional center outside of the United States. Using the GHOST bioinformatics platform, the goal of the study was to gain insight into the HCV variability and any potential transmission networks in recently seroconverted and reinfected persons who inject drugs (PWID) in selected harm reduction (HR) centers of Georgia.

Method: GHOST uses next-generation deep sequencing of Hyper Variable Region 1 (HVR1) of the HCV. Genotypes of the HCV strains were determined by HVR1 sequence data analysis. Two HR sites in the cities of Tbilisi and Zugdidi were selected for participation. Samples were collected from HR beneficiaries with documented reinfection or seroconversion. All participants provided written informed consent to participate in the study and completed a questionnaire on the relevant epidemiologic information. All specimen processing and molecular testing laboratory methods were executed according to the respective Standard Operating Procedures developed and approved by the Division of Viral Hepatitis Laboratory (CDC Atlanta, GA)

Results: Overall, 131 PWID were recruited to participate, including 55 (42%) in Tbilisi and 76 (58%) in Zugdidi. Among the 131 participants observed between June 2021-May 2022, 12 (9%) had HCV reinfection and 119 (91%) seroconverted during the observation period. In the 6 months prior to the study, 109 participants (83%) reported injecting drugs and 4 (3%) reported needle sharing. Among participants experiencing reinfection, 1 (8%) received a blood transfusion, and 11 (92%) had an invasive medical procedure; none were incarcerated. Among participants with new infection, 23 (19%) received a blood transfusion, 58 (49%) had invasive medical procedures more than 1 year prior, and 8 (7%) were incarcerated prior to seroconversion. HCV recombinant genotype 2k/1b was predominant (n = 22, 36%), followed by 1b genotype (n = 18, 29%), 3a (n = 11, 18%), 2c (n = 5, 8%), 1a (n = 3, 5%) and 2a (n = 1, 2%). Using the GHOST transmission detection module, two transmission clusters consisting of 3 and 6 individuals reinfected with HCV genotypes 2c and 1b were identified in Tbilisi. No linkage among the individuals from Zugdidi was found. The Tbilisi participant carried mixed HCV genotype infection (clade with 6 individuals). Additionally, we found two mixed infections, one in Tbilisi and one in Zugdidi, indicating a high rate of exposure.

Conclusion: This is the molecular epidemiological report among the high-risk PWID population of Georgia using GHOST. The detected transmission clusters and mixed genotype infections indicate a high rate of exposure in these communities. GHOST can be utilized for surveillance for early intervention on networks as well as successfully applied to other infectious diseases including hepatitis B virus, hepatitis A virus and HIV-coinfection.

FRI-137

Zero-HCV before end stage renal disease (ESRD): a collaborative "treat-all" approach to eliminate HCV in chronic kidney disease population in Taiwan

Tsung-Hui Hu[1], Shiou-Shiang Chen[2], Chen-Yang Hsu[3], Wei-Wen Su[4], Sam Li-Sheng Chen[5], Chih-Chao Yang[6], Yen-Po Yeh[2], Hsiu-Hsi Chen[7]. *[1]Kaohsiung Chang Gung Memorial Hospital, and Chang Gung University College of Medicine, Kaohsiung, Taiwan, Taiwan; [2]Changhua County Public Health Bureau, Changhua, Taiwan, Taiwan; [3]Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan, Taiwan; [4]Changhua Christian Hospital, Changua, Taiwan, Taiwan; [5]School of Oral Hygiene, College of Oral Medicine, Taipei Medical University, Taipei, Taiwan, Taiwan; [6]Changhua Hospital, Ministry of Health and Welfare, Changhua, Taiwan, Taiwan; [7]Graduate Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan, Taiwan*
Email: yeh.leego@gmail.com

Background and aims: The Changhua integrated program to stop HCV infection (CHIPS-C) adopted a multidisciplinary care approach since 2019. The elimination of HCV among dialysis population has been successfully completed in Changhua in 2019[1]. To ensure the quality of achievement, we move forward to the HCV elimination in Chronic Kidney Disease (CKD) population to prevent new infection and disease burden in dialysis units from new participants.

Method: Changhua county has conducted Chronic Kidney Disease (CKD) program (including early CKD, stage 1-3a; and pre-ESRD stage 3b, 4, 5 and proteinuria) since 2006. For a better containment of HCV among the well-recognized high-risk population of CKD, a systematic approach by integrating health administrative, health care facilities from primary to medical center guided by CHIPS-C was utilized since 2019. HCV screening and treatment were implemented and evaluated. The achievement rate of HCV care chain-related indicators, and treatment rate were analyzed. The end of follow-up was Dec 31, 2022.

Results: Following the initiation of CHIPS-C for pre-ESRD cohort in Changhua in 2019, there were total 9,155 subjects included. By excluding those who were unable to enter the program such as deaths, aging, and mobility, the screening targets total 8,933 people. The HCV antibody screening rate reached 94.45% (8,438 people), with HCV antibody positive rate of 7.44% (628 people), HCV RNA virus checking rate of 91.7% (576 people), detectable HCV RNA rate of 63.0% (363 people), eligible treatment rate was 98.6% (358 people), and final treatment rate was 91.1% (326 people). Furthermore, there have been total 71,949 CKD subjects initially included. The HCV antibody screening rate reached 81.4% (58,536 people), with HCV antibody positive rate of 6.6% (3,883 people), HCV RNA virus checking rate of 83.1% (3,226 people), detectable HCV RNA rate of 59.4% (1,916

people), and final treatment rate was 89.2% (1,710 people). We further evaluate the impact of treatment of CKD cohort on the dialysis unit. There have been 1683 new participant of dialysis since 2019 in Changhua County. The positivity rate of HCV RNA was 50% at the end of 2019; 28.6% at the end of 2020; 7.7% at end of 2021, and 0% at June of 2022.

Conclusion: After implementation of the CKD program, the percentage of people who were with active hepatitis C (viremic) upon entry into dialysis units gradually decreased. Zero HCV before ESRD could serve as a surveillance surrogate indicator to monitor the progress of HCV elimination in CKD.

FRI-138

Low coverage of hepatitis D virus testing in individuals with HIV and HBV in the Netherlands: a retrospective, cross-sectional and longitudinal study

Anders Boyd[1], Colette Smit[1], Annemiek Van der Eijk[2], Hans Zaaijer[3], Bart Rijnders[2], Berend van Welzen[4], Marc Classen[5], Katalin Pogany[6], Theodora de Vries-Sluijs[2], Eline Op de Coul[7], Marc van der Valk[1].
[1]Stichting Hiv Monitoring, Netherlands; [2]Erasmus MC University Medical Center, Netherlands; [3]Amsterdam University Medical Centers, Netherlands; [4]University Medical Center Utrecht, Netherlands; [5]Rijnstate Ziekenhuis, Netherlands; [6]Maasstad Hospital, Netherlands; [7]National Institute for Public Health and the Environment (RIVM), Netherlands
Email: a.c.boyd@amsterdamumc.nl

Background and aims: European guidance recommends that all individuals with hepatitis B virus (HBV) be tested for hepatitis D virus (HDV). Little is known on the extent of and reasons for HDV testing in individuals with HIV and HBV during routine practice. We aimed to assess the changes in HDV testing in 2000 to 2021 in individuals with HIV and HBV infection in care in the Netherlands, both overall and according to key population. We also intended to understand the determinants of those who ever received an HDV test.

Method: Data from the ATHENA cohort of people with HIV who were ever hepatitis B surface antigen positive, aged ≥18 years or older, and attended any of the 24 HIV treatment centers in the Netherlands between 2000 and 2021 were assessed. We estimated the percent of included individuals ever tested for HDV (i.e., documented anti-HDV antibody or HDV RNA test) across calendar years. Determinants for ever being tested by the end of follow-up were assessed using relative risk (RR) regression using a Poisson regression model with robust variance estimation.

Results: Of the 1668 included individuals with HIV and HBV, only 212 (12.7%) had a documented HDV test. The percentage of individuals tested for HDV increased from 5.0% (95% confidence interval [CI] = 3.4–7.3) in 2000 to 14.0% (95%CI = 12.1–16.2) in 2021. In 2021, the percentage tested for HDV was 13.0% (95%CI = 10.7–15.7) in men who have sex with men, 23.5% (95%CI = 9.1–48.6) in persons who inject drugs, and 15.6% (95%CI = 12.2–19.8) in heterosexual/others. In multivariable analysis, ever having an HDV test was associated with ever having detectable HBV DNA viral load during follow-up (adjusted RR = 3.61, 2.39–5.46, p < 0.001), ever presenting with elevated alanine aminotransferase (ALT) levels (adjusted RR = 1.48, 95%CI = 1.14–1.93, p = 0.003), advanced fibrosis/cirrhosis (versus no fibrosis/cirrhosis, adjusted RR = 1.78, 95%CI = 1.35–2.34, p = 0.001), and being overweight/obese (versus normal/underweight, adjusted RR = 1.44, 95%CI = 1.11–1.87, p = 0.006). The percentage of individuals with HIV and HBV who tested positive for HDV remained relatively stable over calendar year: 15.4% (n = 4/26; 95%CI = 5.9–34.6) in 2000 and 7.2% (n = 11/152; 95%CI = 4.1–12.6) in 2021.

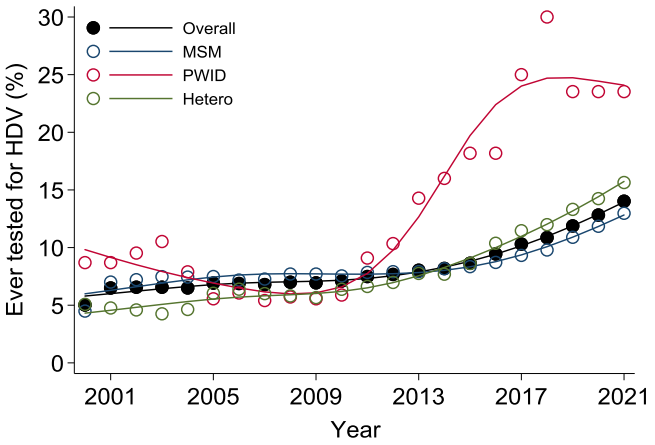

Figure: Hepatitis D virus testing in individuals with HIV and hepatitis B virus in the Netherlands.

Conclusion: HDV testing coverage in the Netherlands is low for individuals with HIV and HBV. Although testing was more common in those with advanced liver disease, a considerable proportion at risk of HDV still needs HDV testing in the Netherlands.

FRI-139

Retrospective study of hepatitis C virus antibodies and active viral replication in at-risk population with dual diagnosis in a Spanish university hospital

Cristina del Rio-Cubilledo[1], Aitana Carla Morano Vázquez[2], Denise Monserrat Arroyo Jarrin[3], Miriam Soriano García[3], Henar las Heras Miralles[1], Jose Manuel Olivares Díez[4], Luis Enrique Morano Amado[5]. *[1]South Galicia Health Research Institute, South Galicia Biomedical Foundation, Vigo, Spain; [2]Preventive Medicine Service, Gregorio Marañón University Hospital, Madrid, Spain; [3]Psychiatry Service, Álvaro Cunqueiro University Hospital, Vigo, Spain; [4]Psychiatry Service, Vigo Health Area, Álvaro Cunqueiro University Hospital, Vigo, Spain; [5]Infectious Disease Unit, Álvaro Cunqueiro University Hospital, Vigo, Spain*
Email: cristina.delrio@iisgaliciasur.es

Background and aims: In 2019, WHO estimated the prevalence of chronic HCV about 58 million globally, however only 21% were diagnosed and 9.4 million were treated with direct-acting antivirals. In Spain the prevalence of antibodies was 0.85% and the active infection 0.22% in general population between 2017 and 2018. HCV can cause hepatocellular carcinoma and cirrhosis. Among at-risk groups, HCV and other Blood-Borne Viruses (BBV) are very common in people with dual diagnosis (DD), whose infection complicates due to alcohol and substance abuse. People with DD should be screened for BBV as a standard health assessment. Screening in the psychiatric unit of a hospital showed that 9% of patients were VHC positive. Other study showed that testing all psychiatric patients is cost-effective and helps to wipe out HCV. However, people with DD have been under-recognized as a priority group for HCV screening, and studies in patients with DD are few. We aimed to analyse the prevalence of HCV in DD patients at our Psychiatry Unit.

Method: We did a retrospective study of 1631 patients admitted in the Psychiatry Unit at Álvaro Cunqueiro University Hospital between 2019 and 2021 to identify patients with DD to detect the presence of HCV antibodies (anti-HCV) and HCV ribonucleic acid (RNA). We searched for HCV-untreated patients with active viral replication (AVR), HCV-treated patients with sustained virologic response (SVR), spontaneous viral clearance (SVC), HCV-uninfected and HCV-unknown. The selected covariates were age, sex and other BBV.

Results: 291 patients had DD, 186 were male, 105 female and their age average was 41 years. 22.3% of patients had alcohol abuse, 44.7% single drug abuse and 33% several substance abuses. 249 (85.6%) were tested for HCV antibodies. anti-HCV were confirmed in 62

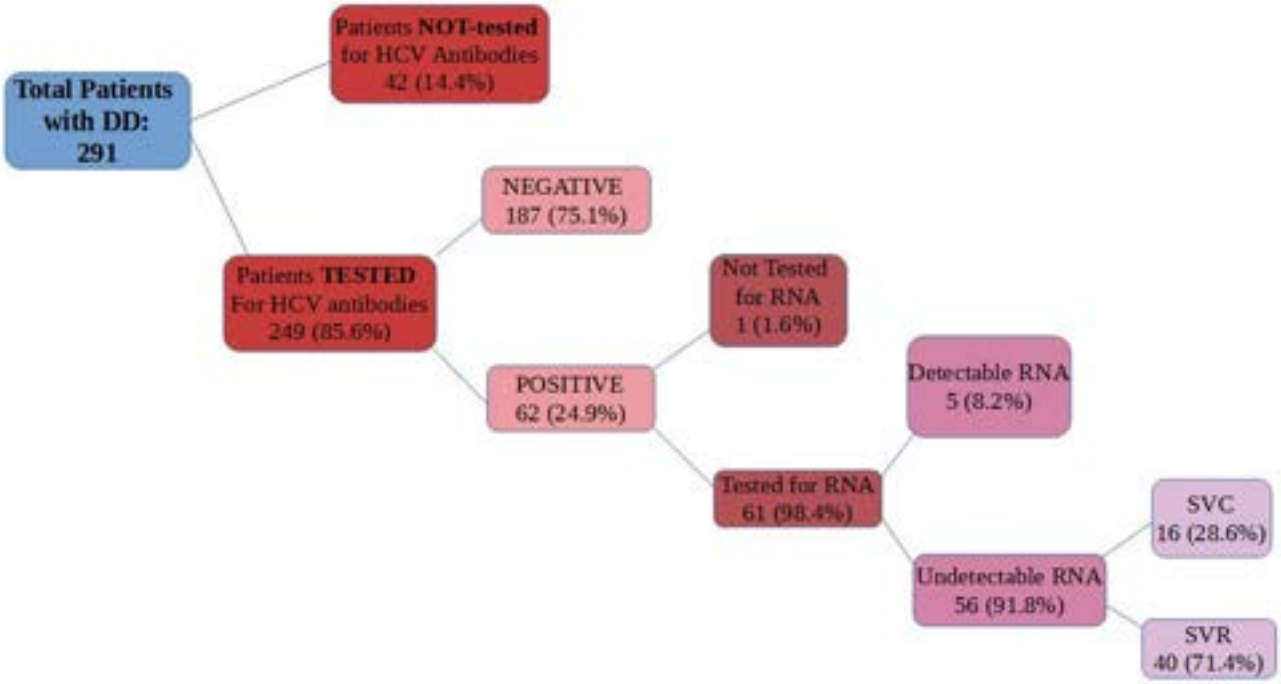

Figure: (abstract: FRI-139): Percentages of patients with DD who had HCV antibodies, RNA detectable or undetectable and patients who received treatment or who reached SVC.

(24.9%) patients. Among these, 56 (91.8%) showed undetectable RNA, of which only 40 (71.4%) received treatment with SVR and the rest reached SVC. 1.6% were not tested for RNA replication and 5 (8.2%) had AVR and did not follow any treatment. Finally, 69 (23.7%) had also other BBV.

Conclusion: The prevalence of anti-HCV in our Psychiatry Unit was 29.3 times higher than in general population in Spain. Our results highlight the need to address the high prevalence of HCV in people with DD. The Health System should provide an effective screening method to identify patients with HCV at at-risk populations and develop a system to test all patients admitted in psychiatry units in hospitals.

FRI-140

Acceptance and feasibility of hepatitis C screening by assisted self-testing in high-risk and general population: a randomized clinical trial

Federica Benitez Zafra[1], Felicitas Diaz-Flores[2], Francisco Javier Perez-Hernandez[3], Paula Haridian Quintana Diaz[1], Fabiola Perez Gonzalez[1], Maria Jesus Medina Alonso[4], María Cristina Reygosa Castro[1], Dalia Morales Arraez[1],

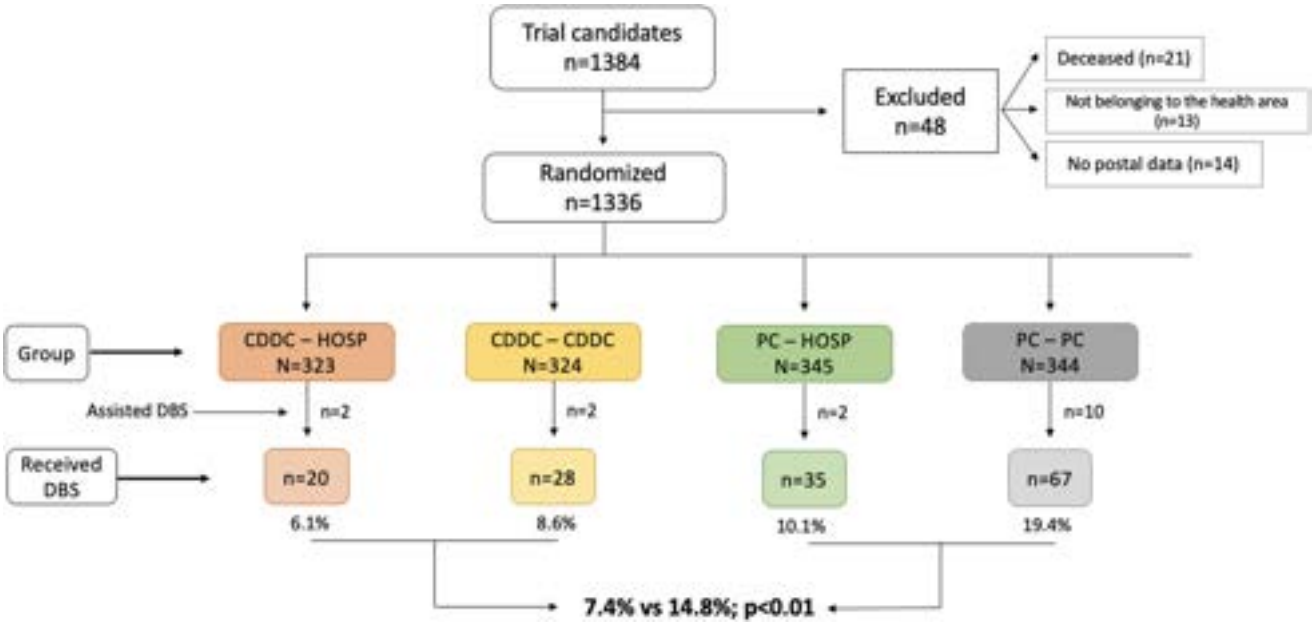

Figure: (abstract: FRI-140).

[1]*Servicio de Aparato Digestivo, Hospital Universitario de Canarias, Tenerife, Spain;* [2]*Laboratorio Central, Hospital Universitario de Canarias, Tenerife, Spain;* [3]*Servicio de Medicina Familiar y Comunitaria de la Zona Norte de Tenerife, La Laguna, Spain;* [4]*Unidad de atención a las drogodependencias, Spain*
Email: federicabenitezafra@gmail.com

Background and aims: Strategies for the micro-elimination of hepatitis C virus (HCV) have been implemented, including integrated decentralized diagnostic programs at centers for drug dependence care (CDDC) using the dried blood spot test (DBS). However, many subjects at high-risk of having HCV infection were discharged or lost from follow-up from CDDC before these actions were taken. This study aims to evaluate the effectiveness (acceptance and feasibility) of an HCV screening strategy using home-based self-testing with DBS in patients that missed HCV screening at CDDC and compare it with general population.
Method: Patients who were attended and discharged or lost to follow-up by the CDDC between 2013 and 2017 and subjects from a primary care (PC; general population) cohort were identified and offered to participate by sending the self-testing kit. Deceased subjects, those not belonging to the health area, and those with no postal data were excluded. They were randomized (clinicaltrial.gov NCT05146609) into two groups in each population, according to whether they were offered assistance to perform the test in the hospital, CDDC, or PC center. The sample return rate of the test and the feasibility of processing DBS samples and obtaining ARN results were evaluated. Characteristics associated with sample return were analyzed using logistic regression.
Results: Overall, 1336 subjects (67.7% males, 48.8 ± 0.3 years) were included and the figure shows acceptance rates in each group. The home-based screening was lower in high-risk population compared to general population (7.4% vs 14.8%; p < 0.01). Subjects that returned de sample were older (51.0 ± 14.3 vs 43.7 ± 14 years; p = 0.04), had longer drug use duration (25.8 ± 15.1 vs 19.0 ± 13.5 years, p = 0.001), daily drug consumption (9.3 vs 5.0%, p = 0.04), a previous HCV positive test (19.5 vs 6.8%, p = 0.08), previous digestive system specialist's appointment (15.6 vs 5.9%, p = 0.001) and absence of psychiatric doctor's appointment (19 vs 6.3%, p = 0.004). Having a previous HCV positive test was the only predictive factor associated with a high rate of returning the sample (OR 6.6, CI95% 2.1–20.7; p = 0.001). All returned samples, except 2 DBS, were valid and negative for viremia.
Conclusion: This retrieval home-based self-testing screening strategy is feasible, but has a low acceptance rate in the high-risk population, especially among those unaware of the disease. More effective targeted strategies must be sought to achieve 2030 WHO goals.

FRI-141
Cost-effectiveness analysis of a new paradigm to simplify testing, monitoring and treatment of hepatitis C virus in the United States

Douglas T. Dieterich[1], Nancy S. Reau[2], Aijaz Ahmed[3], Rob Blissett[4], Adam Igloi-Nagy[4], Alon Yehoshua[5]. [1]*Institute for Liver Medicine, Mount Sinai Health System, United States;* [2]*Rush University Medical Center, Department of Hepatology, Chicago, United States;* [3]*Stanford University School of Medicine, Division of Gastroenterology and Hepatology, Stanford, United States;* [4]*Maple Health Group, LLC, New York, United States;* [5]*Gilead Sciences, Inc, United States*
Email: douglas.dieterich@mountsinai.org

Background and aims: The current treatment pathway for hepatitis C virus (HCV) patients in the United States (US) includes a range of tests and appointments that delay treatment and cause substantial loss to follow-up. Our analysis aimed to assess the cost-effectiveness of simplifying the testing and treatment of HCV patients from the US payer perspective.
Method: A series of linked Markov models were developed to estimate the health outcomes and cost differences of simplifying the treatment pathway for HCV patients in the US. The analysis compared three scenarios, one based on the latest treatment guidelines ("status quo" [SQ]), one based on real-world practice as informed by expert opinion ("real-world scenario" [RW]) and a hypothetical scenario with a simplified pathway ("new paradigm" [NP]). The scenarios differed in testing and treatment process steps and time needed to complete each step. Patients in the new paradigm initiated treatment earlier and with fewer tests and appointments required, resulting in a shorter overall process time and less resource use. The model considered the US HCV population, stratified by subpopulations (general population, incarcerated, people who inject drugs, men who have sex with men). Model inputs included direct costs (health state, testing, treatment), treatment effectiveness expressed as sustained virologic response at 12 weeks (SVR12) and health state utilities. Outcomes included the incremental cost per quality-adjusted life year (QALY) and per life year (LY) of introducing the new paradigm compared to the SQ and RW scenarios. Advanced liver disease outcomes (compensated and decompensated cirrhosis, hepatocellular carcinoma, liver transplant, and extrahepatic mortality) were also compared between each scenario. Costs and health effects were discounted at 3.0% over a lifetime horizon.
Results: In the base case analysis with all subpopulations considered, the new paradigm resulted in incremental costs of –$19,751 (vs. SQ) and –$16,448 (vs. RW). The new paradigm was associated with incremental QALYs of 0.42 and 0.70 compared to the SQ and RW scenarios, respectively, and therefore was a dominant strategy compared to both. In addition, the new paradigm was associated with a 60.4% and 58.2% reduction in total advanced liver disease outcomes, compared to the SQ and RW scenarios, respectively. Sensitivity and scenario analyses confirmed the robustness of the model; key drivers included health state utilities and treatment effectiveness inputs.

Table: Summary Model Results

	Status Quo	Real-World Scenario	New Paradigm
Cumulative outcomes, discounted			
LYs per person	13.31	12.97	13.66
QALYs per person	10.81	10.53	11.23
Cumulative costs, discounted			
Total costs per person ($)	65,461	62,158	45,710
Cost effectiveness ratios-New Paradigm vs. Status Quo			
Incremental cost per QALY ($)	DOMINANT		
Net mean benefit @ 100,000 WTP ($)	61,660		
Cost effectiveness ratios-New Paradigm vs. Real-World Scenario			
Incremental cost per QALY ($)	DOMINANT		
Net mean benefit @ 100,000 WTP ($)	85,884		

HCV: hepatitis C virus; **QALY:** quality adjusted life year; **LY:** life year; **WTP;** willingness to pay.

Conclusion: This analysis demonstrated that simplifying the testing and treatment of HCV patients in the US may be a cost-effective strategy that would allow a quicker path to successful treatment and reduce the number of patients lost to follow-up.

FRI-142
Consider schistosomiasis screening in hepatitis B patients from endemic regions: a hepatic comorbidity that should not be neglected

Oriane Palaprat[1], Marie Gladys Robert[1], Marie-Pierre Brenier-Pinchart[1], Justine Barthemon[2], Hélène Fricker Hidalgo[2], Cécile Garnaud[1], Hervé Pelloux[1], Marie-Noëlle Hilleret[2]. [1]*Grenoble Alpes University Hospital,*

Parasitology-Mycology Laboratory, Grenoble, France; [2]Grenoble Alpes University Hospital, Hepatology-Gastroenterology Department, Grenoble, France
Email: mrobert2@chu-grenoble.fr

Background and aims: Highly endemic countries for hepatitis B virus (HBV), particularly sub-Saharan Africa, are also endemic regions for schistosomiasis, a parasitic infection affecting more than 200 million people worldwide and caused by helminths of the genus *Schistosoma*. HBV-schistosomiasis co-infection is therefore common in these regions and can lead to cumulative chronic liver disease and especially to portal hypertension. Thus, it is recommended to screen all migrants from sub-Saharan Africa for both HBs antigen (HBsAg), and anti-*Schistosoma* antibodies. The aim of this study was to evaluate the effectiveness of this serological screening for schistosomiasis following the diagnosis of hepatitis B in our center.
Method: This single-center retrospective study investigated the records of all patients with a positive HBsAg from January 1, 2012 to November 30, 2022 in the hepato-gastro-enterology department of the Grenoble Alpes University Hospital. The availability of a serological screening for schistosomiasis by ELISA, rapid diagnostic test and/or western blot was examined for patients originating from Africa.
Results: Over the past 10 years, of the 1136 HBsAg-positive patients in our center, 562 (49.5%) were from schistosomiasis-endemic areas. However, serological screening for schistosomiasis was available for only 155 (27.6%) of these patients. In addition, 71 (45.8%) of the schistosomiasis serology performed in patients born in endemic areas were positive by at least one technique. Review of hepatic events related to schistosomiasis is currently ongoing among this population.
Conclusion: Although the prevalence of hepatitis B-schistosomiasis co-infection is significant in the population followed in hepato-gastroenterology for hepatitis B in France, screening for schistosomiasis remains insufficiently solicited. It is therefore essential to emphasize the potential impact this parasitic infection may have on the clinical outcomes of these patients and to remind the importance of screening at-risk patients and treating them if necessary.

FRI-143
Micro-elimination of Hepatitis C virus infection in mountainous and remote areas of Taiwan-a multi-center collaborative care model

Email: fish6069@gmail.com

Background and aims: Taiwan has several hepatitis C virus (HCV) hyper-endemic areas. We aimed to evaluate the effectiveness and safety of a collaborative HCV care system with an outreach decentralized strategy among the resource-constrained Mountainous/remote areas of Taiwan
Method: The pilot study was conducted in four high HCV-endemic townships in the rural/remote areas of Taoyuan, Alishan, Zhuoxi and Xiulin. Registered residents who worked or lived in the four areas and were aged 30 to 75 years were invited to participate in this program. Multidisciplinary HCV care teams provided outreach decentralized services of anti-HCV screening, link-to-diagnosis, and link-to-treatment with direct-acting antiviral agents (DAA). The primary end point was sustained virological response (SVR).
Results: Of 8,291 registered residents who were invited as the target population, 7,807 (94.2%) subjects received anti-HCV screening, with the average anti-HCV prevalence rate of 14.2% (1108/7807) (range among four areas: 11.8%–16.7%). The rate of link-to-diagnosis was 94.4% (1046/1108) of anti-HCV-positive subjects (range: 90.9%–100%) with an average HCV viremic rate of 55.1% (576/1046) (range: 50.0%–64.3%). The link-to-treat rate was 94.4% (544/576) in HCV-viremic subjects (range from 92.7%–97.2%). Overall, 523 (96.1%) patients achieved an SVR (range: 94.7%–97.6%). Eventually, the overall effectiveness was 80.7% (range:74.6%–93.1%) (Table 1). The presence of hepatocellular carcinoma at baseline was the only factor associated with DAA failure. The DAA regimens were well-tolerated.

Table: (abstract: FRI-143): HCV care cascade of HCV micro-elimination program in Mountainous/remote areas of Taiwan

		(A) Subjects receiving screening, n (%)	Anti-HCV seropositive n (%)	(B) Link-to-care n (%)	HCV RNA seropositive n (%)	(C) DAA treatment n (%)	(D) SVR12 n (%)	(E) Effectiveness
Taoyuan District	1092	1092 (100%)	129 (11.8%)	129 (100%)	72 (55.8%)	70 (97.2%)	67 (95.7%)	93.1%
Alishan Township	2600	2511 (96.6%)	319 (12.7%)	311 (97.5%)	200 (64.3%)	192 (96.0%)	184 (95.8%)	86.6%
Zhuoxi Township	1982	1833 (92.5%)	264 (14.4%)	246 (93.2%)	123 (50.0%)	114 (92.7%)	108 (94.7%)	75.7%
Xiulin Township	2617	2371 (90.6%)	396 (16.7%)	360 (90.9%)	181 (50.3%)	168 (92.8%)	164 (97.6%)	74.6%
Total	8291	7807 (94.2%)	1108 (14.2%)	1046 (94.4%)	576 (55.1%)	544 (94.4%)	523 (96.1%)	80.7%

(E) = (A) × (B) × (C) × (D).

Conclusion: The outreach decentralized community-based care system with DAA therapy was highly effective and safe in the achievement of HCV micro-elimination in the resource-constrained rural and remote regions, which could help us to tackle the disparity.

FRI-144

Impact of the anti-HDV reflex testing on the reduction of hepatitis D burden in Spain

Maria Buti[1,2], Raquel Domínguez-Hernández[3], Adriana Palom[1,2], Ariadna Rando-Segura[2,4], Mar Riveiro Barciela[1,2], Rafael Esteban[1,2], Francisco Rodríguez-Frías[2,4], Miguel Ángel Casado[3]. [1]*Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain, Spain;* [2]*Centro de investigación biomédica en red de enfermedades hepáticas y digestivas, Instituto de Salud Carlos III, Madrid, Spain, Spain;* [3]*Pharmacoeconomics and Outcomes Research Iberia (PORIB), Madrid, Spain, Spain;* [4]*Microbiology Department, Clinical Laboratories, Hospital Universitari Vall d'Hebron, Barcelona, Spain, Spain*
Email: mariabutiferret@gmail.com

Background and aims: Chronic hepatitis D (CHD) is the most severe form of chronic viral hepatitis due to rapid progression to liver cirrhosis and hepatocellular carcinoma. Early diagnosis and treatment could be able to stop the disease progression if suppression of viral replication is achieved. The aim of this study is to evaluate the impact of performing anti-HDV reflex testing in all HBsAg-positive subjects, on the burden of CHD in Spain in the coming years.

Method: A decision tree was designed to simulate the CHD care cascade from screening to treatment within a temporal horizon of 8 years. Two scenarios were compared: the current screening scenario (7.64% of HBsAg-positive patients tested for anti-HDV), and a reflex test screening scenario (100% of HBsAg-positive patients tested).
The study target was the adult Spanish population (18–80 years). The estimated prevalence of HBsAg was 0.22% and of anti-HDV between 7.7%-9.6% of those HBsAg-positive. HDV-RNA was detectable in 60–73% of cases. It was assumed that 66% of viraemic patients would receive pegIFN with a 10% of long-term response. The incidence of complications and hepatic mortality were estimated based on the results of a cohort of patients previously followed for more than 8 years.

Results: The implementation of anti-HDV reflex testing in the HBsAg-positive Spanish population (total 78,965 subjects) would increase the diagnosis of 5,498 positive anti-HDV cases compared to the current scenario, of which 3,225 would be viraemic (Fig 1a). The cost for each anti-HDV+ diagnosed case would be €129. Considering that when using reflex testing, 2,128 more patients would receive treatment and 213 would achieve undetectable HDV-RNA levels, in the median time of the analysis, liver complications would be reduced between 7%–31% (Fig 1b). The prevention of these liver complications would estimatedly save around 40 M euros.

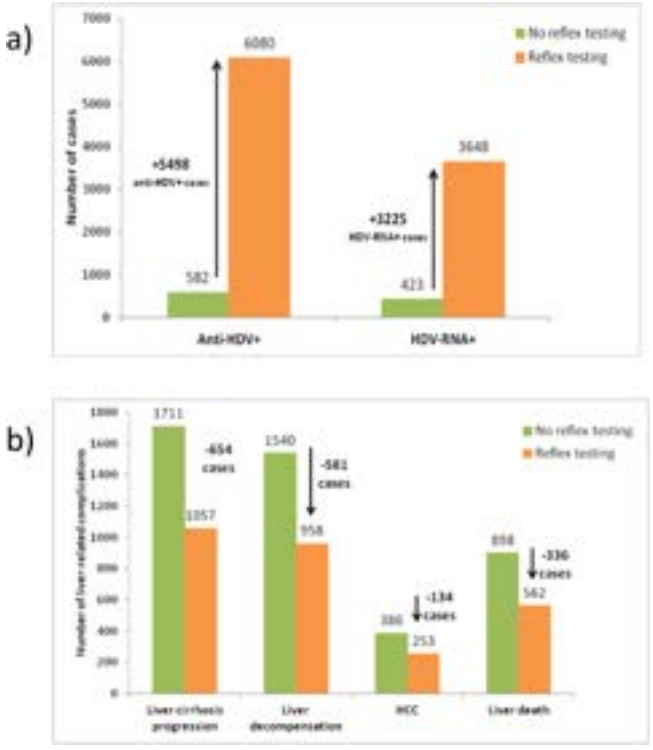

Figure:

Conclusion: In Spain, the use of anti-HDV reflex testing would increase more than 9 times the diagnoses of CHD, reducing the clinical and economic burden of the disease in the next 8 years.

FRI-145

Final results of a hepatitis C micro-elimination campaign in a highly endemic, well-defined demographic area of peri-urban Karachi, Pakistan

Saeed Sadiq Hamid[1], Aliya Hasnain[1], Sultan Salahuddin[1], Wasiuddin Shah[1], Taj Muhammad[1]. [1]*Aga Khan University, Medicine, Pakistan*
Email: saeed.hamid@aku.edu

Background and aims: Pakistan has one of the highest burden of HCV with a nationwide prevalence of 6% with recognized "hot spots" where prevalence and liver disease related mortality is reported to be much higher. The aim of this study was to achieve highest possible HCV elimination in an endemic district by implementing and scaling

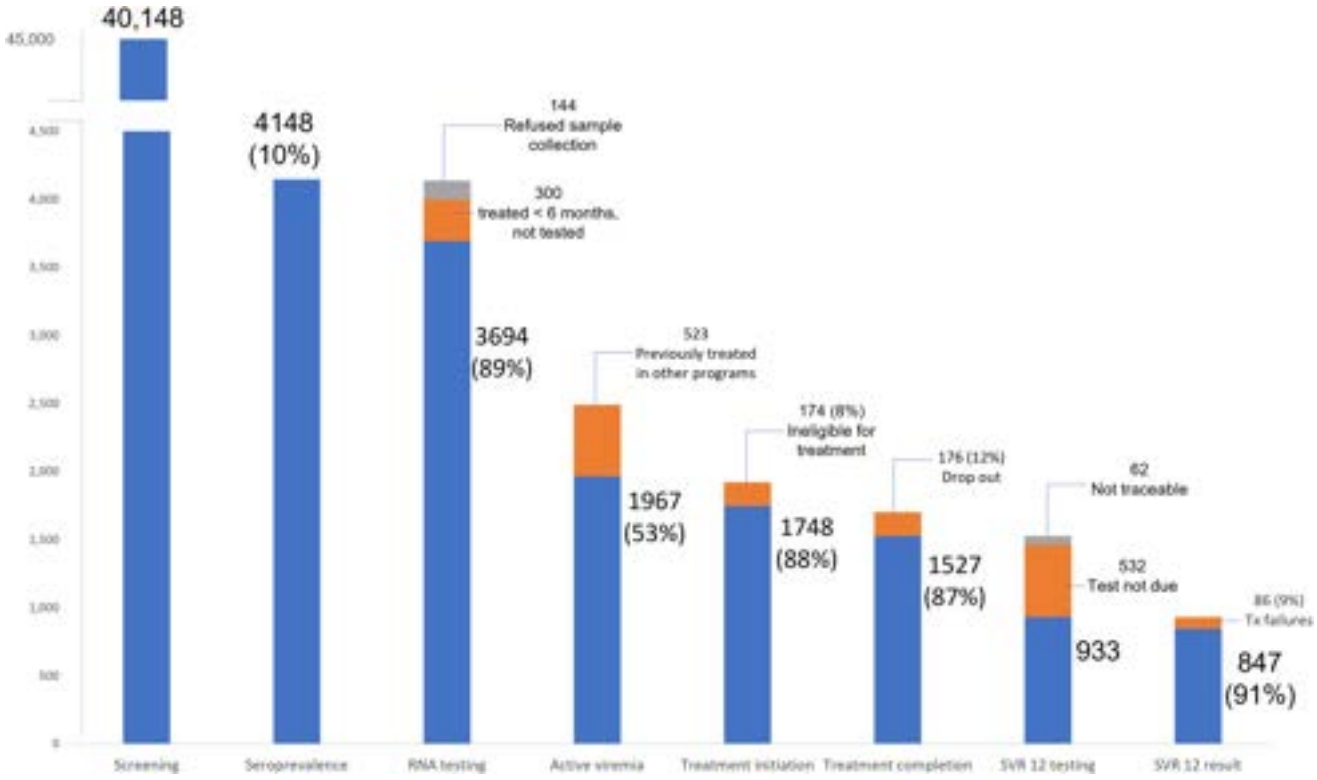

Figure: (abstract: FRI-145): Cascade of Care for Elimination.

up a highly simplified, community based, low-cost test-and-treat model.

Method: This study targeted 40,000 individuals over 12 years of age, across selected Union Councils (UCs) of Malir district, Karachi, based on known sero-prevalence in previous studies After a concentrated campaign of public awareness, a two-step test and teat campaign was started through door-to-door visits guided by community mapping. First, a finger-stick rapid-diagnostic test (RDT) was used to screen for HCV. In those screened positive, reflex testing was done for confirmation of infection using GeneXpert, or HCV core antigen, and blood tests to calculate APRI and FIB-4. On the 2nd visit, individuals with confirmed infection were started on Sofosbuvir plus daclatasvir, for 12 or 24 weeks based on APRI and/or FIB-4 scores, after clinical evaluation by a physician. Follow-up visits were done on monthly basis to deliver medication. RNA testing was done 12 weeks after last dose to assess sustained viral response (SVR). A cohort of individuals previously screened negative was selected for re-screening to identify incidence of HCV infection in this population.

Results: Of the 40,148 individuals screened, 4148 (10%) were positive (mean age 48.37 ± 14.46 years with 69% females). Average seroprevalence in males and females was 10% and 12% respectively. 3694 individuals underwent HCV RNA testing of which 53% (1967/3494) had active viremia. 89% (1748/1967) of these patients started treatment of which currently 1527 have completed treatment, with a dropout rate of 12% (176/1693). Sustained virologic response (SVR) was achieved in 91%. Incidence of infection in the population re-screened was found to be 0.6% (6/1008), with 2/6 viremic cases.

Conclusion: This study demonstrates feasibility of a highly simplified HCV-micro elimination program, using a low-cost community-based model which can be scaled up and implemented in diverse resource-limited settings

FRI-146

Evaluation of hepatitis B core-related antigen rapid test (HBcrAg-RDT) to identify HBV-infected women eligible for peripartum antiviral prophylaxis in resource-limited countries

Jeanne Perpétue Vincent[1], Olivier Segeral[2], Amariane Kone[3], Laurence Borand[4], Jean-Pierre Adoukara[5], Dramane Kania[3], Abdoul Tiendrebeogo[6], Adeline Pivert[7], Saren Sovan[4], Jee-Seon Yang[4], Gauthier Delvallez[4], Françoise Lunel Fabiani[7], Yasuhito Tanaka[8], Yusuke Shimakawa[1]. *[1]Institut Pasteur, France; [2]French Agency for Research on AIDS, Viral Hepatitis and Emerging Infectious Diseases (ANRS-MIE), Cambodia; [3]Centre Muraz, Burkina Faso; [4]Institut Pasteur du Cambodge, Cambodia; [5]Hôpital de Tokombéré, Cameroon; [6]Agence de Médecine Préventive (AMP), Burkina Faso; [7]University Hospital of Angers, France; [8]Kumamoto University, Japan*
Email: yusuke.shimakawa@pasteur.fr

Background and aims: Prevention of mother-to-child transmission (PMTCT) of hepatitis B virus (HBV) is a key intervention to globally eliminate HBV as a public health issue. WHO currently recommends universal infant hepatitis B vaccination starting immediately after birth and peripartum antiviral prophylaxis to HBV-infected pregnant women having high HBV DNA levels (≥200,000 IU/ml). However, access to HBV DNA test is severely limited for pregnant women living in resource-limited countries. To enable decentralization of HBV PMTCT to antenatal care services at peripheral health facilities, we recently developed an immunochromatographic rapid test for hepatitis B core-related antigen (HBcrAg). We evaluated its diagnostic performance to identify HBV-infected women with high viral loads (≥200,000 IU/ml) using real-time PCR as reference in three countries with high HBV prevalence: Cambodia, Cameroon, and Burkina Faso.

Method: We evaluated the performance of HBcrAg-RDT: i) retrospectively using stored sera obtained from pregnant women positive for hepatitis B surface antigen (HBsAg) who participated in two large cohorts in Cambodia (ANRS 12345 TA PROHM) and Cameroon (ANRS 12303); and ii) prospectively using capillary blood collected by finger prick from mothers of infants in Burkina Faso (NéoVac study).

Results: In Cambodia, a total of 1194 HBsAg-positive pregnant women were tested and 367 had HBV DNA levels ≥200,000 IU/ml. The sensitivity and specificity (95% CI) were 93.7% (90.7–96.0) and 95.2% (93.5–96.5), respectively. In Cameroon, of 502 HBsAg-positive pregnant women 88 had high viral load ≥200,000 IU/ml. The sensitivity and specificity were 89.8% (81.5–95.2) and 91.7% (88.6–94.2), respectively. In Burkina Faso, a total of 1338 women participated, of whom 115 (8.6%) were positive for HBsAg and 14 had high viral load ≥200,000 IU/ml. The sensitivity was 85.7% (57.2–98.2) and the specificity was 96.7% (90.6–99.3). In 1223 HBsAg-negative women, none were tested positive for HBcrAg-RDT.
Conclusion: HBcrAg-RDT may be a useful alternative to identify pregnant women eligible for peripartum antiviral prophylaxis at decentralized settings in resource-limited context.

FRI-147
Implementing hepatitis C self-testing (HCVST) among the general population in Georgia: preliminary results

Ketevan Stvilia[1], Maia Tsereteli[2], Ketevan Galdavadze[2], Senad Handanagic[3], Shaun Shadaker[3], Niklas Luhmann[4], Irinka Tskhomelidze[5], Antons Mozalevskis[4], Sonjelle Shilton[6], Tamar Gabunia[7,8]. *[1]National Center for Disease Control and Public Health, Georgia; [2]National Center for Disease Control and Public Health, Georgia; [3]Centers for Disease Control, United States; [4]WHO Headquarters, Testing, Prevention and Populations Team, Global HIV, Hepatitis and Sexually Transmitted Infections Programmes, Swaziland; [5]The Task Force for Global Health, Georgia; [6]FIND, Operational and Implementation Research Unit, Swaziland; [7]Ministry of Internally Displaced Persons from Occupied Territories, Labour, Health and Social Affairs, Deputy Minister, Georgia; [8]National Center for Disease Control and Public Health, Acting Director General, Georgia*
Email: stviliak@gmail.com

Background and aims: The 2015 hepatitis C virus (HCV) serosurvey estimated that more than half (57.3%) of all anti-HCV positive persons were males aged 30–59 years in Georgia. Innovative testing strategies to reach this group-such as HCV self-testing (HCVST)-are important to reach elimination. HCVST is recommended by the World Health Organization as a safe, acceptable, and feasible approach. Despite this, some questions remain about uptake and linkage to treatment following HCVST in different settings and populations. Thus, we evaluated both the uptake of HCVST and linkage to care for a secondary distribution model of HCVST among males aged 30–59 in Tbilisi, Georgia.
Method: This is an observational implementation study of a model of secondary distribution of HCVST among men aged 30–59 years recruited through female household members attending cancer screening clinics in Tbilisi, Georgia. Women who were amenable to recruiting their male household members were provided with HCVST kits to take home. After HCVST, male participants were able to register on an online platform to self-report their test results and complete an online survey to provide their demographic data, knowledge of HCV, HCV risk factors, and their experience with self-testing. Participants received a monetary incentive (about 3 USD) for completing the survey. Survey data will be linked with the national Hepatitis C Elimination Program database to assess linkage-to-care and treatment initiation among the anti-HCV positive participants.
Results: During June 9, 2022-January 1, 2023, a total of 1040 female participants were enrolled in the study (refusal rate 29%). A total of 541 male partners self-tested and shared their test results. Seven (1.3%) participants reported a reactive anti-HCV test result; all were more than age 43 years. Of those completing the online survey (n = 533), most said they would self-test again (n = 421, 78.9%); 455 (85.4%) felt they were able to correctly self-test and interpret the test result, and 15 (2.8%) said the self-tests did not work. Most participants reported self-testing independently (n = 288, 60.0%) or receiving assistance from a friend or household member (n = 177, 36.9%). The remaining participants were assisted by the study team (n = 7) or found information online (n = 4).
Conclusion: Preliminary results from this study show that more than half of women who received HCVST kits at the cancer screening sites were able to recruit male partners/household members into the HCV self-testing study. Implementation of this test distribution model was limited because of low internet literacy among the target population, thus additional options should be developed for reporting the HCV self-testing results. Engaging female household members may be instrumental in reaching important, highly burdened segments of the population who are unlikely to access traditional testing strategies.

FRI-148
Retrospective study of hepatitis C virus antibodies and active viral replication in patients with severe mental illness in a Spanish university hospital

Cristina del Rio-Cubilledo[1], Aitana Carla Morano Vázquez[2], Denise Monserrat Arroyo Jarrin[3], Miriam Soriano García[3], Henar las Heras Miralles[1], Jose Manuel Olivares Díez[4], Luis Enrique Morano Amado[5]. *[1]South Galicia Health Research Institute, South Galicia Biomedical Foundation, Vigo, Spain; [2]Preventive Medicine Service, Gregorio Marañón University Hospital, Madrid, Spain; [3]Psychiatry Service, Álvaro Cunqueiro University Hospital, Vigo, Spain; [4]Psychiatry Service, Vigo Health Area, Álvaro Cunqueiro University Hospital, Vigo, Spain; [5]Infectious Disease Unit, Álvaro Cunqueiro University Hospital, Vigo, Spain*
Email: cristina.delrio@iisgaliciasur.es

Background and aims: In 2019, WHO estimated the prevalence of chronic HCV about 58 million globally, however only 21% were diagnosed and 9.4 million were treated with direct-acting antivirals (DAA). In Spain the prevalence of antibodies was 0.85% and the active infection was 0.22% in general population. HCV can cause hepatocellular carcinoma and cirrhosis. Among at-risk groups, HCV and other Blood-Borne Viruses (BBV) are very common in people with severe mental illness (SMI). People with SMI should be screened for BBV as a standard health assessment. Screening in the psychiatric unit of a hospital showed that 9% of patients were HCV positive. Other study showed that testing all psychiatric patients is cost-effective and should help to wipe out HCV. However, people with SMI have been under-recognized as a priority group for HCV screening.
Method: We did a retrospective study of 1631 patients admitted in the Psychiatry Unit at Álvaro Cunqueiro University Hospital (Vigo, Spain) between 2019 and 2021 to detect patients with HCV antibodies, HCV-untreated patients with active RNA replication, HCV-treated patients with sustained virologic response (SVR), HCV spontaneous viral clearance, HCV-uninfected and HCV-unknown. The selected covariates were age, sex, psychiatric diagnosis and other BBV.
Results: From 1631 patients with age average of 46 years, 785 were male and 846 female. 1097 (67.3%) were tested for antibodies. Antibodies were confirmed in 102 (9.3%) patients. Among these patients 93 (93.0%) showed undetectable RNA replication, of which only 64 (68.8%) have followed a treatment with SVR and the rest reached spontaneous viral clearance (SVC). 2% were not tested for RNA replication and 7 (7.0%) had active replication and did not follow any treatment. Among patients with positive antibodies, 26.5% had schizophrenia and 18.6% other psychotic disorder, followed by patients with personality disorder (15.7%), bipolar disorder (7.8%), depressive disorder (5.9%), adaptive disorders (3.9%) and 21.6% had other disorders.
Conclusion: The prevalence of HCV in our Psychiatry Unit was 10.9 times higher than in general population. Our results highlight the need to address the issue of higher prevalence of HCV in people with severe mental illness. The Health System should provide an effective screening method to identify patients with HCV at at-risk

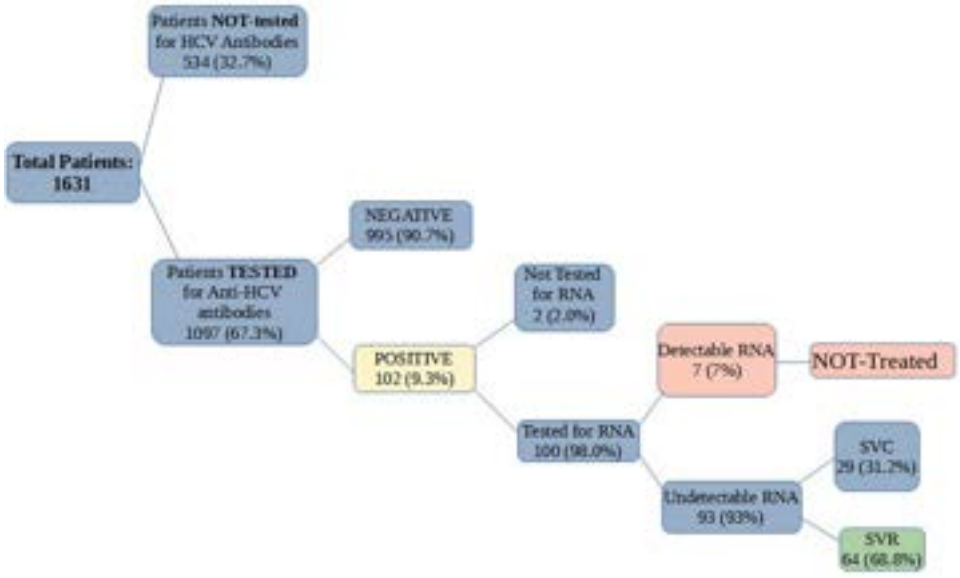

Figure: (abstract: FRI-148): Percentages of patients with HCV antibodies, RNA detectable or undetectable and patients who took treatment or reached SVC.

populations and develop a system to test all patients admitted in psychiatric units in hospitals.

FRI-149

Tailored message intervention by nudge theory increases the number of the viral hepatitis screening for Japanese workers and consultation behavior of positive patients -Consideration of 1.7 million general check-up participants

Masaaki Korenaga[1], Chieko Ooe[2], Keiko Kamimura[2], Tatsuya Ide[3], Tatsuya Kanto[4]. *[1]Hepatitis Information Center, The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa Chiba, Japan; [2]Japan Health Insurance Association, Japan; [3]Kurume University, Japan; [4]Hepatitis Information Center, The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Japan*
Email: dmkorenaga@hospk.ncgm.go.jp

Background and aims: Although the overall number of hepatitis B virus (HBV) and hepatitis C virus (HCV) carriers in Japan has decreased, actions against hepatitis at work sites in Japan have not yet been fully implemented. In Japan Health Insurance Association (JHIA), which is belonged to more than 40 million Japanese who are working in Medium and Small Sized Companies, the attendance rates of hepatitis screening were less than 2% even the cost of only €6.The aim of this study was to investigate the effectiveness of a tailored message intervention using nudge theory promoted the numbers of viral hepatitis screening and how many of those found to be positive patients have been followed up with examinations and hospital treatment.
Method: More than 1.7 million Japanese workers at Fukuoka branch of the JHIA who wish to get annual general checkup from 2017 to 2020 received client reminders by using nudge theory for an optional hepatitis virus screening. For control subjects, we enrolled general checkup applicants with typical message condition in 2016. The main outcome measure was attendance rates in HBV and HCV screening which were examined HBs antigen (HBsAg) and Anti-HCV antibody (HCVAb), respectively. In addition, 6 months after the checkup, we analyzed how many workers who were positive for HCVAb visited to physicians by medical prescription system.
Results: There was a significant difference in viral hepatitis screening attendance rates between the client reminders by using nudge theory (n = 109,003 6.5%) and the control (n = 4,791 1.2%; $p < 0.001$). One thousand four workers (0.94%) were positive of HBsAg (n = 631, 0.58%) and HCVAb (n = 373, 0.38%), respectively. The positive rate of HCV Ab in the 50 s (0.60%) were higher than those in 60 s (0.49%). One hundred eighty-five with HCVAb positive (50%) were confirmed to visit specialists within 6 months after the screening. Seventy (38%) were treated with IFN-free direct-acting antivirals and three males (1.6%) in 60 s were detected hepatocellular carcinoma.
Conclusion: There were still many positive patients with viral hepatitis at work sites. A simply modifying the client reminders using nudge theory could increase the viral hepatitis screening rates. Promoting hepatitis virus screening for workers at general checkup can rescue hepatitis virus carriers who are unaware of their infection and require to therapy for viral elimination and liver cancer.

FRI-150

Metabolic-associated fatty liver disease in socio-economic vulnerable population with chronic hepatitis B and C

Speranta Iacob[1,2], Razvan Iacob[1,2], Mihaela Ghioca[1,2], Cristian Gheorghe[1,2], Liana Gheorghe[1,2]. *[1]Carol Davila University of Medicine and Pharmacy, Gastroenterology, București, Romania; [2]Fundeni Clinical Institute, București, Romania*
Email: msiacob@gmail.com

Background and aims: Viral hepatitis and metabolic-associated fatty liver disease (MAFLD) are the two leading causes of chronic liver disease in Romania. We are currently conducting a screening project in vulnerable population intended to provide preventive medical services, screening, diagnosis and linkage to care for patients detected with chronic HBV and HCV infection. The aim of our study was to investigate the presence of MAFLD in patients detected with viral hepatitis B and C in the screening project.
Method: 724 patients with B and C viral hepatitis detected at screening, staged and treated during 1 year period (September 2021–2022) in Fundeni Clinical Institute, were also screened for MAFLD using ultrasound, Fibroscan with CAP, FINDRISC (Finnish diabetes risk) score and AUDIT-C score.
Results: There were 61.5% of patients with HBV infection and 38.5% with chronic hepatitis C. Associated MAFLD was encountered in 55.8% of patients. The following statistical significant differences were encountered in HCV vs HBV infections: older age, higher prevalence of diabetes mellitus, higher liver stiffness values, higher percentage of cardiovascular and psychiatric disorders (p values <0.05), but had

similar nonsignificant differences regarding BMI values, liver steatosis evaluated by CAP and chronic alcohol consumption. Liver stiffness values were not influenced by the presence of severe steatosis. Grade III liver steatosis evaluated by CAP was significantly higher in patients with higher BMI values and excessive alcohol drinking evaluated by AUDIT-C score ≥3. FINDRISC score was significantly higher in female patients with HCV infection and correlated well with BMI values. Moderate FINDRISC score to develop diabetes mellitus in the next 10 years was associated with higher AST, ALT, triglycerides and BMI values. A higher FINDRISC and AUDIT scores were not associated with higher liver stiffness measurement. **Conclusion:** MAFLD is highly prevalent in patients with chronic hepatitis B and C in Romania, being associated with high BMI and AUDIT-C scores. Liver stiffness measurement was not influenced by the presence of MAFLD, but was significantly higher in HCV chronic hepatitis patients.

Email: jparab@gmail.com

Background and aims: Although the WHO strategy has the goal to eliminate the hepatitis C virus (HCV) as a public health threat by 2030, the existence of national strategies is variable worldwide. We

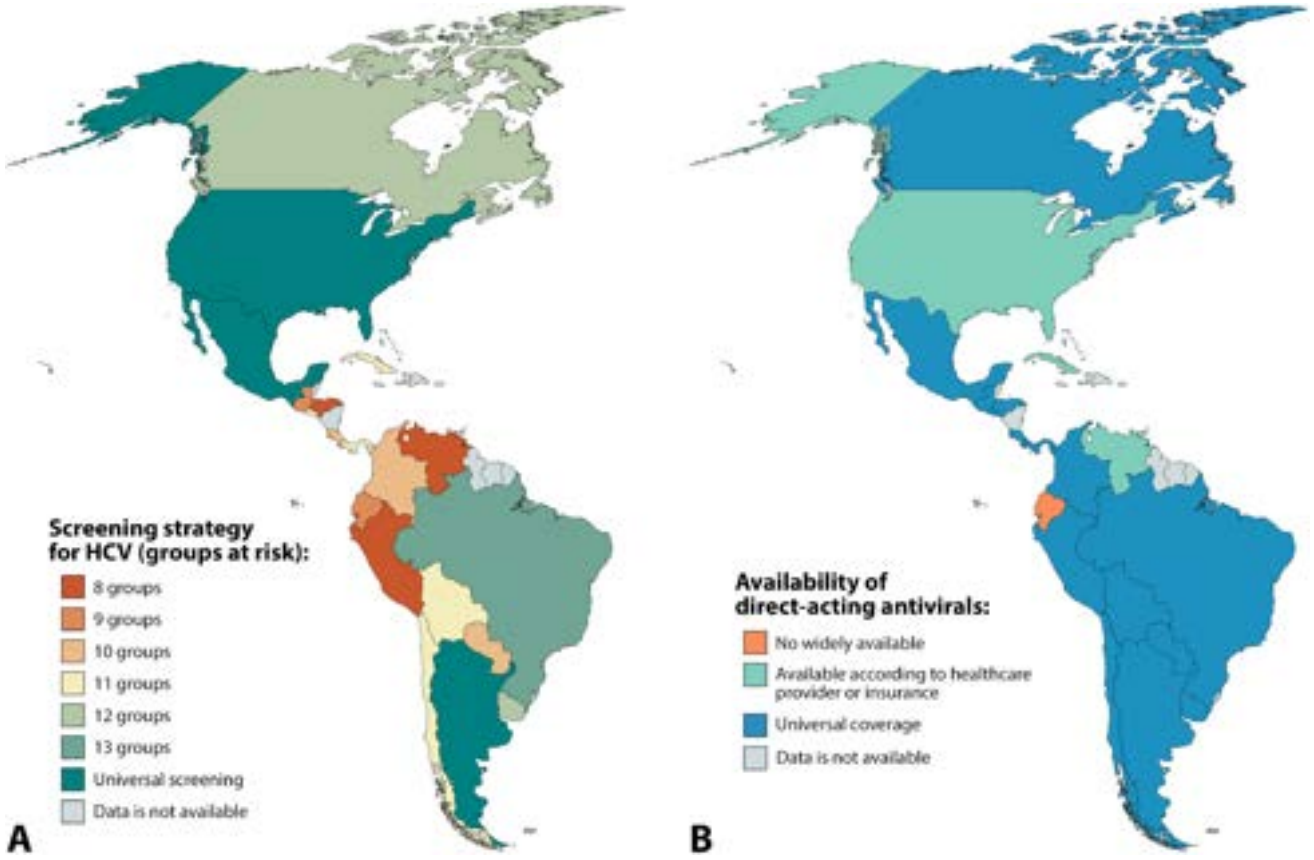

Figure: (abstract: FRI-151): Screening strategies (A) and availability of direct-acting antiviral treatments (B) among 19 countries in the Americas. The potential groups for screen were solid organ transplantation, haematological transplantation, chronic kidney disease, haemodialysis, human immunodeficiency virus infection, cirrhosis (any aetiology), hepatocellular carcinoma, bleeding disorders who have received a transfusion of blood products, sexually transmitted infections, injectable drug users, serious mental health disorders, migrants from countries with a high prevalence of HCV, pregnant women, and people of a certain age (e.g., baby boomers).

aimed to assess the establishment of different policies and strategies to eliminate HCV in the Americas.

Method: We conducted a 23-item survey about HCV infection among gastroenterologists and hepatologists in the Americas. Questions were classified into four categories: policies and civil society (1 question), diagnosis (6 questions), care management (14 questions), and monitoring systems (2 questions). The survey was administered using an electronic form between November 7, 2022- January 8, 2023. Data were collected in a spreadsheet, revised by two independent reviewers, and compared with governmental institutions, regulatory agencies, scientific societies, and scientific publications.

Results: We obtained 47 responses from 19 out of 21 countries targeted (Argentina, Bolivia, Brazil, Canada, Chile, Colombia, Costa Rica, Cuba, Ecuador, El Salvador, Guatemala, Honduras, Mexico, Panama, Paraguay, Peru, United States, Uruguay, and Venezuela). Fifteen (78.9%) countries have adopted a national strategic plan to eliminate HCV. Three (15.8%) countries have universal screening for HCV infection (Figure 1A). HCV was more commonly diagnosed in older cirrhotic patients (57.8%), followed by young patients who inject drugs (21.1%), and men who have sex with men (21.1%). After a positive HCV serological test, 10 (52.6%) countries perform reflex testing to confirm HCV diagnosis using the same sample. However, only 7 (36.8%) countries have an alert system for the requesting physician. Twelve (63.2%) countries have a direct referral system for specialized care of HCV positive cases. There is universal access to direct-acting antivirals (DAAs) in 15 (78.9%) countries (Figure 1B). Seven (36.8%) countries have generic DAAs available. Only 3 (15.8%) countries perform a retrospective search for HCV positive cases that could have been lost to follow-up.

Conclusion: Although most countries have adopted a national strategic plan to eliminate HCV, there are several issues and barriers to elimination in the Americas.

FRI-152

Qualitative interviews to assess the impact of chronic hepatitis delta virus infection on health-related quality of life in untreated patients from the US, Italy, Spain, and Germany

Pietro Lampertico[1,2], Robert G. Gish[3], Nancy S. Reau[4], Heiner Wedemeyer[5], Maria Buti[6], Hannah Elwick[7], Nicola Williamson[7], Aishwarya Chohan[7], Margaret Guy[7], Rowena Jones[7], Ankita Kaushik[8], Alon Yehoshua[8]. *[1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Division of Gastroenterology and Hepatology, Milan, Italy, Italy; [2]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy, Italy; [3]Hepatitis B Foundation, Doylestown, PA, United States; [4]Department of Internal Medicine, Division of Digestive Diseases and Nutrition, Rush Medical College, Chicargo, United States; [5]Department of Gastroenterology, Hepatology, and Endocrinology, Hannover Medical School, Hannover, Germany; [6]Liver Unit, Hospital Universitario Valle Hebron and Ciber-ehd del Instituto Carlos III, Barcelona, Spain; [7]Patient-Centred Outcomes, Adelphi Values, Bollington, United Kingdom; [8]Gilead Sciences, California, United States*

Email: pietro.lampertico@unimi.it

Background and aims: Hepatitis delta virus (HDV) is the most severe form of viral hepatitis, which often results in accelerated progression to cirrhosis and poor prognosis, impacting patients' health-related quality of life (HRQoL). Patient-Reported Outcome (PRO) instruments can capture the patient perspective and provide additional insights beyond surrogate markers such as viral load and alanine amino-transferase changes. The US Food and Drug Administration's guidance states that PRO instruments should have sufficient evidence of content validity in the target population prior to use. This study aimed to explore the experience of patients living with chronic HDV and evaluate the content validity of the Hepatitis Quality of Life Questionnaire (HQLQ) and the Fatigue Severity Scale (FSS) for use in HDV.
Method: Semi-structured concept elicitation and cognitive debriefing qualitative interviews were conducted with patients in the US, Germany, Italy, and Spain with a clinician-confirmed diagnosis of chronic HDV. Patients were eligible to participate if they were not treated with interferon at the time of the study or in the previous six months. Patients diagnosed with Hepatitis C or had experienced an acute episode of liver disease in the previous six months were excluded. Participants described their experience living with HDV and then completed two instruments using a think-aloud technique to assess understanding, comprehension, and relevance of items, instructions, response scales, and recall period. Interviews were conducted in the native language of each country, and official translations of instruments were used. Thematic and framework analyses of verbatim interview transcripts were performed.
Results: The study sample (n = 32) included participants with a range of liver fibrosis stages from F0–F3 or F4 compensated, and two participants diagnosed with hepatocellular carcinoma. The majority of participants were aged over 55, and 63% of the sample were female. Fatigue, loss of appetite, pain over liver, nausea, and fever were the most frequently reported symptoms. Participants reported that HDV impacted their emotional wellbeing (low mood, anxiety), physical functioning (inability to exercise, difficulty walking), social functioning (including stigma), and work (difficulty meeting job responsibilities). By this approach, participants demonstrated good understanding of HQLQ and FSS items, instructions, response scales and recall periods, and concepts assessed in the instruments were considered relevant to HDV by most participants.

Table 1. Participant clinical and demographic characteristics

Clinical and demographic characteristics of sample, n (%)	Total (n=32)
Liver fibrosis stage	
F0-F1	17 (53)
F2	5 (16)
F3	3 (9)
F4 compensated	7 (22)
F4 decompensated	0 (0)
HCC diagnosis status	
Diagnosed	2 (6)
Not diagnosed	30 (94)
HBV treatment status	
Untreated	2 (6)
Previously treated	11(34)
Currently treated	19 (60)
HDV treatment status	
Untreated	14 (44)
Previously treated	18 (56)
Currently treated	0 (0)
Age	
18-30 years	3 (10)
31-55 years	11 (34)
>55 years	18 (56)
Sex	
Male	12 (37)
Female	20 (63)

Conclusion: Findings contribute to the understanding of the patient experience of HDV and support the content validity of the HQLQ and FSS as outcome assessments for use in HDV. Further research to examine the psychometric validity of the PRO instruments and support their use as clinical trial end points is recommended.

FRI-153

Microbiological analysis of acute hepatitis of unknown aetiology in children in Spain

Ana Avellon Calvo[1,2], Milagros Munoz-Chimeno[1], Carmen Varela[3], Maria Guerrero[3], Marina Peñuelas[3], Lucia Morago[1], Nazaret Sanchez[1], Monica Gonzalez[4], David Tarrago[5], Juan Emilio Echevarria[5], Maria Dolores Fernandez[5], Raquel Escudero[6], Francisco Pozo[7], Sarai Varona[8], Victoria Hernando[3], Asuncion Diaz[3]. *[1]National Centre for Microbiology, Hepatitis Unit, Spain; [2]Instituto de Salud Carlos III, Hepatitis Unit, Spain; [3]National Centre for Epidemiology, Spain; [4]National Centre for Microbiology, Central Laboratory, Spain; [5]National Centre for Microbiology, Viral Detection Unit, Spain; [6]National Centre for Microbiology, Bacteriology, Spain; [7]National Centre for Microbiology, Respiratory Viruses, Spain; [8]Instituto de Salud Carlos III, Bioinformatics Unit, Spain*
Email: aavellon@isciii.es

Background and aims: On 2022 5th April, United Kingdom notified to WHO an alert of severe acute hepatitis in children. Since then to the end of 2022 Spain has detected 61 cases with 3 deaths. Microbiological analysis, complementary to that performed at the hospitals, has been performed at the National Centre for Microbiology in 42 cases.
The aim of this report is to describe the microbiological analysis performed at the National Centre for Microbiology in 42 cases, including the metagenomic analysis.
Method: Samples (serum, total blood, faeces, urine and nasopharyngeal swab) were studied through PCRs of: herpes simplex viruses, virus varicella-zoster, cytomegalovirus, Epstein-Barr virus, herpes 6, 7 and 8, enterovirus, parvovirus B19, adenovirus, hepatitis A and E, norovirus and leptospira. Massive sequencing was performed in most of the cases with a metagenomic approach.
Results: Among serum and total blood samples, 11/42 (26.2%) cases were positive to herpes and 3/42 (7.1%) positive to enterovirus. Adenovirus were detected in 18/42 (42.8%) of the cases, obtaining 2 complete genomes. Adeno-associated viruses were detected by metagenomics in 8/42 (19.0%) cases. Some other viruses were detected as: CoVNL63, Coronavirus HKU1, Sapporovirus, Respirovirus and Parechovirus.
Conclusion: Obtained results parallels those reported in other European countries in where adenoviruses and adeno-associated viruses were the most common viruses detected. However, the aetiology of the hepatitis cases remains unclear, as more case and control studies are needed to define the exact role of each microorganism.

FRI-154

Emergency department contribution to hepatitis C elimination through opportunistic screening in Cascais, Portugal

Inês Vaz Pinto[1], Catarina Esteves Santos[1], Mafalda Guimarães[1], Rita Vale Rodrigues[1], Vanda Castro[1], Alba Carrodeguas[2], Diogo Medina[2]. *[1]Hospital de Cascais Dr. José de Almeida, Alcabideche, Portugal; [2]Gilead Sciences, Lda, FOCUS Program, Lisboa, Portugal*
Email: diogomedina@gmail.com

Background and aims: Advancing screening and linkage to care practices is necessary to eliminate hepatitis C in Portugal toward WHO goals for 2030. We aimed to ascertain whether screening of patients seeking urgent care could effectively complement existing targeted screening policies.
Method: We implemented opportunistic screening in the emergency department from September 2018 to September 2021 (36 months), using existing infrastructure and staff, aided by electronic health

record system automations to identify screening eligibility and request serologies. Patients aged 18–64 were eligible upon verbal consent IF they had no recorded tests in the previous year AND required blood work. Follow-up or discharge were provided regardless of test results. Case managers contacted positive patients to ensure linkage to care.
Results: We screened 88.9% (n = 38,357) of eligible patients, finding 1.49% (n = 571) HCV antibody seroprevalence, 0.56% (n = 215) HCV RNA prevalence, and 26.5% (n = 57) unknown infection. Most were Portuguese (74%), male (61%), with an average age of 51.3 (19–65). Injected drug use and heterosexual transmission accounted for 75% and 25% of known modes of transmission. 1a (44%) and 3 (32%) were the most found genotypes. We linked 80.7% (n = 46) of patients to care post-diagnosis. Of 38 patients subject to real-time elastography or serum biomarkers for liver stiffness measurement at our hospital, 31% presented with either advanced fibrosis (F3) or cirrhosis (F4).
Conclusion: Our project led to a significant increase in the number of patients diagnosed at our hospital. Changes in testing stigma were also apparent, with high patient and provider adherence to screening. Opportunistic blood-borne virus screening approaches in emergency departments are feasible and effective.

FRI-155
Implementation of anti-HDV reflex testing among HBsAg-positive in a tertiary center in South Italy
Valentina Cossiga[1], Annachiara De Conte[1], Stefano Brusa[2], Eduardo Molinari[2], Francesco Maria Cutolo[1], Luisa Ranieri[1], Raffaele Lieto[1], Enza Zacchia[2], Maria Rosaria Attanasio[1], Fortunato Mazzitelli[1], Maria Guarino[1], Giuseppe Portella[2], Filomena Morisco[1]. *[1]Department of Clinical Medicine and Surgery, Diseases of the Liver and Biliary System Unit, University of Naples "Federico II", Naples, Italy, Italy; [2]Department of Translational Medical Science, University of Naples "Federico II", 80131 Naples, Italy, Italy*
Email: valentina.cossiga@gmail.com

Background and aims: In Italy, the prevalence of HDV infection in HBsAg carriers is about 9.9% (6.4% in Italian natives and 26.4% in immigrants) [1]. However, the actual prevalence is probably underestimated because the anti-HDV test is not performed routinely in all HBsAg carriers. The HDV causes a rapidly progressive liver disease and as new antiviral therapies are coming, it is fundamental to known the exact HDV prevalence. The aim of this study was to describe the impact of the introduction of anti-HDV reflex test in all HBsAg-positive subjects at AOU Federico II and to compare the results before and after its implementation.
Method: From April 2021 to December 2022, reflex test for the detection of total HDV antibodies was performed in all HBsAg positive subjects observed at AOU Federico II. Demographic, clinical and laboratory data were collected. Liver fibrosis was evaluated with FIB-4. Sera were evaluated with ADVIA Centaur HBsAgII Qualitative, Liaison Murex HBsAg Quantitative and Liaison Murex Total Anti-HDV Qualitative.
Results: Before reflex testing, anti-HDV had been tested in 16.4% (84/512) of HBsAg positive subjects, while after its implementation, 100% (423/423) of HBsAg positive patients was tested for anti-HDV. The anti-HDV positive prevalence was higher before the introduction of reflex test (16% vs 12%), but the absolute number of anti-HDV positive patients increased (14 vs 51). Of 423 HBsAg carriers, 51 (12%) resulted positive for total anti-HDV. The majority of them (90.2%) were Italian natives and only 5 (9.8%) of them were immigrants. Twenty-four (47%) were males with a median age of 62.2 years, not different from anti-HDV negative subjects. Twenty (39.2%) patients were already aware of HBV/HDV coinfection. HDV-RNA was performed in 37 (72.5%) subjects and resulted detectable in 22 (59.4%) of them, with a median HDV-RNA level of 84.300 [25th-75th percentiles: 1.685–547.796] IU/ml. Twenty (39.2%) anti-HDV positive subjects had advanced liver fibrosis.
Conclusion: Our data showed that the implementation of anti-HDV reflex test increased the number of diagnosis of HDV infection and revealed the real prevalence of HDV prevalence (higher than expected). Moreover, the HDV-RNA is performed only in a part of the anti-HDV positive subjects. In this setting, due to the forthcoming approval of specific anti-HDV drugs, a reflex test for HDV-RNA should be implemented to identify viremic patients needing antiviral treatment.

FRI-156
Effectiveness of a direct care action strategy at the drug addiction center (test and treat in point of care) for the detection and treatment of hepatitis C in drug users on opioid agonist substitution therapy
Adrià Rodríguez[1,2], Inés Sáenz de Miera[1,2], Maria Assumpció Sendra[3], Patricia Méndez[3], María Ángeles Roch[4], Montserrat Vargas[1], Silvia Montoliu[1,2], Albert Pardo[1,2], Joan Colom[5], Juan Carles Quer Boniquet[1,2]. *[1]Joan XXIII University Hospital of Tarragona, Gastroenterology, Spain; [2]Pere Virgili Health Research Institute, Tarragona, Spain; [3]Tarragona Drug Addiction Center, GIPPS, Spain; [4]Joan XXIII University Hospital of Tarragona, Pharmacy, Spain; [5]Catalonia Public Health Agency (ASPCAT), Program PCAVIHV, Sub-Directorate General of Drug Dependences, Spain*
Email: senisamier@yahoo.com

Background and aims: Drug users are a vulnerable group with difficulty accessing the diagnosis and treatment of chronic infection by the hepatitis C virus (CHC); for this reason, targeted micro-elimination strategies are being developed to act specifically in this group, with the aim to facilitate their access to treatment. This study aims to evaluate the effectiveness of an onsite strategy at the drug addiction center (DAC) (*test and treat in point of care*) to characterize, treat and cure patients with CHC undergoing opioid agonist substitution therapy (OAT) in their usual environment.
Method: Using one-step virological detection, patients with positive viremia were assessed at the DAC's office by a hepatologist, a pharmacist, and DAC professionals. During the same visit, baseline clinical, laboratory and elastographic characteristics were determined, as well as potential drug interactions, before starting direct-acting antivirals (DAA). Therapy began on the same day of the visit and was fully facilitated by the DAC, where adherence control was carried out. Sustained viral response (SVR) was evaluated at week 12 post-treatment (SVR12). We present descriptive data of 48 patients visited and treated at the DAC in the periods of January-March 2020 and November 2020-December 2022.
Results: 91.2% of the patients were men with a mean age of 48 years. 96% were caucasian; 83% were Spanish. 90% were treatment-naive, and genotype 1a was the most frequent (50%). Most were F0-1 (73%) and only 3 (6%) were F4. 35 received treatment for 8 weeks with Glecaprevir/Pibrentasvir and 13 for 12 weeks with Sofosbuvir/Velpatasvir. In the pre-interaction study, only 3 patients required modifications to their usual treatment. In total, 8 patients had side effects (4 mild and 4 moderate) without requiring treatment modifications. The adherence of patients who have already completed treatment (48) has been excellent in 90%. The response of 45 patients is evaluated (2 are completing treatment and 1 died before being evaluated): At the end of treatment: 43 (96%) had responded and in 2 (4%) the response is unknown due to loss of follow-up. At week 12 post-treatment: 40 patients (89%) had achieved SVR12, 1 presented criteria for treatment failure and in 4 (9%) this was unknown due to loss of follow-up. The maintenance of the response one year post-treatment has been evaluated in 43 patients: 25 (58%) maintain SVR, 4 (9%) present criteria for reinfection (3 of them have already been retreated), while in 14 (33%) the response is unknown due to loss of follow-up.
Conclusion: A high adherence to treatment was observed applying the *test and treat in point of care* strategy. The efficacy of the novel

strategy was significantly higher than those described for this group of patients with the usual strategies (*standard of care*). Only one case of virological failure has been observed, however, the loss of follow-up after completing the treatment makes it difficult to obtain efficacy comparable to the general population. The study also found a significant rate of reinfection at one year of follow-up. Most reinfected patients have already been retreated. The center-based action strategy was found to be superior to usual strategies for treating this difficult-to-treat population.

FRI-157

Comparison of HCVRNA results using plasma separation card with gold standard veni-puncture

Huma Qureshi[1], Hassan Mahmood[2], Syeda Zahida Sarwar[3], Khalid Mahmood[4]. [1]*Ministry of National Health Services, Regulations and Coordination, Pakistan, Pakistan;* [2]*Integral Global, Pakistan;* [3]*Independent Consultant, Lahore, Pakistan;* [4]*Punjab Health Department, Lahore, Pakistan*
Email: drhumapmrc@gmail.com

Background and aims: Drawing a venous sample for HCVRNA testing requires an expert. The transportation of this sample and its storage also requires special care and refrigeration especially in the low middle income countries. The plasma separation card is a solution for all these issues where whole blood collected from a finger stick is placed onto the card and is transported without separating or refrigerating it. HCV RNA is extracted from it at the laboratory.
To compare the ease of extraction and results HCVRNA using Plasma Separation Card with Gold standard venous blood collected in a gel tube.
Method: A total of 350 anti HCV reactive persons underwent reflex blood collection for HCVRNA. From each individual 5 ml of venous blood was collected in a gel tube and stored for HCVRNA testing. From the other hand, using a finger stick, 140 microliters of whole blood were collected in the capillary tube and poured over the marked point of the plasma separation card (PSC). The gel tube and the PSC were transported to the main laboratory for RT PCR, where plasma was separated from the gel tubes and was run for HCVRNA testing (both qualitative and quantitative assays). From the plasma separation card, one punch of spot was removed and placed in the virus extracting solution and tested for HCVRNA using standard steps (both qualitative and quantitative assays). The two tests were run simultaneously for comparison. A correlation factor of 50 was applied to the PSC viral quantification and then compared with the quantitative HCVRNA levels obtained from the venous samples.
Results: A total of 352 anti HCV reactive cases underwent venous blood sampling and the finger stick blood collection on PSC. Both samples were run for HCVRNA at the laboratory. There were 54% males and majority were anti HCV reactive between 21 and 50 years. HCVRNA testing was done in 84% cases before starting the treatment while in others it was done after completion of the treatment. Preference for finger stick blood collection was seen in patients and technicians. Time taken in venous collection was much less than that in the finger stick. Gold standard venous sample collected in gel tube detected virus in 144 samples while finger stick blood collected on PSC detected HCVRNA in 153 cases. The sensitivity of the PSC was 93.8% with 91.3% specificity. The positive predictive value was 88.2% and negative predictive value was 95.5%. Overall, a good correlation of r = 0.63 was seen between HCVRNA extracted from venous sample vs PSC.
Conclusion: Plasma separation card for blood collection, transportation, storage and extraction of HCVRNA was found to be user friendly when compared with the venous blood collection. The HCVRNA extracted from the PSC correlated well with the venous sample suggesting its wider use especially in difficult to reach populations and areas.

FRI-158

Patients with hepatitis B and D are more often linked to medical care than patients with hepatitis C

Elena Vargas Accarino[1], Anna Feliu-Prius[1], Adriana Palom[1], Ariadna Rando-Segura[2], Ana Barreira[1], Joan Martinez-Camprecios[1], Judit Vico-Romero[1], Juan Carlos Ruíz-Cobo[1], Jordi Llaneras[1], Mar Riveiro Barciela[1], Francisco Rodríguez-Frías[2], Rafael Esteban[1], Maria Buti[1]. [1]*Vall d'Hebron Universitary Hospital, Liver Unit, Spain;* [2]*Vall d'Hebron Universitary Hospital, Microbiology Deparment, Spain*
Email: mbuti@vhebron.net

Background and aims: The WHO established the goal to decrease hepatitis B and C associated mortality to less than 6 cases/100.000 people for 2030. To achieve this goal, it is important to identify and link to care patients with viral hepatitis. The objective of this study was to retrieve hepatitis B, C and D lost to follow-up patients and to deepen the reasons why they were not linked to care. This study was performed in the Spanish public health system.
Method: Retrospective and prospective search in the microbiology database of the northern area of Barcelona (450.000 inhabitants) of patients with hepatitis C (HCV-RNA+), hepatitis B (HBsAg+) and hepatitis D (anti-HDV+). Patient medical records were reviewed to identify lost to follow-up patients. Candidates to contact were telephoned a maximum of 5 times to offer them a medical visit.
Results: A total of 3407 patients were screened between January 2019 and June 2022. Among them, 1540 (45%) were HBsAg+, 53 (2%) anti-HDV+, and 1.814 (53%) HCV-RNA+. 498 (31%) from the HBsAg+ patients were not linked to care, 14 (26%) from the anti-HDV patients and 1018 (56%) form the HCV-RNA+; being hepatitis D patients significantly more linked to care than hepatitis C patients ($p < 0.0001$). After the telephone calls, 226 (46%) from the 498 HBsAg+ patients not linked to care, 12 (85%) from the 14 anti-HDV+ (2 of which HDV-RNA+) and 54 (5.3%) from the 1.018 HCV-RNA+ were finally linked; being HCV-RNA+ patients significantly less linked to care ($p < 0.0001$). Patients with hepatitis C had significantly more advanced age or comorbidities (703 (23%)), compared to patients with hepatitis B or D (17 (1%) and 1 (2%)) ($p < 0.0001$). Of the total number of patients, 670 (20%) could not be contacted due to missing personal data.

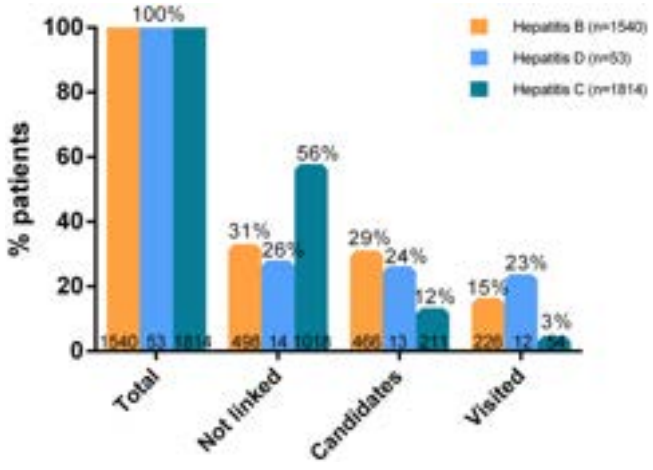

Figure:

Conclusion: From the patients not linked to care, 46% (226) from the HBsAg+, 85% (12) from the anti-HDV+ and 5.3% (54) from the HCV-RNA+ were finally linked. In total, 292 (19%) patients have been linked to care, suggesting this is an effective strategy. Patients with hepatitis D are more linked and predisposed to be linked to care than patients with hepatitis C. The biggest challenge of this strategy has been the lack of contact details.

FRI-159

The impact of hepatitis B and C serologies on the outcomes of non-liver solid organ transplantation

Maria Stepanova[1,2,3], Reem Al Shabeeb[4], Katherine Eberly[5], Janus Ong[6], Saleh Alqahtani[7], Zobair Younossi[1,5]. [1]*Inova Health System, Inova Medicine Services, Falls Church, United States;* [2]*Beatty Liver and Obesity Research Program, Inova Health System, United States;* [3]*Center for Outcomes Research in Liver Disease, United States;* [4]*Inova Fairfax Hospital, Center for Liver Disease, Inova Medicine, United States;* [5]*Inova Fairfax Hospital, Department of Medicine, Center for Liver Diseases, United States;* [6]*College of Medicine, University of the Phillipines, Manila, Philippines;* [7]*Johns Hopkins University, Division of Gastroenterology and Hepatology, Baltimore, United States*
Email: zobair.younossi@inova.org

Background and aims: Viral hepatitis B (HBV) and C (HCV) could negatively affect the outcomes of non-liver solid organ transplantation. Our aim was to assess post-transplant survival in patients with HBV and HCV serologies who received a non-liver solid organ transplants.
Method: We used Scientific Registry of Transplant Recipients (SRTR) 2006–2021 to collect data for all patients ≥18 years of age who received a lung, heart, or kidney single organ transplant in the U.S. History of hepatitis C virus (HCV) infection was determined as positive HCV Ab, and history of hepatitis B (HBV) infection was determined as positive HBsAg.
Results: We included a total 348,024 non-liver solid organ transplant recipients (N = 30,872 lung: mean age 57 ± 13 years, 60% male, 4% re-transplants, 15% type 2 diabetes (T2D); N = 36,990 heart: age 54 ± 13 years, 74% male, 3% re-transplants, 26% T2D; N = 280,162 kidney: age 52 ± 14 years, 61% male, 12% re-transplants, 30% T2D). The prevalence of pre-transplant HBsAg was 1.3% in lung, 1.5% in heart, and 1.7% in kidney transplant recipients. The HCV Ab was positive in 2.2%, 2.2%, and 5.0% in lung, heart, and kidney transplants; respectively. The post-transplant 1- and 5-year survival of patients with vs. without HBsAg was not different in all solid organ transplants (all $p > 0.05$). Similarly, there was no difference in post-transplant survival between lung transplant recipients with vs. without anti-HCV: 42% vs. 43% at 5 years, 69% vs. 69% at 10 years (all $p > 0.05$). In contrast, heart transplant recipients with HCV Ab (+) had higher crude post-transplant mortality: 27% vs. 21% at 5 years, 50% vs. 38% at 10 years (all $p < 0.01$). Similarly, there was higher post-transplant mortality in kidney transplant recipients with HCV Ab (+): 6% vs. 3% at 1 year, 21% vs. 13% at 5 years, 47% vs. 31% at 10 years (all $p < 0.0001$). In multivariate analysis controlling for confounders, the association of HCV Ab (+) with higher post-kidney transplant mortality remained significant: adjusted hazard ratio (aHR) (95% CI) = 1.13 (1.09–1.17), $p < 0.0001$. There was no association of viral hepatitis with the risk of graft failure in solid organ transplants ($p > 0.05$) except for the association of HBsAg with the risk of kidney graft loss (cumulative 4.3% vs. 3.1%, $p < 0.01$).
Conclusion: In most cases, presence of HBV and HCV serologies are not associated with adverse post-transplant outcomes in non-liver solid organ transplantation. However, kidney transplant recipients with HCV Ab (+) seem to have an increased risk for post-transplant mortality.

FRI-160

Development of a rapid workflow for detecting HCV RNA from whole blood

Matthew Pauly[1], Sabrina Torres[1], Tonya Hayden[1], Lilia Ganova-Raeva[1], Saleem Kamili[1]. [1]*Centers for Disease Control and Prevention, United States*
Email: omx4@cdc.gov

Background and aims: Chronic hepatitis C virus (HCV) infection is a leading cause of cirrhosis, hepatocellular carcinoma, and other liver complications. Effective treatments are available, yet only 20% of the estimated 58 million global HCV infections have been diagnosed. Accurate and timely diagnosis of HCV infection is important for linking people with HCV infections to care and stopping virus spread. Most diagnostic tests for HCV are expensive and performed in a laboratory, which limits their effectiveness in some at-risk populations. Diagnostic tests for HCV infection that are compatible with point-of-care use could greatly improve access to testing.
Method: We developed a workflow for the extraction, amplification, and detection of HCV RNA from whole blood samples that uses simple and inexpensive equipment. First, a brief spin in a mini-centrifuge removes blood cells from a small volume of whole blood. Cell-free blood is mixed with a lysis solution containing paramagnetic solid phase reversible immobilization (SPRI) beads capable of binding nucleic acids. The beads are washed once, and then the bound nucleic acids are eluted. The eluted nucleic acids are added to an HCV-specific reverse-transcription loop-mediated isothermal amplification (RT-LAMP) reaction. Positive amplification is detected using either measured fluorescence or lateral-flow test strips.
Results: The workflow for HCV RNA detection from whole blood takes 45 minutes from sample preparation to result and the reagents can cost less than 5.00 USD per sample. The 95% limit of detection by probit analysis is 2.8 $\log_{10}$ (IU/ml) (95% CI 2.5–3.4) for HCV RNA in whole blood, which would permit detection of approximately 98% of global HCV infections. This workflow can detect HCV genotypes 1–6. This workflow detected 75/80 (94%) samples from a panel of whole blood spiked with diverse HCV RNA-positive plasma samples. Each of the samples from this panel that were not detected contained HCV RNA levels below 3.0 $\log_{10}$ (IU/ml). Simplifying the procedure to include a magnetic wand in place of precision pipettes for processing the paramagnetic SPRI beads during the nucleic acid extraction steps allowed for similar HCV RNA detection results.
Conclusion: We have developed a rapid, sensitive, and inexpensive workflow for the detection of HCV RNA from small volumes of whole blood. With additional procedural simplifications, this workflow may form the basis for a point-of-care test for the detection of HCV RNA from clinical samples.

FRI-161

Hepatitis D infection in a HBsAg cohorts referred from specialist liver clinics vs. reflex community referred patients in South East London

Ivana Carey[1], James Lok[1], Maria Guerra Veloz[1], Christiana Moigboi[1], Geoffrey Dusheiko[1], Kosh Agarwal[1]. [1]*King's College Hospital, Institute of Liver Studies, London, United Kingdom*
Email: ivana.kraslova@kcl.ac.uk

Background and aims: Chronic hepatitis delta (HDV) represents the most severe form of chronic viral hepatitis with accelerated rates of advanced liver fibrosis and hepatocellular carcinoma, compared to those infected with hepatitis B alone, and for this reason early diagnosis is critical despite the lack of curative therapies. It is estimated that 5% of HBV infected patients are co-infected with hepatitis D virus (HDV). The true prevalence is not known, as HBsAg positive patients are not universally screened for the presence of anti-HDV antibodies, and the data may be skewed in cohorts referred for chronic liver disease. We aimed to compare the seroprevalence of anti-HDV antibodies and HDV RNA status in two referral settings: a specialist viral hepatitis laboratory ('liver specialist cohort') where testing for anti-HDV antibodies all newly diagnosed HBsAg positive patients is universally applied vs. a community laboratory ('community reflex cohort') where reflex testing of all HBsAg positive patients was similarly applied.
Methods: All new HBsAg-positive patients seen in a tertiary hospital liver clinic-'liver specialist cohort 2021' (n = 238) between 1.1.2021–31.12.2021 were tested for the presence of anti-HDV (ETI-AB-DELTAK-2 by DiaSorin) and all anti-HDV-positive samples were tested by a pan-genotypic in-house HDV RNA assay (LLQD = 640 IU/ml). Testing in a second cohort of newly diagnosed HBsAg-positive patients in the liver clinic ('liver specialist cohort 2022')-was repeated between

1.1.2022–31.12.2022 (n = 322). For comparison of the prevalence of hepatitis D infection, samples from 214 HBsAg-positive patients referred from a community laboratory-'community reflex cohort'- (i.e. a cohort identified in GP practice and non-liver clinics/wards) between 1.1.2022–31.12.2022 had a sample sent for reflex testing in liver specialist laboratory for anti-HDV antibodies and similarly all anti-HDV-positive samples were tested for HDV RNA.
Results: In 2021, out of 238 newly referred liver clinic referred HBsAg positive patients-'liver specialist cohort 2021' (tested in a specialist laboratory) 17 (7%) were anti-HDV- positive; 9 (3.8%) had detectable HDV RNA. In 2022, out of 322 newly diagnosed HBsAg positive patients ('liver specialist cohort 2022') similarly tested 23 (7%) patients were anti-HDV positive and 12 (3.7%) of these patients had detectable HDV RNA. In contrast, out of 214 HBsAg-positive patients (35 newly diagnosed) tested from the community laboratory referral cohort ('community reflex cohort') only 5 (2.3%) were anti-HDV-positive and only one (0.5%) was HDV RNA positive. All newly diagnosed HBsAg-positive patients tested in a community laboratory including 1 (2.8%) anti-HDV positive patient (1 was HDV RNA positive) were linked into care in liver clinics.
Conclusion: The seroprevalence of anti-HDV was lower in HBsAg-positive patients tested in community referral laboratory setting than in newly diagnosed HBsAg-positive patients diagnosed in a specialist liver setting (2.3% vs. 7%). Similarly, there was a higher proportion of HDV RNA- positive patients in the 'liver specialist' cohorts vs. 'community reflex cohort'. Reflex testing in both settings facilitated linkage to specialist care for HDV RNA positive patients.

FRI-162
Screening, confirmation, and treatment rates of hepatitis C virus infections in patients undergoing surgery in a single tertiary academic centre
Jae Seung Lee[1,2,3], Hye Won Lee[1,2,3], Beom Kyung Kim[1,2,3], Jun Yong Park[1,2,3], Do Young Kim[1,2,3], Sang Hoon Ahn[1,2,3], Seung Up Kim[1,2,3]. *[1]Yonsei University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South; [2]Yonsei University College of Medicine, Institute of Gastroenterology, Seoul, Korea, Rep. of South; [3]Severance Hospital, Yonsei Liver Center, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: A lack of awareness compromises appropriate consideration of hepatitis C virus (HCV) infections in patients undergoing surgery. We evaluated the status of HCV screening, confirmation, and treatment in patients undergoing surgery.
Method: Patients who underwent surgery in a tertiary academic center between 2019 and 2021 were eligible for this retrospective study. The testing and positivity rates for anti-HCV antibodies and HCV RNA were analyzed.
Results: Among 96,894 patients (40,121 males, 41.4%) who underwent surgery under general anaesthesia, 83,920 (86.6%) were tested for anti-HCV antibodies before surgery. Of these patients, 576 (0.7%) were positive for anti-HCV antibodies and had significantly higher rates of diabetes mellitus (32.6% vs. 18.5%), hypertension (50.5% vs. 28.6%), liver cirrhosis (13.2% vs. 1.7%), and unfavourable laboratory test results compared with those who were negative (all $p < 0.05$). The HCV RNA status was assessed in 215 (37.3%) of the anti-HCV antibody-positive patients, and the rate of HCV RNA positivity was 20.5% (n = 44 of 215). Of these 44 patients, 42 (95.5%) were referred for treatment, and all 29 treatable patients were successfully treated with direct-acting antiviral therapy. The HCV RNA positivity rate was significantly higher in the hepatobiliary and transplant surgery department (76.6%) than in other surgical departments (25.0–33.5%).
Conclusion: A significant number of preoperative anti-HCV antibody-positive patients did not receive appropriate HCV management. An automated alert system may be required.

FRI-163
Impact of hepatitis B family screening, counselling and education program on active case detection: a step towards elimination through preventive hepatology clinic in India
Ajeet Singh Bhadoria[1], Gaurika Saxena[1], Abhishek Sadasivan[1], Rohit Gupta[2]. *[1]All India Institute of Medical Sciences Sciences Rishikesh, Preventive Hepatology, Rishikesh, India; [2]All India Institute of Medical Sciences Rishikesh, Gastroanterology, Rishikesh, India*
Email: ajeetsinghbhadoria@gmail.com

Background and aims: Finding the missing millions is the biggest challenge towards elimination by 2030. Recent studies have documented intrafamilial transmission including vertical transmission as the most common mode of transmission for Hepatitis B virus (HBV) infection. Thus, we targeted maximum yield in case detection via counselling and screening of first degree relatives of Hepatitis B infected patients and their spouse for hepatitis B infection through preventive hepatology clinic in India
Method: A multi-level public health approach was utilized to implement Hepatitis B family screening, counselling and education program to persuade first degree relatives (parents, siblings, and children) and spouse of HBV infected patients for HBV screening. The enrolled and counselled relatives got themselves tested, either at our institute's virology laboratory or from any recognized laboratory in the country as per their convenience. A 3 tier counselling and education by Gastroenterologist, Public Health Specialist and Resident was adopted for screening for 3 HBV markers:-HBsAg, Anti-HBc (total), and Anti-HBs. Necessary actions were taken as per the lab results i.e. vaccination, further investigations for treatment eligibility. The information and education material was also distributed to the relatives, consisting of literature on natural history of hepatitis B infection, available diagnostic and screening tests.
Results: A total of 463 family members were approached from 93 index cases of chronic hepatitis B (CHB) infection (age 33.1 ± 12.3 years, 72.8% males). A total of 40.3% of CHB patients were HBeAg +ve. Median HBV DNA levels was 29.8 (IQR 0.8–5312 × 10^3) IU/ml. We have successfully screened 221 contacts out of 463 relatives which include

Table: (abstract: FRI-162): HCV RNA status and treatment of HCV RNA-positive patients according to preoperative anti-HCV antibody status.

Population	Tested for anti-HCV antibodies (patients)	Tested for HCV RNA status in anti-HCV antibody-positive patients	Treated patients positive for HCV RNA
All	83,920 of 96,894 (86.6)	215 of 576 (37.3)	29 of 42 (69.0)
Surgery department			
Hepatobiliary and transplantation	5,154 of 6,886 (74.8)	72 of 94 (76.6)	13 of 17 (76.5)
Other GS, paediatric*, and OBGY	31,729 of 37,932 (83.6)	34 of 121 (28.1)	4 of 8 (50.0)
CS, NS, and OS	26,031 of 29,484 (88.3)	74 of 221 (33.5)	10 of 14 (71.4)
Others†	21,006 of 22,592 (93.0)	35 of 140 (25.0)	2 of 5 (40.0)

Variables are expressed as "number of number (%)."
*Surgery in adult patients (age ≥19 years) performed by paediatric surgeons.
†Ear, neck, and throat surgery, oral and maxillofacial surgery, plastic surgery, urology, ophthalmology, and dermatology.
Abbreviations: HCV, hepatitis C virus; GS, general surgery; OBGY, obstetrics and gynaecology; CS, cardiothoracic surgery; NS, neurosurgery; OS, orthopaedic surgery.

Figure: (abstract: FRI-163): Patient Information Brochure.

parents, siblings, children and spouse. The efficacy of HBSCE program was 47.7% (221/463). HBsAg was found positive in one fourth (24.2%) of contacts and Anti- HBc was positive in about two third (31.2%) of contacts. The overall infection rate (either HBsAg+ or any antibody positive with no history of immunization) was 42.1%. Past Exposure Rate (HBsAg -ve with Anti-HBc (Total) +ve, or Anti-HBs +ve, with no history of vaccination) was seen in 15.7%. Out of 128 uninfected individuals, 32 were already vaccinated, and 61 (47.6%) were vaccinated after the counselling. Prevalence of HBV infection was significantly higher among mothers (51.1%) as compared to other family members (28.1%) (OR 3.2, 95%CI 2.3–4.6) supporting vertical transmission.

Conclusion: Familial clustering of HBV infection was seen. Opportunistic screening and multilevel counselling of family members was an effective strategy for active case finding. Younger index cases, with two out of every four mothers being infected strongly suggest vertical transmission as the most common mode of infection. This data suggests family screening as important additional strategy to eliminate hepatitis B by 2030 via test and treat approach.

Email: antonella.darminio@unimi.it

Background and aims: PLWH are often HCV coinfected and undergo more frequently to progressive disease. Early diagnosis and treatment are essential to eliminate HCV in this population. No-Co is a prospective cohort study on PLWH aimed to estimate: prevalence of past and active HCV infection in PLWH in care in 2017–2022, the incidence of HCV re-infections and HCV seroconversions and DAA-uptake and response.

Method: No-Co study included PLWH screened for HCV from Sept-2017 to Oct-2022, independently of their HCV status, belonging to centers of the Italian ICONA network. Prevalence of HCV infection (HCVAb+) and active HCV infection (HCV-RNA+) were evaluated at baseline. Incidence of HCV seroconversions, in those HCVAb-at baseline, and of HCV re-infections (in those HCVAb+/HCV-RNA- who turned to HCV-RNA+) were evaluated and predictors identified by Poisson regression models. Standard survival methods (Kaplan-Meier curves and Cox models) used to estimate the probability and predictors of DAA-start from first HCV screening in the study, for those HCV-RNA +. Logistic regression models have been used to investigate predictors of SVR12.

Results: 4,569/16,743 (27.3%) were HCVAb + at baseline. HCVAb + were older (median 54 vs 46 yrs), more frequently Italian (94% vs 78%), and with higher CD4/mmc (median 644 vs 598). In a median follow-up of 1.6 years, 42/4,890 seroconverted, with KM probability of 0.5% (95%CI 0.3–0.7) at 1 year. No factors were associated with seroconversion. 1,732/4,569 (37.9%) were HCV-RNA –; in a median follow-up of 1.3 years, 38 turned to HCV-RNA +; 10 relapsed, 28 were re-infections), KM probability of HCV reinfection at 1 year was 1.3% (95%CI 0.7–2.3). Younger age was the only factor independently associated to higher incidence of re-infection (aIRR 1.67, 95%CI 1.05–2.64). 1,374/1,732 HCV-RNA + PLWH had a follow-up, 1,184 (86.2%) started DAA, the KM probability of DAA uptake at 1-year was 79.5% (95%CI 77.3–81.7). Independent predictor of reduced access to DAA was CD4<200/mmc (aHR 0.59, 95%CI 0.43–0.80), HIV-RNA >50 copies/ml (aHR 0.72, 95CI% 0.57–0.91) and being IDU (aHR 0.72, 95%CI 0.60–0.87). SVR12 was obtained in 95.5%, CD4<200/mmc were associated with lower probability of SVR12 (aHR 0.18, 95%CI 0.06–0.52). Globally, the cascade of care of HCV indicates that 86.2% of HCV-RNA + were treated, of these 77, 2% reached 12 weeks follow-up after DAA, and 95.5% of these obtained SVR12, resulting in 63.6% of SVR among HCV-RNA + (Figure 1A-B). Finally, the yearly prevalence of active HCV infection decrease from 41.7% in 2017 to 11.7% in 2022 ($p < 0.001$, Figure 1C).

Conclusion: Only 12% of PLWH in this cohort are still viremic. Prevalence of active HCV infection decreased over time in PLWH, both because of DAA treatment and relatively low rate of new infection or reinfections. Access to DAA was lower in IDU and in those with uncontrolled HV infection. Low CD4 counts were independent predictors of non-response.

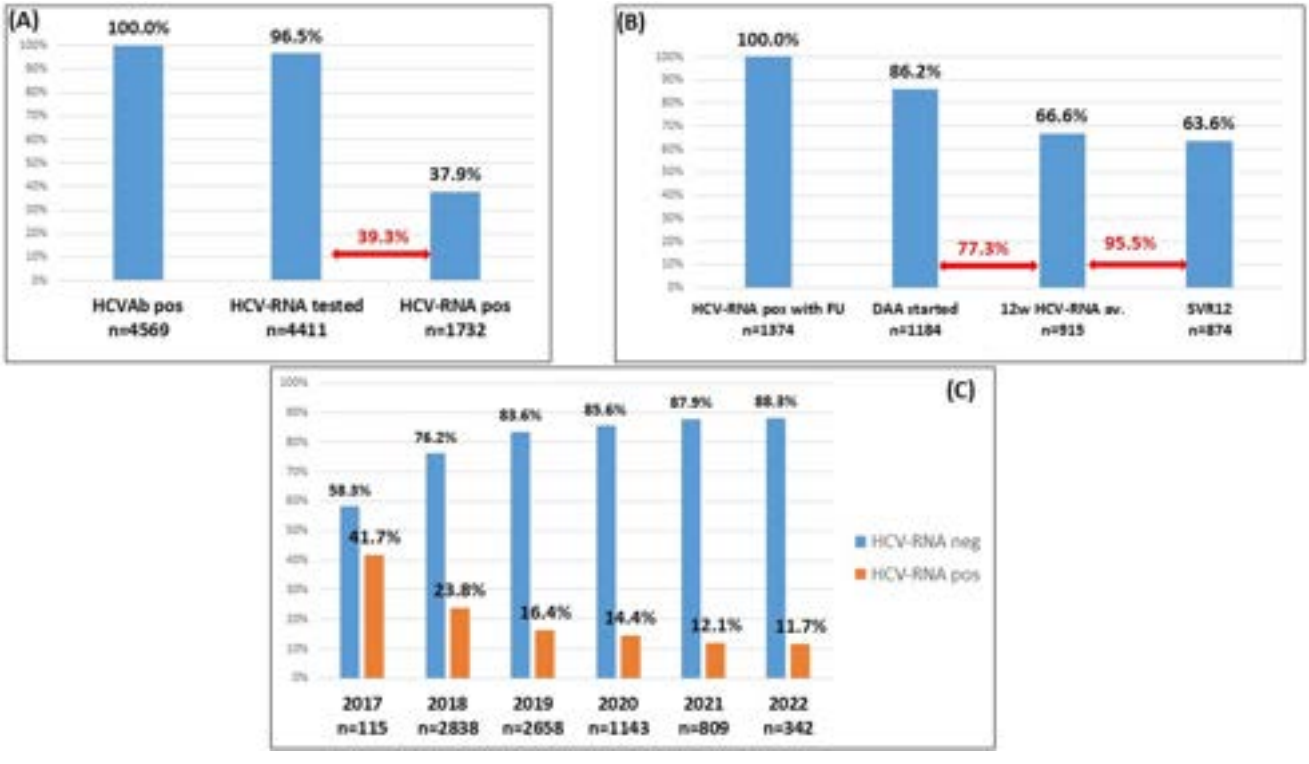

Figure: (abstract: FRI-164): HCV Cascade of Care in NoCo study (A-B) and proportion of HCV-RNA viremic subjcests according to calendar year of test (C).

FRI-165

A modelling study of the impact of scaling up of HCV case finding and treatment for people who inject drugs in English region of Bristol and Severn

Zoe Ward[1], Hannah Fraser[1], Adam Trickey[1], Jo Kesten[1], Andy Gibson[2], Leila Reid[3], Fiona Gordon[4], Alec Miners[5], Jack Williams[6], Matthew Hickman[1], Graham Foster[7], Monica Desai[8], Sema Mandal[8], Laura Coughlan[8], Ruth Simmons[8], Ross Harris[8], Peter Vickerman[1].
[1]University of Bristol, United Kingdom; [2]University of West of England, United Kingdom; [3]HepC Trust, United Kingdom; [4]University Hospitals Bristol and Weston Trust, United Kingdom; [5]Source Health Economics, United Kingdom; [6]London School of Hygiene and Tropical Medicine, United Kingdom; [7]Queen Mary University of London, United Kingdom; [8]United Kingdom Health Security Agency, United Kingdom
Email: zoe.ward@bristol.ac.uk

Background and aims: People who inject drugs (PWID) are the main risk group affected by Hepatitis C (HCV) in the UK. The National Health Service in England (NHSE) aims to eliminate HCV as a public health threat by 2025, ahead of the WHO target of 2030. Scaling up HCV testing and treatment among PWID will be critical for reaching this elimination goal. This entails decreasing the incidence of HCV among PWID by 80% compared to 2015 levels or <2 per 100 person years (py) by 2025. We assess whether existing strategies are sufficient for reaching these elimination goals.
Method: A dynamic HCV transmission model among PWID, including incarceration and drug treatment centres (DTC), was used to project the impact of existing prevention, testing and treatment services in the Bristol and Severn region (defined by NHSE Operational Delivery Networks responsible for delivering HCV treatment). The model includes the pathway from testing to treatment in prison, DTC and other settings. Detailed data from NHSE HCV treatment database and HCV testing sentinel surveillance database and a yearly bio-behavioural survey among PWID were used to parameterise and calibrate the model using Approximate Bayesian Computation. Model outputs were used to project HCV chronic prevalence, incidence and number of treatments over time and determine whether existing testing and treatment strategies will reach the elimination goals by 2025 or 2030.
Results: Data suggests that 178, 72 and 270 treatments were undertaken in DTC, prison and other settings over 2015–2019 in Bristol and Severn, with the time from diagnosis to treatment decreasing from >1 year to <3 months in all settings. Our model projects that this treatment scale-up resulted in prevalence decreasing by median of 51% (47.9–58.6%) and incidence decreasing by 48.4% (44.6–56.2%) by start of 2020. If testing and treatment continued at the same rates from 2020, then chronic prevalence will decrease by 84.1% (79.8–91.1%) from 31.9% in 2015 to 5.0% by 2030 and incidence will decrease by 83.1% (78.1–90.6%) from 9.4 (8.0–11.4) to 1.5 per 100 py (0.8–2.3). In total, 2083 (1882–2217) treatments would be used over 2015–2030 (PWID population~5300). By 2025, incidence will decrease by 70.9% (65.9–79.9%) to 2.7 per 100 py (1.8–3.6) following 1722 (1536–1861) treatments.
Conclusion: Our modelling suggests the scale-up of HCV testing and treatment among PWID in Bristol and Severn will reach the WHO targets for HCV elimination between 2025 and 2030.

FRI-166

Treatment start resilience but testing decrement in a coordinated statewide HCV treatment program during COVID: lessons learned and future steps

Yvonne Lynch-Hill[1], Christina Leblanc[1], Barbara Goodall[1], Lisa Barrett[2] .[1]*Nova Scotia Health Authority, Infectious Diseases, Halifax, Canada;* [2]*Dalhousie University, Infectious Diseases, Halifax, Canada*
Email: lisabarrett@me.com

Background and aims: The SARS-CoV-2 pandemic was associated with marked decreases in access to lab based blood borne pathogen testing, including HCV molecular diagnostics. While new diagnoses may have decreased, it was unclear if all other parts of the HCV care cascade engagement would also decrease during each year of the pandemic. Our goal was to describe engagement in care across the care cascade before and during the SARS-CoV-2 pandemic in a statewide coordinated virtual HCV care program.
Method: Nova Scotia is a Canadian province with approximately 1,000,000 population. From 2017 to 2022, the majority of HCV care was initiated through in a province wide program which converted to a fully virtual, nurse delegated program in July 2020 with the advent of the pandemic. We measured the number of referrals, care engagements, treatment starts, documented SVRs (sustained virologic responses), and treatment failures annually from 2019 (considered pre-pandemic) until December 2022.
Results: HCV program referrals decreased approximately 30% in 2020/21 (187, 183) compared to 2019 (264) and 2022 (220). However, initial virtual visits to establish care were stable across 2019 (69), 2020 (85), and 2021 (67), and increase to 114 in 2022. 158 people initiated treatment in 2019, compared with 135 in 2020, 115 in 2021 and 93 in 2022. SVR was status was known in 111 people in 2019, compared to 104 people in 2020, 75 in 2021, and 21 in 2022. Treatment failure or reinfection was stable over all years.
Conclusion: New HCV infection estimation was limited during the pandemic, given the lack of point of care and lab-based HCV testing in the province. However, conversion to a virtual platform, centralized referral and treatment, as well as expert delegated nurse role was associated with equivalent engagement in care but slightly decreased treatment initiation. Building HCV care resilience through virtual and delegated collaborative prescriber programs should be considered in future pandemic preparedness planning and blood borne pathogen management.

FRI-167

Who is missing? Analysis of the 2021 Georgian seroprevalence survey to identify the population left to be screened for hepatitis C

Sophia Surguladze[1], Davit Baliashvili[1], Shaun Shadaker[2], Tamar Gabunia[3], Maia Tsereteli[4], Paige A. Armstrong[2], Senad Handanagic[2]. [1]*The Task Force for Global Health, Georgia;* [2]*Centers for Disease Control and Prevention, United States;* [3]*Ministry of Labour, Health and Social Affairs of Georgia, Tbilisi, Georgia, Georgia;* [4]*National Center for Disease Control and Public Health, Georgia*
Email: sophiesurrguladze@gmail.com

Background and aims: Georgia has made great progress towards hepatitis C virus (HCV) elimination since starting their elimination program in 2015; a 2021 serosurvey showed a 67% decrease in prevalence of current HCV infection. As a part of the program, people are screened at multiple different sites, the most common being mandatory inpatient screening at hospitals. However, low awareness of infection status and loss to follow-up after reactive HCV antibody or detected HCV RNA or HCV core antigen remains a challenge. This study used data from the 2021 survey to identify sub-groups of adults with low HCV screening and status awareness, highlighting gaps in the HCV elimination program and groups least served by the HCV elimination program.
Method: The 2021 serosurvey used a stratified, multi-stage cluster design with systematic sampling. Participants were interviewed and tested for anti-HCV. The weighted proportions with 95% confidence intervals (CI) for ever been screened for hepatitis C were calculated and stratified by demographic and behavioral variables to assess screening coverage in different groups. To assess awareness of anti-HCV status, weighted proportions of anti-HCV reactive persons who reported ever being screened positive were also calculated.
Results: Overall, 42.1% (95% CI: 39.6%-44.7%) of participants reported ever being screened for anti-HCV. This proportion was similar in men and women at 35.5% (95% CI: 32.7%–38.4%) and 39.9%% (95% CI: 37.2%–42.5%) respectively. Reported screening was lowest in those aged >60 years (27.8% [95% CI: 25.3%–30.6%]) and the highest in the 30–39 year age group (49.9% [45.3%–54.5%]).

Among anti-HCV-reactive persons overall, 75.6% (95% CI: 68.2%–81.7%) knew their screening status. This proportion was 56.4% (95% CI: 47.9%–64.5%) for anti-HCV-reactive men and 38.8% (95% CI: 29.2%–49.3%) for anti-HCV-reactive women. Among those who were reactive, the proportion aware of their status was lowest in the 18–29 year age group (34.7% [95% CI: 8.5%–75.4%]) and highest in those aged 40–49 years (63.3% [95% CI: 50.1%–74.7%]). In terms of risk groups, awareness of anti-HCV reactivity was 61.4% (95% CI: 42.0%–77.7%) in previously incarcerated individuals, 62.2% (95% CI: 46.8–75.5%) in reported injection drug users, and 63.7% (95% CI: 47.1%–77.6%) in those reporting having ever received a blood transfusion.
Conclusion: Our analysis identified sub-groups in Georgia with low HCV screening and status awareness. The youngest and oldest participants had the lowest reported screening. Targeted interventions to improve HCV screening are needed in these sub-groups. Awareness of anti-HCV reactivity was lowest in the 18–29 year age group, and was higher in risk groups compared to the general population; improved follow-up for people with positive screening results is needed to ensure they are notified of their status.

FRI-168
Are primary healthcare facilities ready to provide hepatitis delta services in Mongolia: service availability and readiness assessment findings
Azzaya Oktyabri[1], Badmaa Otgonbayar[2], Enkhjargal Altangerel[2].
[1]*Mongolian National University of Medical Sciences, Mongolia;*
[2]*Anagaakh Ukhaany Mergejiltnuudiin Academy, Mongolia*
Email: mdnzula@gmail.com

Background and aims: Primary health care (PHC) facilities are the frontline service providers responsible for provision of the essential services to the population. Some portions of the clinical management for hepatitis patients are provided at PHC facilities within the National Liver Programme, especially for HBV and HCV related services. However, information on HDV service provision at PHC is uncertain. Therefore, we aimed to explore what services are available and how are they ready for HDV patients at the PHC level.
Method: WHO developed a tool for service availability and readiness assessment (SARA) was used, which comprised a set of indicators to define whether a health facility meets the required conditions for providing basic and specific services. The cross-sectional study examined randomly selected 79 PHC facilities from urban (82.3%) and rural (17.7%) areas. The assessment questionnaire was modified to the country context with focus on hepatitis and immunization services. Immunization service assessment was included to explore the possibility of applying temperature-controlled daily injections of Bulevirtide for HDV patients. Collected data was analyzed using SPSS 21.0 to define the indicators of availability and readiness.
Results: Overall PHC basic service readiness score was 62.1%. Almost all (96.2%) of the facilities conduct rapid testing for HBV, with 70.83% have ready stock of the test strips. They do not provide HDV rapid testing. 45.83% of the facilities managed to train the staff for hepatitis management within the last two years. There is no unified registry system for HDV patients, and 44.3% of the facilities maintain the monitoring of the diagnosed patients, through referral to secondary hospitals and counseling on disease management. The immunization service readiness was assessed by exploring the presence of the routine vaccines, cold chain equipment, and trained staff and guidelines. All PHC facilities provide immunization services in both urban and rural areas. Overall readiness for immunization services was 86.87%, which included trained staff (80.38%), required equipment (99.79%); and supplies (69.11%).
Conclusion: The study revealed that the availability and readiness of basic PHC services is considerably good within the facilities. The service provision at PHC for HBV and HCV, obliged by the National Liver Programme, is well maintained at both urban and rural places. The screening and testing for HDV are not delivered at all PHC facilities. The availability of HDV specific treatment is none. The required condition and readiness for immunization is built up well, therefore, it could be used for daily injectable treatment (Bulevertide) for hepatitis D patients at PHC facilities. The good level of availability and readiness for basic and hepatitis (B and C) services could serve as a good foundation for future introduction of HDV related services at PHC facilities in both urban and rural places.

Background and aims: Hepatitis B virus (HBV) care cascade characterisation is important for monitoring progress towards HBV elimination. This study evaluated the care cascade and factors associated with HBV DNA testing and treatment uptake during 2010–2018 in New South Wales, Australia.
Method: HBV testing, specialist consultation, and treatment care cascade were determined through linkage of HBV diagnoses/notifications (generally serological, 1993–2017) to Medicare and pharmaceutical benefits schemes (2010–2018), hospital admissions (2001–2018), and mortality (1993–2018) databases. Timely HBV testing was defined as DNA testing at or within four weeks of HBV notification. Multivariate cox proportional-hazards regression analyses were performed to evaluate factors associated with HBV DNA testing and antiviral treatment.
Results: Among 15,202 people with an HBV notification, 10,368 (68%) were tested for HBV DNA, of whom 5366 (52%) received timely testing. A total of 10,794 (71%) consulted a specialist post-HBV notification, and 3,166 (21%) initiated HBV treatment. HBV DNA testing was more likely among those ≥45 years old at HBV notification (adjusted Hazard Ratio [aHR] 1.13, 95%CI: 1.07, 1.18), those with a history of hepatocellular carcinoma (HCC) (aHR 1.25, 95% CI: 1.02, 1.53) and notified in the later period (2014–17) (aHR 1.46, 95%CI: 1.40, 1.52), and less likely among females (aHR 0.96, 95%CI: 0.92, 0.99), those with a history of alcohol use disorder (AUD) (aHR 0.77, 95%CI: 0.66, 0.89), and those coinfected (HBV/HCV; aHR 0.62, 95%CI: 0.54, 0.69, HBV/HIV; aHR 0.75, 95%CI: 0.58, 0.98). Higher likelihood of HBV treatment was associated with age ≥45 years (aHR 1.40, 95%CI: 1.27, 1.53), a history of decompensated cirrhosis (aHR 2.08, 95%CI: 1.62, 2.66), a history of HCC (aHR 2.89, 95%CI: 2.28, 3.64), HBV/HIV coinfection (aHR 3.71, 95%CI: 2.93, 4.68) and HBV notification in the later period (2014–17) (aHR 1.61, 95%CI: 1.49, 1.73). HBV treatment was less likely among females (aHR 0.68, 95%CI: 0.63, 0.73), people of Indigenous ethnicity (aHR 0.58, 95%CI: 0.42, 0.80), and those with a history of AUD (aHR 0.77, 95%CI: 0.60, 0.98).
Conclusion: Most people with an HBV notification got HBV DNA testing and consulted a specialist. Of those tested, about half received timely HBV DNA testing, higher in the later period. Treatment coverage has increased, but may be sub-optimal among some sub-populations, including Indigenous Australians and those with AUD.

FRI-170
Reimplementation of a revamped cost-effective national elimination strategy is the only way Brazil moves towards eliminating HCV
Alexis Voeller[1], Devin Razavi-Shearer[1], Ivane Gamkrelidze[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, United States*
Email: avoeller@cdafound.org

Background and aims: In 2018, Brazil developed the Hepatitis C Elimination Plan, a national strategy to achieve HCV elimination, but in 2019 the intervention was discontinued by the national

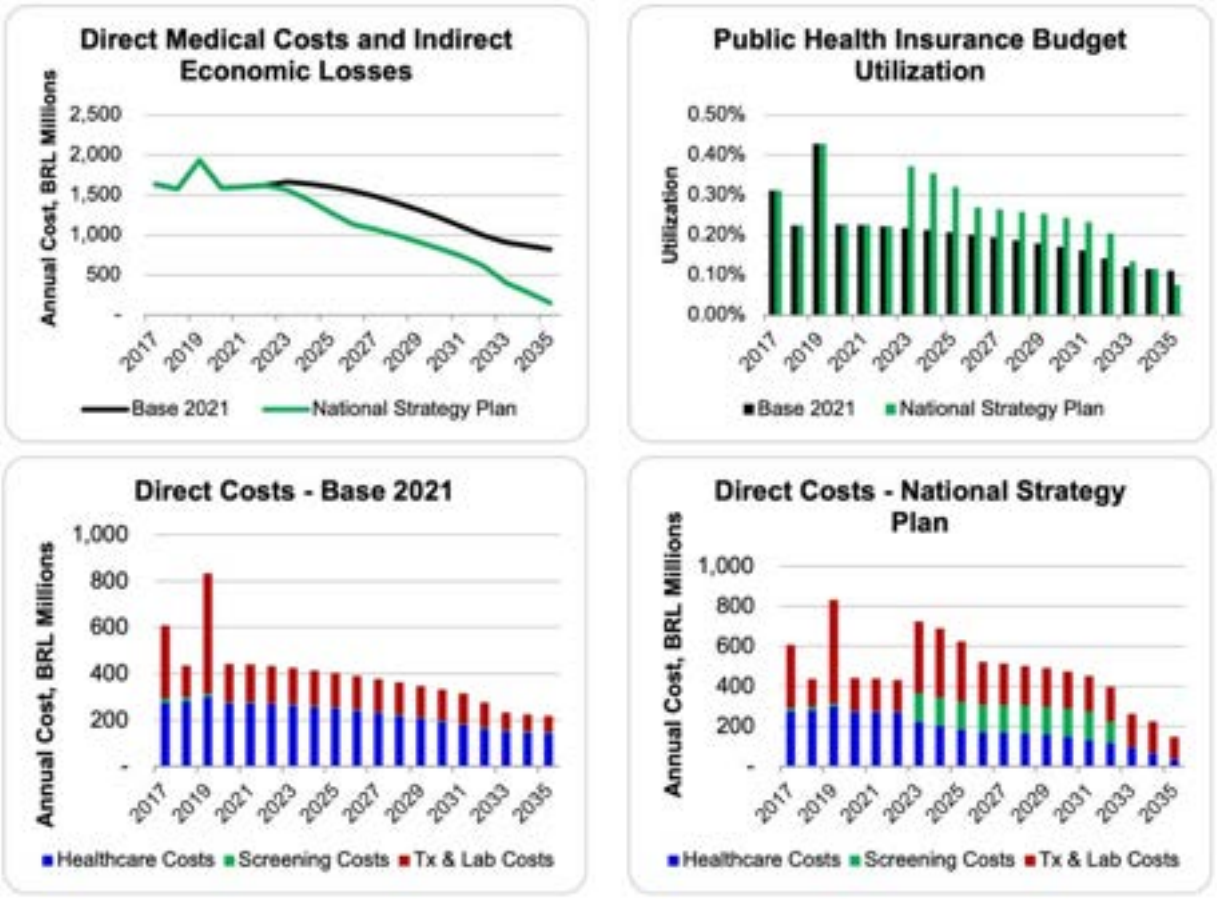

Figure: (abstract: FRI-170).

government. The goal of this analysis was to evaluate the impact of this policy change.

Method: A Markov mathematical model was used to quantify the HCV disease and economic burden under three scenarios: National Elimination (developed in 2018); 2021 base (reflecting empirical data through 2021) and National Elimination Reimplemention (empirical data through 2021; elimination assumptions after 2021). This work built on a previously published model for Brazil that was updated using publicly available data for treatment and diagnosis. The base case was compared to the 2018 elimination plan to evaluate which WHO elimination targets would be met and whether this type of strategy still proved cost-effective given the current HCV burden.

Results: Under the original National Elimination Strategy, Brazil would have seen a 53% decrease in HCV-related mortality and a 51% decrease in HCV-related liver cancer. Considering empirical data through 2021, the 2021 base could result in an additional 207,000 HCV infections by 2030 along with an excess 12,600 liver-related deaths, 1,700 incident HCC cases and 1,340 incident decompensated cirrhosis cases, relative to the original national strategy. Reimplementing the national strategy from 2022 forward would only achieve the absolute, treatment and incidence targets. To reimplement the national strategy beginning in 2022, Brazil would need to undertake up-front direct costs peaking at 724 million BRL for the scaling up of screening, diagnosis, and treatment to meet all elimination targets. These costs would drop to 146 million BRL annually within 10 years to combat HCV. Annual indirect economic losses would decrease dramatically within a similar timeframe from 1,184 million BRL to nearly 3 million BRL as a result of a reimplemented strategy. The cost per DALY averted from 2017 to 2035 with an elimination strategy is estimated to be 5,263 BRL, which is significantly lower than the GNI per capita of 28,757 BRL demonstrating the high cost-effectiveness of disease intervention.

Conclusion: If Brazil wants to move forward to HCV elimination by 2030, a form of the national strategy program needs to be reinstated. If the previous Hepatitis C Elimination Plan is reused, WHO elimination targets will not be met by 2030 due to significant loss of time. For the country to continue combating HCV, it needs to increase screening, diagnosis, and treatment of patients — soon. Model outputs demonstrate that Brazil is not currently on track to eliminate viral hepatitis C by 2030 without utilizing a revamped intervention.

FRI-171

The evaluation of people suspected of sexually transmitted diseases requires tools for the comprehensive diagnosis of viral hepatitis and HIV

Joaquin Cabezas[1,2], Eva Torres-Sangiao[3,4], Susana Llerena[1,2], Carmen Ribes[1,2], Carlos Gutierrez[1,2], Sara Alonso[1,2], Victor Echavarria[1,2], Ángela Antón[1,2], Andrea González[1,2], María Eliece Cano[3], Jorge Calvo[3], Javier Crespo[1,2]. *[1]Marqués de Valdecilla University Hospital, Gastroenterology and Hepatology Department, Santander, Spain; [2]Research Institute Valdecilla-IDIVAL, Santander, Spain; [3]Marqués de Valdecilla University Hospital, Microbiology Department, Santander, Spain; [4]Clinic University Hospital Of Santiago de Compostela, Microbiology Department, Santiago de Compostela, Spain*
Email: joweycabezas@gmail.com

Background and aims: The prevalence of viral hepatitis is higher in patients with a sexually transmitted disease (STD). The World Health

Organization recommends ruling out the existence of a secondary STD and/or concomitant viral hepatitis in all people with a suspected STD. Objective: To evaluate the simultaneous diagnosis of viral hepatitis in subjects suspected of having an STD.
Method: Review of STD studies (syphilis, *Trichomonas vaginalis, Chlamydia trachomatis, Mycoplasma genitalum, and Neisseria gonorrhoeae*) to assess the performance of diagnostic tests for hepatitis B, hepatitis C, and HIV in the three months before or after the index sample for STD diagnosis. The results available between April 2019 and September 2022 from the Microbiology Department of our center were evaluated.
Results: We found 157,185 serology determinations against syphilis and/or exudates against STD. Of the 49,664 serologies for the study of syphilis, anti-HCV serology was determined in 62.2% of the cases; in 1092 subjects with syphilis, an anti-HCV prevalence of 2.3% was detected; 3 viremic, 12 with sustained viral response and 8 spontaneous clearance. HBsAg was requested in 82.4%, detecting 20 positive cases (0.8% prevalence in patients with anti-treponemal antibodies). Finally, the presence of anti-HIV was evaluated in 89.3% of the requests for syphilis, being positive in 150 cases (prevalence = 5.8%; 72 new cases and 78 already known). The determination of HBsAg and anti-HCV and anti-HIV antibodies in subjects with other STD were respectively: 1) Trichomonas vaginalis (27,924 samples): 1.6% of the cases had a study for HBsAg, detecting 2 positives; 1% study for HCV (1 positive) and 1.6% study for HIV (2 positive). 2) Chlamydia trachomatis (6,018 samples): 2.2%, 2.3% and 2.7% had an HBV, HCV and HIV study, respectively; detecting 2 anti-HCV positive subjects and 4 anti-HIV positive subjects. 3) Mycoplasma genitalum (4,879 samples): 1.9%, 2.1% and 2.5% had an HBV, HCV and HIV study respectively, detecting 2 positive anti-HCV and 4 positive anti-HIV. 4) Neisseria gonorrhoeae (5,978): 2.2%, 2.3% and 2.7% had an HBV, HCV and HIV study respectively, detecting 3 anti-HCV positive subjects and 4 anti-HIV positive subjects.
Conclusion: In subjects with suspected syphilis there is an underdiagnosis of viral hepatitis, higher for HCV than for HBV (60% vs 80%). The reflex diagnosis of HIV, although not optimal, is clearly better (90%). The absence of a diagnostic study aimed at ruling out a concomitant infection by viral hepatitis is the rule in the rest of the STD. These results highlight the need to implement tools for the complete and comprehensive diagnosis of viral hepatitis in subjects with suspected sexually transmitted diseases.

FRI-172
The impact of hepatitis C and socio-demographic variables on Health-related quality of life among patients in Pakistan

Siwaporn Niyomsri[1], Josephine Walker[1], Ejaz Alam[2], Ambreen Arif[2], Muhammad Asim[3], Bazil Ather[3], Mishal Azam[4], Auj Chaudhry[4], Asad Chaudhry[4], Naheed Choudhry[5], Graham Foster[5], Saeed Sadiq Hamid[6], Aliya Hasnain[6], Polychronis Kemos[5], Pir Zarak Khan[3], Aaron G. Lim[1], Saad Niaz[3], Noor Saba[6], Sultan Sallahuddin[6], Muhammad Nabeel Shafqat[4], Huma Qureshi[2], Wasiuddin Shah[6], Peter Vickerman[1]. *[1]Bristol Medical School, Population Health Sciences, United Kingdom; [2]Doctors Plaza, Karachi, Pakistan; [3]Dow University of Health Sciences (DUHS), Karachi, Pakistan; [4]The Liver Clinic, Gujranwala, Pakistan; [5]Queen Mary University of London, United Kingdom; [6]Aga Khan University, Karachi, Pakistan*
Email: josephine.walker@bristol.ac.uk

Background and aims: Pakistan has a high burden of hepatitis C virus. We assessed health-related quality of life (HRQoL) among the general population screened for hepatitis C virus in Pakistan, and identified key socio-demographic factors associated with HRQoL
Method: We conducted a case-control study to measure HRQoL among patients screened for HCV in four community and clinic-based settings in Karachi and Gujranwala, Pakistan. Cases were those diagnosed with chronic hepatitis C (CHC) and controls were negative for HCV antibodies (HCV Ab-negative). Patients diagnosed with CHC were initiated on treatment for 12 weeks, or 24 weeks if APRI and Fib-4 scores suggested liver cirrhosis. At the point of screening, prior to HCV antibody status being reported to the patient, HRQoL was assessed using the EuroQol EQ-5D-3L survey tool and Visual Analogue Scale from 0 to 100 (VAS). EQ-5D-3L scores were converted to HRQoL weights between 0 and 1 based on a value set from the United Kingdom general population as no value set is available for Pakistan. Beta regression analyses were performed to identify associations between HCV status or cirrhosis status (defined by treatment duration for those who started treatment) and HRQoL, controlling for patient socio-demographic characteristics (age, gender, employment status, rural/urban location, ethnicity, education level, and city). Model selection was performed using a stepwise algorithm to define the best linear predictor according to Akaike Information Criterion (AIC).
Results: The study included a total of 4,402 participants, with a median age of 36.2 (inter-quartile range: 27.1, 47.6) years and 59.6% males. Of these, 836 individuals were identified as having CHC (HCV RNA positive). The average HRQoL and VAS of CHC patients were 0.855 (95%CI: 0.842–0.867) and 68.5 (95%CI: 67.5–69.4), lower than for HCV Ab-negative controls (0.937, 95%CI: 0.932–0.939 and 80.7, 95%CI: 80.3–81.2, $p < 0.001$, respectively). Among all patients, the best fit model included city, employment, age, gender, and HCV status. Having CHC was significantly associated with lower HRQoL ($B = -0.236$, $p < 0.001$), as was being unemployed ($B = -0.296$, $p < 0.001$), living in Gujranwala ($B = -0.552$, $p < 0.001$), older age ($B = -0.011$, $p < 0.001$), or being female ($B = -0.327$, $p < 0.001$). Among CHC patients, older age ($B = -0.017$, $p < 0.001$), living in Gujranwala ($B = -0.368$, $p < 0.001$), and being female ($B = -0.230$, $p = 0.05$) were significantly associated with lower HRQoL. Having cirrhosis (defined by being on longer treatment regimen) was not significantly associated with HRQoL.
Conclusion: HRQoL was worse among individuals with chronic Hepatitis C infection or if they had older age, female gender, were unemployed or came from study sites based in Gujranwala. The study findings suggests that the high burden of HCV in Pakistan is associated with reduced HRQoL and emphasizes the need for health promotion, diagnosis and treatment for Hepatitis C patients.

FRI-173
Hepatitis C screening program in Lithuania: first results and scenarios for virus elimination

Limas Kupcinskas[1], Egle Ciupkeviciene[2], Alexis Voeller[3], Gediminas Urbonas[4], Ligita Jancoriene[5], Valentina Liakina[6,7], Danute Speiciene[6], Viaceslavas Zaksas[8], Marcelo Naveira[3], Sarah Blach[3], Janina Petkeviciene[2]. *[1]Lithuanian University of Health Sciences, Department of Gastroenterology and Institute for Digestive Research, Kaunas, Lithuania; [2]Lithuanian University of Health Sciences, Health Research Institute, Kaunas, Lithuania; [3]Centre for Disease Analysis Foundation, Lafayette, United States; [4]Lithuanian University of Health Sciences, Department of Family Medicine, Kaunas, Lithuania; [5]Vilnius University, Clinic of Infectious Diseases and Dermatovenerology, Vilnius, Lithuania; [6]Vilnius University, Clinic of Gastroenterology, Nephrourology and Surgery, Vilnius, Lithuania; [7]Vilnius Gediminas Technical University, Department of Chemistry and Bioengineering, Vilnius, Lithuania; [8]National Health Insurance Fund under the Ministry of Health, Vilnius, Lithuania*
Email: l.kupcinskas@gmail.com

Background and aims: In 2016, WHO announced a plan to eliminate viral hepatitis C as a public health threat by 2030. To achieve this goal, it is important to detect hidden infections by launching national screening programs. In 2022, Lithuanian health authorities decided to pay general practitioners (GPs) a special fee for a service of promoting and performing serological tests for hepatitis C virus (HCV) antibodies: 1) for the population born in 1945–1994 (once per life) and 2) for people who inject drugs (PWID) or are HIV-infected (annual HCV testing). Such an initiative is the first in Central and Eastern Europe. This study aimed to evaluate the first results of the

HCV screening program and develop different scenarios to achieve WHO targets.
Method: Patients were invited to participate in the HCV screening by GPs during the visits. Screening included a serum blood test for the presence of HCV antibodies. Patients who tested positive were referred to a gastroenterologist or infectious disease doctor. HCV RNA testing was used to identify the current infection. If the test result was positive, the doctor prescribed direct-acting antiviral (DAA) therapy. Information about screened and treated patients was obtained from the database of the National Health Insurance Fund. The Markov disease progression model elaborated by the CDA Foundation was used to assess HCV elimination progress in Lithuania. The data from the 2022 screening and previously published data were used as inputs. Three scenarios were developed: the 'Base' scenario-return to pre-screening program level in 2023 and 2 scenarios with different extents of treatment.
Results: At the beginning of 2022, about 1.8 million people born in 1945–1994 lived in Lithuania. Between May 5 and December 31 458980 people (59.5% women) were tested for HCV antibodies. Positive test results were found in 7494 (1.6%) people. Seroprevalence of HCV antibodies was higher among men than women, 2.0% and 1.4%, respectively. In the risk group, 4681 PWID and HIV-infected people were screened, of whom 32.8% were seropositive. Viremia was detected in 58.2% of patients. In 2022, 1586 patients were treated with DAA. If the number of tested patients remains the same as in the last three months in 2022, HCV antibody testing will be completed in 2023/2024. Scenario 1: if the same number of patients are treated as before the screening, the WHO targets will not be reached. Scenario 2: treating 70% of infected patients (13000 in 2023/2024) will meet most but not all WHO targets. Scenario 3: by treating all infected patients by 2030, the WHO target will be met by saving 150 lives and preventing 90 new cases of decompensated cirrhosis and 120 cases of hepatocellular carcinoma.
Conclusion: In the Lithuanian screening program, HCV antibody testing by GPs is active; however, the number of patients treated needs to be increased to reach the WHO targets.

FRI-174

Challenges and strategies to improve linkage to care and treatment for hepatitis C in pregnancy: perspectives from a global community of practice

Neil Gupta[1], Lindsey Hiebert[1], Martina Badell[2,3], Megan Buresh[4,5], Catherine Chappell[6,7], Manal Hamdy El-Sayed[8], Saeed Sadiq Hamid[9], Ravi Jhaveri[10,11,12], Ali Judd[13], Tatyana Kushner[11,14], Mona Prasad[7,15], Jennifer Price[11,16,17], John Ward[18]. *[1]Coalition for Global Hepatitis Elimination, The Task Force for Global Health, United States; [2]Emory University School of Medicine, Department of Gynecology and Obstetrics, Atlanta, United States; [3]Society of Maternal Fetal Medicine, United States; [4]Johns Hopkins University School of Medicine, Division of Addiction Medicine, Baltimore, United States; [5]American Society of Addiction Medicine, United States; [6]University of Pittsburgh, Department of Obstetrics, Gynecology, and Reproductive Sciences, United States; [7]American College of Obstetrics and Gynecology, United States; [8]Ain-Shams University, Pediatric Department, Cairo, Egypt; [9]The Aga Khan University, Department of Medicine, Karachi, Pakistan; [10]Northwestern University Feinberg School of Medicine, Department of Pediatrics, Chicago, United States; [11]AASLD/IDSA HCV Guidelines Panel, United States; [12]AASLD Viral Hepatitis Elimination Task Force, United States; [13]University College London, MRC Clinical Trials Unit, United States; [14]Icahn School of Medicine at Mount Sinai, Division of Liver Diseases, United States; [15]OhioHealth, System Chief of Obstetrics, Columbus, United States; [16]University of California San Francisco, Division of Gastroenterology and Hepatology, San Francisco, United States; [17]AASLD Hepatitis C Special Interest Group, United States; [18]Coalition for Global Hepatitis Elimination, The Task Force for Global Health, Decatur, United States*
Email: ngupta-consultant@taskforce.org

Background and aims: Approximately 15 million women of reproductive age are estimated to have chronic hepatitis C virus (HCV) infection worldwide, and an increasing number are diagnosed during pregnancy. Treatment is not currently recommended during pregnancy or breastfeeding due to a lack of safety data. Routine clinical practice is to refer pregnant individuals for treatment after pregnancy and breastfeeding; however, successful linkage to care is extremely limited. The Coalition for Global Hepatitis Elimination established a Community of Practice (CoP) to share existing programmatic experiences and identify best practices for linkage and treatment for pregnant individuals.
Method: A virtual CoP was advertised to interested clinicians, public health professionals, researchers, and advocates, via website posting, social media, professional societies, and targeted outreach. From November 2022 to January 2023, two 90-minute online sessions were conducted, consisting of expert presentations, panel discussions, and first-hand accounts from affected persons. CoP members were polled at the conclusion of each session.
Results: In total, 378 participants from 43 countries attended the CoP sessions, representing all six WHO regions. Most participants self-identified in the fields of public health (33%), primary care (family medicine, obstetrics, pediatrics, or other healthcare provider) (24%), or specialties (hepatology or infectious diseases) (23%). The most frequent challenges for linkage and treatment in pregnancy reported by participants were lack of safety data for HCV treatment in pregnancy (55%), lack of guidelines or recommendations (48%), lack of provider understanding of treatment options (40%), inadequate insurance coverage or payment restrictions (35%), high cost or unavailability of HCV medications (32%), and other patient-side socioeconomic barriers (28%) (n = 96 respondents). The most frequent recommendations to improve linkage to care and treatment were co-location of perinatal and HCV treatment services (76%), training of antenatal care providers in HCV treatment (68%), integration of harm reduction or opiate use disorder services (67%), outreach programs (59%), patient navigators (58%), patient communication materials (54%), and guidance from professional societies (48%) (n = 85). More participants believed that referral during pregnancy (75%) or HCV treatment during pregnancy (71%) were optimal strategies compared to immediate post-partum treatment (42%), treatment after delivery and breastfeeding (38%), or referral immediately after delivery (35%).
Conclusion: Through a CoP, specific challenges for HCV linkage and treatment for pregnant individuals were identified, and actionable strategies were defined to improve linkage and treatment. Adequate safety data for antenatal administration of direct-acting antivirals, evidence-based operational guidance, and innovative clinical models to increase linkage and treatment for pregnant individuals are urgently needed in order to achieve HCV elimination goals.

FRI-175

New and easy strategy for mass screening for hepatitis C in leisure spaces

Sonia Albertos Rubio[1,2,3], Rafael Esteban[4], Joan Colom[5], Maria Buti[4]. *[1]Hospital Residència Sant Camil, Division of Gastroenterology and Hepatology, Barcelona, Spain; [2]Hospital Residència Sant Camil, Barcelona, Spain; [3]Hospital Residència Sant Camil, Spain; [4]Vall d'Hebron University Hospital, Barcelona, Spain; [5]Agència de Salut Pública de Catalunya ASPCAT, Barcelona, Spain*
Email: sonia.albertos@gmail.com

Background and aims: Spain in one of the high income countries on the track for hepatitis C elimination. The prevalence of active hepatitis C in the general population is 0.22% but is higher in vulnerable group. Data from Men who have Sex with Men (MSM) in Catalonia has been established at 0.75%[1]. The aim of the study is the HCV screening of the population at street level in leisure events of the LGTBI+ collective, using a new screening strategy in leisure spaces. Saludes, V. *et al.* Community-based screening of hepatitis C with a one-step RNA

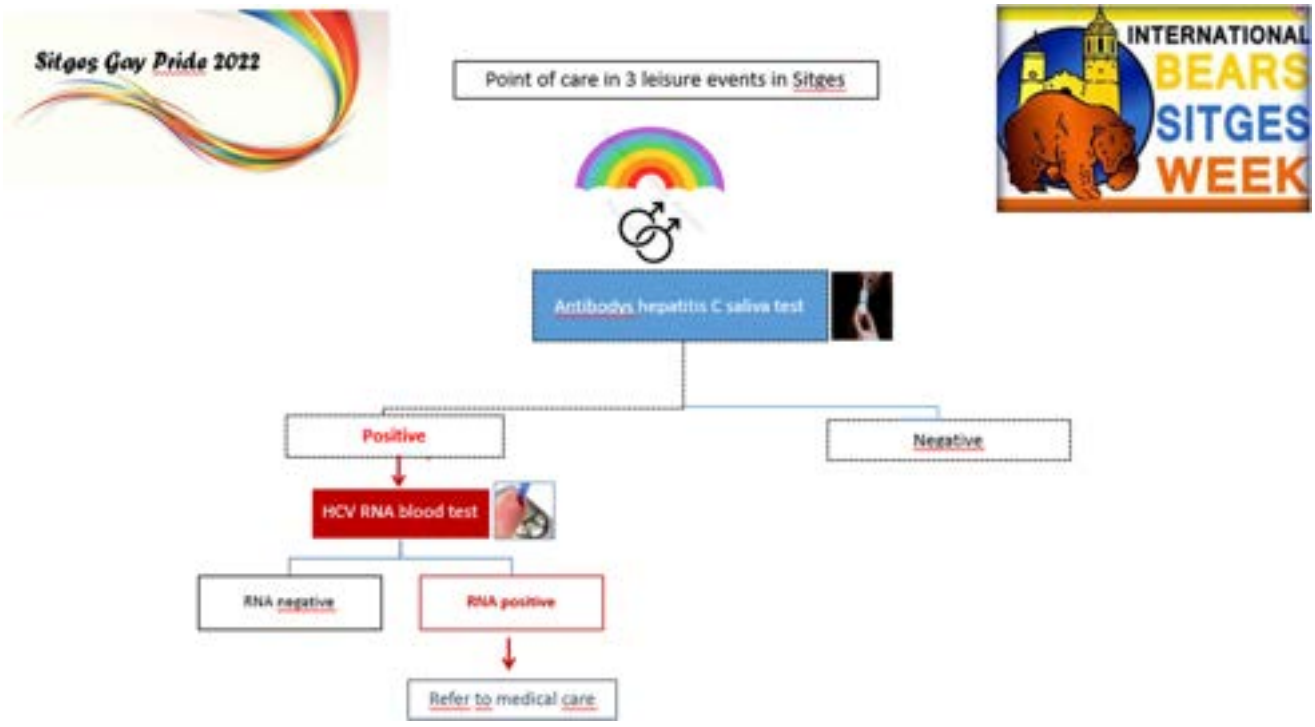

Figure: (abstract: FRI-175).

detection algorithm from dried-blood spots: Analysis of key populations in Barcelona, Spain. *J. Viral Hepat.* 25, 236–244 (2018).

Method: We designed a new method of mass screening for hepatitis C in adults, in 3 festive events of the LGTBI+ community in Sitges (Catalonia), in 2022. The participants were cared for in tents located in leisure spaces where an antibody saliva test was performed -ORAQUICK®- and, if positive, a second HCV RNA test was offered -Xpert HCV Fingerstick®. The baseline demographic value, prior knowledge of having or having had hepatitis C, self-perception of sexual transmission disease risk (visual scale from 0 to 10), risk practices identification test (RPIT) and informed consent were collected (8 items). The project was supported by a scholarship Gilead and Spanish Society of Hepatology, local authorities and the Colors Sitges LGTBI+ association.

Results: We tested 1249 adults, 1197 (96%) identified as MSM. Median age of 44 years (35–54), and 49 different nationalities (24.3% Spanish). The tests were performed in 33 hours (an average of 39 tests/hour). There were only 4 positive tests (3 from the MSM collective), all of them with undetectable RNA. Of the MSM group, 13% did not know their previous hepatitis C status, expressed self-perception of sexual transmission disease risk of 3 out of 10 and an average TISPR of 1.4 out of 8.

Conclusion: We present an efficient and well-accepted hepatitis C screening strategy at the community level, allowing rapid screening of large groups. Although the majority was MSM population exposed to STDs, we have only found a 0.32% HCV serological prevalence and no viremic. This strategy should be explored in other high-risk groups, with difficult access to medical care, such as parenteral drug addicts or homeless people.

FRI-176

Burden of hepatitis C in pregnant women and children in the United States

Paul Wasuwanich[1], Joshua So[1], Tony Wen[2], Robert Egerman[2], Wikrom Karnsakul[3]. [1]*University of Florida College of Medicine, Gainesville, United States;* [2]*University of Florida College of Medicine, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Gainesville, United States;* [3]*The Johns Hopkins University School of Medicine, Division of Pediatric Gastroenterology, Hepatology, and Nutrition, Department of Pediatrics, Baltimore, United States*
Email: p.wasuwanich@ufl.edu

Background and aims: Cases of hepatitis C virus (HCV) infection are increasing every year in the United States, and while injection drug use remains the largest contributor to HCV transmission, another major route is vertical transmission. We aim to elucidate and extrapolate the financial and health burden of vertically transmitted hepatitis C in pregnant women and children with hepatitis C.

Method: We utilized the 2010–2019 National Inpatient Sample, a nationwide database of hospitalizations in the United States. We identified hepatitis C-related hospitalizations in pregnant women and children using ICD-9 and ICD-10 diagnosis codes. We extracted demographic, financial, and clinical data including all-cause mortality, length of stay, co-infections, and pregnancy outcomes. Financial calculations are inflation adjusted to 2020 and reported in USD. Trends were analyzed by Poisson regression and frequencies by chi-squared test, with significance defined as $p < 0.05$.

Results: We identified a total of 174,430 pregnancies and 134,574 deliveries between 2010 and 2019 that involved hepatitis C. Between 2010–2019, there is an increasing trend of hospitalizations of pregnant women with hepatitis C (incidence rate ratio = 1.14; 95% CI = 1.13–1.16; $p < 0.001$). Maternal deaths were rare (<0.1%) and similar to the non-hepatitis C pregnancy cohort ($p = 0.147$). However, the length of hospitalization was longer in the hepatitis C pregnancy cohort, 3 days versus 2 days ($p < 0.001$). Additionally, preterm delivery was more common in pregnant women with hepatitis C, 19.1% versus 10.2% ($p < 0.001$). Post-term deliveries were less common in pregnant women with hepatitis C, 8.7% versus 13.2%, ($p < 0.001$). Rates of stillbirths were similar in hepatitis C and non-hepatitis C pregnant cohorts ($p = 0.253$). HIV co-infection was also more common in the pregnant women with hepatitis C, 0.9% versus 0.1% ($p < 0.001$). Additionally, Caesarian deliveries were more frequent in the hepatitis C pregnancy cohort, 19.5% versus

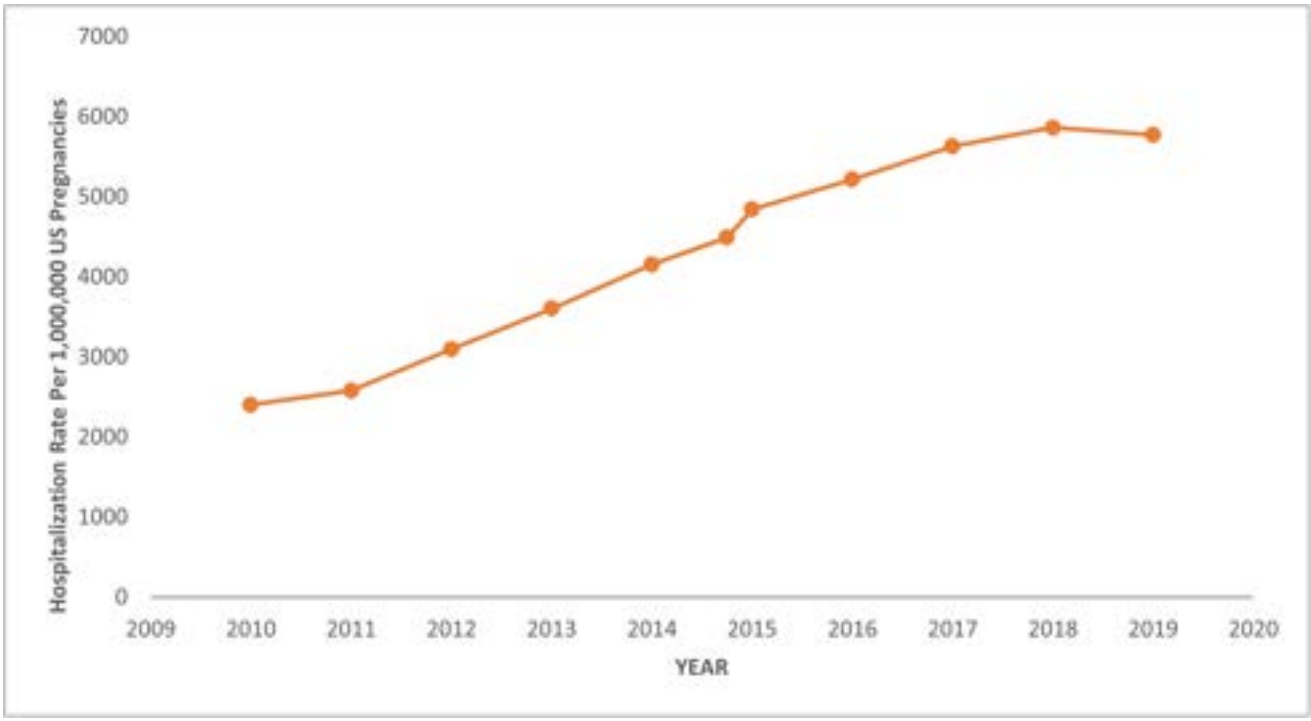

Figure: (abstract: FRI-176): Hepatitis C-related hospitalizations of pregnant women in the United States, 2010–2019.

16.8% ($p < 0.001$). Among the children (≤18 years) with hepatitis C, 4.1% developed non-alcoholic cirrhosis. In 2019, there was a financial burden of $30,414 in excess cost in infants who have hepatitis C per hospitalization. However, for the pregnant women, hospitalization costs were similar between the hepatitis C and non-hepatitis C populations.

Conclusion: Hepatitis C-related hospitalizations in the pregnancy population are increasing yearly and so are the health burdens of the disease, on both the pregnant women and the infants/children. While the financial burden was not obvious the pregnant women, there is a clear cost burden is on the infants with hepatitis C.

FRI-177

Micro-elimination of chronic hepatitis C virus in patients with psychiatric disorders: a multidisciplinary strategy in the outpatient mental health center

Inés Sáenz de Miera[1,2], Joel López[1,2], Maite Royo[2,3], Isabel Plo[2,4], Adrià Rodríguez[1,2], Silvia Montoliu[1,2], Albert Pardo[1,2], Joaquín Ruiz[2,3], Juan Carles Quer Boniquet[1,2]. *[1]Joan XXIII University Hospital of Tarragona, Gastroenterology, Spain; [2]Pere Virgili Health Research Institute, Tarragona, Spain; [3]Pere Mata Institute, Mental Health Center for Adults, Tarragona, Spain; [4]Joan XXIII University Hospital of Tarragona, Pharmacy, Spain*
Email: senisamier@yahoo.com

Background and aims: The psychiatric population is considered a vulnerable group with difficulties in accessing diagnostic services and treatment for chronic hepatitis C virus (HCV) (CHC). The seroprevalence of the disease in the psychiatric population is not well known and ranges from 4 to 17%. Data on seroprevalence in Spain are scarce. A multidisciplinary care strategy has been implemented for screening, diagnosis, and treatment of CHC in patients with psychiatric pathology treated in the outpatient mental health center for adults (MHCA) in Tarragona, where the studied and treated population does not move from their usual care environment. The aims of the study are to evaluate the prevalence of CHC in this population and to assess the efficiency of the established circuit for its diagnosis and treatment.

Method: Prospective observational study. Preliminary data are presented with a analised period of 9 months (January-September 2022). Rapid screening is offered with determination of antibodies for HCV (Ab-HCV) in saliva (OraQuick HCV). In positive cases, viral load of HCV (RNA-HCV) is performed. In cases with proven infection, a study of interactions (Pharmacy-Psychiatry) and prescription of treatment is carried out. The clinical visit, elastography, and initiation of treatment are performed on the same day. The medication is provided to patients at the MHCA, where adherence to treatment is monitored.

Results: Screening was offered to 610 individuals, 349 accepted inclusion (57.2%). 50% are men, median age 47 years; 39% with psychotic disorder, 13% bipolar disorder; 32% with a history of risk factor. Ab-HCV was detected in 9 cases (seroprevalence 2.6%): 7 men, median age 54 years; 8 of them with a history of drug use. Of the 9 cases, 3 had positive RNA-HCV (prevalence 0.85%); 2 of them with criteria for non-response to a previous treatment with Interferon-Ribavirin. 2 have received 12 weeks of treatment with Sofosbuvir-Velpatasvir, with good adherence. They did not require significant modifications of their usual psychiatric therapy and achieved SVR. The third is pending initiation. Of the remaining 6 seropositive cases, 5 had previously been treated and it is confirmed that they maintain SVR; the remaining one, does not have a risk factor and meets criteria for spontaneous resolution. 4 of the seropositive cases in blood had a negative saliva test result.

Conclusion: The inclusion rate of patients in the screening program has been acceptable, nevertheless, measures have been taken to improve recruitment. The seroprevalence of HCV detected in the sample analised is higher than that described for the general population. Most of the seropositives had already been diagnosed and treated previously. The saliva test is reliable, so the false negative results obtained imply a need to improve the collection technique to avoid underdiagnosis. The treated cases have maintained excellent adherence and have required few modifications to their psychiatric therapy. These results suggest that a management strategy in the patient's environment can be effective.

FRI-178

Simple treatment eligibility score for chronic HBV infection at peripheral health facilities in sub-Saharan Africa

Email: yusuke.shimakawa@pasteur.fr

Background and aims: To eliminate hepatitis B virus (HBV) infection in resource-limited settings, it is essential to decentralize HBV care services to peripheral health facilities. However, at these facilities, access to recommended diagnostic tools to assess eligibility for antiviral therapy (AVT), particularly quantitative HBV DNA tests and transient elastography, is severely limited. Through a multi-regional collaboration in sub-Saharan Africa (SSA), we developed and evaluated a simple scoring system, using tests available at peripheral health facilities, to identify eligibility for AVT in people with HBV.
Method: Through HEPSANET (Hepatitis B in Africa Collaborative Network), we conducted a site survey to define the availability of biomarkers potentially useful for HBV management at different levels of health facilities. Then, using the HEPSANET dataset, the largest cross-sectional database of people with chronic HBV in SSA, we divided the sample into derivation and validation sets. We used data from those with a known HBV DNA levels, elastography score, and treatment eligibility status according to the EASL 2017 criteria, which was used as a reference. Using the derivation set, we identified a combination of variables available at peripheral health facilities that can best identify people eligible for AVT through a stepwise logistic regression. With the validation set, we estimated the sensitivity and specificity of the simplified score to identify people eligible for AVT.
Results: The survey of 11 sites found that on average, transaminases (AST, ALT) and platelet counts were available at the district hospital level, hepatitis B e antigen (HBeAg) and near point-of-care HBV DNA test (Xpert) at regional/provincial hospital level, and transient elastography and conventional quantitative HBV DNA tests were only available at national reference centers. Liver decompensation (jaundice, ascites, encephalopathy, etc) was diagnosed clinically at all levels. We proceeded to create a scoring tool for use at district level. The analysis included 2928 treatment naïve individuals with HBV-mono from seven SSA countries, of which 398 (13.6%) were eligible for AVT according to EASL guidelines. AST, ALT, and platelet count remained in the multivariable stepwise regression model and the following scoring system was developed: platelet counts (10^9/L), <100 (+2), 100–149 (+1), ≥150 (±0); AST (IU/L), <40 (±0), 40–79 (+1), ≥80 (+2); and ALT (IU/L), <40 (±0), 40–79 (+1), ≥80 (+2). Using a cut-off of ≥2, the score had a sensitivity of 79% and specificity of 87% to identify treatment-eligible individuals in the validation dataset.
Conclusion: We found that a low cost combination of platelet counts, AST and ALT levels-tests available even at low level health facilities-can identify the majority of people with HBV in need of AVT in SSA. This suggests that even in the absence of upgrades in laboratory/radiology, decentralization of clinical staging for people with HBV people may be realized in resource-limited settings.

FRI-179

A nationwide study on the core indicators related to elimination of viral hepatitis B and C in Korea

Chang Hun Lee[1], Gwang Hyeon Choi[2], Hwa Young Choi[3], Sojung Han[4], Young Eun Chon[5], Young Chang[6], Eun Sun Jang[2], Kyung-ah Kim[7], Do Young Kim[8], Hyung Joon Yim[9], Hye-Lin Kim[10], Sook-Hyang Jeong[2], In Hee Kim[1]. *[1]Research Institute of Clinical Medicine of Jeonbuk National University-Biomedical Research Institute of Jeonbuk National University Hospital, Jeonju, Korea, Rep. of South; [2]Seoul National University Bundang Hospital, Seoul National University College of Medicine, Internal Medicine, Seongnam-si, Korea, Rep. of South; [3]Cancer Control and Population Health, Graduate School of Cancer Science and Policy, National Cancer Center, Goyang-si, Korea, Rep. of South; [4]Uijeongbu Eulji Medical Center, Eulji University School of Medicine, Euijeongbu, Korea, Rep. of South; [5]CHA Bundang Medical Center, CHA University, Internal Medicine, Seongnam-si, Korea, Rep. of South; [6]Institute for Digestive Research, Digestive Disease Center, Soonchunhyang University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [7]Inje University Ilsan Paik Hospital, Internal Medicine, Goyang-si, Korea, Rep. of South; [8]Yonsei University College of Medicine, Severance Hospital, Seoul, Korea, Rep. of South; [9]Korea University Ansan Hospital, Korea University College of Medicine, Ansan-si, Korea, Rep. of South; [10]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South*
Email: ihkimmd@jbnu.ac.kr

Background and aims: The World Health Organization (WHO) recognizes viral hepatitis as a global public health problem and proposed the elimination of viral hepatitis as a goal to be achieved by 2030. In June 2021, WHO published an interim guideline that sets impact and programmatic targets for country validation of viral hepatitis elimination. We aimed to calculate core indicators for country validation of viral hepatitis elimination in Korea.
Method: The incidence, linkage-to-care rate, treatment rate, and mortality rate related to hepatitis B and C in Korea were analyzed using the health insurance claims data provided by the Korean National Health Insurance Service (NHIS), infectious disease surveillance data from Korea Centers for Disease Control and Prevention Agency, and cause-of-death data from Statistics Korea.
Results: The incidence of acute hepatitis B in Korea was 0.71 per 100,000 patients, and the linkage-to-care rate of hepatitis B was only about 39.1% Among those who need hepatitis B treatment, the treatment rate was 67.3%, which did not reach the WHO program index of 80%. Regarding liver-specific mortality, the annual liver-related mortality rate is as high as 18.1 per 100,000 people, and liver

Figure 1. Cascade of care of hepatitis B and C in Korea. (A) Hepatitis B (B) Hepatitis C

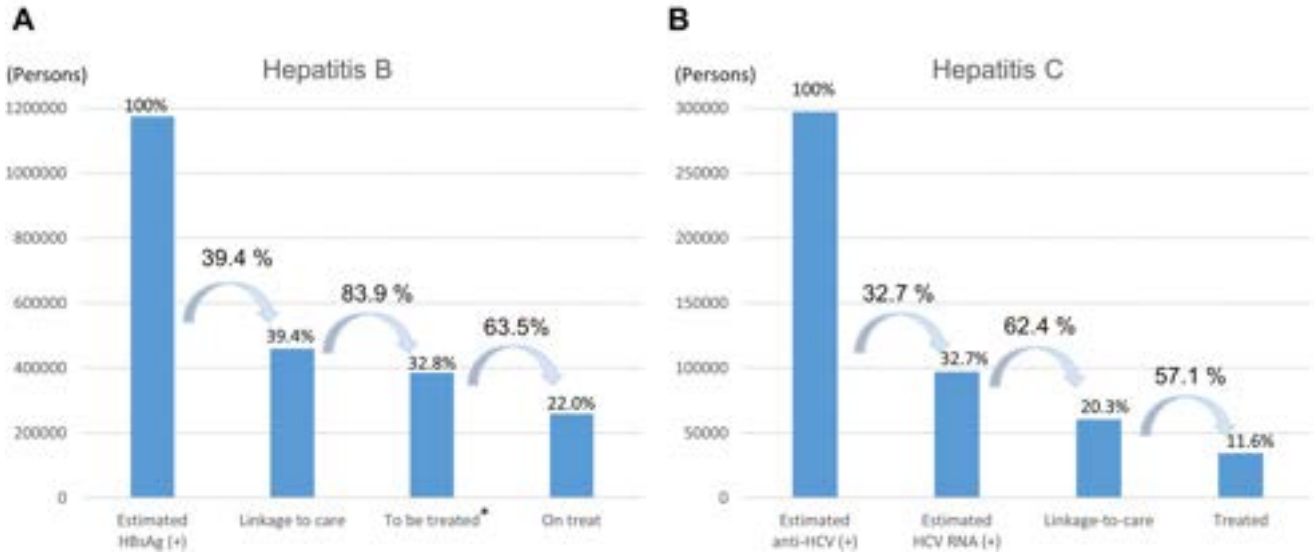

Figure: (abstract: FRI-179).

cancer accounted for the leading cause of death at about 54%. In Korea, the annual incidence of hepatitis C remains high at 11.0 per 100,000 people, whereas the hepatitis C linkage-to-care rate and the treatment rate are low (61.3% and 57.1%, respectively). Regarding the liver-specific mortality rate, the annual liver-related mortality rate for hepatitis C is 1.92 per 100,000 people.

Conclusion: A considerable number of core indicators of country validation for viral hepatitis elimination in Korea have not yet met the certification criteria. It is required to continuously monitor the certification criteria for viral hepatitis elimination in Korea and develop a comprehensive national viral hepatitis elimination strategy.

FRI-180

Hepatitis C seroprevalence screening and linkage to care of unknown infected patients admitted to a tertiary care emergency departement: on the road to achieve the WHO 2030 virus elimination target

Background and aims: direct-acting antivirals (DAAs), with their proven effectiveness, allowed WHO to define the elimination of the Hepatitis C virus (HCV) as a health-related global goal by 2030. Hence, worldwide screening campaigns were developed to detect unknown infections. The current study aims to determine the prevalence and characteristics associated with positive HCV serology in patients admitted to an academic tertiary care emergency department to increase diagnosis, define predictors of linkage to care (LTC) and properly achieve anti-viral treatment.

Method: a prospective screening was conducted between November 2021 and October 2022, in patients attending the Emergency Room (E.R.) of the Molinette Hospital of Turin. Individuals with reactive HCV-Ab test were informed and, if the infection was unknown, HCV RNA testing was proposed. HCV-Ab production was investigated with ELISA method and HCV RNA was performed by RT-PCR testing. Patients were then interviewed to assess LTC and administer DAAs therapy.

Results: among 57715 patients attending the E.R. in study period, 5418 participated to the HCV screening. On a total of 5418 screened patients (51.1% Male/48.9% Female), we identified 188 (3.47%) HCV-Ab reactive patients. The positivity rate was higher in males than in females (4.6 vs 2.3%, p < 0, 001), in over 50 years old than under 50 years old patients (4.4 vs 1.5, p < 0, 001), in patients with severe triage tags than in those with moderate tags (3.0% vs 4.2, p value = 0.014) and in patients admitted to hospital than home discharged patients (14.9% vs 8.5%, p = 0.008). Of the 188 HCV-Ab reactive patients, 53 (28.19%) were not aware of the Ab-positivity and 33 (17.6%) resulted HCV-RNA positive. Between the HCV-RNA positive patients, 17 (51.5%) had a new diagnosis of ongoing infection and 16 (41%) agreed to be treated with DAAs. Of these, 100% reached a viral sustained virological response (SVR).

Conclusion: the prevalence of HCV infection in the population recruited in the E.R. is greater than in general population (3.5% vs. 1%). HCV screening in the E.R. could be an effective way of identifying ongoing unknown infections and achieve the WHO 2030 elimination targets. Currently, the screening is still ongoing. A case control study has been designed to explore HCV risk factor and determinants to LTC.

FRI-181

D-Mongolia: new strategy for hepatitis B, D and C screening and linkage to care in Mongolians living in Spain

Adriana Palom[1,2], Edurne Almandoz[3], Antonio Madejón[2,4], Ariadna Rando-Segura[2,5], Ylenia Pérez Castaño[6], Judit Vico-Romero[1], Naranbaatar Battulga[1], Mar Riveiro Barciela[1,2], Jordi Gómez-Prat[7], Juan Ignacio Arenas[2,3], Francisco Javier Garcia-Samaniego Rey[2,4], Maria Buti[1,2]. *[1]Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain, Spain; [2]Centro de Investigación Biomédica en Red en Enfermedades Hepáticas y Digestivas, Instituto de Salud Carlos III, Madrid, Spain, Spain; [3]Gastrointestinal Unit, Hospital Universitario Donostia, Instituto de Investigación Biodonostia, San Sebastian, Spain, Spain; [4]Liver Unit, Hospital Universitario La Paz, IdiPAZ, Madrid, Spain,*

Email: mariabutiferret@gmail.com

Background and aims: Mongolia is one of the countries with the highest prevalence of viral hepatitis (B, C and D) in the world. One third of Mongolia's population lives outside the country. In Spain, there are 853 Mongolians registered on the census, mostly distributed between Barcelona, San Sebastián and Madrid. The reported prevalence of viral hepatitis in Spain is 0.22% for HBsAg, 0.85% for anti-HCV and 0.22% for HCV-RNA. The aims of this study were to screen Mongolians living in Spain for viral hepatitis B, D and C, describe their characteristics and in positive cases, offer them the possibility to be linked to care.
Method: Mongolian adults residing in Spain were contacted by a community worker to attend a community program consisting of an educational activity (audiovisual information on viral hepatitis), an epidemiological questionnaire (knowledge of the disease, risk factors…) and a point-of-care rapid test for hepatitis B and C. In positive cases, a dried blood spot test was performed to determine HBV-DNA, HCV-RNA and anti-HDV, and a blood test that included serological and virological parameters. The positive cases were linked to care during the same screening.
Results: From a total of 709 Mongolians residing in Barcelona, San Sebastián and Madrid, 290 were invited to the community program and 216 (75%) subjects carried out the educational activity and were tested. One-hundred-thirty-five were women (62.5%), mean age 41.1 ± 11.6 years, 73 (34%) subjects had one or more viral hepatitis risk factor, and 46 (21%) reported being already vaccinated against HBV. The rest were unaware of their vaccination status.
Among them, 14 (6.5%) were anti-HCV+, 2 had detectable HCV-RNA (0.9%); 9 were HBsAg+ (4.2%) and 8 with detectable HBV-DNA (3.7%). From those HBsAg+, 2 had hepatitis B/D co-infection (0.9%), both with undetectable HDV-RNA. Peripheral blood serology confirmed the results of the rapid test in all cases. However, the virological dried blood tests showed lower virological values than the peripheral blood ones. Among the 23 diagnosed patients, 15 (65%) were unaware of their diagnosis. All of them are currently linked to care.
Conclusion: The community program was feasible, widely accepted, and allowed linkage to care of 23 subjects, 65% of whom were unaware of the infection. The prevalence of viral hepatitis was higher than that described in the Spanish population. Among the screened participants, the prevalence of hepatitis B was higher than active hepatitis C, and an important number of adults were not aware of being vaccinated against HBV. In the future, hepatitis B vaccination needs to be included in these community programs.
This project has been funded by Gilead Sciences (GLD21/00139).

FRI-182

Improving blood borne virus screening in immigration removal centres in the UK

Katie Abraham[1], Nichola Royal[1], Arran Ludlow-Rhodes[1], Louise Missen[2]. *[1]Practice Plus Group Ltd, United Kingdom; [2]Gilead Sciences Ltd, United Kingdom*
Email: katie.abraham@practiceplusgroup.com

Background and aims: There are currently 7 Immigration Removal Centres (IRC) in the UK with 24,497 individuals being detained in 2021. Prevalence of blood borne viruses (BBVs) in IRCs is poorly understood, but residents in UK foreign national prisons have been shown to have significantly higher hepatitis B virus (HBV) and human immunodeficiency virus (HIV) prevalence compared to the general prison population. As a result of this, IRCs are potentially important sites to test for these BBVs and hepatitis C (HCV). Barriers to BBV testing include fast turnover of patients and hesitancy to treat due to risk of deportation. The aim of this pilot project is to assess and overcome potential barriers to implementation of BBV screening and linkage to care in IRCs.
Method: As part of National Health Service England plans to eliminate HCV in England by 2025, Practice Plus Group (PPG) and Gilead Sciences formed a partnership in May 2019 with the aim to optimise hepatitis C virus (HCV) testing and treatment in their secure

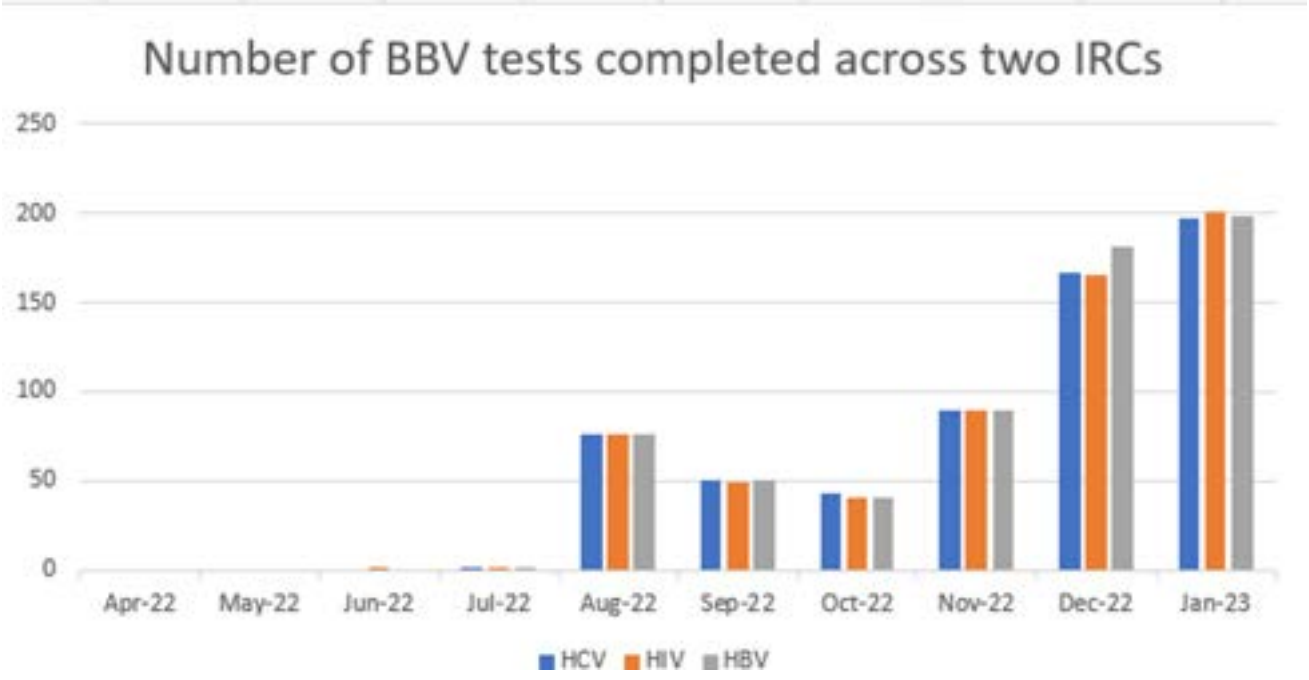

Figure: (abstract: FRI-182).

settings. A pilot project was developed at two London based IRCs where healthcare is provided by PPG. PPG regional BBV Lead Nurses and a Gilead Medical Scientist worked with the IRC and BBV stakeholders to optimise test and treat pathways for new IRC admissions. An important step was to gain agreement that every effort would be made to delay the transfer of residents if diagnosed, an issue that has previously been a barrier to screening. All IRC staff were trained in offering and administering point of care (PoC) BBV testing and regular review meetings were implemented to discuss progress and targets.

Results: The number of residents offered and tested increased rapidly from the start of the pilot in August 2022 with the majority of those tested being screened for all three BBVs (see Figure). Across both IRCs between April 2022 and December 2022, 18 HCV antibody positive cases, 14 hepatitis B surface antigen (HbSAg) positive cases and 9 HIV RNA positive cases were identified. The prevalence of HCV antibody, HbSAg and HIV RNA positivity was 2.9%, 2.2% and 1.4% respectively. Updated data on referral to treatment and treatment initiation for these cases will be available at the conference.

Conclusion: This pilot highlights the importance of ensuring that HBV, HCV, and HIV are all included in screening in IRC populations. Data from this project demonstrates that the BBV prevalence is significantly different to that of other UK secure settings and indicates the need for a multi-agency approach.

FRI-183

Exploring the impacts of the COVID-19 pandemic on access to HCV-related care and support: findings from a survey of people with lived experience of incarceration and/or substance use in British Columbia, Canada

Terri Buller-Taylor[1], Georgine Cua[2], Dahn Jeong[3,4], Naveed Janjua[1,4,5], Mawuena Binka[1,4]. *[1]British Columbia Centre for Disease Control, Vancouver, Canada; [2]University of British Columbia, Canada; [3]British Columbia Centre for Disease Control, Canada; [4]School of Population and Public Health, University of British Columbia, Vancouver, Canada; [5]Centre for Health Outcomes and Evaluation, St Paul's Hospital, Vancouver, Canada*
Email: terri.buller-taylor@bccdc.ca

Background and aims: Understanding the size and scope of the impact of the COVID-19 pandemic and associated control measures on access to hepatitis C (HCV)-related services among marginalized groups is important for planning and resource allocation now, and during future pandemics. To address existing knowledge gaps, we surveyed people with lived experience of incarceration and/or substance use in British Columbia (BC) about barriers to accessing HCV-related care during the COVID-19 pandemic and preferred potential solutions.

Method: Between August and November 2022, people previously diagnosed with HCV were recruited through selected BC recovery houses (e.g., posters, e-mails to directors) who often serve people with histories of incarceration or substance use. The online survey included questions on the impact of the COVID-19 pandemic on access to HCV-related services. Participants were characterized overall, and then grouped by whether or not they received HCV-related (i) medical services, or (ii) support services (not mutually exclusive). Data on changes in services, the barriers experienced, and preferred solutions to these barriers were collected and analyzed.

Results: A total of 149 people participated in the survey: 56.4% male; 40.3% Indigenous, 39.6% White; and 30.2% 35–44 or 28.9% 45–54 years old. Participants were socially disadvantaged, including 95.3% people who use drugs, 87.2% experiencing food insecurity, 87.2% under-housed, 71.1% with a history of incarceration, 65.1% unemployed, and 38.3% with a disability. Among people who received HCV-related medical (n = 95) and support services (n = 91), 59.3% and 76.2% reported a worsening in access to these services during the pandemic, respectively. Many reported at least one cancelled/postponed HCV medical (38.9%) or support service (74.7%) appointment. COVID-19-specific barriers at HCV testing/treatment facilities included COVID-19 control measures (28.4%) and concern about getting COVID-19 (29.5%). Top selected solutions to improving access to HCV-related services included increased peer worker funding/support (77.2%), same-day diagnosis and treatment initiation (71.1%), and no tax return requirement for treatment coverage (67.1%).

Conclusion: Survey findings suggest that the COVID-19 pandemic exacerbated existing barriers to HCV medical and support services for economically and socially marginalized individuals. Addressing respondents' preferred solutions will be vital to improving ongoing access to HCV care and for mitigating barriers in future pandemics.

FRI-184

Tenofovir prophylaxis during pregnancy for the elimination of mother-to-child transmission of hepatitis B virus: a cost-effectiveness analysis

Chawisar Janekrongtham[1], Wirichada Pan-ngum[2], Kittiyod Poovorawan[3], Pisit Tangkijvanich[4]. *[1]Department of Disease Control, Thailand Ministry of Public Health, Thailand; [2]Department of Tropical Hygiene, Faculty of Tropical Medicine, Mahidol University, Thailand; [3]Department of Clinical Tropical Medicine, Faculty of Tropical Medicine, Mahidol University, Thailand; [4]Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand*
Email: pisittkvn@yahoo.com

Background and aims: Despite implementing hepatitis B immunoglobulin (HBIG) and vaccination, Tenofovir Disoproxil Fumarate (TDF) has been added for HBeAg-positive mothers during pregnancy to reduce HBV-DNA at birth. To optimize national strategies in Thailand, we assessed the effectiveness of TDF in preventing maternal to child transmission and conducted cost-effectiveness of different TDF-based strategies.

Method: We retrospectively reviewed medical records of mother and infant pairs whose mothers have HBeAg-positive and received TDF in preventing maternal to child transmission of viral hepatitis B according to Thai national guidelines during 2018–2020. Based on the available data of transmission rate, we also applied a decision tree to estimate the cost-effectiveness of different TDF-based strategies to eligible mothers. These included [1] HBIG for all HBV-exposed infants ("HBIG for all") [2] HBIG for only infants of HBeAg-positive mothers ("HBIG for e-positive") and [3] without HBIG to infants ("HBIG-free") The incremental cost-effectiveness ratio (ICER) between the different strategies and baseline intervention without TDF was calculated. The one-way sensitivity analysis was used to adjust prevalence of HBeAg-positive mothers, cost of HBIG, cost of TDF, and transmission rate.

Results: Of 223 infants enrolled, 212 (95.0%) received HBIG while 11 (5.0%) did not. None (0%, 95%CI = [0, 1.69]) of the infants had chronic HBV infection (Figure). The most cost-saving intervention was "HBIG-free" followed by "HBIG for e-positive." The one-way sensitivity demonstrated that the results were reasonably robust to changes. The cost-effectiveness was greater with a higher HBeAg prevalence. The HBIG-free strategy remained best at transmission rates of 0–1.4%, meeting the additional target for eliminations.

Conclusion: The study is the first cost-effectiveness analysis to provide evidence supporting HBIG-free strategy in the era of antivirals. This approach should be considered for preventing maternal to child transmission in resource-constrained settings, particularly in countries with high HBeAg prevalence.

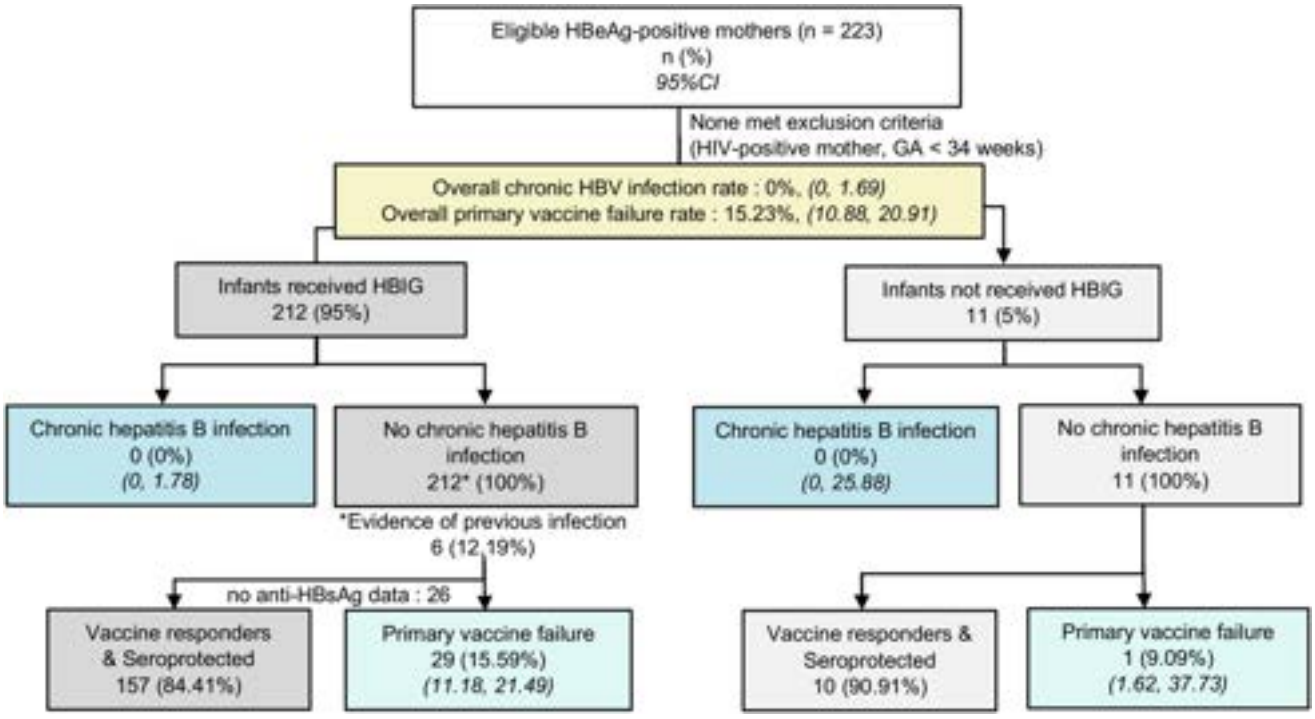

Figure: (abstract: FRI-184): Infant outcomes stratified by HBIG exposure.

A territory-wide opportunistic, hospital-based HCV screening in the general population from northern Italy: the 1969–1989 birth-cohort

Roberta D'Ambrosio[1], Sara Piccinelli[2], Benedetta Beccalli[3], Angiola Spinetti[4], Massimo Puoti[5], Stefano Fagiuoli[6], Carlo Federico Magni[7], Silvana Castaldi[8], Giulia Bombardieri[9], Claudio Farina[9], Sabrina Buoro[3], Alessandro Amorosi[3], Danilo Cereda[3], Matteo Corradin[3], Pietro Lampertico[1,10]. *[1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Gastroenterology and Hepatology, Milan, Italy; [2]University of Milan, Department of Biomedical Sciences for Health, Milan, Italy; [3]DG Welfare Lombardy Region, Milan, Italy; [4]ASST Ospedali Civili, Division of Infectious and Tropical Diseaese, Department of Clinical and Experimental Sciences, Brescia, Italy; [5]ASST GOM Niguarda Milan and University of Milan Bicocca, Milan, Italy; [6]ASST Papa Giovanni XXIII, Gastroenterology Hepatology and Transplantation Division, Bergamo, Italy; [7]ASST Fatebenefratelli Sacco, First Division of Infectious Diseases, Milan, Italy; [8]Foundation IRCCS ca' Granda Ospedale Maggiore Policlinico, Quality Department, Milan, Italy; [9]ASST Papa Giovanni XXIII, Microbiology and Virology Laboratory, Bergamo, Italy; [10]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Italy*
Email: roberta.dambrosio@policlinico.mi.it

Background and aims: The World Health Organization (WHO) goal of Hepatitis C Virus (HCV) elimination by 2030 rose awareness about the need of screening plans, worldwide. In Italy, it has been estimated that graduated screening starting from people born between 1969 and 1989 might be the most-effective strategy. Aim of this study was to perform a territory-wide opportunistic HCV screening study in the general population born between 1969 and 1989 and attending hospitals and outpatient blood collection centers in Lombardy region, Northern Italy.

Method: This is a prospective multicenter territory-wide opportunistic HCV screening study supported by the Regional Government of Lombardy, Italy. Between June 2022 and December 2022, all subjects born between 1969 and 1989 and hospitalized or accessing outpatient blood collection centers in Lombardy were offered for-free anti-HCV and HCV-RNA tests. Patients with known anti-HCV positivity and/or previous anti-HCV treatment were excluded. Demographic features were uploaded into a regional web-based platform.

Results: 120,193 individuals underwent HCV screening in 76 screening centers in Lombardy. Their mean age was 44 ± 6 years, 65.2% were females, 83.7% were tested at outpatient blood collection centers. Anti-HCV tested positive in 604 (0.50%) subjects: mean age 47 (±5), 51.1% females. HCV seroprevalence was higher in males than in females (0.71% vs. 0.39%; $p < 0.0001$), in elderly ($p < 0.00001$) and in in- vs. out-patients ($p = 0.0007$). HCV-RNA was detectable in 125 out of 441 (28.3%) anti-HCV positive subjects with available HCV-RNA. Patients with active HCV infection were 46 ± 6 years-old, mostly males (56.8%) and screened in wards or DH/DS services ($p < 0.00001$). Overall, the prevalence of active HCV infection in the overall population was 0.10%, and differed according to age-groups ($p = 0.001$), being higher in elderly.

Conclusion: The prevalence of active HCV infection in the general population born between 1969 and 1989 hospitalized or referred for blood testing in Northern Italy was low. However, since this prevalence was higher in older individuals, the extension of such opportunistic screening programs to lower birth-cohorts could be considered.

FRI-186

Cascade of care and HCV treatment of inner city populations engaged in care through community pop-up clinics (CPCs)

Brian Conway[1,2], Shawn Sharma[1], Shana Yi[1], Giorgia Toniato[1], David Truong[1], Rossitta Yung[1]. *[1]Vancouver Infectious Diseases Centre, Vancouver, Canada; [2]Simon Fraser University, Burnaby, Canada*
Email: brian.conway@vidc.ca

Background and aims: Elimination of HCV infection as a public health concern by the end of this decade will require a concerted effort in all target populations, including vulnerable inner-city populations, many of whom are actively using drugs and are facing other issues more pressing than HCV infection. Several strategies

have been proposed to identify HCV-infected inner-city residents, engage them in care, provide them with antiviral therapy, establish conditions to maximize the likelihood of completion of treatment and cure of HCV infection. We have evaluated a novel approach of Community Pop-Up Clinics (CPCs) to achieve this goal within the inner city of Vancouver, Canada.

Method: CPC events are held weekly at various locations (mainly single room occupancy housing projects) interacting with up to 30 residents/half-day event. Point of care antibody testing for HCV is provided in the context of an offer of engagement of multidisciplinary care to address medical, social, psychologic and addiction-related concerns in a co-located manner. For those found to carry HCV antibodies, viremia is assessed by accessing the provincial database for prior results or on-site phlebotomy if required. All viremic individuals are offered HCV treatment in the context of other interventions, with medications administered at the place of residence or pharmacy as most appropriate. Daily/weekly dispensing is available as required. The end points of this analysis are the number of viremic individuals identified per event, the time from engagement to treatment initiation, and the outcome of HCV therapy.

Results: From 01/21–12/22 (24 months), we conducted 80 CPCs and evaluated 1420 individuals. 477 individuals (33.6%) were found to carry HCV antibodies. Of these, 331 individuals (69.4%) were found to be viremic, a mean of 4.1/event. Engagement in HCV therapy has been secured in 289 cases (87%). 247 (85%) individuals have started treatment and 41 remain in the pre-treatment phase, and 1 died of an overdose in the pre-treatment phase. The median time from CPC attendance to HCV treatment initiation was 6 weeks. Of 247, 233 have completed treatment, 9 are currently on treatment, 3 patients did not complete treatment, 2 died of an overdose while on treatment and 1 has been lost to follow-up. Of 233 subjects who have completed treatment, 205 are confirmed as cured (SVR 4/12), 25 are awaiting SVR 4, 2 have documented virologic relapse and 1 has been reinfected, a rate of 0.31/100 person-years. Of participants in whom an outcome of treatment has been ascertained, the cure rate is 97.2% (205/211).

Conclusion: Our program is very cost-effective, identifying over 4 individuals requiring HCV therapy per half-day event. The vast majority initiate treatment within weeks and complete it successfully, with a LTFU rate below 5%. Cure rates match or exceed those reported in clinical trials. Taken together, the data we present validates the development of multidisciplinary programs such as ours to eliminate HCV infection in vulnerable inner city populations.

FRI-187

Incidence of hepatitis C virus antibody seroconversion among people who inject drugs in Tbilisi, Georgia

Tengiz Tsertsvadze[1,2], Nikoloz Chkhartishvili[1], Akaki Abutidze[1,2], Marine Gogia[3], Ketevan Shermadini[1], Francisco Averhoff[4]. *[1]Infectious Diseases, AIDS and Clinical Immunology Research Center, Georgia; [2]Ivane Javakhishvili Tbilisi State University, Georgia; [3]Georgian Harm Reduction Network, Georgia; [4]Department of Family and Preventive Medicine, Emory University School of Medicine, United States*
Email: tt@aidscenter.ge

Background and aims: One of the priority directions of Georgian hepatitis C virus (HCV) elimination program is the prevention of HCV transmission among people who inject drugs (PWID). Furthermore, hepatitis C incidence among PWID is one of the key indicators set by the World Health Organization (WHO) for validating the elimination of hepatitis C, with a target of ≤2 cases per 100 person-years (PY). We established Georgian PWID cohort study to estimate incidence of HCV antibody (anti-HCV) seroconversion.

Method: This prospective observational cohort study enrolled PWIDs in the capital city of Tbilisi in 2017–2019. Participants were recruited using incentivized chain-referral sampling, with maximum of 5 peers recruited by each participant. The outcome of interest was anti-HCV seroconversion. Incidence was calculated as number of new anti-HCV seroconversions divided by the number of total person-years of follow-up (PYFU). Crude estimates were adjusted using post-stratification weights. Factors associated with seroconversion were evaluated in Cox proportional hazards regression model.

Results: Study enrolled 1,744 PWID; among them, 563 (32.3%) were positive for anti-HCV+ at baseline and were excluded from follow-up. Among remaining 1,181 anti-HCV- PWID, 929 (78.7%) returned for at least one visit. Overall, 929 participants were followed for the mean of 11.7 months, contributing to the total of 906 PYFU. During the follow-up, 7 (0.8%) persons seroconverted, corresponding to an incidence rate of 0.77 (95% CI: 0.31–1.59) new infections per 100 PYFU. After adjusting for post-stratification weights, the incidence increased to 0.87 (95% CI: 0.43–1.74) new infections per 100 PYFU. In regression analysis, the only factor significantly associated with seroconversion was a history of sharing injection equipment (Hazard ratio: 50.51, 95% CI: 2.46–611.58, p = 0.01).

Conclusion: Our study suggests that the incidence of hepatitis C seroconversion among PWID is below the target set by the WHO. However, PWID remain at risk of contracting the virus, primarily through unsafe injection practices. Further scaling-up harm reduction services is needed to reach the elimination of hepatitis C.

FRI-188

Survey to evaluate the implementation of the recommendations on the comprehensive diagnosis of viral hepatitis in a single extraction: where are we?

Background and aims: The SEPD (Spanish Association for Digestive Diseases), AEEH (Spanish Association for the Study of the Liver), SEIMC (Spanish Society of Infectious Diseases and Clinical Microbiology), SEIMC-GEHEP (Work-group for Viral Hepatitis) and AEHVE (Spanish Viral Hepatitis Elimination Alliance) agreed on a document at the beginning of 2022 to carry out a comprehensive diagnosis of viral hepatitis (B, C and D): a positive result in serology to detect viral hepatitis (HBV, HCV and HDV), as well as HIV, would trigger the analysis of the rest of the virus, including the viral load when necessary, from the same blood sample. This process would increase the diagnosis rate and it would reduce the time to be evaluated. Aim: To evaluate the situation in Spain regarding the comprehensive diagnosis of viral hepatitis in a single blood draw.
Method: A panel of experts prepared a structured survey disseminated through the Google Forms platform to all Spanish hospitals, public or private with teaching accreditation, with 200 beds or more. The survey was sent on 20th Oct 2022 and the reception of the results closed on 1st Dec. 2022.
Results: Of the 130 hospitals with inclusion criteria, 48 responded (37% response rate, 34 centers >500 beds). All centers have tools for the determination of HBV surface antigen, anti-HCV and HIV serology. 92% have a PCR technique for HBV/HCV. Only 67% of the centers have capacity for the determination of anti-HDV, and this drops to 31% for the detection of HDV-RNA; 88%, who do not have this technique, outsource it. The availability of Point-of-Care (POC) tests is low (21% of centers), GenXpert HCV (38%) and dry blood spot (38%) being the most frequent. Most of the POCs (90%) are supervised by Microbiologists and are always included in the clinical records. Reflex-test diagnosis is performed simultaneously in 88% of centers for HCV, 62% for HBV, 50% for HDV, and only 41% for HBV-HDV. Although 90% of centers believe that HBV and HCV serology should be performed on HIV-positive patients in the same sample, it is only done on 18% of HBsAg-positive and/or anti-HCV-positive subjects. When there is an active infection, any communication strategy is used in 38/48 (79%) of the hospitals (38 hospitals for HCV, 18 for HBV and 10 for HDV). The automated appointment arrangement is only available in 19% of the centers. Only 44.2% of the respondents believe that the determinations to reach a definitive diagnosis must be made with a single blood sample.
Conclusion: Although most hospitals have the procedures to carry out a comprehensive diagnosis of viral hepatitis in a single analytical sample, this is used in less than 50% of cases for HBV/HDV. Alerts to maintain continuity of care are widely available for hepatitis C, but they need to be increased for HBV and HDV. Likewise, it is necessary to implement the devices for decentralized diagnosis.

FRI-189
Occult hepatitis B virus infection among blood donors in northwestern Greece

Maria Leontari[1], Fotios Fousekis[1], Gerasimos Baltayiannis[1], Dimitrios Christodoulou[1], Peter Karayiannis[2]. *[1]Department of Gastroenterology and Hepatology, University Hospital of Ioannina, Ioannina, Greece, Greece; [2]Medical School, University of Nicosia, Cyprus, Greece*
Email: fotisfous@gmail.com

Background and aims: Occult hepatitis B virus (HBV) infection (OBI) is characterized by the presence of HBV-DNA in blood or tissues in individuals with undetectable serum HBsAg. This study aimed to assess the prevalence and characteristics of (OBI) in Northwestern Greece.
Method: Serum samples from 702 blood donors were prospectively collected at University Hospital of Ioannina between February 2018 to September 2022 and were investigated for presence of HBV markers. The Abbott Architect HBsAg and HBcAb HB Qualitative II kit were used for detection of HBsAg and anti-HBc respectively. Serum from patients who were HBsAg (−)/anti-HBc (+) was further tested by polymerase chain reaction (PCR) for the detection of HBV-DNA. In cases of OBI, sequencing and mutation analysis of the HBV pre-S/S gene were performed.

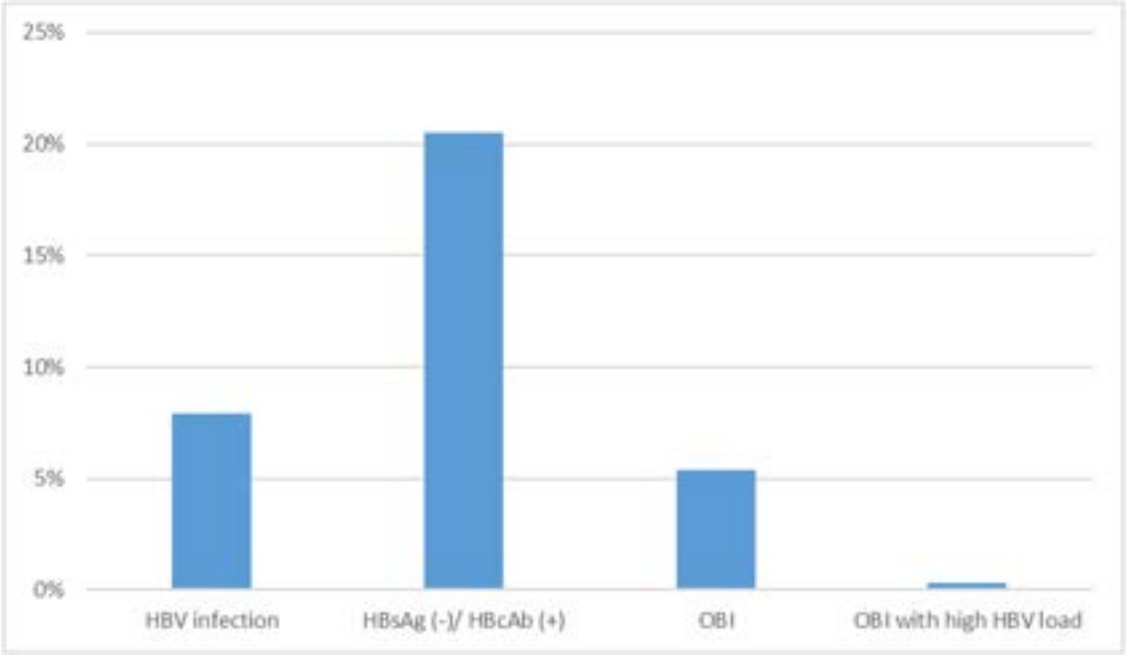

Figure: (abstract: FRI-189): Prevalence of HBV infection, occult HBV infection (OBI) and OBI with high HBV-DNA levels in blood donors.

Results: Screening revealed 56 cases (7.9%) with HBV infection (HBsAg positive) and 144 cases (20.5%) of past HBV infection [(HBsAg (−)/anti-HBc (+)], while 38 cases of OBI were identified. In 36 out of 38 cases, the HBV DNA load was <225 IU/ml. One patient with OBI had HIV co-infection. Furthermore, there were two cases with OBI and high HBV-DNA levels (>200,000 IU/ml). Sequencing demonstrated S- and pre-S mutations in 4 cases of OBI, including both OBI cases with high HBV-DNA levels.
Conclusion: High prevalence of HBV infection and OBI was detected in a region with a high proportion of immigrants from endemic countries. In addition, S gene mutations were associated with cases of OBI with high HBV-DNA levels.

FRI-190

Hepatitis E virus seroprevalence in immunosuppressed patients in Belgium: a prospective study

Marie Philippart[1], Michael Peeters[2], Hubert Piessevaux[1], Maria Badii[3], Sarah Bailly[4], Xavier Poiré[4], Nada Kanaan[5], Arnaud Devresse[5], Benoit Kabamba[6], Géraldine Dahlqvist[1]. *[1]Cliniques Universitaire Saint Luc, Service d'Hépato-Gastroentérologie, Bruxelles, Belgium; [2]Sciensano, Viral Disease Department, Bruxelles, Belgium; [3]Cliniques Universitaire Saint Luc, Service de cardiologie, Bruxelles, Belgium; [4]Cliniques Universitaire Saint Luc, Service d'hématologie, Bruxelles, Belgium; [5]Cliniques Universitaire Saint Luc, Service de néphrologie, Bruxelles, Belgium; [6]Cliniques Universitaire Saint Luc, Laboratoire de microbiologie médicale, Bruxelles, Belgium*
Email: marie.philippart01@gmail.com

Background and aims: Hepatitis E virus (HEV) is the commonest cause of acute viral hepatitis in Western countries. In immunocompromised patients, chronic HEV have been described, leading in certain cases to cirrhosis, decompensation and death or liver transplantation.
The aim of the study is to determine the prevalence of HEV infections in the immunosuppressed population followed in a single tertiary center in Belgium.
Method: From May 2022 to April 2023, we are prospectively screening for HEV (IgG, IgM and PCR) all patients transplanted from a solid organ (SOT) as well as patients suffering from a lymphoma or followed in the hematology department for a bone marrow transplantation under immunosuppression from at least three months.
We compared the data from our immunosuppressed patients to the data collected from national serum banks in Belgium in 2014 by Ho et al., representing the general seroprevalence in Belgian population. Chi^2 test or Fisher exact test were performed to compare the groups.
Results: We present here an intermediate analysis after 8 months of screening. Among 570 patients, 240 were followed for a kidney transplantation (KT), 139 for a heart transplantation (HT), 163 for a liver transplantation (LT), and 55 for haematological disease (HD). The median age was 61. The sex ratio F/M was 1/2. The mean IgG HEV seroprevalence was 9.29% in our population, 8.1% in KT, 13% in HT, 14.8% in LT and 0% in HD. A positive HEV PCR was found in 6 patients, 5 in the KT group and one followed for HD and genotype 3c was identified in all of them. There is a significative difference between the HEV IgG seroprevalence in Belgian population in 2014 (5,8%) and our population ($p = 0.001$). In subgroup analysis, there is a significative difference between the Belgian population and the patients followed for LT ($p = 0.0006$) and HT ($p = 0.0114$). There is also a significative difference between the different SOT groups and the patients followed for hematological diseases (LT vs HD: $p = 0.0026$; HT vs HD: $p = 0.0068$; KT vs HD: $p = 0.03$).

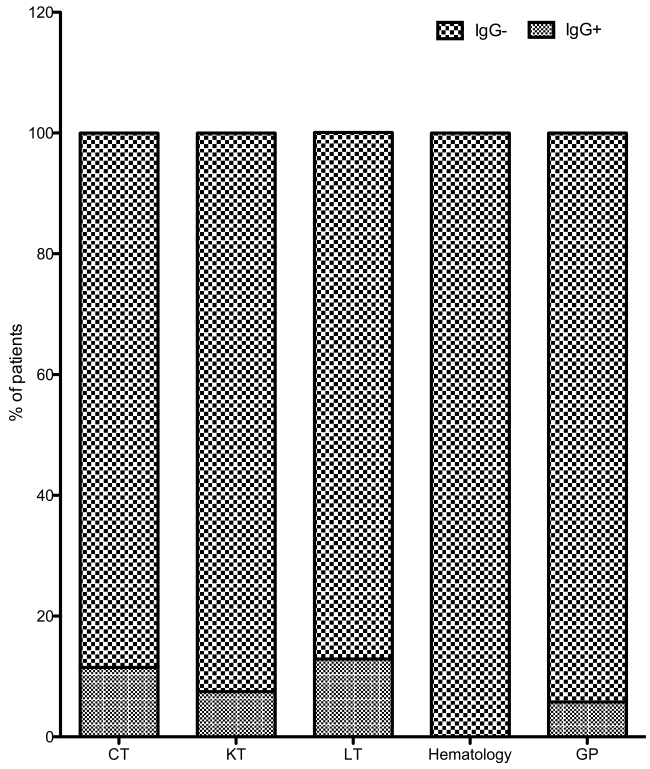

Figure:

Conclusion: The seroprevalence between our group of immunosuppressed patients and the Belgian population is significantly higher. Subgroup analysis showed a significantly higher seroprevalence in HT and LT patients but does not translate into an actual chronic infection rate. KT is a risk factor for the occurrence of chronic HEV compared to other SOT groups. The seroprevalence is however not significantly different in this group compared to the general population. More data are awaiting to draw conclusions on the importance of systematic screening in these immunosuppressed populations.
This study is supported by a Gilead fellowship grant.

What is the most effective strategy to identify HBV-infected pregnant women eligible for antiviral prophylaxis in Burkina Faso? A modelling study on different testing strategies

Andréa Gosset[1], Yusuke Shimakawa[2], Alice N. Guingané[3], Abdoul Tiendrebeogo[4], Maria Patrizia Carrieri[1], Tim Hallett[5], Shevanthi Nayagam[5,6], Sylvie Boyer[1]. *[1]Aix Marseille University, INSERM, IRD, SESSTIM, Sciences Economiques and Sociales de la Santé and Traitement de l'Information Médicale, ISSPAM, 13005 Marseille, France, France; [2]Unité d'Epidémiologie des Maladies Emergentes, Institut Pasteur, 75015 Paris, France, France; [3]Hepatogastroenterology Department, Bogodogo University Hospital Center, Ouagadougou, Burkina Faso, Burkina Faso; [4]Epidémiologie des Maladies Evitables par la Vaccination, Agence de Médecine Préventive (AMP), Ouagadougou BP 638, Burkina Faso, Burkina Faso; [5]MRC Centre for Global Infectious Disease Analysis, School of Public Health, Imperial College London, London, United Kingdom, United Kingdom; [6]Department of Surgery and Cancer, Imperial College London, London, United Kingdom, United Kingdom*
Email: andrea.gosset@inserm.fr

Background and aims: To prevent mother-to-child transmission of hepatitis B (HBV), WHO recommends tenofovir (TDF) prophylaxis in high-risk pregnant women from the 28th week of pregnancy until at least birth, in addition to 3–4 doses of hepatitis B vaccination (HepB3) in all infants, including a timely birth dose (HepB-BD). TDF

Scenarios	Total number of new chronic infections	Total number of new chronic infections due to MTCT	Number of new chronic infections averted	Number of new chronic infections due to MTCT averted	Total number of pregnancies under antiviral treatment
0. HepB-BD + HepB3	84,091	29,976	-	-	0
1. TDF if high viral load + HepB-BD + HepB3	80,539	26,871	3,552 (-4.2%)	3,105 (-10.4%)	10,567
2. TDF if HBeAg+ + HepB-BD + HepB3	81,536	27,742	2,555 (-3.0%)	2,234 (-7.5%)	17,729
3. TDF if HBcrAg+ + HepB-BD + HepB3	80,350	26,706	3,741 (-4.4%)	3,270 (-15.6%)	40,573
4. TDF if HBsAg+ + HepB-BD + HepB3	78,743	25,313	5,348 (-6.4%)	4,663 (-10.9%)	263,779

Figure: (abstract: FRI-191): Total number of new chronic infections and number of pregnancies under antiviral treatment over the period 2021–2030 according to the different scenarios.

prophylaxis is recommended for HBV-infected pregnant women with an HBV DNA ≥5.3 $\log_{10}$ IU/ml or those positive for hepatitis B e antigen (HBeAg) in settings without access to HBV DNA quantification. However, HBV DNA testing is not widely available at antenatal care in Burkina Faso (BF) and rapid diagnostic tests (RDTs) to detect HBeAg lack sensitivity. Therefore, alternative strategies could be to use hepatitis B core-related antigen (HBcrAg) RDT (data from The Gambia: 100% sensitivity and 87% specificity to detect HBV DNA ≥5.3 $\log_{10}$ IU/ml) or to treat all pregnant women positive for hepatitis B surface antigen (HBsAg) without any additional tests. This study assessed the impact of different testing strategies to identify HBV-infected pregnant women who should receive TDF prophylaxis in BF.

Method: We analysed five intervention strategies and used a deterministic model specified by age, sex, and type of transmission to estimate the effectiveness of each strategy over the period 2021–2030 in BF. The baseline strategy was the current policy-HepB-BD in addition of HepB3. The four other strategies additionally considered screening pregnant women for HBsAg using a RDT, and providing TDF prophylaxis to HBsAg-positive women if they had: i) HBV DNA ≥5.3 $\log_{10}$ IU/ml, ii) positive HBeAg using RDT, iii) positive HBcrAg using RDT, or iv) without additional test. HepB-BD was introduced in 2022 in BF. We introduced TDF prophylaxis in 2023 in the model. We considered a linear scale up of HepB-BD, HBsAg screening and TDF prophylaxis to achieve 90% over 5 years. We estimated the costs of each strategy using a health system perspective.

Results: In 2021–2030, the total number of pregnancies requiring TDF treatment would be 10,567 in the HBV-DNA strategy, 17,729 in the HBeAg strategy, 40,573 in the HBcrAg strategy (including a higher number of women with low HBV-DNA treated unlike the first strategy), and 263,779 in the treat all strategy. In the baseline scenario, we estimated 84,091 new chronic infections including 29,976 infections due to MTCT in 2021–2030. Compared to the baseline scenario, the addition of TDF prophylaxis would allow to avert 3,552 new chronic infections (−4.2%) in the first strategy, 2,555 (−3.0%) in the second strategy, 3,741 (−4.4%) in the third strategy, 5,348 (−6.4%) in the fourth strategy.

Conclusion: The treat all strategy might be most effective, however the effects of treating all HBsAg-positive women are unknown and will drastically increase treatment needs in pregnant women and costs. The cost-effective analysis is ongoing and results will be presented at the conference.

FRI-192

Results from a community-based intervention to increase viral hepatitis screening among at-risk African migrants in Catalonia, Spain (2020–2022)

Camila Picchio[1], Daniel K. Nomah[2], Ariadna Rando-Segura[3], Sabela Lens[4,5], Xavier Forns[4,5], Sergio Rodriguez-Tajes[4,5], Lena van Selm[1], Delfina Boudou[1], Francisco Javier Pamplona Portero[6], Carmen López Núñez[7], Francisco Rodríguez-Frías[3], Maria Buti[5,8], Jeffrey Lazarus[1,9]. *[1]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain; [2]Center for Epidemiological Studies on Sexually Transmitted Infections and HIV/AIDS in Catalonia (CEEISCAT), Department of Health, Generalitat of Catalonia, Badalona, Spain; [3]Liver Pathology Unit, Biochemistry and Microbiology Service, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [4]Liver Unit, Hospital Clínic, IDIBAPS, University of Barcelona, Barcelona, Spain; [5]CIBER Hepatic and Digestive Diseases (CIBERehd), Instituto Carlos III, Madrid, Spain; [6]Department of Digestive Diseases, Hospital de Santa Caterina, Salt, Girona, Spain; [7]Department of Digestive*

Diseases, Hospital Dr Josep Trueta, Girona, Spain; [8]Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [9]CUNY Graduate School of Public Health and Health Policy, New York, New York, United States
Email: camila.picchio@isglobal.org

Background and aims: Africans in Europe migrating from high-endemic hepatitis B and C virus (HBV and HCV) areas may not know their disease status due to unreliable testing and vaccination in their home countries and underutilization of the host country health services. In Catalonia, Spain, universal health coverage grants migrants access to health services, which offers an entry point into the health system. We aimed to use point-of-care testing in community settings to identify and link to care or vaccinate West African migrants in the greater Barcelona area, Spain.
Method: Between November 2020 and December 2022, viral hepatitis testing was offered to 636 people. Testing in community settings used an HBV surface antigen (HBsAg) rapid lateral flow test (DETERMINE® HBsAg 2) followed by whole blood sample collection using a plasma separation card (Roche Diagnostics), which analyzed HBV-DNA and anti-hepatitis D virus (HDV) among those HBsAg+ and anti-HBV core antigen (anti-HBc) among those HBsAg–. Anti-HCV testing with the OraQuick® was incorporated in June 2022. HBsAg+ participants were immediately referred to a collaborating tertiary hospital for full assessment.
Results: 622 participants were included for analysis (mean age 42 [SD 10]). They were primarily from Ghana (81%) and Senegal (16%), were male (63%), and 17% (n = 104) arrived to Spain ≤5 years ago. Most participants had never been tested for HBV nor HCV (70%), while 15% were unsure if they had been. HBsAg+ prevalence was 10% (n = 62) and no one was anti-HCV+. Of those HBsAg+, 50% (n = 31) had detectable HBV-DNA and one person was anti-HDV+. Of those who were HBsAg- (n = 560), 38% (n = 216) were anti-HBc+. The remaining, if not previously vaccinated (n = 292), were offered the first dose of the HBV vaccination *in situ* during the second visit (191 returned for results), of which, 85% (n = 164) accepted. Overall, 76% (n = 49) of those who were HBsAg+ had a first documented visit with a collaborating tertiary hospital; three preferred to visit their own physicians. The mean number of days between testing and linkage to care was 26 (SD 10.5). Successful linkage to care was documented in 65% of all participants.
Conclusion: This community-based viral hepatitis screening program provides an effective model for identifying and providing care to migrant populations at high risk of HBV infection who may otherwise not engage in care. Nearly half of all participants had evidence of past or current HBV virus, highlighting the importance of targeted interventions for this population.

FRI-193
Innovation linkage model to re-engage lost-to-follow-up individuals in the national hepatitis C elimination program in Georgia

Tamar Gabunia[1], Maia Tsereteli[2], Vladimer Getia[2], Sophia Surguladze[3], Irina Tskhomelidze[3], Shaun Shadaker[4].
[1]Georgian Ministry of IDPs from the Occupied Territories, Labour, Health, and Social Affairs, Tbilisi, Georgia; [2]National Center for Disease Control and Public Health Georgia; Tbilisi, Georgia; [3]The Task Force for Global Health, Tbilisi, Georgia; [4]Centers for Disease Control and Prevention, Atlanta, United States
Email: tgabunia@moh.gov.ge

Background and aims: The National Hepatitis C Elimination Program has made notable progress in Georgia. However, in the setting of COVID-19 related restrictions, the number of individuals registering in the treatment program has declined over time. As of September 30, 2022, 72,5% (n = 2,1 million) of the adult population of Georgia had been screened for hepatitis C virus (HCV) antibodies, but among 146,518 antibody-reactive adults, 20,464 (14%) had not completed a viremia test. During 2019, the National Center for Disease Control and Public Health of Georgia piloted a project to link to care those individuals who screened reactive for anti-HCV but had not completed a viremia test. The initial pilot was successful, and the model was scaled up across Georgia.
Method: All anti-HCV reactive adults (aged ≥18 years) who did not have a record of viremia testing in the national HCV electronic database 3 months from the date of an anti-HCV reactive result, and who were not registered in the HIV/AIDS treatment program or with a correctional facility, were eligible for follow-up. Using the phone number listed in the database, individuals were contacted by phone or home visit by patient navigators (trained epidemiologists and primary health care physicians) and referred to HCV care and treatment. If the first attempt was unsuccessful, one repeat attempt was made to contact the individual. Incentives were provided to navigators for each patient who was successfully linked to care, defined as presenting for viremia testing.
Results: As of December 2022, 18,063 phone numbers were identified for 20,464 anti-HCV reactive persons who did not complete a viremia test; patient navigators attempted to reach 18,063 (100%) with phone numbers in the database; 12,794 (70,8%) were reached. The remaining 5,269 did not answer, had an incorrect phone number, moved, or emigrated. Of those contacted, 2,349 (18,4%) presented for viremia testing, and 1,722 (73,3%) had HCV RNA or HCV core antigen detected. Overall, 620 (36,0%) persons with chronic HCV infection were enrolled in the hepatitis C treatment program as a result of this effort.
Conclusion: Program-wide implementation of the piloted model showed that this activity can be scaled up and is effective for re-engaging people in care. The main challenge in Georgia remains linkage to care, which is essential to meet hepatitis C elimination goals. Innovative approaches are necessary to reinforce linkage to care. This is especially important during the COVID-19 pandemic when there is an increased need for programs that can re-engage people in hepatitis C care.

FRI-194
Hepatocellular carcinoma associated with chronic hepatitis C: a case for an annual mortality and morbidity review

Neil McInnes[1], Peter Davies[1], Lynn Laverty[2], Stephen Barclay[3], Erica Peters[1]. *[1]Queen Elizabeth University Hospital, Infectious Diseases, Glasgow, United Kingdom; [2]Hunter Street Health Centre, Community Blood Borne Viruses, United Kingdom; [3]Glasgow Royal Infirmary, Gastroenterology Department, Glasgow, United Kingdom*
Email: neil.mcinnes4@nhs.scot

Background and aims: The concept of a *late diagnosis and mortality meeting* is well established in HIV services for clinical governance, and to disseminate wider learning to the clinical community. In Scotland, there is no equivalent for Hepatitis C (HCV) despite a significant associated morbidity and mortality, and similar "missed diagnosis opportunities." This cohort study aims to reflect on those with HCV and Hepatocellular carcinoma (HCC), to identify missed opportunities for earlier diagnosis with a view to wider clinical learning.
Method: From the Scottish HCV registry, 40 patients with both an HCV and subsequent HCC diagnosis between 2011 and 2021 were extracted. Demographics, risk factors for chronic liver disease (CLD), dates of HCC and HCV diagnosis, and circumstances of HCV diagnosis were extracted from the registry and electronic patient records. Date of peak-alanine aminotransferase (ALT) and first abnormal ALT (>50 U/L) prior to Hep-C diagnosis were recorded. Prior healthcare exposure to addiction liaison (via EMIS®) or hospitalisation was recorded.
Results: Of forty patients identified, 85% were male with a median age of 59 years. 23 (58%) patients had a raised ALT, on at least one occasion, >1 year prior to a Hep-C diagnosis, with a median time from first deranged ALT to HCV diagnosis of 2.5 years (IQR 6 years) and a median peak ALT of 112 U/L. The most common indication for HCV testing was deranged liver function and, at diagnosis, 7 (18%) patients

had developed HCC, with a further 7 presenting with decompensated liver disease. 24 (60%) had co-existing risk factors for CLD e.g. alcohol excess or Hepatitis-B. Ten (25%) had a pre-diagnostic inpatient stay and 3 (8%) pre-diagnostic Addictions input.
Conclusion: Abnormal biochemistry prior to a HCV diagnosis, often for many years, is a common finding. Where other CLD risk factors are present, HCV testing may be overlooked. Highlighting episodes of missed opportunities for HCV diagnosis in a timely manner to clinical teams involved in previous care episodes, using established clinical governance models, may reduce the risk of future similar missed diagnoses. Review of local data may lead to a consideration of reflex HCV testing in all patients with abnormal LFTs, or similar responses, to support early HCV diagnosis; not only to reduce liver related mortality but to support HCV elimination.

FRI-195
Prevalence of hepatitis B and C viral infections among transgenders and men who have sex with men in Pakistan
Hassan Mahmood[1], Quaid Saeed[2], Francisco Averhoff[3], Huma Qureshi[4]. *[1]Integral Global (IG), Pakistan; [2]Islamabad Healthcare Regulatory Authority, Islamabad, Pakistan; [3]Abbott Diagnostics, United States; [4]Ministry of National Health Services, Regulations and Coordination, Pakistan, Pakistan*
Email: hassanmahmood1@hotmail.com

Background and aims: In Pakistan, Transgenders (TGs) and Men who Have Sex with Men (MSM) are marginalized communities at high risk of sexually and parenterally transmitted infectious diseases. The prevalence of hepatitis B virus (HBV) and hepatitis C virus (HCV) infection in these populations has not been well described, and access to care and treatment is lacking.
To estimate the prevalence of HBV and HCV infection among TGs and MSM in two cities in Pakistan, Lahore and Larkana. To assess the effectiveness of screening and referral for treatment among those who screen positive for HBV and HCV, and response to treatment
Method: During 2020–2022 community health workers identified and recruited a total of 2241 TGs and MSM for testing by who prequalified rapid test for hepatitis B surface antigen (HBsAg) and antibody to HCV (anti-HCV) in the community. All participants who tested positive for HBsAg were referred to their respective public sector provincial hepatitis control program for further testing and care. For those who tested positive for anti-HCV, a "One Stop Shop" model was established where the local Community Based Organizations (CBOs) who were already providing free HIV care services to these communities were equipped and trained to provide HCV care and treatment services. Those who tested positive for anti-HCV and were referred to the CBO, were tested for HCV viremia (RNA) using GeneXpert machines. All the HCV RNA positive patients had additional testing including a complete blood count (CBC) and testing for aspartate aminotransferase (AST) to calculate their AST to platelet ratio index (APRI) score, to estimate degree of liver fibrosis. HCV cases were provided at the same visit free of cost oral medications (Sofosbuvir and Daclatasvir) to treat their HCV infection. All testing was done on the same day as the visit, and the results were available on the same day of treatment initiation.
Results: A total of 201/2241 (9%) tested positive for anti-HCV, and 69/2241 (3.1%) tested positive for HBsAg. All participants who tested HBsAg+ were referred to the provincial hepatitis control program for additional care. The 201 who tested anti-HCV+ were referred to CBOs for additional testing and care under One Stop Shop model. Of those, 161 (80%) were tested for HCV RNA, of which 99 (62%) tested positive for HCV RNA. Of these 87 (88%) initiated treatment and 77/87 (89%) completed treatment; all were tested for cure (sustained virologic response; SVR), of which 72 (94%) were HCV RNA negative (cured).

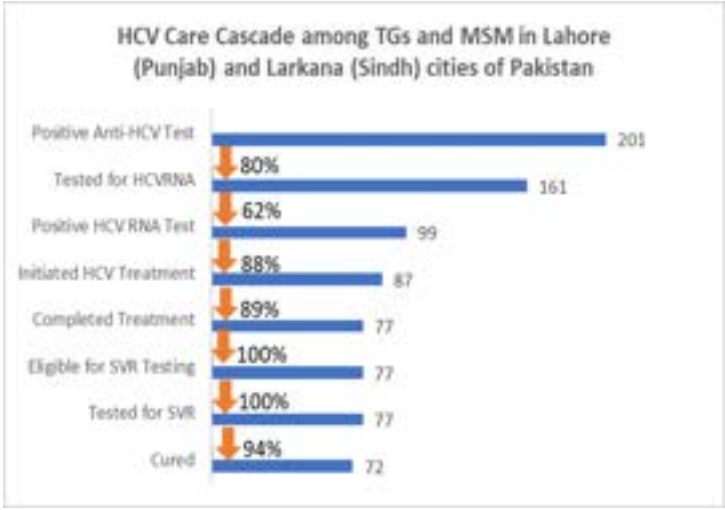

Figure:

Conclusion: Outreach to marginalized populations with same day testing and referral for HBV and HCV is feasible and effective in Pakistan. Partnering with CBOs was key to the success in this pilot project in reaching "key" populations with limited access to health services and achieving high rates of linkage to care and adherence with treatment for HCV and referral for HBV care and treatment.

FRI-196
Multidisciplinary approaches to increase hepatitis C screening rates in a New York City primary care clinic
Carolina Villarroel[1], Silpa Yarra[1], Gres Karim[1], Jake Debroff[1], Einat Kadar[1], Anna Mageras[2], Rebecca Roediger[2], Ilan Weisberg[3]. *[1]Mount Sinai Beth Israel, Internal Medicine, United States; [2]Icahn School of Medicine at Mount Sinai, New York, United States; [3]NewYork-Presbyterian Brooklyn Methodist Hospital, United States*
Email: carolina.villarroel@mountsinai.org

Background and aims: Hepatitis C virus (HCV) infection is a common cause of cirrhosis, hepatocellular carcinoma, and liver-related mortality, but also remains to be one of the leading indications for liver transplantation. In New York City (NYC), two out of five residents with HCV remain undiagnosed. In 2020, the Centers for Disease Control and Prevention (CDC) and the United States Preventive Services Task Force (USPSTF) expanded previous guidelines to recommend universal HCV screening among adults 18 and over. Baseline data of screening rates in 2021 at an NYC primary care clinic were 14%, well below the NYC Department of Health screening goal of 42%. Our study aimed to investigate the causes of low screening rates and promote physician knowledge and behaviors to increase overall screening rates to 20% in 6 months.
Method: Using the Plan-Do-Study-Act (PDSA) quality improvement methodology, an interdisciplinary team including hepatologists, internists, and a viral hepatitis program manager was created to investigate baseline HCV screening rates in an NYC primary care clinic. In January 2022, a campaign was initiated for HCV screening with four initiatives including: patient-facing signage in the clinic, a best practice alert (BPA) for HCV screening via electronic medical record system (EMR), weekly printed lists of eligible patients for screening for each primary care physician (PCP), and an oral educational presentation to providers. Baseline physician knowledge regarding HCV screening guidelines was assessed using a survey composed of six knowledge-based and PCP-level barrier questions as shown in Figure 1 immediately before and six weeks after the educational session to assess for retention of knowledge.
Results: A total of 45 internal medicine physicians were initially provided a survey to assess baseline knowledge regarding HCV screening criteria. Six weeks after an educational session to promote

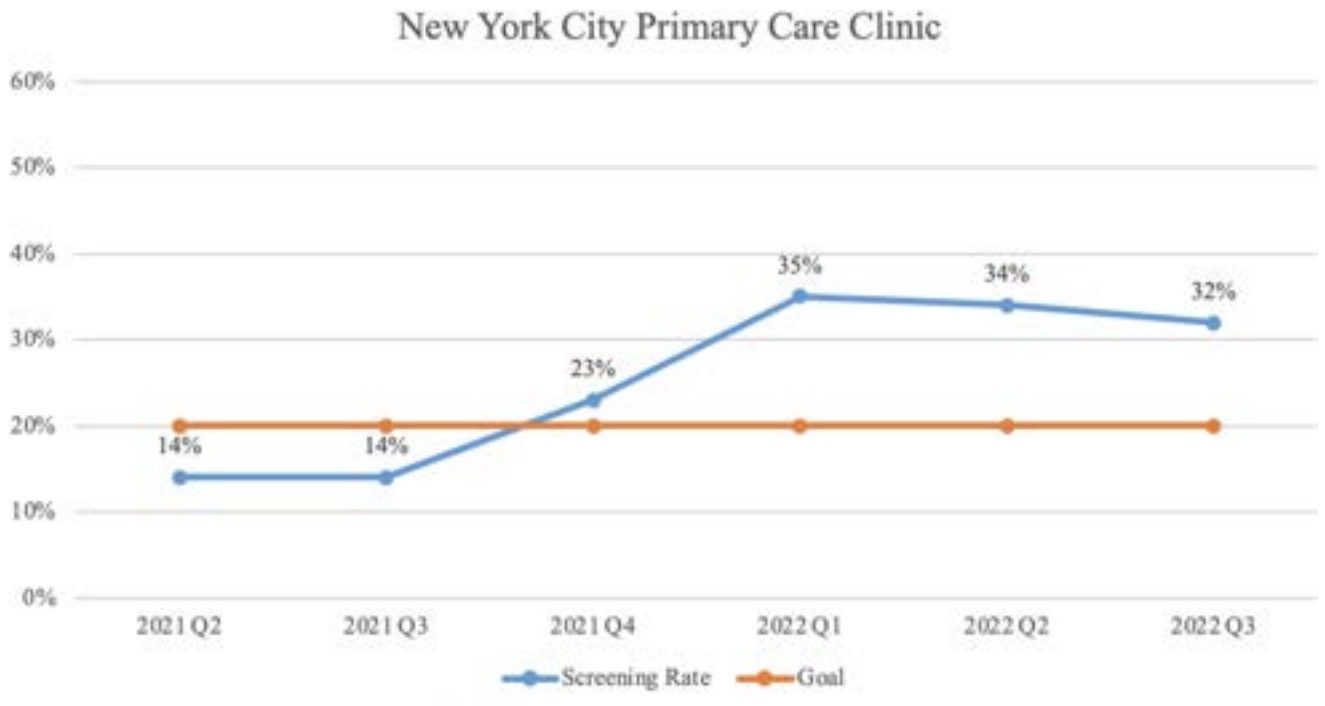

Figure: (abstract: FRI-196): HCV new screening rate.

HCV screening rates, 21 physicians responded (46%) to a follow-up survey to assess retention of knowledge. Respondent knowledge slightly increased after the educational session (80% of correct answers before the lecture vs. 81% after). However, our multi-initiative approach successfully resulted in an increase in HCV screening rates from 14% to 35% in the first quarter of 2022 and 32% by the third quarter of 2022, exceeding the study goal of 20%.
Conclusion: Given that there was a minimal difference in retained knowledge based on pre and post-surveys, we attribute the overall increased HCV screening rates from 14% to 35% to our other initiatives which include utilization of the automated BPA within the EMR and weekly reminders as printed lists for each PCP to increase awareness of HCV screening for timely detection and prompt referral for treatment of newly diagnosed HCV

FRI-197
Effectiveness of birth-dose vaccine in preventing mother-to-child transmission of hepatitis B virus in Ethiopia

Mebrihit Arefaine[1], Asgeir Johannessen[2], Tilahun Teklehaymanot[1], Andargachew Mulu[3], Dawit Hailu[3], Adane Mihret[3], Mahlet Osman[3], Dareskedar Teshay[3], Nega Berhe[4,5]. *[1]Addis Ababa University, Ethiopia; [2]Vestfold Hospital Trust, Norway; [3]Armauer Hansen Research Institute, Ethiopia; [4]Aklilu Lemma Institute of Pathobiology, Addis Ababa University, Infectious Disease, Addis Ababa, Ethiopia; [5]Oslo University Hospital-Ulleval, Regional Centre for Imported and Tropical Diseases, Oslo, Norway*
Email: johannessen.asgeir@gmail.com

Background and aims: Studies from Asia have shown that mother-to-child transmission (MTCT) is a major transmission route of the hepatitis B virus (HBV). Administration of a monovalent HBV vaccine within 24 hours of birth (*viz* birth-dose vaccine), followed by completion of the vaccine series, is 85–95% effective in the prevention of MTCT. In Africa, studies from the 1980s suggested that vertical transmission of HBV was less common than in Asia, which led to a reluctant attitude towards birth-dose vaccination in many African countries. This study aimed to determine the effectiveness of the birth-dose vaccine in preventing MTCT of HBV in Ethiopia.
Method: Hepatitis B surface antigen (HBsAg) positive pregnant women who attended the delivery wards at five public hospitals in

Table: (abstract: FRI-197): Factors associated with mother-to-child transmission of hepatitis B virus, Ethiopia.

	Infant HBsAg at 9 months		Unadjusted			Adjusted		
	HBsAg + N (%)	HBsAg – N (%)	OR	95% CI	P	OR	95% CI	P
Birth-dose vaccine								
Yes	5 (35.7)	134 (83.8)	1	2.9–29.9	<0.001	1	3.5–90.4	<0.001
No	9 (64.3)	26 (16.2)	9.3			17.8		
Maternal HBeAg status								
Neg	6 (42.9)	141 (88.1)	1	3.1–31.7	<0.001	N.S.		
Pos	8 (57.1)	19 (11.9)	9.9					
Maternal viral load								
(IU/ml)	8 (57.1)	154 (96.2)	1	5.1–73.2	<0.001	1	2.0–135.7	0.010
<200 000	6 (42.9)	6 (3.8)	19.3			16.3		
>200 000								

Addis Ababa from January 2019 to May 2021 were included in a prospective, observational study. Maternal hepatitis B e-antigen (HBeAg) status, HBV DNA viral load, and demographic information was collected at birth. HBV birth-dose vaccine was recommended to all study participants, but was not part of the national policy, thus not all infants received it. All infants, however, received three doses of pentavalent HBV vaccine at 6, 10, and 14 weeks of age as part of the national immunization program. The infants were followed up and tested for HBsAg using an ELISA assay at 9 months of age; a positive HBsAg at 9 months was taken as evidence of MTCT. Logistic regression analysis was used to identify factors associated with MTCT of HBV.
Results: Of 12,318 pregnant women screened, 369 (3.0%) were HBsAg positive and 300 were included in this study. The current analysis included 174 infants who had a follow-up evaluation at 9 months of age. Five of 139 (3.6%) infants who received birth-dose vaccine were HBsAg positive at 9 months of age, compared to 9 of 35 (25.7%) who did not receive birth-dose vaccine ($p < 0.001$). Transmission of HBV occurred both in HBeAg positive and negative mothers, and in mothers with high (>200 000 IU/ml) and moderate/low (<200 000 IU/ml) viral load at birth. In multivariable logistic regression analysis, high maternal viral load and the absence of birth-dose vaccine were significantly associated with MTCT of HBV (Table 1).
Conclusion: Administration of birth-dose vaccine significantly reduced the risk of MTCT of HBV. Improved coverage of birth-dose vaccine will be needed to control the HBV epidemic in Africa.

FRI-198

Complete and maintained elimination of hepatitis C in patients in methadone substitution program

Esther Rodríguez Candelaria[1], Ana Laserna Ramos[2], Silvia Acosta-López[1], Pilar Díaz Ruiz[3], Magdalena Lara[4], Teresa De la Rosa Vilar[2], Luz Goretti Santiago Gutiérrez[2], Francisco Andrés Pérez Hernández[1]. *[1]Hospital Universitario Nuestra Señora de La Candelaria, Aparato Digestivo, Spain; [2]San Miguel Adicciones, Spain; [3]Hospital Universitario Nuestra Señora de La Candelaria, Farmacia, Spain; [4]Hospital Universitario Nuestra Señora de La Candelaria, Microbiología, Spain*
Email: estherrg65@gmail.com

Background and aims: To achieve WHO goals on hepatitis C (HCV) plans are necessary in populations with high prevalence and low adherence like users of centers for addiction treatment (CAT). We designed a Fast Track protocol demonstrating high cure rates (>90%). A meta-analysis estimates the incidence of reinfection in these patients in 6%. Main objective: evaluate effectiveness of our protocol to achieve HCV elimination in Santa Cruz San Miguel CAT (CATSC). Secondary aims: know prevalence, results of treatment, rate of reinfections and incidental new cases.
Method: All CATSC users of Opioid Substitution Therapy (OST) were included. We analyzed with descriptive statistical prevalence of HCV before and after the elimination program, number of patients treated and cured. Patients cured more than a year ago were included for reinfection screening. CATSC new patients, included after the programe initiation, were also analized for new incidental cases.
Results: We include the 231 users of OST of CATSC. At the beginning we knew the HCV status in 72%. Among this patients, HCV prevalence was 42.5%; of negative RNA patients 43% were after treatment. These positive HCV patients weren't under treatment. After the implementation of screening program at CATSC we found out HCV diagnostic situation in 95.4%. Prevalence of viremic patients was 41% (55): prevalent genotypes were 1a (42%) and 3a (28%), 37.5% had advanced fibrosis or cirrhosis. None with negative serology before the study had been infected later. 50 patients (91%) were treated; one didn't receive treatment due to terminal illness. Virological cure was achieved in 49 (98%), the other abandoned treatment. In 2022 a new HCV screening was carried out in these users: 85% adhered. Only 3 were viremic: one wasńt treated due to severe comorbidity and the other two refused treatment. 49 patients received antivirals more than a year ago, reinfection screening was done in 46 (94%): 100% negative. After the study, 46 new OST users were admiten at CATSC: in 44 patients (95.6%) HCV status was known. 6 patients were RNA positive and 5 of them were treated.
Conclusion: Among the OST users of the CATSC, we achieve the WHO objective of eliminating hepatitis C with 97% of patients diagnosed and 90% treated with a cure rate of 98%. The elimination has been maintained after one year with 0 reinfections and 0 new infections. Screening and linkage to care of new patients is necesary to mantein these results.

FRI-199

Hepatitis delta virus infection in Turkey: A meta analysis of prevalence

Mehlika Toy[1], Begüm Güler Şentürk[2], Kayra Somay[2], Genco Gencdal[3], Cihan Yurdaydin[3]. *[1]Stanford University School of Medicine, Palo Alto, USA, Department of Surgery, United States; [2]Koç University, School of Medicine, Department of Internal Medicine, Turkey; [3]Koç University, School of Medicine, Department of Gastroenterology and Hepatology, Turkey*
Email: gencogencdal@yahoo.co.uk

Background and aims: Turkey is a region that has a high burden of hepatitis delta virus (HDV) infection, and is considered an endemic country for the virus, occurring in large proportions of HBsAg-positive individuals. To provide a current and updated HDV prevalence, the authors performed a meta-analysis of prevalence to estimate country and region-specific prevalence of HDV infection in Turkey.

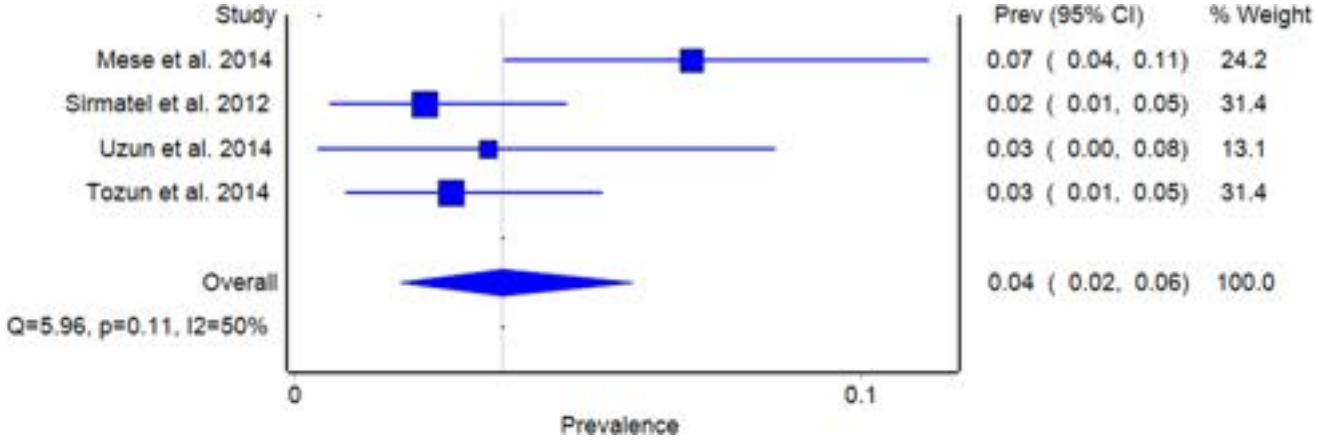

Figure: (abstract: FRI-199): Forrest plot of blood donor studies.

Method: A total of 462 studies with original data on the prevalence of HDV in Turkey and published between 2006 and 2022 were identified through a search of electronic databases, by reviewing citations, and by contacting authors. After a systematic assessment, the authors included 43 studies, divided into blood donor studies, outpatient clinic studies that comprised of asymptomatic and only non-cirrhotic chronic hepatitis B, and inpatient clinic studies that comprised of cirrhotic patients. Turkey was divided into three regions: West-, Central-, and Southeast Turkey. MetaXL software was used to calculate the prevalence.
Results: Using a quality effects model, we estimated that the prevalence for blood donors, outpatient clinic patients, and inpatient clinic patients was 3.65% (CI: 1.88–5.95), 4.41% (CI: 3.02–6.04), and 23% (CI: 5.2–47), respectively. The prevalence for West-, Central-, and Southeast Turkey was 3.28% (CI: 2.37–4.33), 2.09% (CI: 1.31–3.05), and 7.79% (CI: 4.33–12.12), respectively.
Conclusion: The findings of this study suggests that Turkey is still an endemic country for delta hepatitis, with regional differences. The public health efforts should be focused accordingly.

FRI-200

Sofosbuvir/Velpatasvir (S/V) for the treatment of HCV infection among vulnerable inner-city residents: extending the results of clinical trial part 2

Brian Conway[1,2], Rossitta Yung[1], David Truong[1], Shawn Sharma[1], Shana Yi[1], Giorgia Toniato[1]. *[1]Vancouver Infectious Diseases Centre, Vancouver, Canada; [2]Simon Fraser University, Burnaby, Canada*
Email: brian.conway@vidc.ca

Background and aims: The combination of Sofosbuvir/Velpatasvir (S/V) is approved for the treatment of chronic HCV infection. In registrational trials, cure rates of 95% or more were achieved when administered as one pill once a day for a period of 12 weeks regardless of genotype or disease stage. To achieve HCV elimination by 2030, there is a need to develop and evaluate systems of care in populations that are more challenging to engage in care than those enrolled in clinical trials. With this in mind, we evaluated the safety and efficacy of S/V in a prospective study of HCV-infected inner-city residents enriched for risk behaviors for non-adherence to therapy, including problematic drug use and unstable housing.
Method: Through dedicated outreach events, including regular community pop-up clinics (CPCs), we identified HCV-infected patients who were not currently engaged in health care and who were eligible to receive government-funded antiviral treatment for HCV infection. We offered them the opportunity to enroll in a multidisciplinary program of care to address medical, psychological, social, and addiction-related needs, and provide S/V therapy in this context, with daily or weekly supervision of adherence as appropriate. The end point of this preliminary analysis is the achievement of cue (SVR4/12) in those who initiated therapy.
Results: In this ongoing study, we have, to date, identified and started treatment in 203 eligible subjects. We note median age 46 years, 28.8% female, 49.5 and 42.3% GT1 and 3, 13.6% cirrhotic, 99.0% active drug users, 10.2% co-infected with HIV and over 80% unstably housed. The median time from CPC attendance to HCV treatment initiation is 6 weeks. Of 203, 178 have completed treatment, 21 are currently on treatment, 2 died of overdose, 2 discontinued prematurely. Of 178 subjects who have completed treatment, 155 are confirmed as cured (SVR 12), 2 achieved SVR4 (awaiting SVR12), 12 are awaiting SVR4, 4 (2.2%) have a documented virologic relapse and 5 (2.1%) have been lost to follow-up. In the context of an opioid crisis with 6 documented deaths/day in the province of British Columbia, we have observed x deaths in the treated study population from time of initial identification at CPC events to the present (median follow-up 30 weeks. Of participants in whom a final outcome can be ascertained, the cure rate is 97.5% (157/161).
Conclusion: Among inner city residents living with HCV infection, most of whom are active fentanyl users and unstably housed, the administration of S/V in the context of a robust program of engagement in care has led to HCV cure rates that exceed those achieved in clinical trials, with minimal opioid-related morbidity and loss to follow-up within our system of care. The data we present validate the development of multidisciplinary programs as an important tool for HCV elimination in this vulnerable population.

FRI-201

Screening for hepatitis C virus using rapid diagnostic test (RDT) coupled with mammography in women aged from 50 to 74 years in Montpellier (France). (Mamm'OC NCT05067374)

Magdalena Meszaros[1], Severine Coursier[1], Nicolas Nagot[1], Lionel Moulis[1], Patrice Taourel[1], Emma Pages[1], Nathalie Fabre Demard[2,3], Muriel Trentini[4], Georges-Philippe Pageaux[1], Hélène Donnadieu-Rigole[1]. *[1]Hospital Center University De Montpellier, Montpellier, France; [2]Clinique du Millénaire, Montpellier, France; [3]IMACAM-Radiologie, Sénologie, Centre Victor Hugo, Montpellier, France; [4]Clinique Beau Soleil, Montpellier, France*
Email: m-meszaros@chu-montpellier.fr

Background and aims: The seroprevalence of hepatitis C virus (HCV) in the general French population is less than 1%; nevertheless, according to estimations, more than 75,000 people living in France are unaware of their seropositivity. In order to achieve the goal of elimination of hepatitis C by 2025 in France targeted screening of high-risk population is essential to identify asymptomatic carriers prior to development of advanced chronic liver disease. The most common risk factors associated with HCV infection are injection drug use, blood transfusions prior to 1992 and parenteral contamination. It was estimated that the seroprevalence of hepatitis C among women over 60 is higher than that among men of the same age. Organized breast cancer screening was introduced in France in 2004 and more than 70% of women aged from 50 to 74 are participating. We hypothesized that some women between 50 and 74 years may have previously undergone invasive surgical or obstetrical procedures and/or other at risk behaviours associated with HCV infection and may be unaware of their HCV status. Thus, screening for hepatitis C coupled with mammography may represent an efficient HCV micro-elimination strategy. The objective of the study was to assess acceptability rate to breast cancer screening coupled with hepatitis C testing using rapid diagnostic test (RDT) among women aged from 50 to 74 years old. Secondary objective was seroprevalence of HCV in this population.
Method: All women between 50 and 75 years participating in the national organized systematic breast cancer screening were prospectively enrolled in the study after signing informed consent. Adherence to HCV screening as well as data regarding HCV care cascade was recorded.
Results: Among 1430 women prospectively enrolled between March 2022–January 2023, 1173 accepted the two coupled exams (acceptability rate: 82%). The three main reasons for refusal were: recent HCV testing (51%), not feeling at risk of HCV (17%), and anxiety due to HCV testing (12%). The median age of the participants was 61.28 (±7.08) years; 44% were employed and 44% were retired. Among the participants, 86% had never had a blood transfusion, but 83% reported other risk factors such surgery or invasive procedure prior to 1992. Eight (0.68%) participants had a positive HCV RDT. One (0, 08%) participant was HCV RNA-positive and was treated and cured (SVR 100%) during the study period.
Conclusion: The acceptability of HCV screening using RDT coupled with mammography is high. Seroprevalence of hepatitis C in women aged from 50 to 74 years is low, similar to that of the general population.

FRI-202

Hepatitis B, C and D infections among nine high-risk populations in Burkina Faso, West Africa

Armel Moumouni Sanou[1], Aurélie Sausy[2], Abdoul Kader Ilboudo[3], Mohamed Aly Belem[4], Armel Poda[5], Zékiba Tarnagda[3], Judith Huebschen[2]. [1]*Institut de Recherche en Sciences de la Santé (IRSS), Equipe VIH, Hépatites Virales et autres IST, Bobo-Dioulasso, Burkina Faso;* [2]*Luxembourg Institute of Health, Department of Infection and Immunity, Luxembourg;* [3]*Institut de Recherche en Sciences de la Santé, National Influenza Reference Laboratory, Unité des Maladies à Potentiel Epidémique, Maladies Emergentes et Zoonoses, Ouagadougou, Burkina Faso;* [4]*Centre Hospitalier Régional de Fada-Ngourma, Laboratoire d'analyses biomédicales, Burkina Faso;* [5]*Université Nazi Boni (UNB), Institut Supérieur Des Sciences de la Santé (INSSA), Bobo-Dioulasso, Burkina Faso*
Email: armelbf@gmail.com

Background and aims: Certain population groups have an increased risk for hepatitis B and C virus (HBV and HCV) infections due to their profession and/or behaviour. Thus, they constitute potential reservoirs for the spread of these infections to the general population. Despite this, comprehensive studies, including screening for most viral markers in many different risk groups are lacking in Africa. In this study, we investigated viral markers of HBV, HCV and hepatitis D virus (HDV) infections among nine high-risk populations in order to propose interventions for a better control of these infections.
Method: A cross-sectional study was carried out in the two main cities of Burkina Faso, Ouagadougou and Bobo-Dioulasso, and one village (Fandjora). The study population included sex workers (SW), men who have sex with men (MSM), prisoners (P), health care workers (HCW), lorry drivers (LD), illegal gold miners (IGM), hairdressers (H), haemodialysis patients (HD) and human immunodeficiency virus (HIV) patients. From each participant, socio-demographic data and blood were collected by well-trained personal. All serum samples were screened for viral markers of HBV, HCV and HDV infections using serological and molecular tests. Data analysis was performed using STATA SE version 14.0 software (Texas, USA).
Results: A total of 1373 participants were enrolled. HBsAg seroprevalence was 13.5%, ranging from 9.9% in SW to 25.9% in MSM, and anti-HBc seroprevalence was 75.5%. Among HBsAg positive samples, HBeAg, anti-HBe antibodies, and HBV DNA were detected in 18.3%, 79.4%, and 30.1%, respectively. Total anti-HDV antibodies were detectable in 4 (2.1%) samples and HDV RNA in 3 (75.0%). A vaccination profile (isolated anti-HBs) was found in 7.0%. Being male was significantly associated with HBsAg (aOR: 1.6) and anti-HBc (aOR: 1.8) positivity. HD (aOR: 2.13) and SW (aOR: 2.6) had a higher risk of HBsAg positivity than all other groups. Anti-HCV prevalence was 8.5%, ranging from 5.3% in H to 12.4% in HD. HCV RNA was detected in 13.7% of anti-HCV positive samples. The odds of being HCV positive were nearly five times higher in participants with no education (aOR: 4.7) compared to those with other education levels, while it was low in participants between 35 and 49 years of age (aOR: 0.5). Active HBV/HCV coinfection was found in 4 (0.3%) cases. Dual exposure to HBV and HCV was confirmed in 93 (9.0%) cases, and prior exposure to all three hepatitis viruses was detected in one (0.07%) case.
Conclusion: The results show much higher prevalences of HBV and HCV infections than in the general population. They underline the need of targeted programs comprising awareness, screening and treatment for these high-risk groups to support the 2030 hepatitis elimination goals.

FRI-203

Factors associated with HCV reinfection among treated people who inject drugs in the HCV elimination program in Georgia

Lasha Gulbiani[1], Maia Butsashvili[1], George Kamkamidze[1], Davit Baliashvili[2], Senad Handanagic[3], Shaun Shadaker[3], Sonjelle Shilton[4], Maia Japaridze[4], Paige A. Armstrong[3]. [1]*Health Research Union, Tbilisi, Georgia;* [2]*The Task Force for Global Health, Tbilisi, Georgia;* [3]*Centers for Disease Control and Prevention, Division of Viral Hepatitis National Center for HIV, Hepatitis, STDandTB Prevention, Atlanta, United States;* [4]*FIND, the Global Alliance for Diagnostics, Geneva, Switzerland*
Email: lashagulbiani7@gmail.com

Background and aims: During 2015, Georgia launched a hepatitis C elimination program providing free hepatitis C virus (HCV) testing, and treatment at no cost with direct-acting antivirals (DAAs) to all Georgian citizens with chronic HCV infection. People who inject drugs (PWID) are one of the target groups for the program due to high prevalence of HCV infection and risk of reinfection as a result of ongoing injecting. This study aimed to understand the risk factors for HCV reinfection among PWID treated and cured through the HCV elimination program.
Method: A case-control study was conducted among beneficiaries of harm reduction center services in four cities in Georgia (Tbilisi, Telavi, Batumi and Kutaisi). Eligible for inclusion were adults age ≥18 years who achieved sustained viral response (SVR) after hepatitis C treatment with DAAs. Cases were defined as persons with a detectable HCV RNA test result ≥1 year after achieving SVR; controls were defined as persons with an undetectable HCV RNA test result ≥1 year after achieving SVR. Frequent drug use was defined as injecting drugs every day or several times a week or month during the last 12 months. The ratio of cases to controls was 1:3. Socio-demographic and behavioral data were collected by interviewer-administered (face-to-face) questionnaire. Binary logistic regression was performed to understand the independent predictors of detectable HCV RNA after achieving SVR.
Results: A total of 287 PWID were included; 74 cases and 213 controls. The majority of respondents were male (98.6%), Georgian (97.9%), married (77.7%), and >45 years (66.2%). The proportion of PWID who first injected drugs at age ≤18 years was higher among HCV reinfected participants (37.0% vs 21.6%, $p < 0.05$). Sharing injection paraphernalia was twice as common among cases (33.8% vs 14.6%, $p < 0.01$), and 74.0% of cases and 53.3% of controls were injecting drugs frequently during the last 12 months ($p < 0.01$). Reinfected individuals were more likely to have injected drugs in the last month (79.5% vs 65.4%, $p < 0.05$). In multivariable analysis, sharing injection paraphernalia was the only independent predictor of HCV reinfection (odds ratio = 2.63; 95% confidence interval: 1.13–6.25).
Conclusion: To prevent HCV reinfection among PWID, preventive and educational activities should be scaled up focusing on the use of single-use injection paraphernalia together with expanding access to free syringes through needle and syringe programs.

FRI-204

HCV screening before endoscopy in hepatogastroenterology outpatient clinic: results of DEPISTC-ENDO study

André-Jean Remy[1], Serge Bellon[2], Mathias Vidon[3], Ryad Smadhi[4], Jacques Bottlander[5], Armand Garioud[6]. Email: andre.remy@ch-perpignan.fr

Background and aims: Systematic screening for hepatitis C once in a lifetime is recommended but not validated by the health authorities. Screening before digestive endoscopy has become routine since 2020 with the mandatory performance of a COVID PCR before endoscopy under general anesthesia. Two Spanish studies in 2019 had demonstrated the feasibility and acceptability of screening (by blotter and by TROD) for hepatitis C before digestive endoscopy. An older French study had shown its acceptability during the pre-anesthesia consultation. Screening focused on subjects over 40 years of age would seem to be more efficient, as the prevalence of hepatitis C

increases with age. Our aim was to propose HCV screening serology to patients undergoing digestive endoscopy with general anesthesia, to determine if HCV screening from 40 years of age before endoscopy is feasible and accepted, and to evaluate if the prevalence after 40 years of age is higher than in the general population.
Method: Minimal-risk interventional research study; proposal to all patients, men and women, aged over 40 years and having an indication for digestive endoscopy, to undergo HCV serological screening at the time of the gastroenterology consultation prior to the examination. There was no control group. Patients known to have positive HCV serology or negative HCV serology less than one year old and patients already hospitalized were excluded. Study proceeds as follows: 1/inclusion of patient with the provision of an information leaflet and signature of a consent form 2/prescription of HCV serology by the hepato-gastroenterologist during the pre-endoscopy consultation 3/serology performed on site or in a local laboratory 4/possible catch-up of serologies in outpatient hospitalization if serology not done. The objective is to evaluate the feasibility and acceptability of the screening, not the conditions of its realization, which have been adapted to the conditions and habits of each participating center. 5/ Patients with a positive HCV serology will be offered a C viral load and management according to good practice recommendations. Expected results are an acceptability higher than 95% and a prevalence higher than the prevalence in the general population (0.86%).
Results: As of December 31th, 2022, 314 patients were included; 56% men 44% women; average age 56 years (40–90). Screening colonoscopy for 40%, other colonoscopy 40%, gastroscopy for 42% and other exams for 5%; 63% patients had other blood tests, 78% HBV serology. HCV serology was done for 97% with 7,2% positive results (22 patients). Risk factors were drug use in 61%, transfusion history for 22% and endemic country for 17%; average age was 65 years (49–85), 90% men, liver elastometry 8,5 Kpa; 9 patients patients had positive HCV viral load (2,9%) and will be treated. More detailed results on a larger number of patients will be presented at the congress.
Conclusion: The feasibility and acceptability of hepatitis C screening before digestive endoscopy is demonstrated. The prevalence seems to be higher than in the general population.

FRI-205

Progress in hepatitis C screening as part of the hepatitis C elimination program in Georgia

Vladimer Getia[1], Tamar Gabunia[2], Maia Tsereteli[1], Ekaterine Adamia[2], Davit Baliashvili[3], Irina Tskhomelidze[3], Sophia Surguladze[3], Shaun Shadaker[4], Senad Handanagic[4]. *[1]National Center for Disease Control and Public Health Georgia, Tbilisi, Georgia; [2]Georgian Ministry of IDPs, Labour, Health and Social Affairs, Tbilisi, Georgia; [3]The Task Force for Global Health, Tbilisi, Georgia; [4]Centers for Disease Control and Prevention, Division of Viral Hepatitis, Atlanta, United States*
Email: kh.getia@ncdc.ge

Background and aims: The country of Georgia, with a population of 3.7 million and an estimated 150,000 adults with current hepatitis C virus (HCV) infection, initiated a national hepatitis C elimination program in April 2015. One aim of the program is to identify 90% of adults infected with HCV by providing hepatitis C screening (anti-HCV) to all citizens free of charge. Screening increased overall since the start of the program but declined sharply in 2020 due to the Covid-19 pandemic. Screening started increasing gradually after pandemic restrictions started to lift, but more needs to be done to reach elimination goals. The aim of this analysis is to describe coverage in hepatitis C testing by age and sex as part of the HCV elimination program.

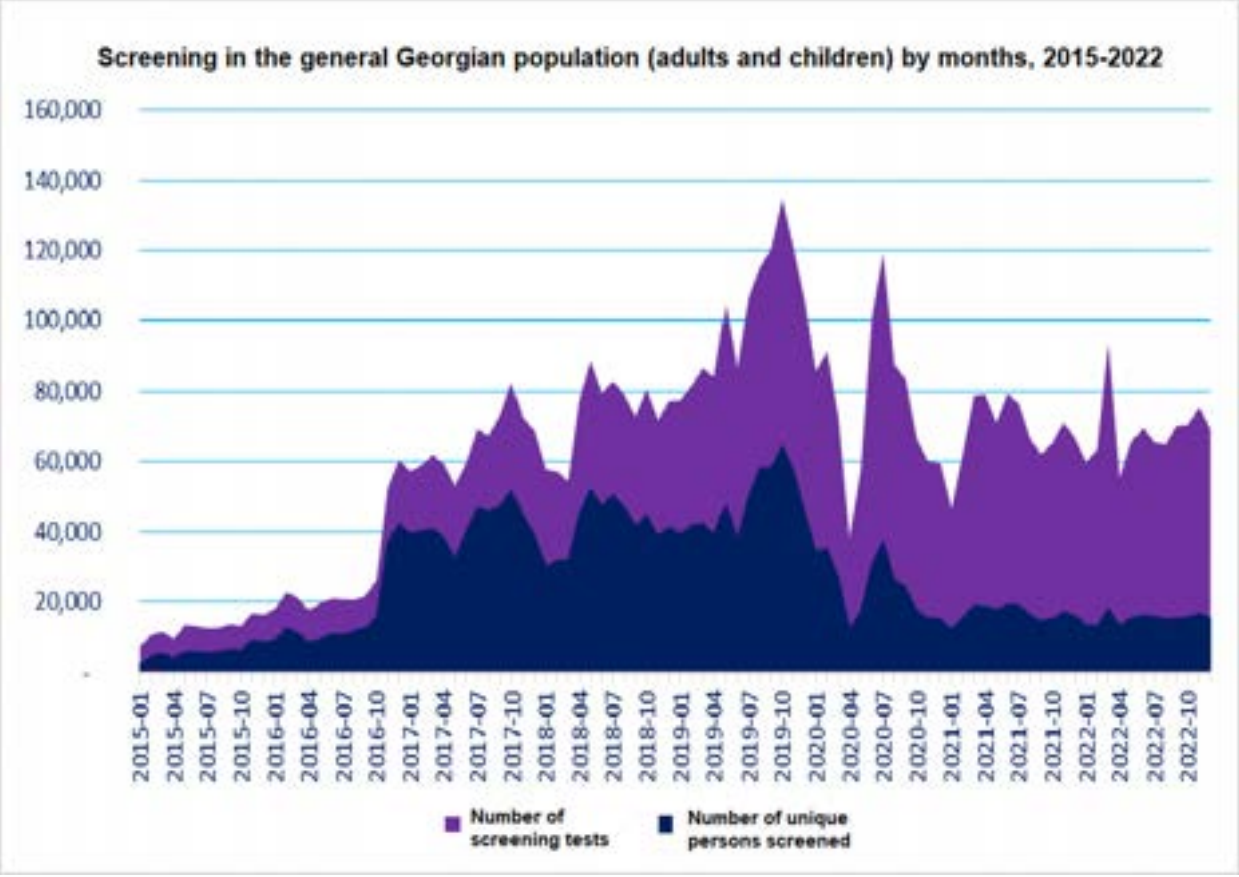

Figure: (abstract: FRI-205).

Method: This analysis utilized Georgia's national screening registry data from 2015 to 2022. This information system collects data from the elimination program utilizing patients' national IDs to monitor and evaluate program performance and surveillance. Required use of the national ID during screening causes duplication in the registry; for this analysis, we calculated unique persons screened. The 2014 general population census data were used to calculate screening coverage at the population level. This analysis excluded those screened anonymously at harm reduction sites; screened individuals who died between 2015 and 2022 were included.
Results: As of December 2022, 2,335,540 Georgian adults have been screened for hepatitis C, corresponding to 83% of the adult population. Screening coverage is similar for men and women at 82% and 84%, respectively. Among men, screening rates are above 70% in all age groups, the highest of which is among those aged 18–29 years at 84% and those aged ≥60 years at 86%. The lowest screening coverage in males is among those aged 40–49 years at 71%. In the general female population screening coverage is also above 70% in all age groups; it is highest among those aged ≥60 years at 95% and lowest among those aged 18–29 years at 70%.
Conclusion: Over 80% of the adult population in Georgia has been screened for hepatitis C. However, the remaining infected individuals still need to be identified. Innovative approaches to increase screening in the general population are needed to reach elimination goals.

FRI-206
New hepatitis C diagnoses in 2022. Who and where. Referral efficiency

Cristina Suárez Montesdeoca[1], Paula Moreno Martin[1], Magdalena Lara[2], Ruth Suarez Darias[1], Antonio González Rodríguez[1], Francisco Andrés Pérez Hernández[1]. [1]*Hospital Universitario Nuestra Señora de Candelaria, Digestive Department, Spain;* [2]*Hospital Universitario Nuestra Señora de Candelaria, Microbiology Department, Spain*
Email: cris.sua.mon@gmail.com

Background and aims: We have previously communicated our hepatitis C (HCV) elimination programme developed in several phases: 1) Treatment of known patients or new patients referred to our clinics. 2) Screening and treatment of patients in Primary Care (PC) and in Drug Dependency Care Units (DCU) or Prison. 3) Recovery of patients diagnosed from microbiology registers. But to complete the elimination we must also access new HCV diagnoses. 1. To describe the origin and characteristics of the new hepatitis C diagnoses. 2. To assess the efficiency of referral of these patients to hepatitis consultations (CH).
Method: A list of patients with positive RNA for HCV from January 1st to November 30th of 2022 was requested from the Microbiology Service. The clinical and laboratory history of these patients was reviewed.
Results: 148 patients were HCV RNA positive. There were 77 (52%) new diagnoses, 21 females and 56 males. However, in 23 (29%) patients a previous positive serological history was identified but the diagnosis had not been completed. The diagnosis had been made: in 40 (52%) in PC, in 16 (21%) digestive consultations in the context of study because of hypertransaminasemia; the rest were widely distributed: nephrology (2), psychiatry (2), paediatrics (2), emergency unit (2), medical oncology (2), endocrinology (1), pneumology (1), orthopaedics (1), DCU (2), intensive care unit (1). From the epidemiological background, it should be noted that in 27 (35%) patients there was a history of parenteral drug use; only in 3 (4.7%) the origin was attributed to post-transfusion, although 3 other patients had remote surgeries and did not know whether or not they had been transfused. 1 patient attributed the origin to accidental injection and in 5 (7.8%) patients there was a multiple history of sexually transmitted diseases. In 19 (24.7%) patients no epidemiological history was recorded in the clinical history.In 57 (74%) patients there had been appropriate referral to CH and they were already on treatment or had been treated at the time of analysis.
Conclusion: Despite a large and prolonged HCV elimination plan, new diagnoses are still occurring in 2022. Some of these patients are not newly infected: they either have a previous positive serological result or an epidemiological history suggestive of remote infection. The population with a history of injecting drug use remains the main source. The majority of new HCV diagnoses occur in primary care or in digestive consultations due to hypertransaminasemia, although in up to a third of cases the diagnosis occurs in other contexts.

FRI-207
Hepatitis C screening and elimination strategy: implementation of the FOCUS program in Almería, Spain

Anny Camelo Castillo[1], Manuel Rodriguez Maresca[1], Teresa Cabezas Fernandez[1], Teresa Maria Jordan Madrid[1], Antonio Duarte Carazo[1], Alba Carrodeguas[2], Diogo Medina[3], José Luis Vega Sáenz[1], Marta Casado[1]. [1]*Torrecárdenas University Hospital, Spain;* [2]*Gilead Sciences-Madrid, Spain, Spain;* [3]*Gilead Sciences –Lisboa, Portugal, Portugal*
Email: mm.casado.m@gmail.com

Background and aims: Spain may be one of the first countries to achieve the World Health Organization's goal of eliminating viral hepatitis C by 2030. A serosurvey by the Ministry of Health 2017–2018 estimated a 0.22% hepatitis C virus (HCV) active infection prevalence among the general Spanish population, with 29.4% unknown infections. Increasing HCV screening is key. Emergency Departments (ED) often act as safety nets due to health equity issues for key populations affected by viral hepatitis, as they often lack optimal links with their primary care providers. We aimed to evaluate HCV screening efficacy in the ED of Torrecárdenas University Hospital, in Almería, Spain.
Method: We implemented opportunistic HCV screening in the ED (FOCUS Program), using existing infrastructure and staff. Patients ages 18 to 69 were eligible for testing if they did not have a known diagnosis or test performed in the previous year and required blood tests at the current ED visit. We used the LIAISON®X- Diasorin assay for HCV antibodies (anti-HCV) and the Roche Cobas® 6800 for viral RNA (HCV RNA) in the same specimen. Appropriate follow-up or discharge was given regardless of test results. We contacted positive patients to ensure linkage to care.
Results: We screened 9,384 patients from August 2021 to December 2022, finding 159 (1.69%) anti-HCV positive patients (average age of 56, 76% male) and 38 (0.40%) HCV RNA positive patients (82% males). We identified risk exposures in 64% of viremic patients' records. Injected drug use (36%), HIV or HBV coinfection (36%), a history of incarceration (14%), and origin from countries with medium or high HCV prevalence (11%) were the top and only recorded risk exposures of the guidelines' 11 criteria. 93% of viremic patients had previously visited ED, and as of reporting, 16 patients have started antiviral treatment.
Conclusion: Undocumented HCV infection among our population is twice that estimated in the Spanish population. Hepatitis C screening in EDs is an effective strategy and should be considered in more hospitals.

FRI-208
Low prevalence found in HCV micro-elimination program among HIV-negative MSM and TW in a community center in Spain

Àngel Rivero Calaf[1,2,3], Felix Pérez Tejera[1], Albet Dalmau-Bueno[1], Pep Coll Verd[2,3,4], Jose Miguel Cabrera Guarin[1,2,3], Mariusz Lucejko[1,2,3], Joan Reguant Guitart[1,3], Javier Fernandez Pérez[1,3], Jorge Calderon Torres[1,3], Jaime Romero Rodriguez[1,3], Federico Caballero[1,3], Giovanni Marazzi[1], Carlos Oro[1], Daniel Jacobs[1], Horacio Vicioso[1], Lisandro Moises Enrique[1], Hector Taboada Gonzalez[1], Jorge Saz Berges[1], Ferran Pujol Roca[1], Michael Meulbroek[1],

Roger Paredes Deirós[2,3,4]. [1]*BCN Checkpoint-Projecte dels NOMS HISPANOSIDA, Spain;* [2]*Fundació Lluita Contra les Infeccions, Badalona, Spain;* [3]*Hospital Germans Trias i Pujol, Infectious Diseases Unit, Badalona, Spain;* [4]*IrsiCaixa AIDS Research Institute, Spain*
Email: angel.rivero.calaf@outlook.com

Background and aims: Since 2000, multiple HCV outbreaks have been reported in Men who have Sex with Men and Transgender Women (MSM/TW) living with HIV, but to a much lesser extent in their HIV-negative peers. New developments (U = U, PrEP implementation and extension of ChemSex) may have contributed to fueling the transmission chain. A community center with experience of early HIV detection, linkage to care and treatment might be able to create a model with Point-of-Care (PoC) HCV detection in this understudied population. The study aims to determine the prevalence of acute and chronic HCV infection in HIV-negative MSM/TW community and to assess associated risk factors.
Method: All clients who entered the center for routine HIV testing, PrEP and non-PrEP users, were offered to be screened for HCV. A PoC serology test (Abbott® Bioline™ HCV) was performed. Positive results were immediately confirmed by a PoC PCR test (Xpert® HCV VL Fingerstick). Additionally, clients with a negative serology and predefined criteria (e.g. ChemSex, fisting, recent HIV diagnosis) were offered the PCR test to detect a potential acute infection. All confirmed cases were referred to start treatment rapidly. Sexual behavior and drug use were assessed with questionnaires.
Results: Between 23 August 2021 and 19 December 2022 a total of 8,570 MSM/TW were included (27.9% PrEP users). A total of 11 HCV active infections were found (3 among PrEP users), HCV prevalence 0.13% (IC95%: 0.07%-0.23%). From 43 (0.53%) users with previously known HCV infection 3 (7.0%) were reinfections. Also, 23 (0.53%) serologic scars were found in people without previously known HCV history. From 921 (10.7%) participants with negative serology who complied criteria for PCR testing 1 (0.11%) acute infection was uncovered. Percentage of HCV transmission risk factors during last 6 months are reported in Table 1, highlighting "Slamming," OR 20.1 (IC95%: 4.6–88.6) and "Anal penetration with someone who practices slamming," OR 8.5 (IC95%: 2.4–30.7).

Table:

Risk Factor over last 6 months	HCV+	HCV–
Alcohol	27,3%	31,4%
Cocaine	36,4%	28,5%
GHB	36,4%	19,4%
Ketamine	0,0%	7,1%
MDMA	9,1%	21,0%
Marijuana	9,1%	11,4%
Mephedrone	18,2%	11,0%
Amphetamines	0,0%	6,5%
Methamphetamine	27,3%	12,2%
Sildenafil/Tadalafil	0,0%	4,3%
Popper (Amyl Nitrite)	0,0%	13,4%
Sharing sniffing roll for drug consume	63,6%	61,2%
Sharing Needles	0,0%	0,8%
Infection by Venereal Lymphogranuloma,syphilis or genital herpes (12 months)	18,2%	29,1%
Practice of fisting	27,3%	20,9%
Anal penetration with someone who practices slamming	36,4%	6,3%
Receptive anal sex with occasional partners	45,5%	62,4%
Group sex without condom	54,5%	32,7%
Group Sex with Chemsex involved	54,5%	34,4%
Slamming	27,3%	1,8%
Tattoos or Piercings	27,3%	15,9%
Sharing sexual toys for anal sex.	0,0%	20,1%

Conclusion: Results show a low prevalence of HCV in HIV-negative MSM/TW. This study produced criteria that allow a follow-up phase of targeted screening to establish effective HCV testing and treat strategies. Community centers play an important role in detecting cases not linked to the health system or subpopulations with difficulties in accessing the public system.

FRI-209

Late presentation for hepatitis C treatment; prevalence and risk factors in the Swiss hepatitis C cohort

Nathalie Brunner[1], Thomas Grischott[2], Philip Bruggmann[1]. [1]*Arud Centres for Addiction Medicine, Switzerland;* [2]*University Hospital Zurich, University of Zurich, Institute of Primary Care, Switzerland*
Email: nbrunner@gmx.ch

Background and aims: Patients with 'late presentation' (LP) of chronic hepatitis C infection (HCV) have already developed advanced or late-stage liver disease before entering specialised care and direct-acting antiviral (DAA) treatment. Even after successful treatment of HCV, the risk of morbidity and premature death remains elevated in this population of LP, leading to an unnecessary burden of disease. HCV LP should therefore be considered a healthcare system failure, primarily in high-income economies. This study aimed to assess the prevalence of LP within the prospective observational Swiss hepatitis C cohort (SCCS) since the introduction of DAAs, and evaluate demographics, clinical and behavioural factors as determinants of LP.
Method: Treatment-naïve participants of SCCS who received DAA treatment between 2014 and 2022 were included. LP was specified as the presence of advanced or late-stage liver disease at the treatment initiation. Demographic (age, gender, origin, education), clinical (e.g., psychiatric treatment, HIV status), and behaviour (e.g., substance use, history of alcohol) data were summarised for the whole study population and compared between the LP and non-LP strata. LP prevalence was calculated over time. LASSO regression was used in a stacked multiply imputed dataset to identify potential risk factors for LP, and odds ratios were calculated by refitting logistic regression models to the same multiply imputed data.
Results: Of the total SCCS population at the end of 2022 (n = 5829), 1258 patients (21.6%) matched the inclusion criteria. The LP prevalence decreased from mid-2015 and stabilised at 46.3% (n = 583) by the end of the study period. Among the assessed factors, male gender, higher age, and a history of alcohol drinking were associated with a higher risk of LP.
Conclusion: A startling percentage of patients with LP was found in the SCCS compared to similar studies. A particular limiting selection bias must be acknowledged, as SCCS recruits mainly in tertiary treatment centres, representing more severe cases. Regardless, LP prevalence remains higher than anticipated, considering the period of availability of DAAs. As the appearance of LP is directly linked to the disease burden, LP must be included as a mandatory parameter in surveillance response systems of viral hepatitis elimination programs.

FRI-210

Characterizing individuals who remain to be screened and those lost to follow-up from Georgia's HCV elimination program

Sophia Surguladze[1], Davit Baliashvili[1], Irina Tskhomelidze[1], Tamar Gabunia[2], Vladimer Getia[3], Maia Tsreteli[3], Paige A. Armstrong[4], Senad Handanagic[4], Shaun Shadaker[4]. [1]*The Task Force for Global Health, Georgia;* [2]*Ministry of Labour, Health and Social Affairs of Georgia, Tbilisi, Georgia, Georgia;* [3]*National Center for Disease Control and Public Health, Georgia;* [4]*Centers for Disease Control and Prevention, United States*
Email: sophiesurrguladze@gmail.com

Background and aims: Georgia initiated a National Hepatitis C Virus (HCV) Elimination program in 2015, aiming to diagnose 90% of those infected with HCV and treat 95% of those diagnosed. Individuals are tested for HCV antibodies (anti-HCV) and those reactive are tested for

viremia (HCV RNA or core antigen). By 2023, 83.4% of adults were screened, 86.3% of those anti-HCV reactive were tested for viremia, and 84.7% of those with current infection initiated treatment. This study aims to characterize those left to screen, anti-HCV-reactive individuals with no viremia testing, and currently infected persons who have not initiated treatment.

Method: This study used nationwide hepatitis C screening and treatment databases. The unscreened population was estimated by comparing the number of screened adults with 2021 adult population data from the Georgian National Statistics Office. Individuals without viremia testing and treatment were identified by linking screening and treatment databases using the Georgian unique 11-digit personal ID; children were included in these analyses. Persons with documented death dates in vital statistics and those screened anonymously at harm reduction sites (n = 150, 288) were excluded.

Results: As of April 2022, there were an estimated 848,100 adults (around 30% of the total adult population) to be screened, 21,597 anti-HCV reactive persons to be tested for viremia, and 14,435 persons with current HCV infection to be treated.

The majority of those not screened were male (51.1%); among unscreened males, the highest percentage were aged 60–69 years (20.2%) and the lowest were aged >80 years (4.8%). Among unscreened females, a plurality were aged 50–59 years (20.4%) and the lowest percentage were aged 18–29 years (6.6%). The majority of 21,597 anti-HCV-reactive persons without viremia testing were male (66.7%). A plurality of both males and females not tested were aged 40–49 years (28.5% and 17.4% respectively); the lowest percentage in males were aged >80 years (1.9%) and in females aged <18 years (4.0%). Loss to follow-up before viremia testing was more common among those screened in blood banks (38.2%) and prisons (36.0%) compared to other screening settings.

Among 14,435 persons with untreated HCV infection, 73.4% were male. Most individuals not initiating treatment were among those aged 40–49 years for males (30.6%) and 70–79 years for females (19.1%). The percentage of individuals with current HCV infection who had not initiated treatment was highest in those screened in hospital inpatient settings (34.5%).

Conclusion: Georgia has made substantial progress towards elimination, but loss-to-follow-up remains a challenge. While screening and testing in certain settings may be prone to loss-to-follow-up, retention in care should be ensured, especially in settings such as prisons. Innovative approaches to beneficiary retention are needed to reach elimination.

FRI-211

Cantabria on the way to HCV elimination. Differential prevalence of hepatitis C in Cantabria: @CohorteCantabria vs ETHON cohort

Joaquin Cabezas[1,2], Marta Alonso-Peña[2], Susana Llerena[1], Paula Iruzubieta[1,2], Antonio Cuadrado[1,2], María Eliece Cano[3], Carlos Fernández-Carrillo[4,5], José Luis Calleja Panero[4,5], Javier Crespo[1,2]. *[1]University Hospital Marques de Valdecilla, Gastroenterology and Hepatology Department, Santander, Spain; [2]Valdecilla Research Institute-IDIVAL, Santander, Spain; [3]University Hospital Marqués de Valdecilla, Microbiology Department, Santander, Spain; [4]University Hospital Puerta de Hierro, Gastroenterology and Hepatology Department, Madrid, Spain; [5]Research Institute Puerta de Hierro Majadahonda-IDIPHIM, Madrid, Spain*
Email: joweycabezas@gmail.com

Background and aims: The overall prevalence of anti-HCV in the ETOHN cohort (EC; general population of Cantabria) in 2016 was 1.1%, with a prevalence of viremia of 0.34%. It is likely that the universal treatment of patients with HCV hepatitis in recent years has brought us closer to its elimination in our region.

Aims: 1) To determine the prevalence of seropositivity and chronic HCV infection and to analyze the associated factors in the Cantabria Cohort (CC, CohorteCantabria) in the year 2022. 2) To determine the incidence of new cases of hepatitis C and analyze the associated factors. 3) To compare these results with those obtained in the EC (year 2016).

Method: 1) CC: Cross-sectional study in the general population participating in the CC project, which includes volunteers and random sampling of the entire population of Cantabria between 40 and 70 years old. In the blood sample at baseline, HCV antibody (anti-HCV) detection was carried out and, in positive cases, automatic viraemia quantification was performed. The volunteers included in this cohort between March 2021 and March 2022 were analyzed. 2) EC: Population-based cross-sectional epidemiological study, carried out during the years 2015–2016, exclusively including the population of the Santander node. 3) Analysis of the set of all viremic subjects in Cantabria in the same period.

Results: CC: 11,094 subjects were included (4,355 from 40 to 49 years; 3,823 from 50 to 59 years and 2,916 from 60 to 69 years), 38% male. Anti-HCV was detected in 102 cases (0.9% prevalence). Excluding 10 cases pending definitive study, positive HCV-RNA was detected only in 7 cases (0.06% prevalence). The remaining anti-HCV positive subjects are divided into 18 cases with spontaneous clearance and 77 cases with SVR. The total incidence of viremic patients of the entire population of Cantabria (585,000 subjects) in this period was calculated (112 cases, 19 cases/100,000 inhabitants/year), of which 65 (58%) were previously known, accordingly the incidence rate of new cases was 10 cases/100,000 inhabitants/year. When we compare these results with those obtained in the EC (previously published, doi: 10.1111/jvh.13238) we observed a lower prevalence (1.1% vs 0.9%, $p < 0.001$) and a great decrease in the viraemia rate among seropositives in CC (34% vs 6%, $p < 0.0001$). The CC showed 11.8% (1310) of volunteers with elevated transaminases levels, compared to 17.8% of the population analyzed in the EC.

Conclusion: The current prevalence (2022) of anti-HCV was slightly lower than that reported previously (2016) in the same population; In addition, and as the most outstanding fact of the study, the prevalence of viraemia was less than 10% of the seropositives. This fact, associated with an incidence of 10 new-cases/100,000 inhab./year, places Cantabria close to the goals set by the WHO for the definition of HCV elimination in a certain geographical region.

FRI-212

Risk of developing cancer-comparison of HBV, HCV and smoking

Homie Razavi[1], Devin Razavi-Shearer[1], Sarah Blach[1], Kathryn Razavi-Shearer[1], Alexis Voeller[1], Ivane Gamkrelidze[1], Chris Estes[1]. *[1]Center for Disease Analysis Foundation, Lafayette, United States*
Email: hrazavi@cdafound.org

Background and aims: Hepatitis B and C viruses (HBV and HCV) are oncoviruses, but the risk of developing cancer is often stated in an annual rate which is difficult to interpret by patients and healthcare workers. The objective of this work was to quantify the risk of cancer from viral hepatitis as compared to a known cancer-causing agent-smoking.

Method: A literature search was conducted to find longitudinal studies that reported the adjusted hazard ratio and odd ratio of developing hepatocellular carcinoma (HCC) among HBV/HCV infected individuals and cancer among active smokers.

Results: Fourteen studies were found, and the results are shown below. Adjusted hazard ratio of developing HCC for individuals infected with HBV or HCV was comparable to the risk of developing cancer for someone who is an active smoker. The odds ratio of developing HCC from HBV/HCV infection was 4–8 times higher than someone who actively smokes one pack of cigarette per day.

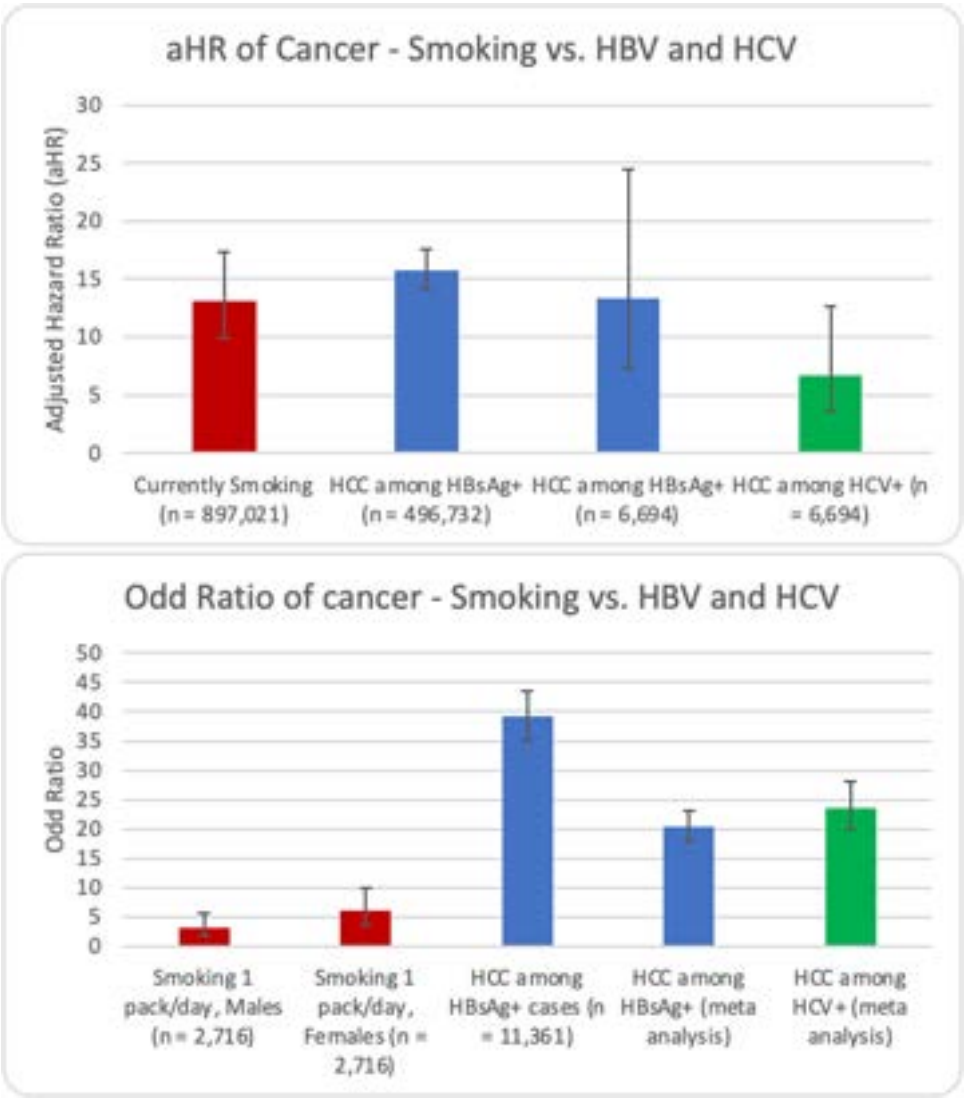

Figure: (abstract: FRI-212).

Conclusion: HBV/HCV infections are highly oncogenic and infected individuals have a similar or significantly higher risk of developing cancer than an active smoker or someone who smokes one pack of cigarette per day.

FRI-213

Pandemic preparedness and viral hepatitis-Global survey of hepatitis program managers and healthcare providers

Nida Ali[1], John Ward[1], Neil Gupta[1], Lindsey Hiebert[1]. [1]*Coalition for Global Hepatitis Elimination-Task Force for Global Health, Decatur, United States*
Email: nida.ali4883@gmail.com

Background and aims: At the advent of COVID-19 pandemic, hepatitis programs testing, and clinical care resources were repurposed for pandemic response before the direct investments for pandemic were operationalized. The Coalition for Global Hepatitis Elimination (CGHE) conducted a survey of hepatitis program managers (PMs) and hepatitis healthcare providers (HCPs) to assess 1) the contribution of viral hepatitis care and treatment infrastructure to pandemic response and 2) potential opportunities for leveraging the pandemic response capacity for delivery of viral hepatitis care.
Method: A web-based survey was designed in RedCAP in English for PMs and HCPs with a separate set of questions for each. The study team sent targeted solicitations via email to professional societies and CGHE networks, alongside promotions over CGHE website and social media.
Results: In all, 79 HCPs and 21 PMs responded to the survey from 46 countries across regions of the Americas (53%), Africa (26%), Eastern Mediterranean (13%), Europe (7%) and Western Pacific (1%).
In some cases, the full requested information was not completed by the respondents, hence the denominators for assessment of some variables differ (particularly for multivariate questions). More than 80% (17/21) of PMs provided direct support to the pandemic response. 73% (58/78) of HCPs provided clinical care to COVID-19 patients and 20% (16/78) are still providing care to COVID-19 patients in addition to hepatitis. 63% (49/78) of HCPs reported that space in their hepatitis clinics was re-purposed for COVID-19 patients. 66% (14/21) of PMs and 71% (56/79) of HCPs reported that PCR platforms for hepatitis testing were repurposed for COVID-19 testing during pandemic. As reported by PMs, there was an increase in PCR testing capacity at national reference laboratories (48%, 10/21), provincial public laboratories (43%, 9/21) and private laboratories (43%, 9/21). 50% (8/16) of PMs and 66% (49/74) of HCPs reported that PCR equipment acquired for COVID-19 is now also being used for hepatitis testing. 67% (10/15) of PMs reported that PCR testing shifted from manual to automated at labs. Almost all (99%, 78/79 HCPs reported

that COVID-19 PCR turnaround time is faster than that for hepatitis B and C. Regarding teleconsultation, 72% (51/71) HCPs reported that teleconsultation was not in use before pandemic, 59% (38/64) reported that teleconsultation was introduced during pandemic and 37% (26/71) of HCPs reported that the use of teleconsultation increased during the pandemic. 42% (33/78) HCPs in the survey prefer in-person consultation, 5% (4/78) telemedicine and 53% (41/78) prefer mix of both approaches.
Conclusion: PMs and HCPs from a diverse set of countries reported that the resources of hepatitis testing and care were repurposed for the pandemic response, demonstrating the utility of robust hepatitis testing and treatment programs for health system resilience and epidemic response. Data suggests that COVID-19 response continues to require the use of care staff and clinic space previously used for delivery of hepatitis services. Respondents reported the expansion of COVID-19 testing services that are now being utilized for hepatitis testing. This reflects how investments in pandemic response have the potential to bolster hepatitis programs.

Background and aims: Hepatitis C virus (HCV) eradication is one of the many goals the WHO has set for 2030, Nevertheless, despite the efforts from the administration, scientific societies and the health care workers, it is still a defying feat. Our strategy for increasing HCV detection focuses on screening every single patient scheduled for a surgical procedure, taking advantage of the blood work extraction during their presurgical evaluation.
Method: We've included patients between 39 and 70 years old (age group with higher HCV prevalence). HCV antibodies (anti-HCV) were automatically added to their blood work requests by the anesthesiologists in the presurgical appointment. Prior to this, the patients are given an informative brochure where VHC is explained and verbal consent is requested, and if it is given, an additional blood sample is extracted for this specific matter. If anti-VHC antibodies come back positive, viral load is automatically added to the blood work. Both results are posteriorly sent to the Hepatology Unit, where the patients are given an appointment in order to perform a thorough physical examination, abdominal ultrasound, transient liver elastography (TLE) and broaden their blood analyses. If no counter-indication is found, antiviral therapy is initiated, which is provided by the Hospital's pharmacy.
Results: 1697 presurgical evaluations were carried out between February and March, 2022. No patients declined the serology extraction. Mean patient age was 56 years old, 52% of them were men. Our strategy entailed an increase by 23.5% in HCV serologies during this period ($p < 0.001$). We detected 17 anti-HCV positive patients, two of which presented a positive viral load, which represent a prevalence of 0.11%. Both patients were provided with a single-act HCV appointment in our unit. One patient presented a low VHC load, thus a second blood sample was extracted, resulting in a negative viral count; the patient was never treated for VHC. The second patient was a 61-year-old male who was unaware of his diagnosis. The patient presented a history of altered liver function tests and moderate alcohol consumption. In 2016, an Anti-HCV test was requested, which was positive, but no viral load was performed and the patient did not return to the follow-up consultation. While at our single-act HCV appointment, severe steatosis and liver fibrosis grade 2 were detected on ultrasound and TLE. Treatment with Sofosbuvir/Velpatasvir was initiated for 12 weeks, pending verification of sustained viral response.
Conclusion: These results demonstrate that the automation of the HCV serology testing in all patients who require blood work extractions, regardless of the reason and the medical unit that requests it, significantly increases the diagnosis of HCV.

Rare liver diseases (including paediatric and genetic)

WEDNESDAY 21 TO SATURDAY 24 JUNE

Clinical features of portal hypertension and their prognostic implication in patients with Wilson's disease
Lukas Burghart[1,2], Oleksander Petrenko[1], Peter Ferenci[1], Michael Trauner[1], Mattias Mandorfer[1], Michael Gschwantler[2], Thomas Reiberger[1], Albert Stättermayer[1]. [1]*Medical University of Vienna, Gastroenterology and Hepatology, Vienna, Austria;* [2]*Klinik Ottakring-Wiener Gesundheitsverbund, Gastroenterology and Hepatology, Wien, Austria*
Email: burghartlukas@gmail.com

Background and aims: Wilson's disease (WD) is a rare inheritable liver disease mediated by hepatic copper overload. Natural history studies indicate half of all WD patients will ultimately progress to advanced chronic liver disease (ACLD). Consequently, portal hypertension (PH) may develop, which in turn drives hepatic decompensation and impairs transplant-free survival (TFS). We therefore assessed (i) the prevalence and incidence of CSPH in the Vienna WD cohort, and (ii) evaluated the impact of CSPH on hepatic decompensation and TFS.
Method: Patients with verified WD diagnosis (Leipzig score ≥4), attending regular clinical visits at the Vienna General Hospital between Q1/2005-Q4/2021, were included in this retrospective study. Clinical information including CSPH-specific features and complications was recorded from individual medical records.
Results: Among 140 WD patients (mean age: 41.8 years, 50% women) 50 (35.7%) showed features of CSPH at diagnosis: 14 (10.0%) had gastroesophageal varices (GEV), 41 (29.3%) splenomegaly, 20 (14.3%) ascites, 19 (13.6%) hepatic encephalopathy (HE) and 3 (2.1%) experienced acute variceal bleeding. Only 10 (20.0%) WD patients with CSPH received NSBB, and only 1 (2.0%) was treated by TIPS. During a median follow-up of 9.2 years, 8 (5.7%) WD patients died with 3 deaths attributable to CSPH-related complications. GEV were associated with an increased 5-year (5Y) risk of decompensation (11.1%) (A) and an impaired 5Y-TFS (71.4%), whereas the occurrence of HE or ascites was associated with a profound decrease in 5Y-TFS to 42.1% and 35.0%, respectively (C). Patients with compensated ACLD (cACLD) had a comparable 5Y-TFS (96.0%) to non-ACLD patients (100%), which was contrasted by the steep decline of 5Y-TFS (42.3%) in patients with decompensated ACLD (dACLD). Importantly, the combination of liver stiffness <15 kPa and platelets ≥150G/L indicated excellent prognosis (5Y decompensation rate: 0%, 5Y-TFS of 97.7%),

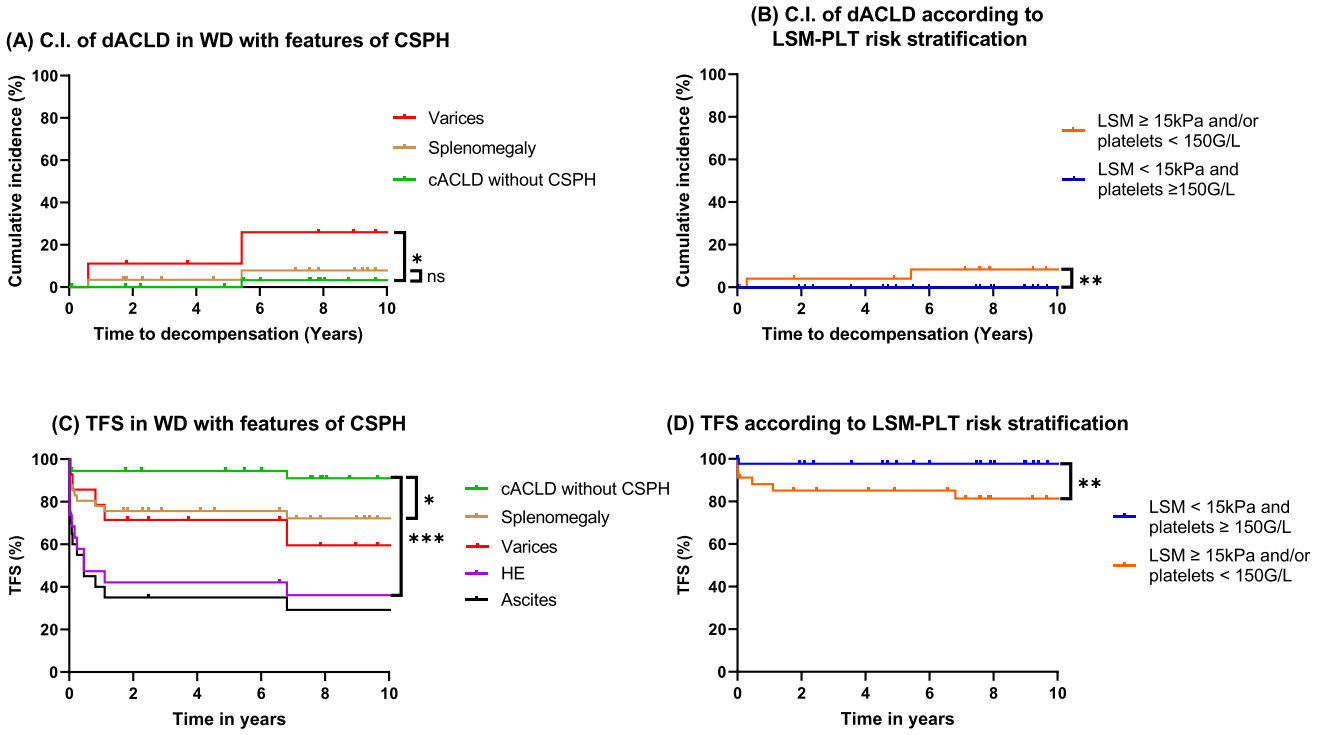

Figure: (abstract: TOP-055).

while patients with either liver stiffness ≥15 kPa or platelets <150G/L showed a 5Y decompensation rate of 4.0% and a 5Y-TFS of 85.1% (B) (D).

Conclusion: WD patients often develop CSPH with the presence of GEV indicating a significant risk for hepatic decompensation. WD patients with ascites and/or HE show a dismal prognosis with impaired survival without liver transplantation. Hence, regular CSPH screening-as by the non-invasive markers liver stiffness ≥15 kPa or platelets <150 G/L-is warranted in patients with WD.

TOP-056

Modeling Alagille syndrome in vitro using complex induced pluripotent stem cell-derived human liver organoids

Marie-Agnès M'Callum[1], Silvia Selleri[1], Toan Pham[1], Alexandre Archambault-Marsan[1], Kristen Vieira Lomasney[1], Massimiliano Paganelli[1]. [1]*CHU Sainte-Justine, Université de Montréal, Liver Tissue Engineering and Cell Therapy, Montreal, Canada*
Email: m.paganelli@umontreal.ca

Background and aims: Alagille syndrome (ALGS) is an autosomal dominant hereditary multisystemic disease. In the liver, ALGS is characterized by bile duct paucity, cholestasis, fibrosis, as well as other heterogeneous clinical manifestations. The genes involved (JAG1, NOTCH2) belong to the Notch signalling pathway. No direct genotype-phenotype correlation has been established. The aim of the study was to develop a representative human model of ALGS to better understand the pathophysiology of the disease.

Method: We developed a new 3D in vitro model of ALGS by generating liver organoids from human induced pluripotent stem cells (iPSC). Two iPSCs clones with mutations in exon 23 of JAG1 were obtained with CRISPR/Cas9: clone A2 had a large deletion, whereas clone B3 presented a single base substitution. We generated hepatic (HPC), mesenchymal (MPC) and endothelial (EPC) progenitor cells from JAG1-mutated iPSC clones and from isogeneic control and used them to create the liver organoids. We previously showed that, within the organoids, these cells interact to become hepatocytes, cholangiocytes/biliary epithelial cells, stellate and sinusoidal cells, and form ductal plate and bile ducts (Raggi et al. Stem Cell Reports 2022). In order to determine which progenitor cell type is more predominant to obtain the disease phenotype, we generated generate hybrid organoids mixing different progenitor cell types obtained from the mutated clones and the control. We studied the impact of the mutations on the different liver cell types, and assessed the ductal plate, bile duct formation and fibrogenesis in the organoids.

Results: HPCs from the two clones with different JAG1 mutations showed different gene expression profiles representing the heterogeneity of ALGS: expression of hepatic markers and Notch pathway targets was strongly decreased in HPCs-A2 compared to HPC-B3 or HPC from control iPSC. Moreover, HPCs-A2 and -B3 showed a strong expression of YAP1, which attests to a dedifferentiation of HPCs. Nevertheless, a strong expression of cytokeratin genes was observed in mutated HPCs compared to healthy cells, which is commonly observed in fibrosis and cholestasis. Organoids from the two mutated clones lacked biliary structures compared to healthy organoids (Figure 1), reproducing the phenotype of ALGS. Mutated organoids from both clones showed an overexpression of inflammatory markers and increased fibrosis, as well as a loss of bile duct-associated markers, compared to control organoids. Among the 18 hybrid organoid conditions generated, only organoids with healthy HPCs were able to form proper biliary structures, attesting that mutation in HPCs (i.e., bipotent hepatic progenitors), hepatocytes and biliary epithelial cells drives the disease phenotype.

Conclusion: We were able to generate a representative human developmental model of Alagille syndrome using complex liver organoids derived from iPSC. These organoids recreate the hepatic niche and reproduce the histological phenotype of Alagille syndrome, which makes them an ideal model to study the pathophysiology of the disease and discover new therapeutic targets.

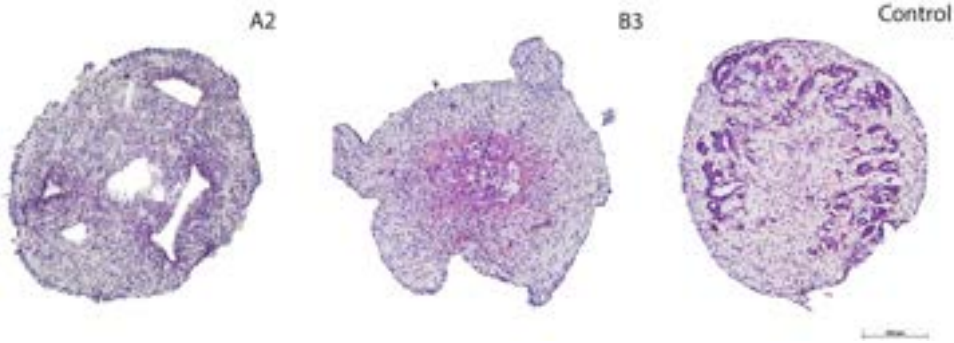

Figure: (abstract: TOP-056): Histological appearance of human liver organoids generated from JAG1-mutated iPSC (A2 and B3) showing bile duct paucity, increased fibrosis and cell death. In comparison, organoids from control iPSC show ductal plate structures with branching immature and mature bile ducts (HandE staining, representative images, scale bar 200 μm).

Long-term efficacy and safety of odevixibat in patients with progressive familial intrahepatic cholestasis: results with 96 weeks or more of treatment

Richard Thompson[1], Ozlem Durmaz[2], Tassos Grammatikopoulos[1,3], Angelo Di Giorgio[4], Quanhong Ni[5], Philip Stein[5], Christine Clemson[5], Ekkehard Sturm[6]. *[1]Institute of Liver Studies, King's College London, United Kingdom; [2]Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey; [3]Paediatric Liver, GI, and Nutrition Centre and MowatLabs, King's College Hospital NHS Trust, United Kingdom; [4]Paediatric Hepatology, Gastroenterology, and Transplantation, ASST Papa Giovanni XXIII, Italy; [5]Albireo Pharma, Inc., Boston, United States; [6]Paediatric Gastroenterology and Hepatology, University Children's Hospital Tübingen, Germany*
Email: richard.j.thompson@kcl.ac.uk

Background and aims: Patients with progressive familial intrahepatic cholestasis (PFIC) may present with elevated serum bile acids (sBAs), intractable pruritus, impaired hepatic function, and growth deficits. The phase 3 studies in patients with PFIC that evaluated odevixibat, an ileal bile acid transporter inhibitor, are called PEDFIC 1 and PEDFIC 2. Using pooled data from these studies, we describe key outcomes in a subgroup of patients treated with odevixibat for ≥96 weeks.
Method: PEDFIC 1 was a 24-week, randomised, placebo-controlled study in children with PFIC1 and PFIC2. PEDFIC 2 is an ongoing 72–week open-label extension study that enrolled patients from PEDFIC 1 or new patients of any age with any type of PFIC. Following 72 weeks of treatment in PEDFIC 2, there is an optional extension period, with visits every 16 weeks. Patients could have reached 96 weeks of odevixibat treatment in various ways, including by receiving 24 weeks of active treatment in PEDFIC 1 plus 72 weeks of treatment in PEDFIC 2 or by receiving 96 weeks of open-label treatment in PEDFIC 2 and its optional extension. This pooled analysis spans from patients' first dose of odevixibat to a cut-off date of 31 January 2022. The following outcomes were evaluated in patients with ≥96 weeks' odevixibat exposure and an sBA measurement at week 96: sBAs, scratching scores, hepatic parameters, growth, and safety. Scratching scores range from 0 to 4, with higher scores indicating worse symptoms. Pruritus data were collected through week 72 of PEDFIC 2.
Results: Of the 111 patients in the pooled population (69 of whom continue on treatment at data cut-off), 36 had ≥96 weeks' odevixibat exposure and an sBA measurement at week 96. Among these 36 (50% female), 36% had PFIC1, 61% had PFIC2, and 3% had MYO5B deficiency. At baseline, patients had elevated mean sBA, transaminase, and total bilirubin levels, moderate-to-severe pruritus, and impaired growth (Table). After 96 weeks of odevixibat treatment, there were significant reductions in mean sBAs, transaminase levels, and scratching scores and improvements in growth; only minimal changes in bilirubin levels were observed (Table). All 36 patients (100%) had treatment-emergent adverse events (TEAEs); most were mild or moderate in severity. Serious TEAEs were recorded in 6 of 36 patients, but none were drug related.
Conclusion: Odevixibat treatment for ≥96 weeks was associated with improvements in sBAs, pruritus, transaminase levels, and growth. Odevixibat was generally well tolerated.

Table: (abstract: TOP-057).

Outcomes in Patients With PFIC Treated With Odevixibat for ≥ 96 Weeks

	Baseline		Week 96		
Outcome	n	Mean (SE)	n	Mean (SE)	p value[a]
Serum bile acids, μmol/L	36	266 (22)	36	118 (20)	**< 0.001**
Scratching score	36	2.8 (0.1)	17	0.9 (0.2)[b]	**< 0.001**
ALT, U/L	36	102 (23)	32	38 (7)	**0.022**
AST, U/L	36	86 (10)	32	49 (5)	**0.001**
Total bilirubin, μmol/L	36	56 (13)	32	50 (17)	0.713
Height Z score	36	−1.5 (0.3)	36	−0.9 (0.2)	**< 0.001**
Weight Z score	36	−0.9 (0.3)	36	−0.2 (0.2)	**< 0.001**

[a]p values are based on 1-sample t test for changes from baseline to the week 96 visit window; [b]The average of daily scratching scores from weeks 85–96 are reported. ALT, alanine aminotransferase; AST, aspartate aminotransferase; PFIC, progressive familial intrahepatic cholestasis.

Email: thomas.reiberger@meduniwien.ac.at

Background and aims: Porto-sinusoidal vascular disorder (PSVD) is a rare vascular liver disease characterized by specific histological findings in the absence of liver cirrhosis (LC). Diagnosis and differentiation from LC remains challenging and importantly requires invasive liver biopsy. The aim of this study was to investigate metabolomic signatures of patients with PSVD, liver cirrhosis (LC) and healthy volunteers (HV) in regards to facilitating diagnosis and identifying metabolites involved in pathogenesis.

Method: We analyzed 20 serum samples from patients with histologically verified PSVD and LC as well as HV (Figure A). Participants were matched by age and gender (all three groups) as well as by BMI, MELD and current/previous hepatic decompensation (PSVD and LC). Following extraction, serum concentrations of lipids, hydrophilic metabolites and free-fatty acids were measured by LC-MS. Metabolites with ≥20% missing entries were excluded. Data were analyzed in R environment (tidyverse, rstatix). Missing values were imputed using k-nearest neighbors algorithm. Concentrations of each run were $\log_2$-normalized, scaled by Pareto technique and merged (POMA package). Partial least squares-discriminant analysis (PLS-DA) was performed for data exploration. Differential metabolites (PSVD vs LC vs HV) were identified using pairwise Limma contrasts and the Wilcoxon test. The diagnostic/discriminative value of metabolites was evaluated with MetaboAnalystR.

Results: From 539 identified metabolites, n = 208 (38.6%) were excluded, and n = 74 (13.7%) were complemented with imputation. PLS-DA discriminated LC and HV with component #1, however, PSVD

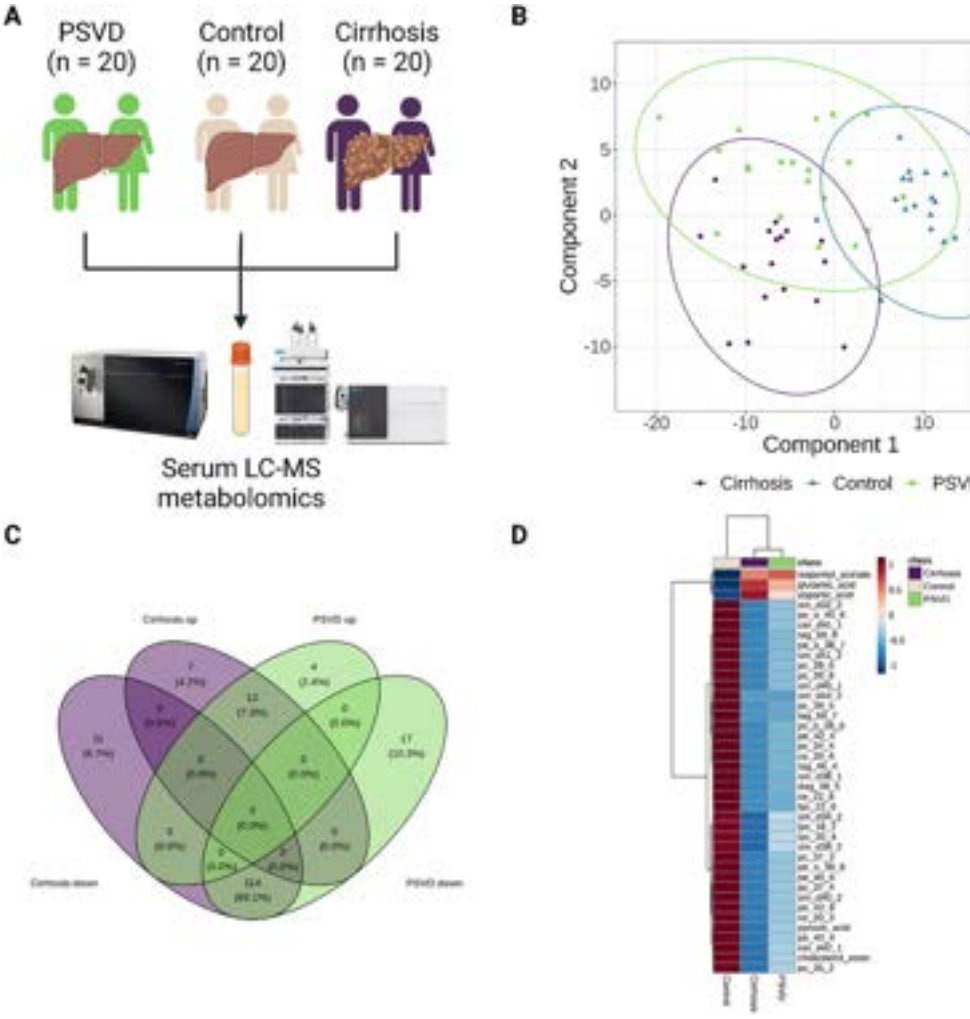

Figure: (abstract: TOP-058).

patients were partly present in both clusters (Figure B). Pyruvic acid, glutamine, triacylglycerols and isovaleric acid were key metabolites of the first component, while phosphatidylethanolamine and cholesteryl icosatetraenoate contributed to PSVD discrimination (component #2). We identified 165 differential metabolites in LC and PSVD versus HV ($p_{adj} \leq 0.01$, Figure C), of which n = 39 (23.6%) were unique to the respective groups. The metabolites that contributed to most of the dataset variation were mainly down-regulated in PSVD and even further in LC (Figure D). When analyzing single differential metabolites, 1-palmitoleyl-2-eicsoateidentified identified PSVD vs HV (mean AUROC = 0.958), while tyrosine (AUROC = 0.859) and adipic acid (AUROC = 0.821) were among the best-performing discriminators between PSVD and LC.

Conclusion: High-throughput metabolomics identified common and unique metabolic profiles in PSVD and LC. Independent validation of the metabolomic signatures is required. If confirmed, mechanistic studies should investigate the underlying molecular mechanisms to gain insights into PSVD pathophysiology.

Email: ghallab@ifado.de

Background and aims: Cholemic nephropathy (CN) is a severe complication of several liver diseases. Since no specific treatment is currently available, we revisited the pathophysiology and tested the therapeutic strategy of inhibiting renal bile acid (BA) uptake.

Method: Cholestasis was induced by bile duct ligation (BDL) in mice. Bile flux in kidneys and livers was visualized by intravital imaging, supported by matrix-assisted laser desorption/ionization-mass spectrometry imaging (MALDI-MSI) and liquid chromatography-tandem mass spectrometry (LC-MS/MS). AS0369, a selective and orally systemically available inhibitor of the apical sodium-dependent bile acid transporter (ASBT) was developed, and its renal and hepatic effects were tested by RNA sequencing, histological, serum, and urine

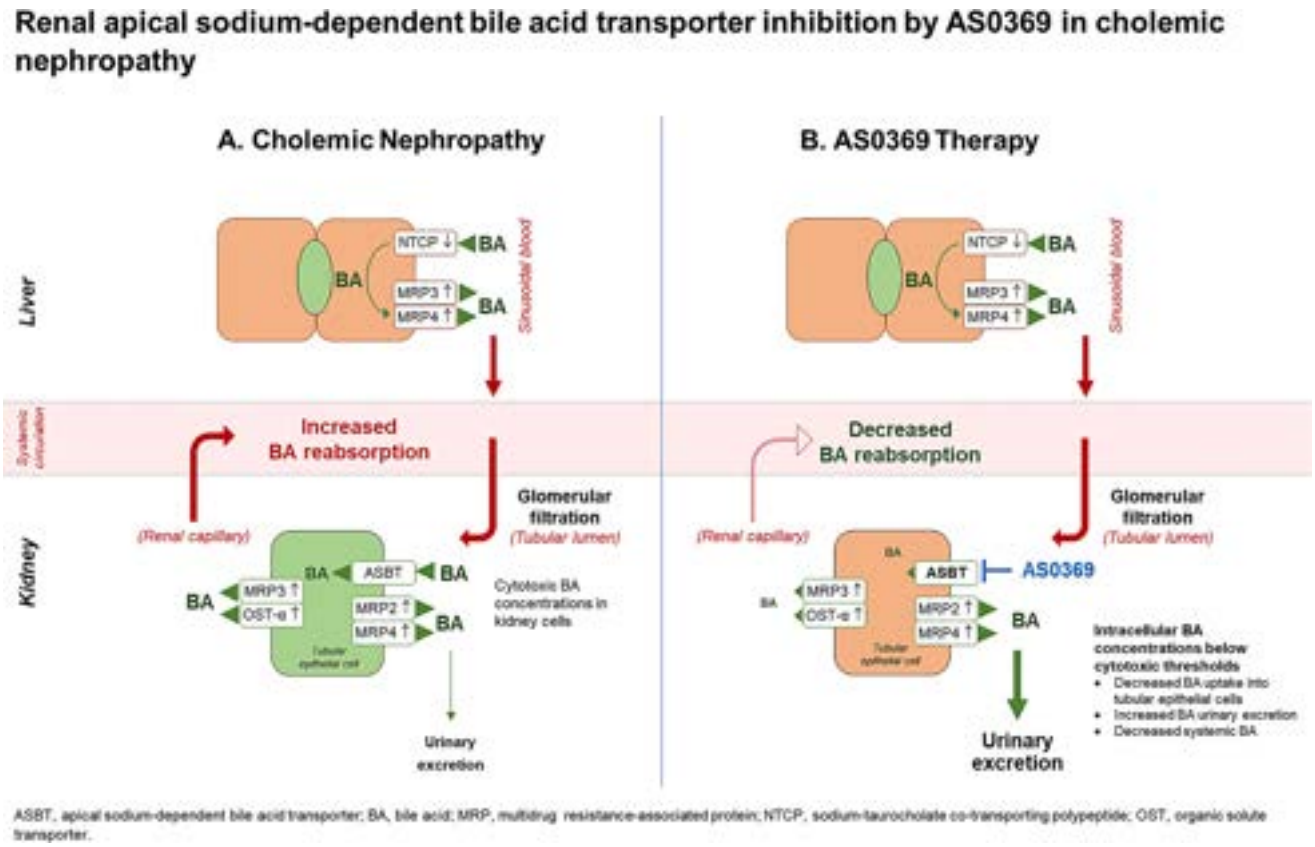

Figure: (abstract: THU-249).

analyses. Translational relevance was evaluated by ASBT immunostaining in renal biopsies from CN patients.
Results: Intravital imaging showed that BAs were reabsorbed from the renal tubular lumen into specific renal tubular epithelial cells (TEC). BA enrichment led to cell death of TEC within the first days after BDL. At week 3 and later, damage of peritubular capillaries and massive leakage of BAs into the renal interstitium were observed, followed by leukocyte infiltration and fibrosis. Renal ASBT expression was maintained in TEC of BDL mice and CN patients, and treatment of BDL mice with AS0369 strongly elevated urinary BA excretion, blocked the uptake of BAs in TEC, and decreased renal tissue BA levels. In addition, AS0369 almost completely prevented kidney injury up to 6 weeks after BDL. All CN hallmarks (ie, cell death events of TEC, tubular casts, immune cell infiltration, and fibrosis) were almost completely absent in AS0369-treated mice. Also, the kidney injury marker neutrophil gelatinase-associated lipocalin (NGAL) in urine was strongly reduced by AS0369 treatment. RNA-Seq analysis demonstrated that ASBT inhibition strongly ameliorated BDL-induced gene expression changes in the kidney, while the corresponding effects in the liver were smaller but still statistically significant. The efficacy of AS0369 is not sex specific since the results were reproducible in both female and male mice.
Conclusion: BA enrichment in TEC followed by cell death is an early key event in CN. Inhibiting renal ASBT and consequently BA uptake into TEC efficiently prevents CN under conditions where serum and urinary BA concentrations are massively increased (Figure). Moreover, ASBT inhibition reduces endothelial exposure by blocking transepithelial transport. The increased urinary excretion of BAs leads to decreased blood concentrations systemically, which is favourable for all cell types that are compromised by exposure to the circulating high BA concentrations. The present findings may have clinical relevance since TEC ASBT expression is also preserved in CN patients.

THU-250

Common, non-pathogenic variants in genes from monogenic disorders confer additional risk of liver injury later in life

Jake Mann[1], Ye Htun Oo[2], Girish Gupte[1], Philip N Newsome[2].
[1]*Birmingham Children's Hospital, Liver Unit, United Kingdom;*
[2]*University of Birmingham, Centre for Liver Research, United Kingdom*
Email: jpmann.gsy@gmail.com

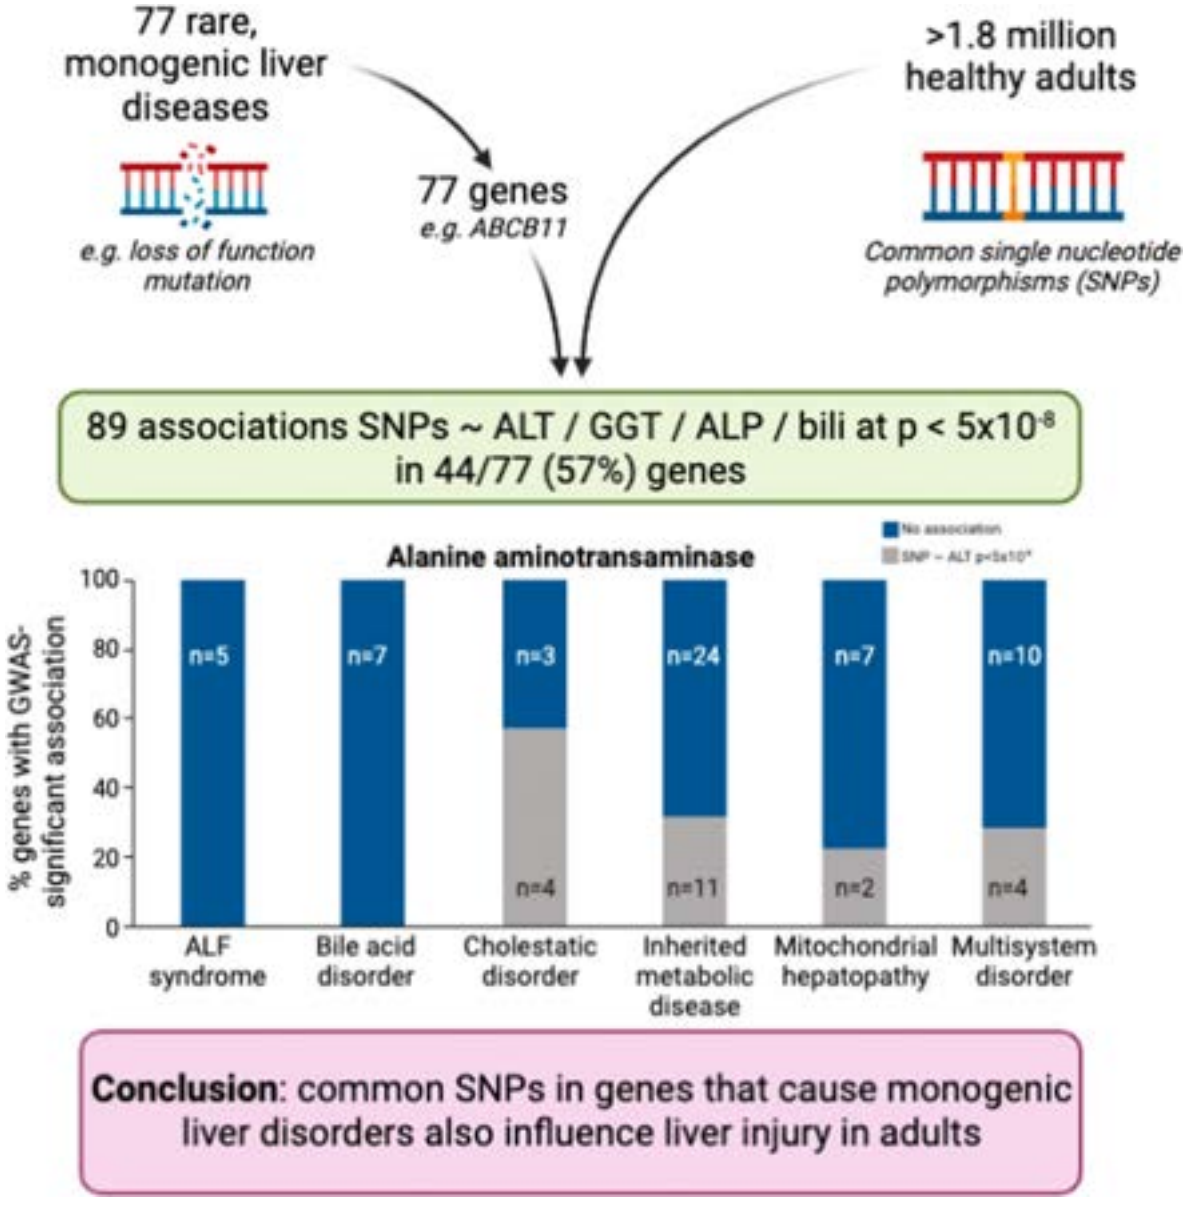

Figure: (abstract: THU-250).

Background and aims: Monogenic liver disease is caused by rare, pathogenic mutations. Exome and genome sequencing frequently identifies variants of unknown significance in these genes. It is not clear whether such non-pathogenic variants confer increased risk of liver injury beyond childhood. Here, we found that these variants increase the severity of liver damage and may act as a 'second hit' in adults.
Method: We identified 77 monogenic paediatric liver diseases. For each gene, we searched for evidence of a liver phenotype in individuals not known to have genetic disease using population-based datasets. We identified genome-wide significant associations ($p < 5 \times 10^{-8}$) between variants (e.g single nucleotide polymorphisms) and liver biochemistry (ALT, bilirubin, GGT, ALP) in n = 1,654,950 participants from the Common Metabolic Disease Portal and n = 394,841 from UK BioBank using GeneBass.
Results: We found 89 genome-wide associations for biomarkers of liver injury in otherwise apparently healthy individuals across genes from 44/77 (57%) monogenic disorders (Fig 1). For example, common variants in *ABCB11* (the cause of PFIC type 2) were associated with GGT ($p = 2.0 \times 10^{-33}$) and ALT ($p = 8.4 \times 10^{-39}$). Similarly, common polymorphisms in *JAG1* (that do not cause Alagille's syndrome) were associated with GGT ($p = 2.3 \times 10^{-9}$) and ALT ($p = 5.9 \times 10^{-10}$). Phenotypes were found most frequently in 5/7 (71%) of cholestatic disorders and 5/7 (71%) of bile acid metabolism disorders, compared to 3/8 (38%) of congenital fibrotic disorders. In addition to affecting liver enzymes, serum lipid profile (e.g total cholesterol) was affected by genes from 23/44 (52%).
Conclusion: Common variants in genes that cause rare monogenic liver disease also confer a risk of liver injury later in life. Understanding the mechanisms of these genes and applying them as predictors for future disease progression in adults may provide an opportunity for treatment of common liver diseases.

Email: p.carotenuto@tigem.it

Background and aims: Tumour heterogeneity and the immunotolerant microenvironment are driving forces of biological aggressiveness and treatment refractoriness in BTCs. Recently, CD73, an ecto-5′-nucleotidase, has been increasingly implicated in cancer promotion and treatment resistance, acting through the enzymatic conversion of AMP to immunosuppressive adenosine and the non-catalytic promotion of cancer plasticity, invasion and migration. Interestingly, CD73 has become a clinically validated target with several compounds undergoing advanced-phase development across various cancer types. Here, we aimed at comprehensively characterizing the role of CD73 in a well-annotated cohort of BTC patients.
Method: Medical records and FFPE tissue blocks from 70 radically-resected BTCs were retrospectively retrieved at the University Hospital of Modena. Immunohistochemistry for CD73, CD4/CD8 and FOXP3 as well as bulk whole-transcriptomic sequencing were performed (Illumina Platform). Silencing of CD73 was achieved by transient transfection of CD73-siRNA, while genetic Knock-out (KO) was performed using CRISPR-Cas system technology in two BTC cell lines (Hucct01; RBE). Tumor growth was assessed in 2D and in 3D cell culture by using MTS assay and spheroid growth analysis before and after treatment with selected drugs. Statistical analyses were performed SPSS software (version 26; SPSS Inc., Chicago, IL, USA).
Results: Overall, 60% of BTC patients showed high CD73 expression ($CD73^{high}$) and this was associated with older age ($p = 0.01$), gallbladder subsite ($p = 0.03$), and nodal involvement ($p = 0.04$). $CD73^{high}$ tumours were significantly enriched in infiltrating FOXP3+ T lymphocytes ($p < 0.001$) and BTC cells genetically depleted for CD73 were more sensitive to killing by reactive T cells. Transcriptomically, $CD73^{high}$ tumours were characterized by a distinct gene signature over-represented in EMT, TNF-alpha/NFKB, hypoxia and G2/M checkpoint signaling pathways. Clinically, $CD73^{high}$ status was an independent predictor of poorer prognosis in multivariate analysis ($p = 0, 03$) with ECOG PS ≥ 2 ($p = 0, 001$) and the pathological stage ($p = 0, 025$); consistently, the negative prognostic significance of CD73 was externally validated in transcriptome datasets of 436 resected BTC patients from three different cohorts globally (Dong et al., Jasakul et al., Nakamura et al.). Notably, $CD73^{high}$ tumours derived lesser benefit from adjuvant chemotherapy: relapse-free survival was 12.69 vs 6.54 months in chemotreated and non-chemotreated patients, compared to not reached vs 14.37 months in $CD73^{low}$ BTCs. In *in vitro* models, siRNA-mediated depletion and CRISPR-CAS9 gene KO of CD73 sensitized BTC 2D and 3D culture to cisplatin/gemcitabine treatment. Moreover, the pharmacological inhibition of CD73 by AMCP enhanced the sensitivity of BTC cell lines to cisplatin/gemcitabine treatment.
Conclusion: We demonstrated that $CD73^{high}$ disease represent a distinct BTC subtype characterized by an aggressive biological phenotype, resistance to standard chemotherapy and poorer prognosis. Interestingly, we provided proof-of-concept evidence that targeted genetic or pharmacologic inhibition of CD73 enhanced chemotherapy efficacy in both 2D and 3D in vitro models of BTC. The clinical targeting of this adenosinergic ectonucleotidase hold promises of improving the efficacy of the recently-established chemo-immunotherapy standard-of-care in BTC.

THU-252

Human cytomegalovirus (HCMV) infection of macrophages induced abnormal development of cholangiocytes in an organoid co-culture model for biliary atresia

Syed Mushfiqur Rahaman[1], Allen KL Cheung[2], Kenneth KY Wong[1], Paul KH Tam[3], Vincent CH Lui[1]. [1]*The University of Hong Kong, Surgery, Hong Kong, Hong Kong;* [2]*Hong Kong Baptist University, Biology, Hong Kong, Hong Kong;* [3]*Macau University of Science and Technology, Macao, Macao*
Email: u3007446@connect.hku.hk

Background and aims: Biliary atresia (BA) is a devastating biliary disease of neonates, but its pathogenesis is unclear. Human cytomegalovirus (HCMV) has been implicated to contribute to BA development from clinical association without mechanistic evidence. Macrophages mediate innate immune responses against HCMV infection. This study addresses how the interactions between HCMV, macrophages and cholangiocytes (bile duct epithelial cells) contribute to BA.
Method: Human induced pluripotent stem cell (iPSC)-derived macrophages infected by HCMV (multiplicity of infection = 1.0) and then cleansed of free viruses were co-cultured with iPSC-derived cholangiocytes in 1:1 ratio. We performed morphological examination; expression analysis of genes relevant for viral propagation/immune responses/cholangiocyte development; single cell RNA-

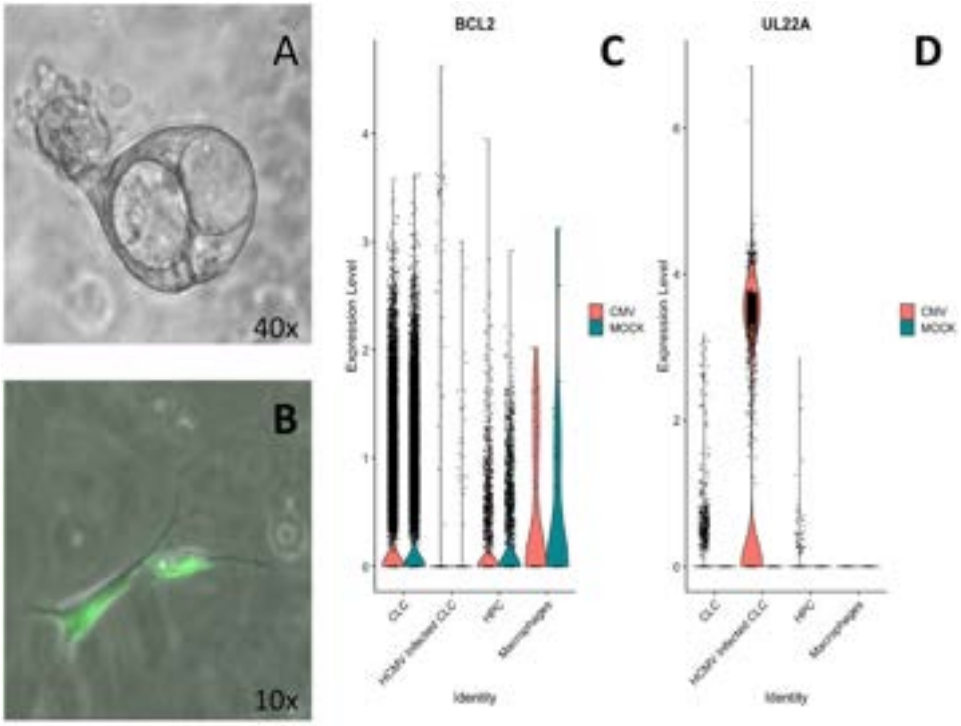

Figure: Microscopic and single cell view of the co-culture system. (A) Poorly expanded organoids with multiple vacuole morphology in the HCMV infected co-culture. (B) HCMV infected macrophages (green fluorescence) in the co-culture system. (C) Small cholangiocytes (BCL2-expressing) but not the large cholangiocytes (BCL2-non-expressing). (D) Viral gene UL22A was highly expressed in the large cholangiocytes. (CLC = Cholangiocyte like cell, HPC = Hepatic progenitor cell)

Figure: (abstract: THU-252).

sequencing (scRNA-seq) of infected and un-infected co-cultures at different post-infection days (PD).
Results: We detected expression of HCMV latent viral genes (UL138 and LUNA), elevated level of pro-inflammatory genes (IL-1β, TNF-α, CD86) in PD5 infected co-cultures; deformed cholangiocyte organoids in PD7 infected co-cultures. Bioinformatics analysis of the scRNA-seq data on PD5 co-cultures revealed two clusters of cholangiocytes (BCL2-expressing small cholangiocytes and BCL2-non-expressing large cholangiocytes). Viral genes were highly expressed in the large cholangiocytes, suggesting that large cholangiocytes were susceptible to HCMV infection. Moreover, we detected downregulation of cholangiocyte markers (KRT19, KRT18, KRT7, KRT8, EPCAM), pro-apoptotic genes (BAX and CYCS), and pro-apoptotic pathways (MYC-target v1, oxidative phosphorylation and reactive oxygen species pathway) in HCMV-infected cholangiocytes.
Conclusion: Our data showed that (i) HCMV-infected macrophages could transfer the virus to the large cholangiocytes; (ii) HCMV-infected cholangiocytes exhibited dysregulated cholangiocytic development; (iii) HCMV-infection induced upregulation of pro-inflammatory genes. HCMV infection could cause abnormal development of bile duct epithelium, promote inflammatory responses in the liver and contribute to disease initiation/progression of BA.

THU-253

Bacterial vesicles associated virulence factors and epitope mimics in autoimmune hepatitis patients

Swati Thangariyal[1], Chhagan Bihari[2], Aakriti Jain[3], Manish Kumar[3], Guresh Kumar[1], Shiv Kumar Sarin[4], Sukriti Sukriti[1]. *[1]Institute of Liver and Biliary Sciences, Molecular and Cellular Medicine, New Delhi, India; [2]Institute of Liver and Biliary Sciences, Department of Pathology, New Delhi, India; [3]University of Delhi, Department of Biophysics, New Delhi, India; [4]Institute of Liver and Biliary Sciences, Department of Hepatology, New Delhi, India*
Email: sukritibiochem@gmail.com

Background and aims: Autoimmune Hepatitis (AIH) is a self-perpetuating, non-resolving hepatic inflammation of unknown cause. Possible mechanism could be epitope mimicry, where antigen shares sequence similarity with self-antigens. We aim to investigate bacterial vesicles BV proteins associated with virulence factors, epitope mimicry, and their role in inducing autoimmune like condition.
Method: Fractionated pre-therapy plasma of AIH patients [n = 61, biopsy proven, Hepatic Activity Index (HAI) score >2, ALT (148 ± 58.4); AST (160.7 ± 60.2)] and healthy controls (HC) n = 30 for BVs using density gradient ultracentrifugation. Confirmed by transmission electron microscopy, western blot of OMP-A and nanoparticle tracking assay. The BV associated proteins were assessed by

proteomics, which was further mapped for virulence factors (VF) using VFDB database (mgc.ac.cn/VFs/main.htm) and epitope mimicry using miPrepbase (proteininformatics.org/mkumar/mipepbase/) (database of experimentally verified mimicry peptides for both host and pathogen). Further, AIH and Healthy (HC)BV were adoptively transferred intravenously in C57BL/6J female mice. The biochemical, histological and molecular markers of hepatic injury were investigated. The immune cells infiltration was estimated in liver, spleen and whole blood using flow cytometry.

Results: Plasma BV were significantly higher in AIH patients than HC [10.5 vs 3.7; p = 0.003, 87.7 vs 10.3;p = 0.015]. Also, the AIH plasma BEVs progressively increase with increasing Histological Activity Index score[r = 0.62;p = 0.001], transaminases {ALT, AST[r = 0.59;p = 0.001, r = 0.57;p = 0.001]} and IgG antibodies [r = 0.37;p = 0.018]. Based on BV associated proteins identified by proteomics, upon VF mapping, we found 23% of proteins were associated with virulence factors mainly the elongation factors in AIH plasma, whereas 0% in HC-BV (p = 0.0009). Depending on the number of residue and homologues sequences, miPrepbase mapping identified an experimentally verified peptide sequence IYQIDNHQQARKPIAD of methyltransferase family mimicking component of pyruvate dehydrogenase complex of the host mitochondria. Next, upon AIH-BV administration in WT mice within 12 h, the liver enzymes, Liver weight index were elevated [AST (p = 0.0286); ALT (p = 0.0452); LI (p = 0.008)] than HC-BV. The liver histology showed *raised* focal acute inflammation in AIH-BV than HC-BV (p < 0.001) with significantly high infiltration of F4/80^{+} macrophages and Ly6G^{+} neutrophils in the liver (p < 0.001).

Conclusion: Patients with AIH carry 23% of virulence factors in BV associated proteins and associated Methyltransferase family as the epitope of pyruvate dehydrogenase complex. Also, AIH-BV upon adoptive transfer in WT mice induce AIH-like systemic inflammation, suggesting a role of bacterial products carried through BVs in the pathogenesis of autoimmune hepatitis.

THU-254

Transcriptomic analysis of biliary atresia finds ongoing hepatic hematopoiesis with elevated IGF2

Jake Mann[1], Ye Htun Oo[2], Girish Gupte[1], Philip N Newsome[2].
[1]*Birmingham Children's Hospital, Liver Unit, Birmingham, United Kingdom;* [2]*University of Birmingham, Centre for Liver Research, United Kingdom*
Email: jpmann.gsy@gmail.com

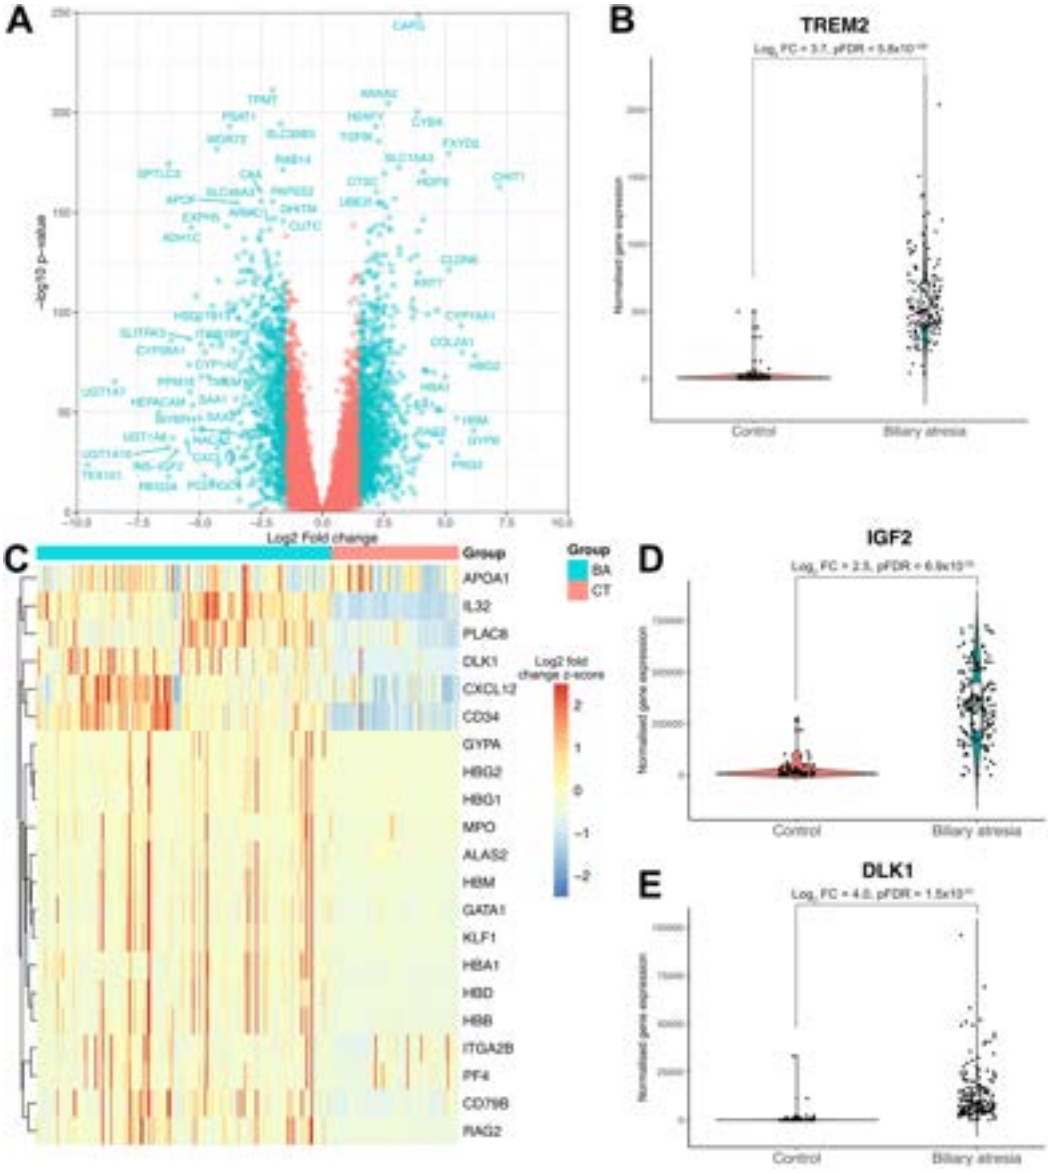

Figure: (abstract: THU-254).

Background and aims: Recent single-cell transcriptomic data has implicated foetal immune cells in the pathogenesis of biliary atresia (BA) with the role of immature B-cells in the postnatal liver particularly remaining unclear. To understand the mechanisms behind this, we performed a meta-analysis of RNA sequencing data from infants with BA at the time of Kasai and age-matched controls. Previous analyses had been limited by small numbers of controls; however, here, we have increased power to detect associations.
Method: We obtained transcriptomic data from n = 177 children with BA and n = 78 controls from Gene Expression Omnibus. After filtering and quality control, we performed differential gene expression analysis comparing BA versus control (using DESeq2), with p value adjustment for multiple testing.
Results: We identified 1,815 significantly differentially expressed genes (Fig. 1A). Many were involved in extracellular matrix remodelling/fibrosis (e.g. *CAPG*, *TGFBI*) and phagocytic activity (e.g. *CHIT1*, *CYBA*). We observed increased expression of *TREM2* (Fig. 1B), which is implicated in profibrogenic scar-associated macrophages in adults and has not previously been described in children. Patients with BA had increased expression of multiple markers of haematopoiesis, including erythroid lineage (e.g. *GYPA*, *HBA1*) and early B-cell (e.g. *RAG2*) (Fig. 1C). We identified up-regulation of insulin-like growth factor 2 (*IGF2*, log2 fold change 2.5, pFDR = 2.8×10^{-40}, Fig. 1D). *IGF2* is a growth factor for haematopoietic stem cells in the foetal liver. IGF2 is secreted by hepatocyte progenitors and we observed upregulation of markers of these progenitors (e.g. *DLK1*, Fig. 1E).
Conclusion: Postnatal liver haematopoiesis is active in children with BA but not controls, and we speculate that interactions between haematopoietic and other immune cells may exacerbate intrahepatic injury in BA. These data suggest that immature B cells production may be driven by *IGF2* secreted by hepatocyte progenitors. Future mechanistic studies exploring interaction of immature immune cells and extracellular matrix remodelling by macrophages will provide pathogenesis mechanism of biliary injury in biliary atresia.

THU-255

Immune cell incompetence and hepatocyte differentiation defects explain mild fibrosis in a model of Alagille syndrome

Jan Mašek[1,2], Iva Filipovic[3], Simona Hankeova[2], Jingyan He[2], Noémi K. M. Van Hul[2], Lenka Belicova[2], Anna Maria Frontino[1], Markéta Jiroušková[4], Daniel Oliveira[1], Fabio Turetti[1], Igor Cervenka[2], Lenka Sarnová[4], Elisabeth Verboven[2], Tomáš Brabec[1], Niklas Björkström[3], Martin Gregor[4], Jan Dobeš[1], Emma Andersson[2].

Email: jan.masek@natur.cuni.cz

Background and aims: Alagille syndrome (ALGS), caused by mutations in the Notch ligand *JAGGED1*, presents with cholestasis due to bile duct paucity. Remarkably few patients develop severe fibrosis or cancer, while recurring infections are common. Notch regulates liver and immune system development, but how these interact in ALGS is unknown. We aimed to determine whether *Jag1* regulates the immune system in a model of ALGS, and how this affects inflammation and liver disease progression.
Method: In a cancer-prone genetic background, fibrosis and liver cancer prevalence were analysed in Jag1Ndr/Ndr mice, an ALGS mouse model Liver cell populations were analysed using single-cell transcriptomics, and liver, thymus and spleen with flow cytometry. Immune cell function was tested using adaptive immune cell transplantation into *Rag1*$^{-/-}$ mice, challenged with dextran sulphate sodium (DSS, ulcerative colitis model), 3,5-Diethoxycarbonyl-1,4-Dihydrocollidine (DDC, hepatocellular cholestasis) or bile duct ligation (BDL, biliary cholestasis).
Results: Forty-five percent of *Jag1*$^{+/+}$ mice on C3H/C57bl6 background developed liver tumors, but no *Jag1*$^{Ndr/Ndr}$ mice developed tumors. Instead, *Jag1*$^{Ndr/Ndr}$ mice developed mild, ALGS-like, chicken-wire hepatocellular fibrosis, delayed hepatocyte differentiation with blunted cholestasis-induced inflammation, and decreased liver infiltration of $CD4^+$ T cells. The splenic $CD4^+/CD8^+$ T cell ratio and Regulatory T-cell numbers were increased. Transplanted *Jag1*$^{Ndr/Ndr}$ lymphocytes were less reactive in a model of ulcerative colitis, with reduced $CD4^+$ and $CD8^+$ T-cell activation. Finally, *Jag1*$^{Ndr/Ndr}$ lymphocyte-transplanted *Rag1*$^{-/-}$ mice subjected to BDL, but not DDC, displayed three-fold less periportal fibrosis than *Jag1*$^{+/+}$-transplanted *Rag1*$^{-/-}$ mice.
Conclusion: *Jag1* mutation results in delayed hepatocyte differentiation blunting inflammatory signaling. *Jag1* regulates immune cell development and competence, modifying the response to bacterial infection and cholestatic liver insult. The compromised immune response of thymocytes leads to milder-than-expected fibrosis. Our study shows that the immune system interacts with liver disease to modulate fibrosis, in an insult-specific manner, with implications for progression to liver cancer. The compromised immunocompetence further concurs with the reported frequent infections in patients with ALGS. Whether Notch-modulating agents could be utilized to fine-tune fibrosis and prevent liver cancer is thus a key question for future research.

THU-256

SARS-CoV-2 productively infects human hepatocytes and induces cell death

Cho-Chin Cheng[1], Chunkyu Ko[1,2], Shubhankar Ambike, Julia Sacherl[1], Stoyan Velkov[1], Bo-Hung Liao[1], Romina Bester[1], Merve Gültan[1], Constanze Jakwerth[3], Carsten Schmidt-Weber[3,4], Joachim Bugert[5], Roman Wölfel[5,6], Vincent Grass[1], Sandra Essbauer[5], Oliver Keppler[4,7], Carolin Mogler[8], Florian Vondran[6,9], Andreas Pichlmair[1,6], Ulrike Protzer[1,6].

Email: protzer@tum.de

Background and aims: Growing evidence suggests a liver tropism of SARS-CoV-2. However, it is unknown whether SARS-CoV-2 directly infects primary hepatocytes, how the virus enters the cell, and whether and to which extent the virus replicates and is cytopathic in hepatocytes. We therefore characterized the features of hepatic SARS-CoV-2 infection.
Method: We analyzed mRNA and protein expression of two major cellular entry factors of SARS-CoV-2, ACE2 and TMPRSS2, in primary human hepatocytes (PHH) and hepatoma cell lines and investigated permissiveness to SARS-CoV-2 and the capacity to replicate and spread the virus. Virus-induced cytopathic effect was monitored by real-time live-cell imaging.
Results: PHH and hepatoma cell lines express ACE2 and TMPRSS2, and their expression levels are comparable to those of lung-derived epithelial cells. Upon SARS-CoV-2 infection of hepatocytes with European lineage B.1.177 or Omicron sublineage BA.1, viral markers were readily detectable, whereas remdesivir treatment reduced viral load by 1.8–4.0 $\log_{10}$, indicating productive replication. Knockdown of ACE2 or TMPRSS2 in hepatocytes impaired virus replication, corroborating the use of the canonical entry pathway exploited by SARS-CoV-2 in cells of the respiratory tract. Progeny viruses shedded by infected hepatocytes showed the typical coronavirus morphology with “crown-like” appearance and induced plaques after secondary

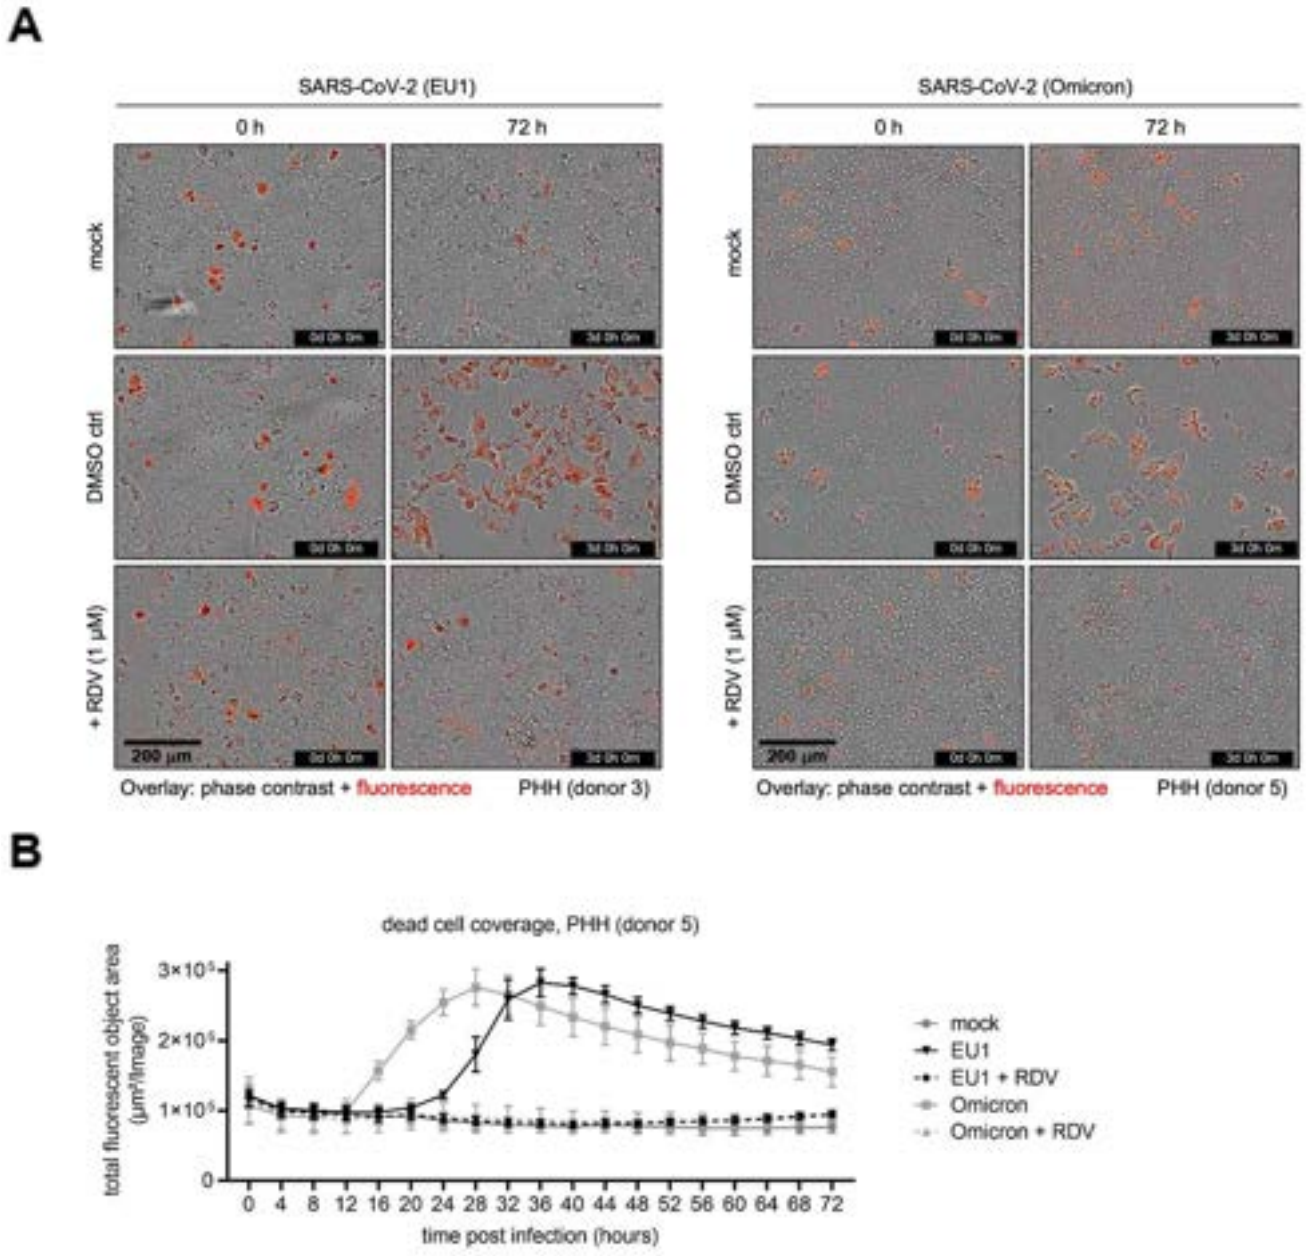

Figure: (abstract: THU-256).

infection, indicating that hepatocytes can support the complete SARS-CoV-2 replication cycle and may thus contribute to virus spread outside of the respiratory tract. Furthermore, SARS-CoV-2 infection of hepatocytes was cytopathic, suggesting that liver damage observed in COVID-19 patients may result from virus-induced cytotoxicity.
Conclusion: SARS-CoV-2 productively infects human hepatocytes via ACE2 and TMPRSS2 and induces hepatocyte death. Our findings help to explain hepatotropism of SARS-CoV-2 and liver damage observed in COVID-19 patients.

THU-257
Characterizing the role of human cytomegalovirus infection associated with biliary atresia

Zuodong Ye[1], Vincent CH Lui[2], Allen KL Cheung[1]. [1]*Hong Kong Baptist University, China;* [2]*The University of Hong Kong, China*
Email: akcheung@hkbu.edu.hk

Background and aims: Congenital Human cytomegalovirus (HCMV) infection cause a broad spectrum of neonatal diseases including biliary atresia (BA), which is the major cause of infantile obstructive jaundice. Although previous studies have implicated a correlation between HCMV and BA, the pathogenesis of HCMV associated BA remains poorly understood. This study aims to illustrate the intrinsic link between HCMV infection and BA and elucidate the molecular mechanism of HCMV-associated BA.
Method: Liver tissue with BA and non-BA (choledochal cysts [CC] and hepatoblastoma [HB]) were used to perform DNAscope assay to detect HCMV-DNA. Moreover, human induced pluripotent stem cell (iPSC)-derived cholangiocyte-like cells (CLC) organoids were used to establish a direct HCMV infection model to investigate the role of HCMV in the development of BA. Mock and HCMV-infected CLC organoids were used to examine morphological features, mode of virus infection and bulk RNA-seq analysis.

Results: A total of 49 human liver tissues (29 with BA and 20 with non-BA) were investigated for HCMV infection. Among them, 19 of BA (65.5%) and 7 of non-BA (35%) were HCMV-DNA positive. The infection of CLC organoids by HCMV strain TB40/E encoding enhanced green fluorescent protein (TB40/E-eGFP) resulted in reduced organoid growth and induced deformation. DNAscope data showed an overall higher presence of HCMV-DNA than GFP^+ cells in infected CLC organoids. Very lower virions production in the supernatant of infected CLC organoids was observed. Bioinformatics analysis of the bulk RNA sequencing data showed that the differential expression genes (DEG) between mock and HCMV infected organoids are highly enriched in the epithelial-mesenchymal transition (EMT) pathway. qRT-PCR and immunostaining data verified that HCMV infection decreased the E-cadherin expression and increased N-cadherin expression. Moreover, HCMV infection induced upregulation of pro-inflammatory genes.
Conclusion: Our data showed that: (1) higher percentage of HCMV infection in BA patients than non-BA patients and HCMV infection is closely related to BA pathogenesis; (2) HCMV infection of CLC organoids exhibited low-level productive or persistent infection; (3) HCMV infection promoted the EMT process of CLC organoids. The persistence of HCMV infection likely induce inflammation and EMT that contribute to the development of BA.

THU-258
Rescue of PKU disease phenotype using hepatic progenitor by cytosine base editor and prime editor in vitro
Myounghoi Kim[1,2], Sung-Ah Hong[3], Hayoon Kim[1,2], Elsy Soraya Salas Silva[1,2], Michael Adisasmita[1,2], Ji hyun Shin[1,2], Sangsu Bae[4], Dongho Choi[1,2]. *[1]Hanyang University College of Medicine, Korea, Rep. of South; [2]Hanyang University, Research Institute of Regenerative Medicine and Stem Cells, Korea, Rep. of South; [3]Seoul National University College of Medicine, Genomic Medicine, Korea, Rep. of South; [4]Seoul National University College of Medicine, Department of Biomedical Sciences, Korea, Rep. of South*
Email: crane87@hanyang.ac.kr

Background and aims: Phenylketonuria (PKU) is an autosomal recessive liver disease caused by point mutation. The PKU patient suffers from seizures, skin rashes, and a musty odor in the breath, skin, or urine due to highly accumulated L-phenylalanine (L-Phe) in the blood by the dysfunction of phenylalanine hydroxylase (Pah). Genome editors such as cytidine base editor (CBE) and prime editor (PE) promise great precise and safe editing of DNA. The CBE converts cytosine to thymine (C > T) using deaminase and the prime editor corrects multiple nucleotides (~80 bp) using reverse transcriptase. To overcome genetic-based PKU diseases, genome editors are powerful treatments option.
Method: Mouse primary hepatocytes (mPHs) were isolated from the PKU disease mouse model liver. To generate mouse chemically derived hepatic progenitors (mCdHs), the mPHs were cultured with a reprogramming medium for 7 days by Kim *et al* in 2019. The mCdHs were transfected with CRISPR-Cas9 and guide RNA (gRNA) plasmids by electroporation and performed sequencing of the *Pah* locus to validate the gene correction efficiency.
Results: We generated normal mCdHs (Pah+/+, Wild-mCdHs) and disease mCdHs (Pah-/-, Homo-mCdHs) to demonstrate the similar properties between them. Then, we transfected the editing tools into Homo-mCdHs and expanded them clonally to enhance the correction rate, demonstrating that the cytosine base editor (CBE) group increased the editing rate from 5.5% to 93%. Next, we used prime editor 3, PE3, and its modified version, PE5 to confirm the editing efficiency and showed a 5-fold increase in PE5 than PE3 (PE3, 1.8% to PE5, 10.7%) without clonal expansion. Finally, we analyzed the Tyr level in all hepatic differentiated groups (Wild-mCdH-Heps, Homo-mCdH-Heps, and Homo-edited-mCdH-Heps) and indicated

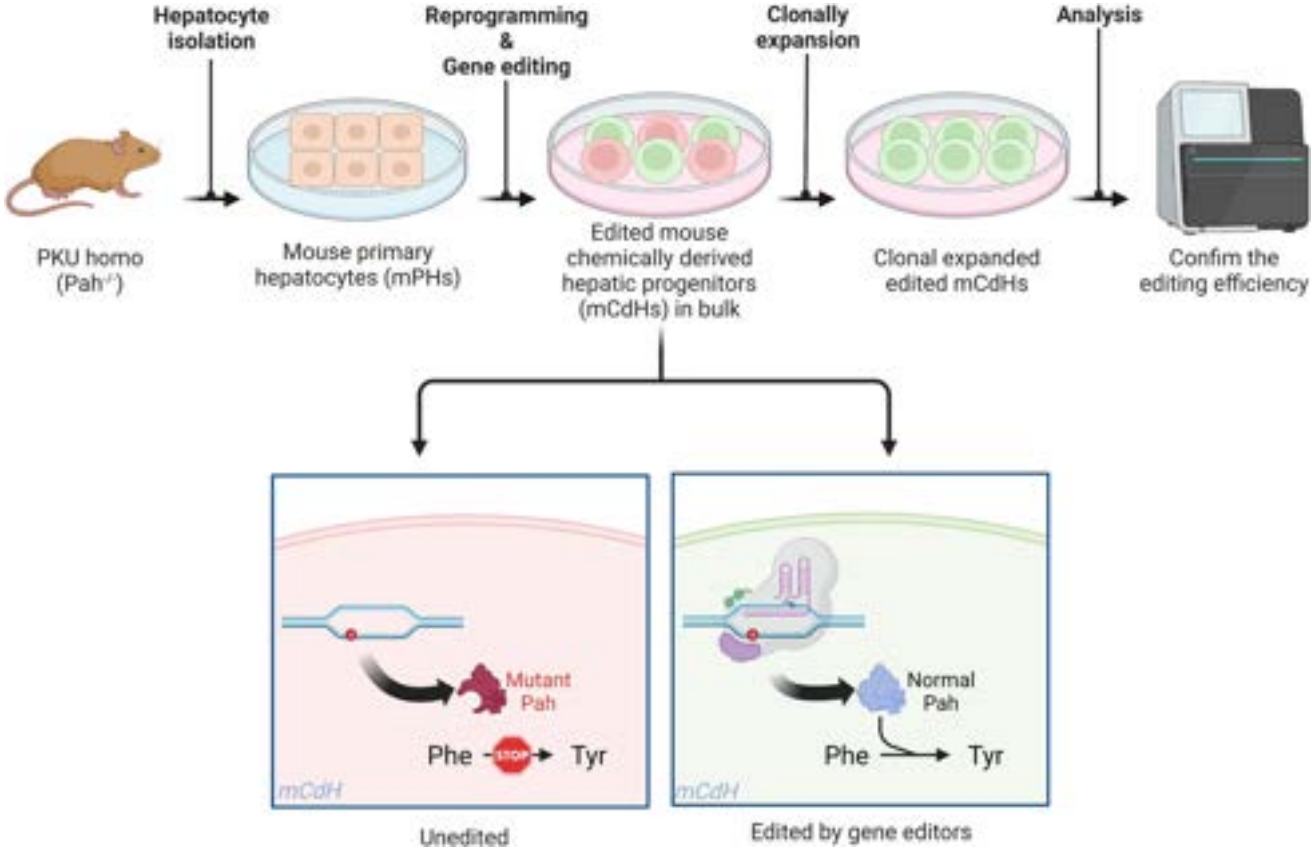

Figure: (abstract: THU-258).

increased Tyr level in the edited group indicating restoration of L-Phe metabolism.
Conclusion: These findings demonstrate an effective and safe gene editing system with high efficiency of gene correction and low frequency of insertion/deletion (indel) mutation for the rescue of PKU disease phenotype in vitro.
Supported by: This research is funded by grants from National Research Foundation of Korea (2021M3A9H3015390) and National Research Foundation of Korea (2022R1F1A1073058).

THU-259

ARBM-101 as an emerging potent therapeutic option for Wilson disease

Banu Akdogan[1], Eun-Jung Kim[2], Emilie Munk[3], Dasol Kim[2], Judith Nagel[4], Eok Park[2], Byong-Keol Min[2], Hongjae Lee[2], Dongsik Park[2], Chunwon Jung[2], Weonbin Im[2], So-Young Eun[2], Jeremy Semrau[5], Alan DiSpirito[6], Simon Hohenester[7], Thomas Damgaard Sandahl[3], Hans Zischka[1,4]. *[1]Helmholtz Munich, Germany; [2]ArborMed Co. Ltd, Korea, Rep. of South; [3]Aarhus University Hospital, Denmark; [4]Technical University Munich, Germany; [5]University of Michigan, United States; [6]Iowa State University, United States; [7]LMU Munich, Germany*
Email: zischka@helmholtz-muenchen.de

Background and aims: Wilson disease (WD) is a rare genetic disorder manifested by acute or chronic liver dysfunction due to copper overload. WD is caused by failure of copper homeostasis in the liver due to disruptive mutations of a copper transporter, ATP7B. Current copper-chelating drugs in clinical use cannot promptly reduce liver copper levels to a normal physiological range. Besides unwanted drug reactions and non-adherence issues, the progression of liver disease is frequently inevitable due to copper toxicity, representing a highly unmet medical need. As previously introduced, methanobactins are natural, bacteria- originated, high-affinity copper chelators. Here we present our recent data on ARBM-101, also known as Methanobactin-SB2, demonstrating its superior therapeutic efficacy in WD rats, insights into its mode of action and its mobilization paths and studies on its unique safety profile at cellular and molecular levels.

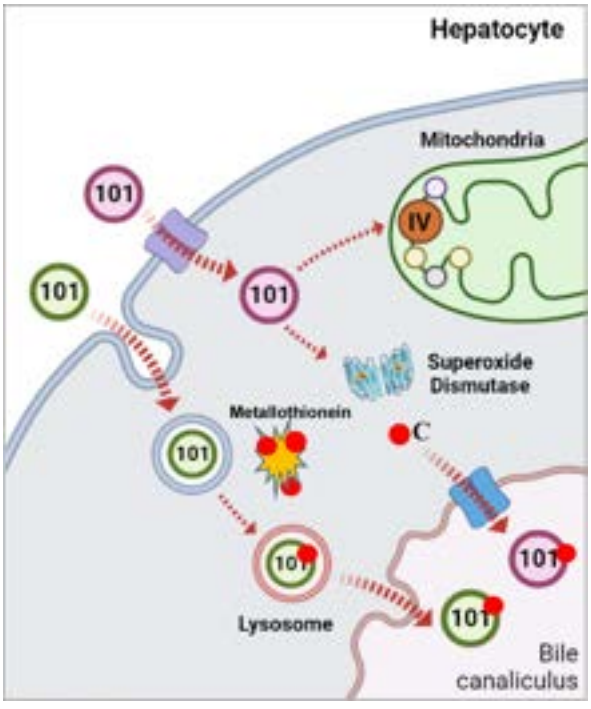

Figure: Potential hepatocyte mechanisms of ADME of ARBM-101.

Method: "LPP" (*Atp7b*$^{-/-}$) rats, an established WD model, were tested for rescue of severe liver damage by ARBM-101. We assessed animals' body weight, faecal, urinary, and hepatic copper levels, as well as plasma levels of liver transaminases and bilirubin. Copper distribution, mobilization, and excretion patterns by ARBM101 were studied by PET-scans in live animals using ^{64}Cu. HepG2 cell lines with or without intact ATP7B were tested for impacts of ARBM-101 on copper-dependent enzymatic activities (e.g., SOD1). In the same cells, we investigated ADME of ARBM-101 using ARBM-101-specific monoclonal antibodies and quantified copper levels using ICP-MS.
Results: As recently introduced, ARBM-101 demonstrated its superior efficacy of reducing copper overload from WD rat livers. Its uniqueness is in its rapid removal of excess copper via biliary/fecal excretion accompanied by profound ameliorations in liver function. PET-scans further validated these results. *In vitro* cellular assay results, including enzyme activity assays, revealed a strong safety profile of ARBM-101 as well as providing first clues on its ADME.
Conclusion: Our data highlight an unprecedented therapeutic potential with a convincing safety profile of ARBM-101 as an emerging potent therapeutic option for WD.

THU-260

Novel pathogenic ABCC2 variants identified in patients with Dubin-Johnson syndrome and further functional evidence in abnormal bilirubin metabolism

Wenting Tan[1], Yunjie Dan[1], Xing Wan[1], Weiwei He[1], Josiah T. George[1], Yan Zhu[1], Xiaomei Xiang[1], Yi Zhou[1], Guohong Deng[1]. *[1]Department of Infectious Diseases, Southwest Hospital, Third Military Medical University, China*
Email: gh_deng@hotmail.com

Background and aims: Dubin-Johnson syndrome (DJS) is an inherited disorder of bilirubin metabolism, characterized by conjugated hyperbilirubinemia, darkly pigmented liver and presence of brown pigment in hepatocytes due to defective bilirubin excretion into bile. This rare condition is caused by mutation in *ABCC2* gene which encodes the transmembrane protein MRP2 acting as a transporter in bilirubin metabolism. However, only a few pathogenic variants were identified. In this study, we aimed to investigated mutation spectrum and related functional explanation for this condition.
Method: An idiopathic jaundice cohort with 229 patients who visited our hospital between Oct 2017 to Sep 2022 were included in this study. We developed a targeted next-generation sequencing panel in which 43 disease-causing genes known to be associated with inherited metabolic liver disease were involved in, including those resulting in unconjugated (*UGT1A1* for Gilbert syndrome, Crigler-Najjar syndrome) and conjugated hyperbilirubinemia (*ABCC2* for DJS, *SLCO1B1* and *SLCO1B3* for Rotor syndrome). All patients applied this panel to explore relevant causing mutations and identify DJS patients as well as its mutation spectrum. Furthermore, we investigated how the *ABCC2* variants affect the function of MRP2 protein in terms of their production, location, and transport activities in HEK293T cells by construction MRP2 expression plasmids with candidate mutations.
Results: Among all patients, 11 cases were diagnosed as DJS (7 males) by biopsy and genetic test. The median age was 26 years (range 18–51 years). All of them had conjugated hyperbilirubinemia with a median DBIL level of 57.1 μmol/L (32.2–119.0 μmol/L) and total serum bilirubin levels of 128.3 μmol/L (64.8–170.2 μmol/L), meanwhile with normal liver enzyme, kidney and coagulation function. In accordance with the ACMG guidelines, we identified 12 pathogenic variants on *ABCC2*, as follows, of which 11 are novel including six frameshift variants which finally resulting protein translation termination (Y39fsX40, I452fsX11, A1413fsX49, S1417fsX13, E1462fsX7, I1512fsX11), two nonsense (Y1275X, R911X), three missense (V1419G, R393W, ITI1489_1491GPQ), and one previously reported pathogenic splice donor mutation (c.1815+2T>A). We

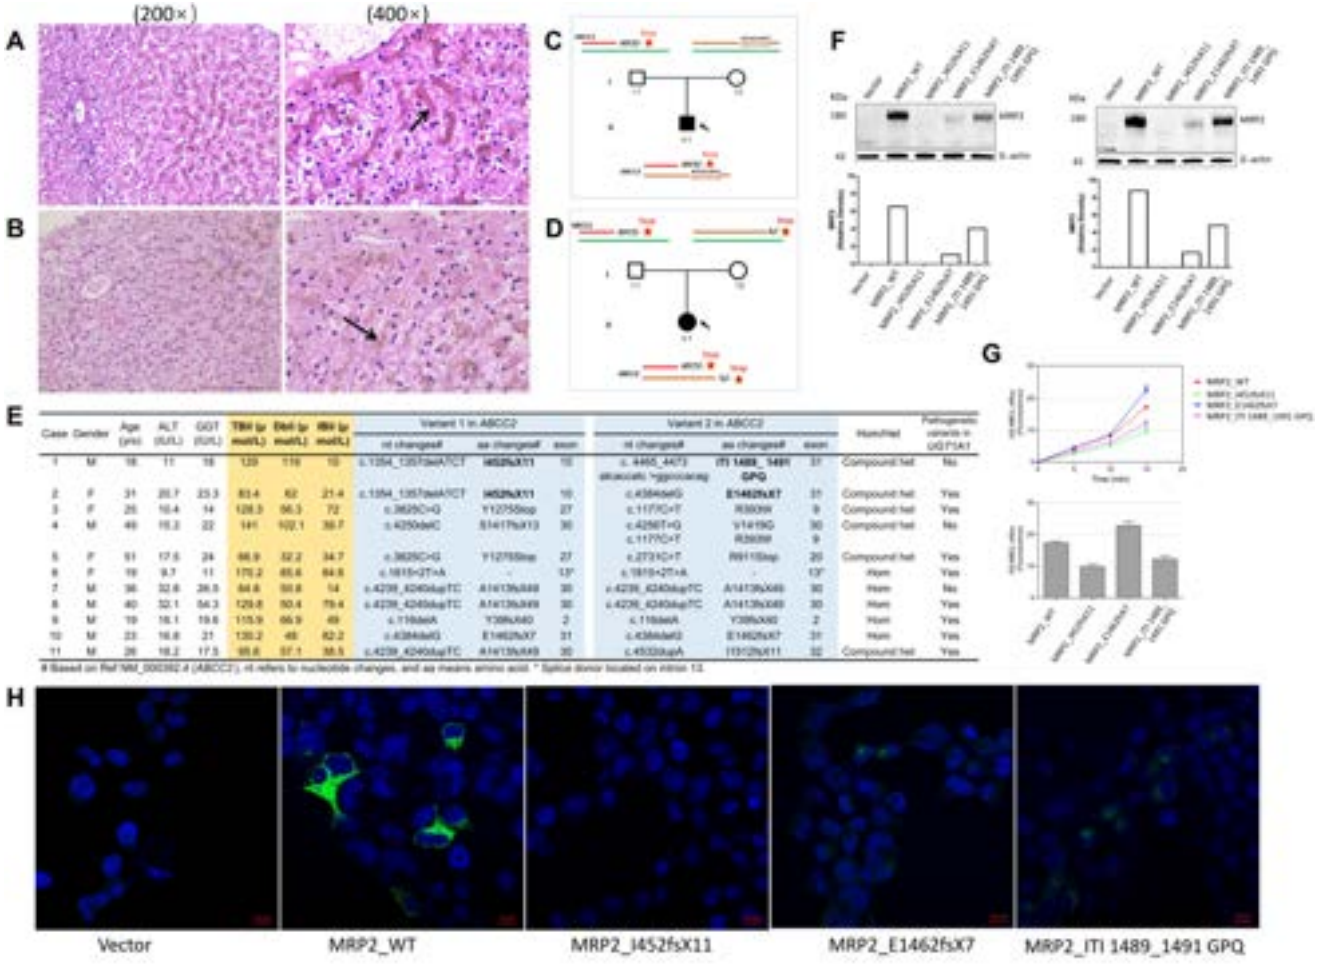

Figure 1. Novel pathogenic ABCC2 variants identified in patients with Dubin-Johnson syndrome and functional analysis. **A-B**: Liver biopsies stain for DJS Case 1 (A) and Case 2 (B), large amounts of pigment deposits found in the hepatocytes, and extensive intrahepatic cholestasis, no evidence of fibrosis was observed. **C-D**: Genogram and mutation patterns for DJS Case 1 (C) and Case 2 (D). Affected individuals are denoted by solid symbols. The mutations were inherited from father and mother respectively for both pedigrees. **E:** Summary of the basic characteristics and pathogenic variants detected in the 11 DJS patients. e.g., I452fsX11 indicates amino acid changed at 452 (Isoleucine, I) due to frameshift mutation and resulting translation termination after 11 amino acids shifting (stop at 453aa). **F:** Western blot analysis of mutant (I452fsX11, E1462fsX7 and ITI 1489_1491 GPQ) MRP2 expressed in HEK293 cells, showing decreased or none protein production. Loading 0.8 μg (left) and 1.6 μg (right) protein. **G:** Export of glutathione-conjugated monochlorobimane (GS-MCLB) by mutant MRP2 from HEK293 cells showing decreased transport activity. **H:** Indirect immunofluorescence for subcellular distribution of mutant MRP2 in HEK293 cells by confocal laser scanning microscopy.

Figure: (abstract: THU-260).

established HEK293 cell lines expressing the first three identified DJS-related variants. Compared to the wild-type, expressed E1462fsX7 and ITI 1489_1491GPQ MRP2 (both in nucleotide-binding domain) were mislocated and mainly retained in the endoplasmic reticulum, meanwhile led to a 50% decreased protein production and 50% decreased transport activity, suggesting defective bilirubin excretion into bile in this condition. No MRP2 protein was expressed from HEK293 cells transfected with a 452fsX11 mutant (located at membrane-spanning domain), suggesting loss-of-function of transporting substrates like bilirubin. Additionally, 8 of

11 cases also presented known pathogenic mutations in *UGT1A1* gene, which suggested an explanation for their accompanying raised serum indirect bilirubin level.
Conclusion: We described here eleven novel pathogenetic ABCC2 mutations in DJS. The functional analysis indicated that these mutations caused deficient maturation and dysfunction/loss-of-function of MRP2 protein in transport activity. These results expand on the spectrum of ABCC2 mutations and provide further evidence that these mutations involved in the defective bilirubin excretion in DJS.

THU-261
Albumin levels are associated with portal hypertension in patients with porto sinusoidal vascular disorder
Lucia Lapenna[1], Simone Di Cola[1], Marco Mattana[1], Stefania Gioia[1], Manuela Merli[1]. [1]*Sapienza University Rome, Department of Translational and Precision Medicine, Italy*
Email: lucia.lapenna@uniroma1.it

Background and aims: Porto sinusoidal vascular disorder (PSVD) is a term recently introduced to identify a group of patients with a rare vascular liver disease characterized by hepatic sinusoidal and portal venules lesions, with or without portal hypertension. Little is known about the natural history of these patients and why some patients will develop specific signs of portal hypertension and others will not. The aim of this study was to investigate differences between these two groups: patients with clinically significant portal hypertension (PSVD/PH+) and patients without it (PSVD/PH-).
Method: we retrospectively evaluate data from 32 patients actively followed at our department with diagnosis of PSVD according to VALDIG criteria. T-test and Fisher statistical analysis were performed.
Results: 32 patients were identified. Among them 21 patients were men (66%) and mean age at diagnosis was 43.9 years. Nineteen patients were PSVD/PH+ and showed specific and non-specific signs of portal hypertension at diagnosis (mainly esophageal or gastric varices (75%)). Thirteen patients were PSVD/PH- with no specific signs of portal hypertension. No significant histological differences were observed between the two groups. Albumin levels at diagnosis were normal in all patients as expected, but PSVD/PH+ patients showed significantly lower albumin level compared to those PSVD/PH- (3.65 vs 4.27, $p < 0.05$, respectively) (Table 1). During a median follow-up of 131 ± 64 months, 5 patients in the PSVD/PH- group developed clinically significant portal hypertension. Interestingly, basal albumin level in this sub-group were significantly lower compared to the sub-group of patients that did not develop portal hypertension (3.72 vs 4.43 $p < 0.05$) in the same time frame.

Table:

Characteristics	PSVD/ PH+ (19)	PSVD/ PH- (13)	p value
Sex (M) n (%)	13 (68)	8 (61)	0.72
Age (yrs)	46 ± 17	39 ± 11	0.23
• Histological lesions			
• Obliterative portal venopathy	4	4	0.68
• Incomplete septal fibrosis	6	2	0.41
• Nodular regenerative hyperplasmia	5	2	0.67
• Portal tract abnormalities	17	11	0.99
• Perisinusoidal fibrosis	8	7	0.72
• Sinusoidal dilatation	10	10	0.26
Albumin at diagnosis (g/dl)	3.65 ± 0.45	4.27 ± 0.36	0.003

Conclusion: albumin level at diagnosis is associated with the presence of portal hypertension in PSVD patients, despite having the same histological lesions. Furthermore, it may predict which patients are more likely to develop specific signs of portal hypertension during the natural history of the disease. Further prospective studies are needed in order to confirm this evidence and to be able to implement a prognostic model for this rare disease.

THU-262
Genetic modifiers of liver phenotypes in pediatric Wilson disease: liver biopsy and transient elastography based study
Marcin Krawczyk[1,2], Wojciech Janczyk[3], Wiktor Smyk[4], Diana Kamińska[3], Piotr Milkiewicz[5], Susanne N Weber[1], Wieslawa Grajkowska[6], Maciej Pronicki[6], Piotr Socha[3]. [1]*Department of Medicine II, Saarland University Medical Center, Saarland University, Homburg, Germany;* [2]*Laboratory of Metabolic Liver Diseases, Medical University of Warsaw, Warsaw, Poland;* [3]*Department of Gastroenterology, Hepatology and Nutrition Disorders, The Children's Memorial Health Institute, Warsaw, Poland;* [4]*Department of Gastroenterology and Hepatology, Medical University of Gdansk, Gdansk, Poland;* [5]*Liver and Internal Medicine Unit, Medical University of Warsaw, Warsaw, Poland;* [6]*Department of Pathology, The Children's Memorial Health Institute, Warsaw, Poland*
Email: marcin.krawczyk@uks.eu

Background and aims: Wilson disease (WD) is a rare, chronic liver disease caused by mutations in the *ATP7B* gene leading to impaired copper metabolism. The progression of WD varies among patients, but fatty liver is present in most cases. In the current study, we investigate potential genetic modifiers of liver disease progression in children with WD, including fatty liver-associated polymorphisms.
Method: Prospectively, we recruited 84 children (boys 50%, mean age 9 ± 5 years) with WD. There were eight pairs of siblings in this cohort, and one sib from each was randomly picked for further analysis. Liver function tests, including copper metabolism parameters, were measured before the initiation of the treatment. A liver biopsy was conducted in 59 children at diagnosis of WD. During the follow-up (median 3.6 years, range 6 months-10 years), a total of 46 patients underwent non-invasive assessment of liver stiffness measurement (LSM) and controlled attenuation parameter (CAP). Genotyping of the seven variants known to modulate liver injury (i.e., *PNPLA3* p.I148M, *TM6SF2* p.E167 K, *MTARC1* p.A165 T, *HSD17B13* rs72613567, *MBOAT7* p.G17E, *ABCB4* p.T175A and *ABCB4* c.711) was performed using TaqMan assays with fluorescence detection. Genotype frequencies in WD patients were compared to 313 adult controls without liver diseases.
Results: A total of 79% of patients displayed steatosis S1-S2 in liver biopsy; fibrosis F2-F4 was present in 75% of patients, whereas 5% had no fibrosis at baseline. At the follow-up, the median LSM was 5.3 (range 3.1–9.0) kPa and CAP was 248 (range 171–363) dB/m. Patients with steatosis S0, S1, S2 and S3 in liver biopsies presented with increasing median CAP at the follow-up, i.e., 218, 240, 255, and 266 dB/m, respectively. The *TM6SF2* p.E167 K polymorphism was more frequent in children with WD ($p = 0.035$) as compared to controls. Carriers of this variant presented with higher CAP at the follow-up despite receiving WD treatment ($p = 0.04$). The *PNPLA3* polymorphism was linked with a trend of increased risk of developing steatosis ≥S2 (OR = 2.40 $p = 0.06$) at baseline. Finally, carriers of the variants associated with protection against fatty liver, namely *HSD17B13* and *MTARC1*, had lower risk of microsteatosis at liver biopsy (OR = 0.34, $p = 0.02$), and presented with a lower CAP at follow-up ($p = 0.01$), respectively.
Conclusion: Common genetic polymorphisms can modulate the course of WD in pediatric patients. Since steatosis is frequent in pediatric WD and persists during follow-up, testing of these genetic variants might help stratify patients risk of disease progression.

THU-263

In vivo adenine base editing reverts C282Y in an HFE- mouse model and improves iron metabolism

Simon Krooss[1], Alice Rovai[2], Michael Ott[1]. [1]*Medizinische Hochschule Hannover, Gastroenterology, Hepatology and Endocrinology, Hannover, Germany;* [2]*Medizinische Hochschule Hannover, Transfusion Medicine, Hannover, Germany*
Email: krooss.simon@mh-hannover.de

Background and aims: Hereditary Hemochromatosis (HH) is one of the most common genetic diseases in the European population, with a prevalence of 1:200/400. Among the four different types, the most common form is Type 1, a homozygous p.C282Y mutation in the HFE gene, in which a guanosine is replaced by an adenosine (c.845 G > A). This mutation results in the misfolding of the HFE protein, thereby losing its ability to work as a sensor for the iron content in the bloodstream. This can cause accumulation of iron in various organs, mostly in the liver, heart and pancreas, thus leading to the development of chronic diseases. Using adenine base editing, we aimed to correct this most common mutation *in vivo* in an HFE-mouse model.
Method: We have developed a precise and sensitive GFP-based reporter system to screen for potent adenine base editor gRNAs targeting the C282Y mutation in the HFE gene. Subsequently 129-Hfetm.1.1Nca mice were treated with an AAV8 split-vector coding for the adenine base editor ABE7.10 and a mutation-specific gRNA. After vector administration, animals were fed with iron-enriched chow and after 4 months, the experiment was terminated. Liver sections and blood parameters were analyzed for changes in iron-specific parameters.

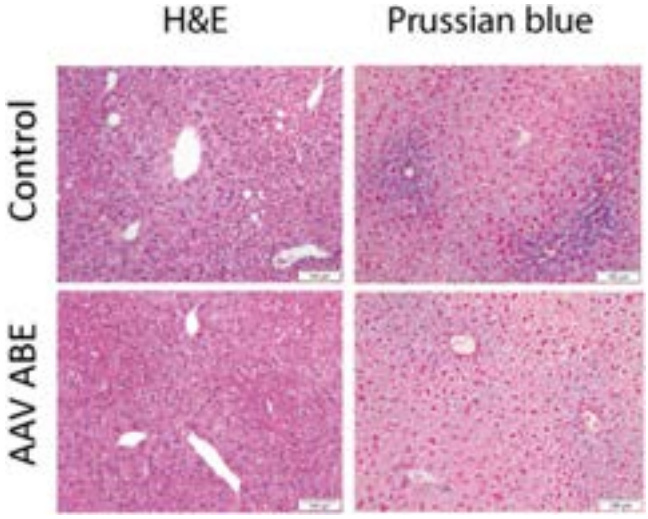

Figure 1: HandE and Prussian blue staining of liver sections obtained from 129-Hfetm.1.1Nca mice either untreated or treated by our AAV8-vector coding for the adenine base editor ABE7.10+gRNA.

Results: Upon a single low-dose (1×10^{11} vector genomes) injection of our therapeutic AAV8 vector, we achieved *in vivo* correction rates of 6.57 ± 2.31% and significant reduction of iron-specific parameters such as transferrin saturation, UIBC and hepcidin. Hepcidin expression of the treated animals was even comparable to healthy animals. Also on hepatic level, we observed significantly reduced iron accumulation detected via Prussian blue staining (Figure 1). After administration of a high vector dose (1×10^{12} vector genomes), we achieved an *in vivo* editing efficiency of 10.65 ± 1.24% and further reduction of hepatic iron accumulation as measured via Prussian blue staining. In addition, using RNAseq analysis of isolated hepatocytes, we could observe the beneficial effect of our therapeutic vector in highly iron-overloaded HFE-mice on transcriptional level.
Conclusion: Both low- and high dose administration of our therapeutic adenine base editing vector led to physiological levels of hepcidin in the blood and significant reduction of hepatic iron overload. Therefore, we consider our therapeutic approach as an important proof-of-principle for future *in vivo* gene correction therapies for monogenic liver diseases.

THU-264

Alpha-1 antitrypsin inclusions sequester 78 kDa glucose-regulated protein in a bile-acid inducible manner

Igor Spivak[1], Nurdan Gueldiken[1], Valentyn Usachov[1], Lei Fu[1,2], Fa-Rong Mo[1], Gökce Kobazi Ensari[1], Franziska Hufnagel[1], Malin Fromme[1], Christian Preisinger[1], Pavel Strnad[1]. [1]*University Hospital RWTH Aachen, Aachen, Germany;* [2]*Ruikang Hospital Affiliated to Guangxi University of Chinese Medicine, Nanning, China*
Email: ispivak@ukaachen.de

Background and aims: The homozygous PiZ mutation (PiZZ genotype) is the predominant cause of severe alpha-1 antitrypsin (AAT) deficiency and leads to liver disease via the polymerization and accumulation of AAT in hepatocytes. To better understand this relationship, we systematically analyzed the composition of AAT aggregates in mice and humans. Since a subset of PiZZ subjects develops neonatal cholestasis, we investigated the impact of cholic acid (CA) challenge in PiZ mice, an animal model of PiZZ-associated liver disease.
Method: AAT inclusions were isolated from PiZ mouse and PiZZ human livers via fluorescence-activated and immunomagnetic sorting (FACS/MACS), while Triton X-insoluble proteins were obtained through high salt extraction. Wild-type (WT) mice and individuals without AAT mutation (PiMM genotype) served as controls. Inclusion composition was evaluated by mass spectrometry (MS), immunoblotting, and immunostaining. Mice were administered 2% CA-supplemented chow for seven days.
Results: In insoluble fractions from PiZ mouse livers, MS identified the endoplasmic reticulum chaperone 78 kDa glucose-regulated protein (GRP78) as the most prominent non-AAT protein. This finding was confirmed via immunoblotting of insoluble fractions and reproduced in FACS/MACS isolates (panel A). In PiZ mice, CA-feeding resulted in higher serum liver enzymes than in their WT littermates (AST: 390 ± 680 vs. 180 ± 185 U/l, $p < 0.05$; ALT: 480 ± 241 vs. 213 ± 82 U/l, $p < 0.01$; AP: 170 ± 20 vs. 100 ± 43 U/l, $p < 0.01$; panel B) and higher levels of apoptotic hepatocytes (3.3 ± 0.5 vs. 1.2 ± 0.3 cells/200x-field; $p < 0.01$). This was accompanied by stronger retention of GRP78 in the AAT inclusions of CA treated versus untreated PiZ mice (32 ± 12% vs. 4.8 ± 5.2%.; $p < 0.05$; panel C) that was seen via immunoblotting and immunostaining, while the total AAT and GRP78 protein levels remained unaltered. The accumulation of GRP78 within AAT inclusions was confirmed in human PiZZ livers (panel D).
Conclusion: Our results demonstrate that GRP78 is a major constituent of AAT inclusions, and its increased retention after CA-feeding may promote cholestatic liver injury.

THU-265

Human induced pluripotent stem cells-derived hepatocytes: a very effective tool for functional studies of rare liver diseases

Benedetta Blarasin[1,2], Valentina Tiriticco[2], Sara Maggiore[1,2], Eva Dariol[1,2], Gabriele Codotto[1,2], Claudio Tiribelli[2], Cristina Bellarosa[2]. [1]*University of Trieste, Department of Life Sciences, Italy;* [2]*Fondazione Italiana Fegato-Italian Liver Foundation, Italy*
Email: benedetta.blarasin@fegato.it

Background and aims: Among the models for the study of rare liver diseases, established cell lines and primary hepatocytes have numerous limitations, including short survival time, incomplete cell polarization, and invasiveness. Induced Pluripotent Stem Cells (iPSCs) represent an important resource since they can be obtained from the patient in a non-invasive way, expanded indefinitely, and differentiated into hepatocytes, carrying the individual-specific genetic background. Moreover, iPSCs obtained from healthy donors are an ideal tool since they can be genetically modified using CRISPR-Cas9 technology, introducing specific disease-related mutations before differentiation into hepatocytes. This study aims to obtain human-derived, polarized, and genetically modifiable hepatocytes to study the molecular mechanisms and perform drug screening for rare hepatic diseases.

Method: iPSC-derived human hepatocytes were obtained from urine samples as described by Zhou (Nat Protoc, 2012, doi: 10.1038/nprot.2012.115) and Matakovic (Methods Mol Biol 2022, doi: 10.1007/978-1-0716-2557-6_4.). Urine was collected from healthy donors, children, and adults of both sexes. Exfoliated renal epithelial cells (i.e. urinary cells) were isolated from the specimen and characterized both morphologically and by RT-qPCR. Urinary cells were de-differentiated through lentiviral vector transduction containing the

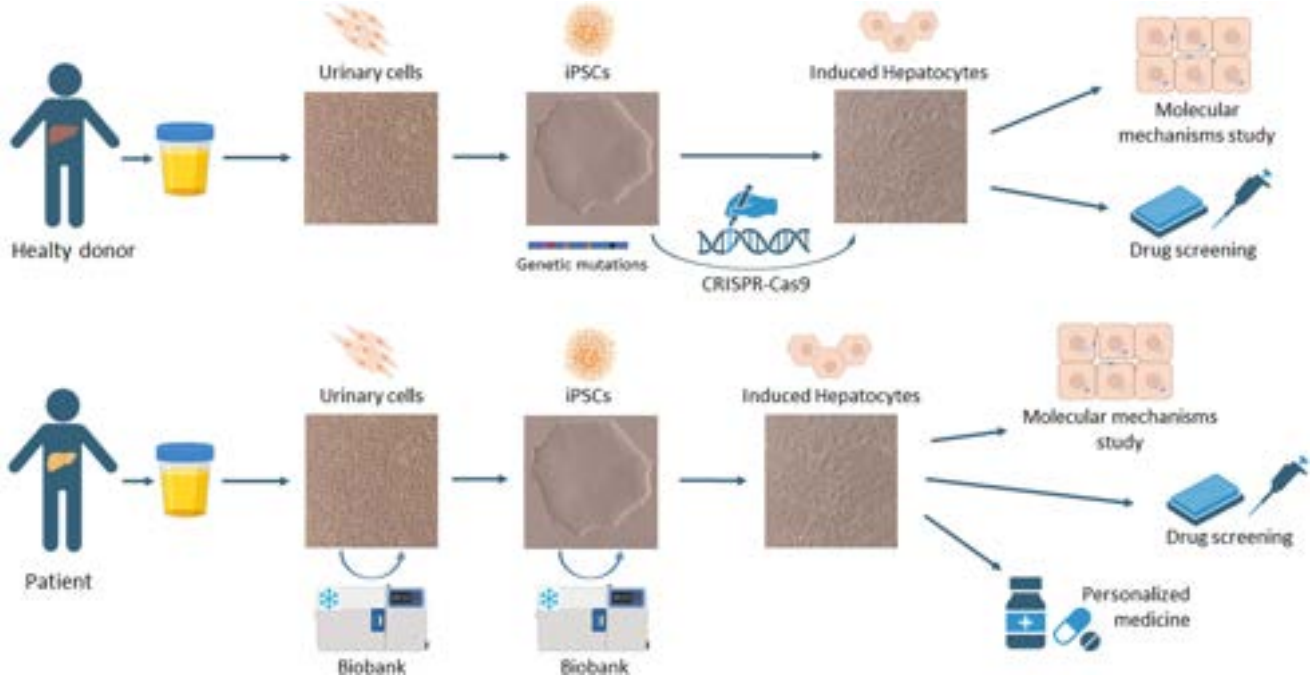

Figure: (abstract: THU-265).

four Yamanaka factors, maintained in culture until iPSC colonies appeared and characterized by RT-qPCR. Differentiation of iPSCs was obtained by sequential changing of culture mediums enriched with specific molecules and growth factors involved in the differentiation process (definitive endoderm, hepatic progenitors, and induced hepatocytes).

Results: Urinary cells m-RNA quantitative PCR analyses confirmed the positive expression of epithelial genes (claudin, E-cadherin) and renal tubular genes (L1CAM, NR3C2) together with the absence of fibroblast gene expression (SLUG). The cells showed to be resistant, enduring without problems with both passaging and thawing. Urinary cells de-differentiated into iPSCs presented the expression of embryonic genes (h-ERT, NANOG and LIN-28). iPSCs showed an unlimited replication potential and sustained repeated freezing and thawing cycles with success. The differentiation of iPSCs to definitive endoderm, hepatic progenitors, and induced hepatocytes was followed morphologically.

Conclusion: We obtained induced hepatocytes from urine-derived iPSC. This model will be used to insert specific disease-related mutations, to study the molecular mechanism of the disease, and to evaluate suitable treatments on iPSC -derived hepatocytes. Urinary cells and iPSCs could be used to establish a biobank. Unfortunately, the entire procedure requires a long time to be performed (2–3 months).

THU-266

Ancillary diagnostic biomarkers in autoimmune hepatitis

Chhagan Bihari[1], S Muralikrishna Shasthry[1], Shabir Hussain[1], Archana Rastogi[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver and Biliary Sciences, Delhi, India*
Email: drcbsharma@gmail.com

Background and aims: There are no specific tests for the diagnosis of autoimmune hepatitis, and it also has overlapping histological features with other conditions like primary biliary cholangitis (PBC), acute hepatitis (AH), drug-induced liver injury (DILI), and chronic hepatitis (CH). We aimed to identify the circulatory and histological repertoires that can serve as auxiliary tests for autoimmune hepatitis.

Method: Serum samples from age and gender matched treatment naïve histologically confirmed cases of autoimmune hepatitis (PBC, AH, DILI, CH, and healthy control, n = 10 each) were subjected to label-free proteomics analysis as a derivation phase. Uniquely expressed proteins in AIH were validated on age and gender matched different subsets of AIH, AH, DILI, CH (N = 50 each), and PBC (n = 26) by ELISA on serum samples and immunohistochemistry (IHC) on liver biopsies. These proteins were also assessed in seropositive and seronegative cases of AIH, and with the disease activity.

Results: In the initial analysis of autoimmune hepatitis as compared to disease and healthy controls, there were 41 differential proteins compared to CH, 28 compared to PBC, 86 compared to healthy controls, 37 to DILI, and 24 to acute hepatitis. After comparing all the groups, 5 uniquely different protein molecules were identified {afamin, epididymis tissue protein Li-173, gelsolin, vitronectin, and interferon alpha inhibitor Ig delta fc region (IGHD)}.On validation, serum samples of afamin, gelsolin, epididymal tissue protein Li-173, and vitronectin were high in AIH cases, whereas IGHD was lowest in AIH cases as compared to other groups (Fig 1A). Seropositive AIH cases (ANA+, ASMA+) had significant elevation of these proteins than seronegative AIH (Fig 1B) except IGHD, where it was lower in seropositive cases. On tissue IHC the expression of afamin, epididymal tissue protein, gelsolin, and vitronectin was most significant in AIH (Fig. 1C). In autoimmune hepatitis cases, serum levels of epididymis tissue protein and gelsolin correlated with histological activity index (HAI) ($r = 0.721$ and 0.616, $p < 0.001$), respectively.

Conclusion: Afamin, Epididymis tissue protein Li-173, Gelsolin, Vitronectin and IGHD can be used as non-invasive auxiliary biomarkers for the diagnosis and severity of autoimmune hepatitis.

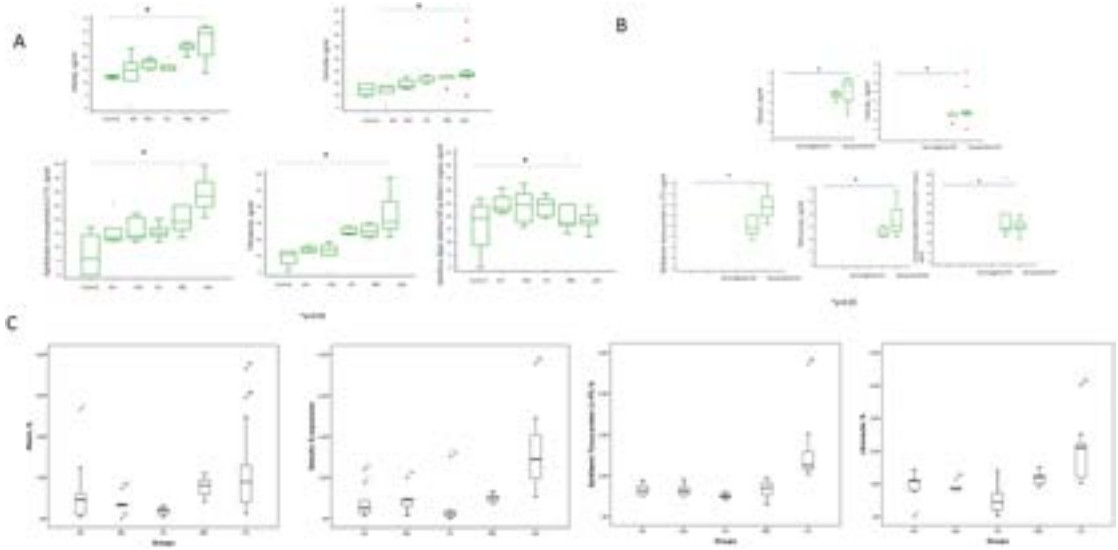

Figure: (abstract: THU-266): A: Serum levels of Afamin, Gelsolin, Epididymis tissue protein Li-173, vitronectin, interferon alpha inhibitor Ig delta fc region (IGHD) among the groups {acute hepatitis (AH), drug induced liver injury (DILI), chronic hepatitis (CH), primary biliary cholangitis (PBC) and autoimmune hepatitis (AIH). B Five protein levels in the serum of AIH based on seronegativity and seropositivity. C. Liver tissue expression of Afamin, Gelsolin, Epididymis tissue protein Li-173, vitronectin in AH, DILI, CH, PBC and AIH.

Identification of correctors for traffic-defective ABCB4 variants by a high-throughput screening approach

Mounia Lakli[1], Julie Dumont-Ryckembusch[2], Veronica Crespi[3], Julie Charton[2], Virginie Vauthier[4], Amel Ben Saad[1], Elodie Mareux[1], Manon Banet[1], Martine Lapalus[1], Emmanuel Gonzalès[1], Emmanuel Jacquemin[1], Florent Di Meo[3], Benoit Deprez[2], Florence Leroux[2], Thomas Falguières[1]. [1]*Université Paris-Saclay, UMR_S 1193 Inserm-Physiopathogenesis and Treatment of Liver Diseases, ORSAY, France;* [2]*Institut Pasteur de Lille, U1177 Inserm, University of Lille-Drugs and Molecules for Living Systems, Lille, France;* [3]*U1248 Pharmacology and Transplantation-Ω-Health Institute, Centre de Biologie et de Recherche en Santé-Université de Limoges, Limoges, France;* [4]*Sorbonne Université, Saint-Antoine Research Center, UMR_S 938 Inserm, Paris, France*
Email: thomas.falguieres@inserm.fr

Background and aims: The ABCB4 (ATP-binding cassette subfamily B member 4) transporter, also known as multidrug resistance protein 3 (MDR3), is a transmembrane protein located at the canalicular membrane of hepatocytes and it ensures the secretion of phosphatidylcholine into bile canaliculi. Phosphatidylcholine is a fundamental component of bile. Through the formation of mixed micelles, it allows the solubilization of cholesterol and the protection of the biliary epithelium from the detergent action of bile salts. Many missense variations in the *ABCB4* gene cause several rare cholestatic diseases, the most severe one being progressive familial intrahepatic cholestasis type 3 (PFIC3), which appears during the first years of life and can evolve into cirrhosis and liver failure before adulthood. To date, more than 50% of patients do not respond to conventional treatments, making liver transplantation the ultimate alternative therapy. Thus, this research project is dedicated to characterize and validate new pharmacological correctors first identified by a high-throughput screening approach for traffic-defective ABCB4 variants.
Method: Six compounds identified by high-throughput screening (CPD-1, 2, 3, 4, 5 and 6) were tested *in vitro* for their capacity to rescue: i) ABCB4 maturation, studied by immunoblot; ii) localization of the transporter at the plasma membrane, analyzed by indirect immunofluorescence; iii) phosphatidylcholine secretion activity, studied by a fluoro-enzymatic assay, of the endoplasmic reticulum-retained ABCB4-I541F, -L556R and -I490T variants. These variants and ABCB4-WT (wild type) were expressed in HEK293 and HepG2 cell models, treated or not with the drug candidates.
Results: In cell models, only CPD-1, –2, and –3 were able to rescue the maturation and canalicular localization of the I541F and L556R traffic defective ABCB4 variants, while no significant effect was observed on the I490T variant. The functional tests showed a partial but significant rescue of the function of ABCB4-I541F and -L556R variants with only one of these molecules (CPD-3). Moreover, these drug candidates inhibit ABCB4-WT activity at different levels. Dose-response analyses were subsequently performed with the three correctors of interest to find a compromise between correction of ABCB4 traffic and inhibition of the secretory function using lower drugs concentrations. These analyses allowed us to decrease the inhibitory effect of the drugs and partially rescue the function of ABCB4-I541F with CPD-2.
Conclusion: Our results allowed us to validate, on the one hand, three pharmacological correctors of the maturation and canalicular localization of ABCB4-I541F and -L556R variants. On the other hand, these three correctors seem to have a variant-specific effect since they do not significantly rescue ABCB4-I490T traffic. Moreover, these molecules inhibit ABCB4-WT function at different levels. These results might be explained by the direct interaction of these molecules with ABCB4 key functional residues during the protein folding process. However, we were able to compass the inhibitory effect by lowering drug concentration in treated cells, and thus partially rescue the function of ABCB4-I541F and -L556R variants. This study opens the path to chemical optimization of these molecules to increase their benefit/inhibition ratio and further considering their validation in preclinical models.

THU-268

Schistosoma mansoni infection-associated oxidative stress triggers hepatocellular proliferation

Verena von Buelow[1], Nicola Buss[2], Jakob Lichtenberger[2], Lukas Härle[2], Christoph G. Grevelding[3], Martin Roderfeld[2], Elke Roeb[2]. [1]*Department of Gastroenterology, Justus Liebig University Giessen, Giessen, Germany;* [2]*Department of Gastroenterology, Justus Liebig University Giessen, Giessen, Germany;* [3]*Institute for Parasitology, Justus Liebig University Giessen, Giessen, Germany*
Email: verena.von-buelow@innere.med.uni-giessen.de

Background and aims: Schistosomiasis is one of the most common parasitic infections of humans worldwide. The eggs of Schistosoma mansoni induce chronic granulomatous liver inflammation. Recent data from animal models and cell culture experiments suggest that this parasite may predispose patients for hepatocellular carcinoma (HCC). Therefore, we analysed whether S. mansoni infection-induced oxidative stress provokes hepatocellular replicative stress in a hamster infection model.
Method: Female hamsters (n = 5) were infected either with male and female cerkariae of S. mansoni (bisex, bs; producing eggs) or cerkariae of one gender (monosex sex, ms; no eggs produced) or non-infected (control). Hepatocellular markers for proliferation, DNA repair, oxidative stress, and cell cycle control were analyzed by qRT-PCR, western blotting and immunohistochemistry. The mechanistic interaction of the forementioned cellular processes were analyzed by gain and loss of function experiments in human hepatoma cells (HepG2) and proliferation was determined by a Bromdesoxyuridin (BrdU)-Assay.
Results: The hepatic expression of Minichromosome maintenance 7 (Mcm7)-mRNA was significantly increased in bs-infected hamsters compared to ms- or non-infected hamsters suggesting the involvement of schistosome eggs. Moreover, in vitro treatment of HepG2 cells with soluble egg antigens (SEA) led to an increase of Mcm7-mRNA. We next investigated hepatic Cyclin D1, required for cell cycle G1/S transition and PCNA, which is central to both DNA replication and repair. Both Cyclin D1 and DNA polymerase processivity factor proliferating cell nuclear antigen (PCNA) were elevated on the protein level in livers of bs-infected hamsters. The addition of GSH diminished SEA-induced Cyclin D1 and PCNA to control levels. p-H2AX, a marker for DNA damage and the proliferation marker Ki67 were colocalized in nuclei of perigranulomatous hepatocytes. SEA-induced proliferation was diminished by the reactive oxygen species (ROS) scavenger GSH.
Conclusion: Recently, S. mansoni infection has been discussed as a predisposition for HCC. We demonstrate that S. mansoni infection, and in particular schistosome egg antigens, not only disturb the DNA replication but also induce aberrant cell cycle regulation and proliferation by hepatocellular oxidative stress. Our results explain at least partially how *S. mansoni* infection promotes the development of HCC.

THU-269

Biliary atresia human cholangiocyte organoids demonstrate increased oxidative stress response

Yara Hamody[1], Adi Har-Zahav[2], Keren danan[3], Raanan Shamir[2], Irit Gat-Viks[3], Orith Waisbourd-Zinman[2]. *[1]Tel aviv universty, Schneider Children's Medical Center of Israel, Petach Tikva, Israel., Israel; [2]Schneider Children's Medical Center of Israel, Petach Tikva, Israel., Israel; [3]Tel aviv universty, Israel*
Email: yarahamody@gmail.com

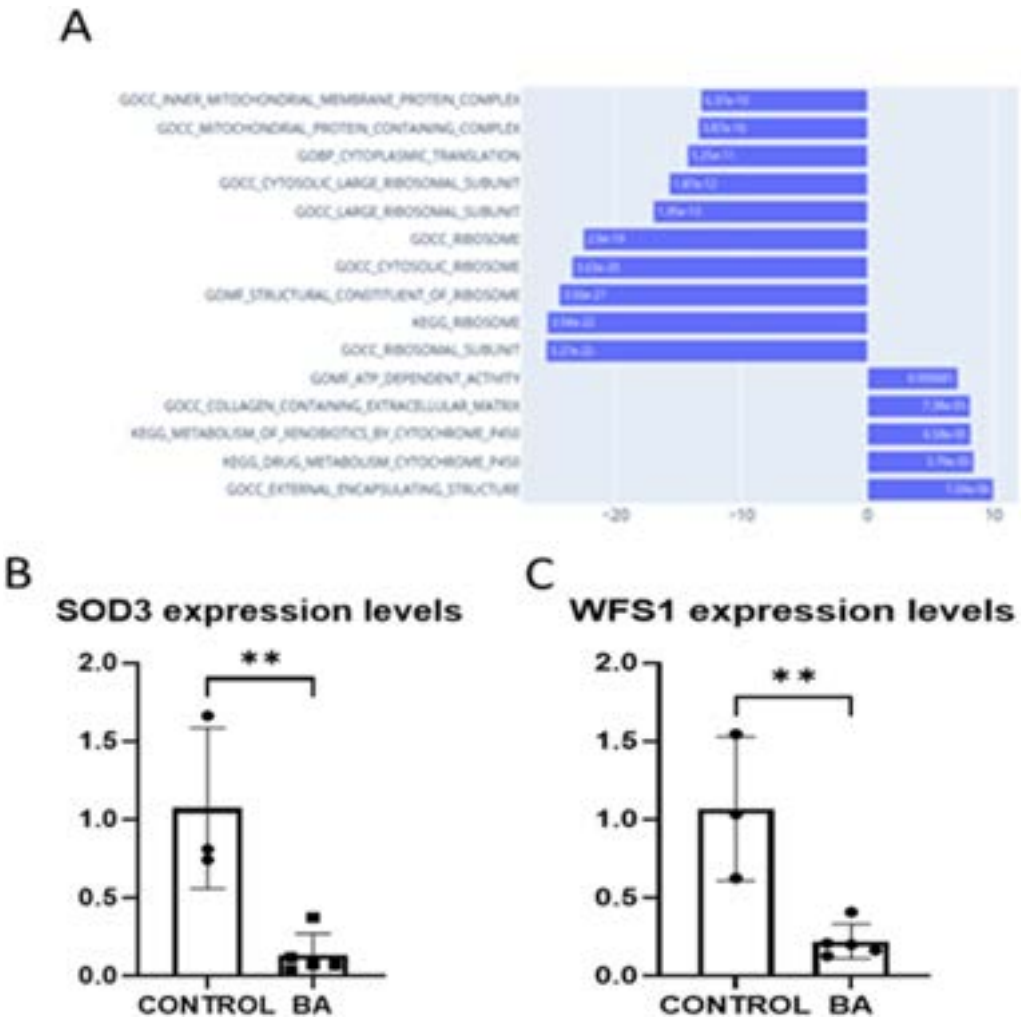

Figure: (abstract: THU-269).

Background and aims: Biliary atresia (BA) is a form of biliary fibrosis typically diagnosed in previously healthy newborns before the age of 3 months, with extrahepatic bile duct obstruction and progressive liver fibrosis. The etiology of the disease is unknown. Here we aimed to identify the pathophysiology of the primary cholangiocyte injury in human BA and the potential for recovery, using bulk and single cell gene expression data from different BA patients.
Method: We cultured human cholangiocyte organoids (HCOs) derived from BA patients and non-BA controls, in order to identify pathways involved with BA cholangiocyte injury. Differentially expressed pathways were further studied using qPCR and western blotting in a candidate gene approach.
Results: BA derived HCOs display deformed shape and lumen obstruction. RNA sequencing results identified differentially expressed genes in BA HCOs involved in several biological pathways, including endoplasmic reticulum (ER) stress, unfolded protein response, generation of reactive oxygen species, and drug metabolism (Figure 1A). The results were validated at the RNA and protein levels. We used RT-PCR to compare differences in gene expression-related ER stress between BA patients and non-BA controls. Superoxide dismutase 3 (SOD3) is an extracellular antioxidant defense against oxidative damage, which deficiency induced spontaneous liver injury and fibrosis.SOD3 was downregulated by 7 fold ($p = 0.0067$) in BA patients compared to control (Figure1B). WFS1 is a component of the IRE1 and PERK signaling pathways which Negatively regulates the ER stress response, was downregulated by 5 fold ($p = 0.0062$) in BA patients compared to control (Figure1C).
Conclusion: BA derived HCOs are characterized by ER stress and unfolded protein response, which may be result in dysfunctional cell-to-cell adhesion. These findings shed light on mechanisms of injury in BA and may contribute to the discovery of potential therapies.

THU-270

Clinical characteristics and pathogenic mechanism of five new ABCB4 missense mutations in progressive familial intrahepatic cholestasis type 3

Yuhang Weng[1,2,2], Yufeng Zheng[1], Dandan Yin[1], Qingfang Xiong[1], Wei Chen[1], Jinlong Li[1], Yongfeng Yang[1]. [1]*The Second Hospital of Nanjing, Affiliated to Nanjing University of Chinese Medicine, China;* [2]*The Second Hospital of Nanjing, Affiliated to Nanjing University of Chinese Medicine, Department of Hepatology, China*
Email: yyf1997@163.com

Background and aims: This study analyzed five new missense variants associated with progressive familial intrahepatic cholestasis type 3 (PFIC-3).
Method: We recruited seven PFIC-3 patients and studied five ABCB4 [adenosine triphosphate (ATP)-binding cassette 4] missense mutations in clinical characteristics and vitro cell model. Especially focus on clinical pathology, ABCB4-mRNA expression, multidrug resistance protein 3 (MDR3) level, cellular sublocalization, stability and phosphatidylcholine functional activity.
Results: We identified five missense mutations in the clinical cohort of this study. Their clinical manifestations are mainly cholestasis. Under HE staining, bile duct injury could be seen, and the immunohistochemical expression could be normal or decreased. In the cell model, the c.1865G>A (p.G622E) mutation resulted in decreased ABCB4-mRNA expression ($p < 0.05$) and endoplasmic reticulum retention in a cell model; c.2777C>T (p.P926L) mutation resulted in MDR3 endoplasmic reticulum retention; The mutations c.1757T>A (p.V586E) ($p < 0.01$), c.2362C>T (p.R788W) and c.3250C>T (p.R1084W) ($p < 0.0001$) reduce MDR3 phosphatidylcholine secretion activity.
Conclusion: The main clinical manifestation of PFIC3 is cholestasis. All five missense mutations were pathogenic in vitro. And the results were also consistent with liver pathology. This further confirms that missense mutations affect clinical outcomes.

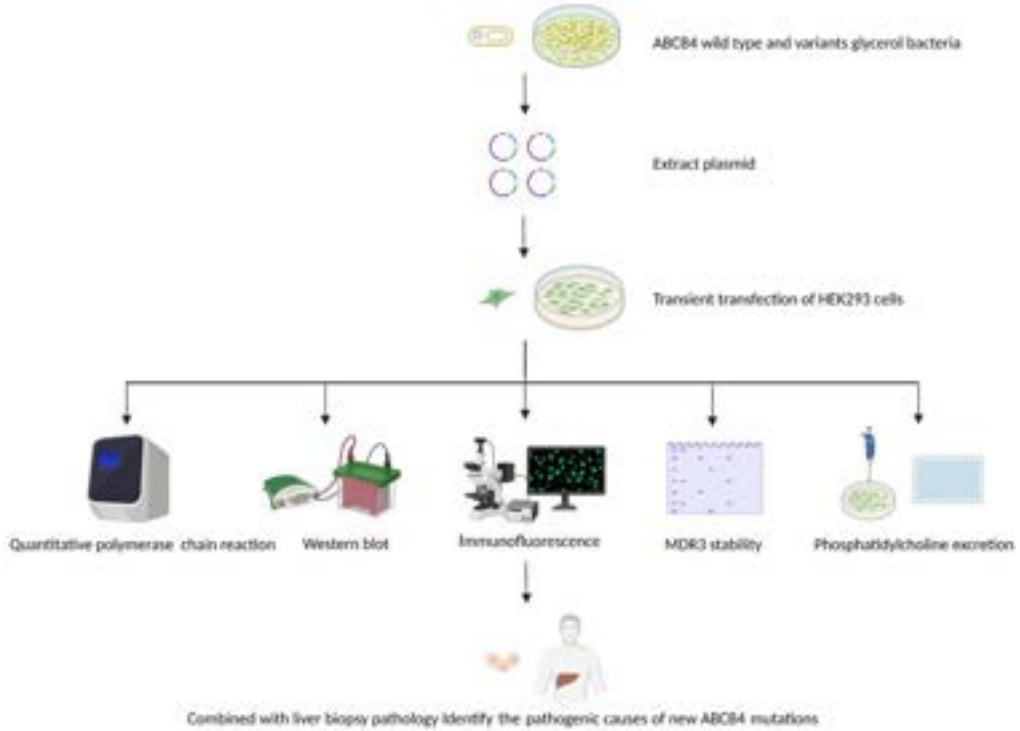

Figure: (abstract: THU-270).

Immortalized patient-derived cell models for analysis of liver disease

Matthias Weiand[1], Vanessa Sandfort[1], Oksana Nadzemova[1], Iyad Kabar[2], Jonel Trebicka[1], Hartmut Schmidt[3], Andree Zibert[1].
[1]Münster University Hospital, Medical Clinic B, Münster, Germany; [2]Raphaelsklinik Münster, Münster, Germany; [3]Essen University Hospital, Essen, Germany
Email: andree.zibert@ukmuenster.de

Background and aims: For many diseases, including rare monogenic liver diseases, patient-derived cells are the gold standard of experimental studies. However, materials derived from biopsies are limited and the proliferation of primary cells is frequently restricted to a few days. Epithelial cells found in the urine (UCs) represent a non-invasive source for establishment of continuously growing cell lines.
The aim of this study was to establish cellular platforms that were used to recapitulate pathomechanisms of liver diseases employing (i) gene transfer of oncogenes and (ii) by reprogramming to induced pluripotent stem cells (iPSCs) followed by differentiation into hepatocyte-like cells (HLCs).
Method: UCs were collected from patients having different liver disease (Wilson disease (WD), hereditary transthyretin amyloidosis (hATTR), HFE-related hemochromatosis, or autosomal dominant polycystic liver disease (ADPLD). Cells were subjected to immortalization by oncogenes (HPVE6E7, cyclinD1/CDK4R24C and hTERT/p53DD) or subjected to reprogramming and differentiation. Cells were analyzed using proliferation assay, flow cytometry, qRT-PCR, and Cyto-ID autophagosome staining.
Results: Gene transfer of several oncogenes led to a stable proliferation of primary cells. Oncogene-immortalized UCs showed similar high expression of epithelial, fibroblast and renal markers. Similarly, primary and immortalized UCs could be efficiently reprogrammed to iPSCs and differentiated to HLCs that showed typical markers of primary hepatocytes. Cells encoding a novel Sec61A1 mutation observed in an ADPLD patient showed a significant downregulation of autophagy suggesting that a reduced autophagy is related to liver cyst formation. Chloroquine could specifically promote autophagy in ADPLD-derived cells.
Conclusion: In summary, our data suggest that immortalization of primary cells by oncogene transfer or reprogramming/differentiation allow establishment of cellular platforms for molecular studies to explore pathways of pathomechanisms in liver disease and the evaluation of drugs for therapy.

THU-272

CRISPR/Cas9-mediated gene correction of Wilson disease H1069Q mutation in an iPS cell model

Andree Zibert[1], Matthias Weiand[2], Oksana Nadzemova[1], Jonel Trebicka[2], Vanessa Sandfort[1]. *[1]Universitätsklinikum Münster, Medizinische Klinik B, Münster, Germany; [2]Universitätsklinikum Münster, Medizinische Klinik B, Münster, Germany*
Email: vanessa.sandfort@ukmuenster.de

Background and aims: Wilson disease (WD) is induced by an autosomal recessive gene defect in the copper transporting protein ATPase7B that leads to cytotoxic copper concentrations in the body, prominently in the liver. The most frequent mutation in the Caucasian population is the point mutation H1069Q. In this study, the H1069Q mutation was targeted by using the clustered regularly interspaced short palindromic repeats (CRISPR) associated nuclease 9 (Cas9) technology in WD specific induced pluripotent stem cells (iPSCs). We asked whether a gene correction is feasible, safe and efficient. Moreover, we studied whether gene-corrected iPSCs maintain the ability to differentiate into hepatocyte-like cells (iHeps) and whether such cells escape from toxic copper.
Method: Epithelial cells from freshly donated urine obtained from a WD patient carrying the compound heterozygous mutation H1069Q/N1270S were collected and reprogrammed into iPSCs. WD iPSCs were transfected with the plasmid PX459.H1069Q plus a set of single-stranded oligo DNA nucleotides (ssODNs) for homology-directed repair (HDR). Single iPSCs clones were analyzed by Sanger sequencing followed by hepatic differentiation and MTT assays.

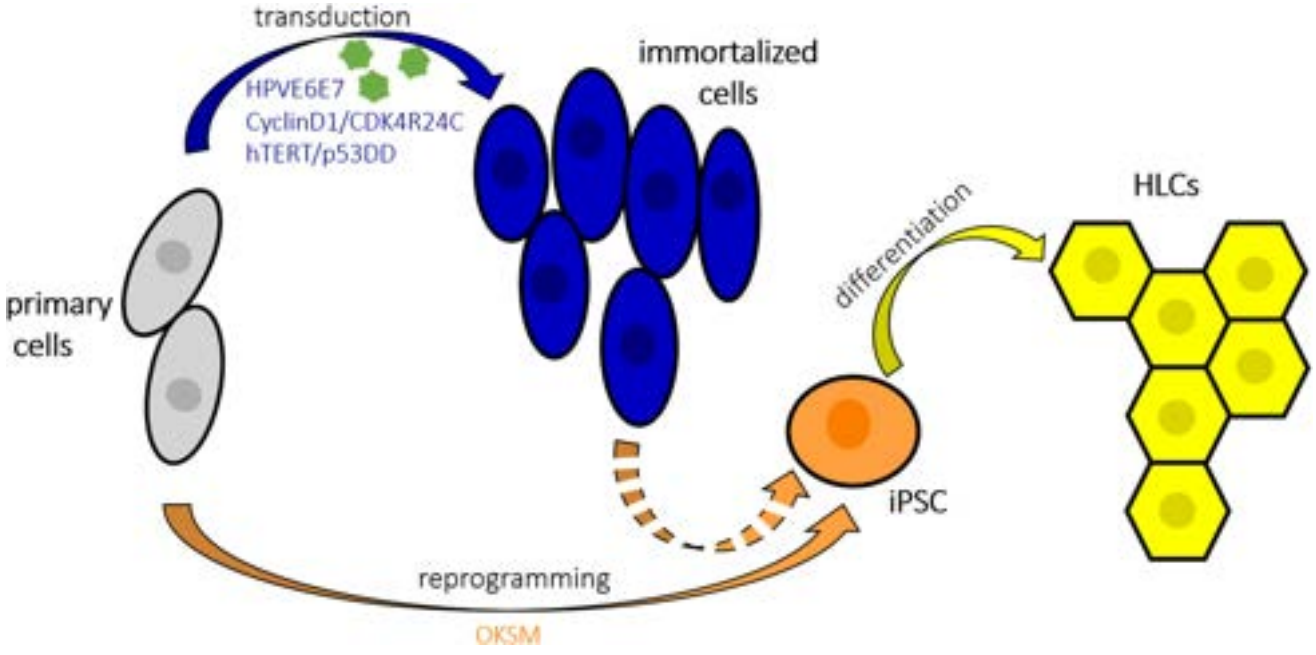

Figure: (abstract: THU-271): Overview of two pathways for immortalization of primary cells. **A** The combined retroviral transfer of oncogenes into primary cells (UCs) was used to gain highly proliferative, immortalized cells (imUCs). **B** Primary cells were reprogrammed to induced pluripotent stem cells (iPSCs) and in vitro differentiation to hepatocyte-like cells (HLCs).

Results: After genome engineering, 46% of the cell clones indicated a gene correction of the H1069Q mutation. The second mutation N1270S was not affected indicating the high specificity of the methodology. Corrected iPSCs could be differentiated to iHeps and indicated an improved resistance to a challenge by high copper concentrations.
Conclusion: The current study demonstrates that in vitro genome engineering with CRISPR/Cas9 has a remarkable therapeutic potential to efficiently correct WD, thus further contributing to novel therapeutic approaches for WD specifically and monogenetic rare diseases in general.

THU-273
Liver transplantation for Wilson disease: single center experience
Amnah Alhanaee[1,2], Khalid Bzeizi[3], Saad Alghamdi[1], Ali Albenmousa[1], Waleed Alhamoudi[1], Dieter Clemens Broering[1]. *[1]King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [2]Tawam Hospital, أبو ظبي, United Arab Emirates; [3]King Faisal Specialist Hospital and Research Centre, liver transplant, Riyadh, Saudi Arabia*
Email: amnahalhanaee@gmail.com

Background and aims: Wilson's disease (WD) is a rare genetic disorder with protean manifestations. Even if liver transplantation (LT) could represent an effective therapeutic option for patients with end-stage liver disease. LT however, remains controversial in the presence of neuropsychiatric involvement. We present our experience on transplantation of Saudi patients with WD.
Method: All patients who had LT in King Faisal Specialist hospital during the period January 2004-January 2021 were included in the analysis. The medical records were accessed for all the information, including the demographics of the patients, genetic screen, MELD score and evidence for neuro-psychiatric WD. Graft and patient survival was determined using Kaplan Meier analysis.
Results: A total of 34 patients with WD were transplanted in our center. Females were 18 (53%). The mean age at the onset of symptoms was 24.7 years [range 13–45 years] were included. WD was diagnosed by genetic testing and or Leipzing scoring system using 24-hours urinary collection. The mean MELD score at the time of transplantation was 23.9 and 70% of the patients had Child-C score. Isolated hepatic phenotype was the referral phenotype for LT in 23 patients (67.6%). The combination of neuro-psychiatric and decompensated liver disease was present in 3 patients (8.8%). 5 patients (14.7%) presented with neurological impairment on decompensated liver disease and one patient had isolated neuro-psychiatric WD. Two patients had LT for acute liver failure. One patient had hepatopulmonary syndrome (HPS) and another presented with hepatocellular carcinoma (HCC). Living-related LT was performed on 18 patients (53%). Post-transplant, 5 patients with neuropsychiatric symptoms recovered completely (14.5%). Biopsy proven, acute cellular rejection occurred in 11and all responded to treatment. Biliary anastomotic strictures developed in 6 patients, managed successfully with ERCP/PTC intervention. PTLD was diagnosed in one patient, 7 years post LT.
Four deaths occurred during the study period (11.7%) and two of them within 30-days post LT. The one, five and ten-years survival rates were 94%, 90% and 80% respectively.
Conclusion: WD remains an uncommon, indication for LT. There was a trend of improvement in the neuro-psychiatric manifestations of WD post transplantation, but more studies are needed. The overall graft and patient survival was excellent and accordingly, LT provides a viable management option for WD with hepatic decompensation.

THU-274
Effects of tetrathiomolybdate, trientine, and penicillamine on intestinal copper uptake: a randomized placebo-controlled 64Cu PET/CT study
Frederik Teicher Kirk[1], Ditte Emilie Munk[1], Eugene Scott Swenson[2], Adam Quicquaro[2], Mikkel Holm Vendelbo[3], Michael Schilsky[4], Peter Ott[1], Thomas Damgaard Sandahl[1]. *[1]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark; [2]Alexion, AstraZeneca Rare Disease, United States; [3]Aarhus University Hospital, Department of Nuclear Medicine and PET-center, Denmark; [4]Yale School of Medicine, Department of Medicine, Section of Digestive Diseases, and Department of Surgery, Section of Transplant and Immunology, United States*
Email: frkirk@rm.dk

Background and aims: In Wilson Disease (WD), ATP7B protein dysfunction leads to copper accumulation with hepatic and neurologic disease. Treatments include D-penicillamine (PEN) and trientine tetrahydrochloride (TRI), which chelate Cu and cause cupriuresis, and the investigational copper binding agent bis-choline-tetrathiomolybdate (TTM). We hypothesized that inhibition of intestinal uptake of copper could be an additional mechanism of action for these drugs. We used PET/CT to investigate the effects of TTM, TRI, PEN and placebo (PLA) on intestinal ^{64}Cu uptake. The study was conducted in healthy volunteers as ATP7B is not involved in intestinal copper absorption.
Method: Healthy subjects (n = 32) were included in a partly double blinded placebo-controlled randomized trial. Subjects underwent ^{64}Cu PET/CT before treatment and after 7 days of treatment with TTM, TRI, PEN or PLA, each serving as their own controls. Subjects fasted 1 h before and after treatment doses, with final dose 1–2 h prior to $^{64}CuCl_2$ ingestion. Participants were scanned 1 h and 15 h after an oral dose of $^{64}CuCl_2$. Radiocopper was quantitated in liver and in blood (aorta). If a drug were to reduce intestinal copper absorption, less copper would be detected in the blood and liver. Subjects followed standardized diets, including a 6 h fast prior to ^{64}Cu ingestion.
Results: Compared to pretreatment, hepatic ^{64}Cu levels measured 1 h post-^{64}Cu dose were reduced by 92% on TTM ($p < 0.02$), 53% on TRI ($p < 0.02$), 23% on PEN ($p = 0.16$), and 3% on PLA ($p = 1.00$) (Figure 1). At 15 h post-^{64}Cu dose, hepatic ^{64}Cu levels were reduced by 82% on TTM ($p < 0.02$), 50% on TRI ($p < 0.02$), 31% on PEN ($p < 0.04$) and increased 12% on PLA ($p = 0.16$). At 15 h, gallbladder ^{64}Cu activity demonstrated biliary excretion after TRI, PEN and PLA, but not after TTM.
TRI, PEN and PLA did not significantly change blood ^{64}Cu activity at 1 h and 15 h post ^{64}Cu administration. Even though TTM reduced hepatic ^{64}Cu activity by 80–90%, blood activity was only 40% less at 15 h indicating reduced hepatic clearance. No compensatory increased ^{64}Cu activity was detected in other organs. In summary, after TTM, a smaller percent of ingested ^{64}Cu dose was present in blood and liver; it was absent in bile and not increased in other organs, indicating significant inhibition of intestinal ^{64}Cu absorption. In addition, the reduced ratio of liver/blood ^{64}Cu activity indicated reduced hepatic clearance, presumably due to formation of TTM-Cu-albumin complexes in blood.
Conclusion: ^{64}Cu PET/CT is useful for evaluating the effect of medical therapy on intestinal copper absorption and copper distribution in the body. The greater inhibition of intestinal copper absorption of TRI compared to PEN may explain recent observations of more urinary copper excretion with PEN but equal efficacy in treating WD patients. TTM markedly reduced hepatic ^{64}Cu uptake, reducing both intestinal absorption and hepatic clearance by TTM-Cu-albumin complex formation.

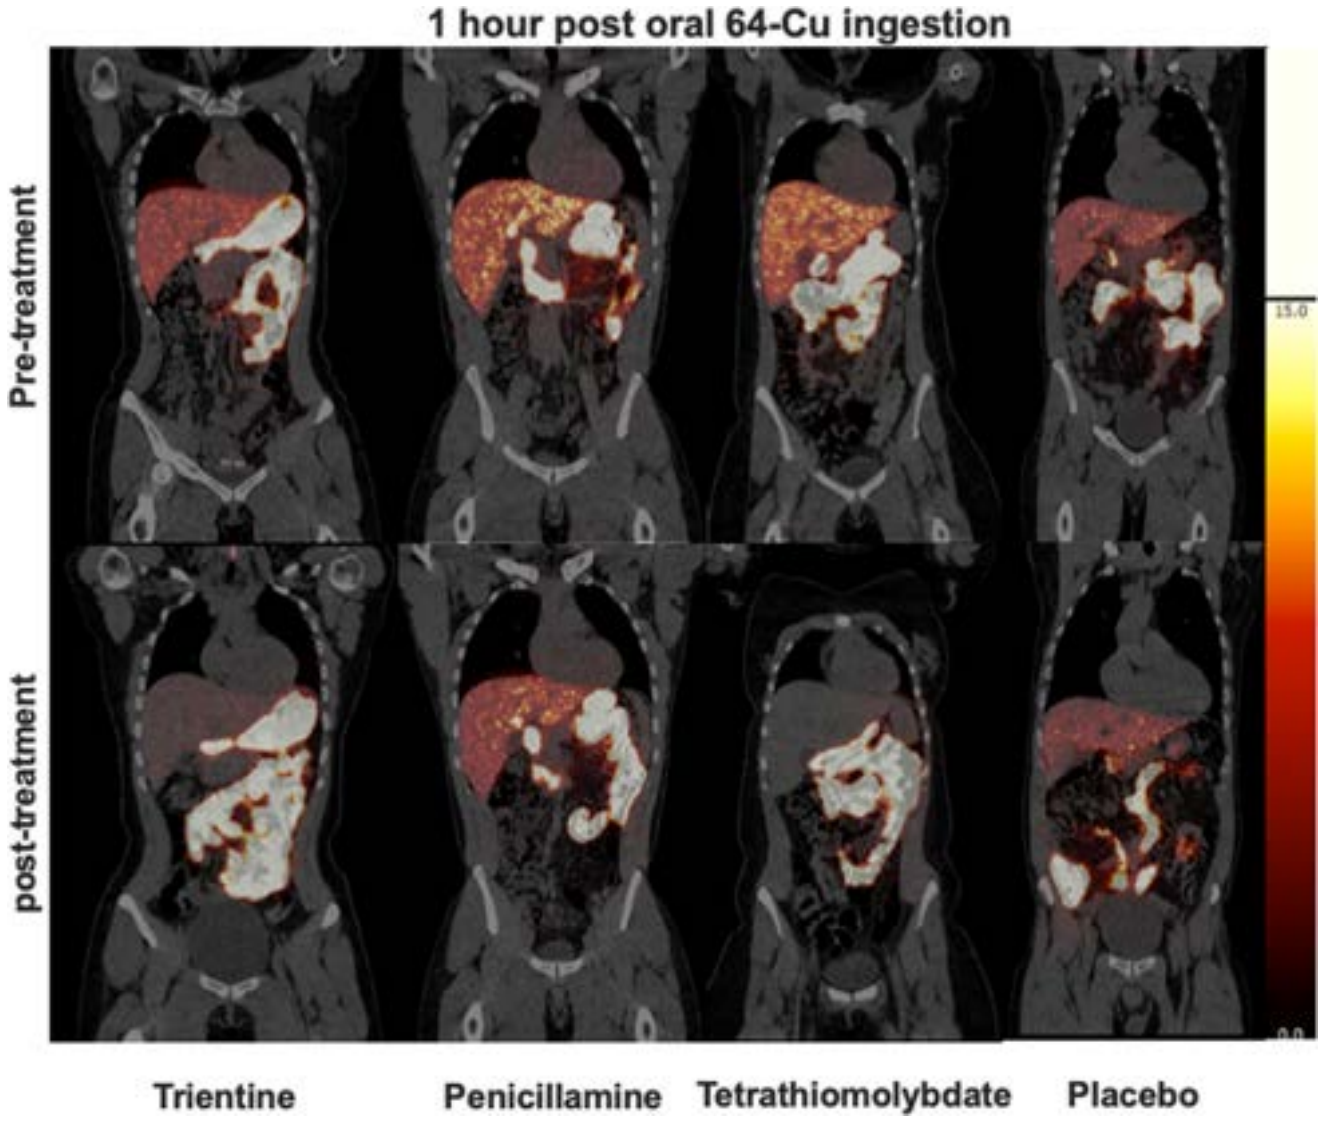

Figure: (abstract: THU-274): Fused coronal paired, representative images from one subject in each group of eight individuals, whole-body PET/CT images showing ^{64}Cu activity in the liver, heart and parts of the small intestine and colon. 1 hour after ^{64}Cu ingestion. Radioactivity scale 0 (black)-15 (white).

THU-275

Four-fold increased mortality rate in patients with Wilson's disease: a population-based cohort study of 151 patients

Fredrik Åberg[1], Ying Shang[2], Rickard Strandberg[2], Axel Wester[2], Linnea Widman[2], Hannes Hagström[2]. [1]*University of Helsinki, Finland;* [2]*Karolinska Institutet, Sweden*
Email: hannes.hagstrom@ki.se

Background and aims: Few studies have investigated mortality rates in patients with Wilson's disease and compared these to the general population. Further, there is a lack of information on the risk of other potential outcomes. Here, we examined mortality and other outcomes in a population-based study of patients with Wilson's disease in Sweden.

Method: We did a population-based cohort study, using nation-wide registers to identify all patients with a first diagnosis of Wilson's disease between 2002 and 2020 in Sweden. Each patient was matched by age, sex and municipality with up to 10 reference individuals from the general population. Validated registers were used to investigate outcomes up to 19 years after baseline in patients and reference individuals. Cox regression was used to examine overall mortality, while Fine and Gray regression models were used for secondary outcomes, considering non-outcome death and liver transplantation as competing events. Validation of the ICD-10 code for Wilson's disease was performed by comparing ICD-codes to medical journals from 26 patients seen at the Karolinska University Hospital.

Results: A total of 151 patients with a first diagnosis of Wilson's disease were identified and matched with 1,441 reference individuals. The positive predictive value for the ICD-10-code for Wilson's disease was 100%. Median age at baseline was 26 years (interquartile range [IQR] 17–42) and 50% were males. At baseline, previous diagnoses of neurologic disease were seen in 17%, and psychiatric diagnoses had been made in 24%, figures considerably higher than in reference individuals (7% and 10%, respectively, both $p < 0.001$). During a mean follow-up of 6.6 years (range 0–19), 10 (6.6%) patients with Wilson's disease died, compared with 31 (2.2%) reference individuals. This translated to a hazard ratio of 3.84 (95%CI = 1.84–8.05). The excess risk of death was confined to patients aged 20 or more at diagnosis. Cumulative mortality at 10 years was estimated to

Table: (abstract: THU-275): Incident secondary outcomes in patients with Wilson's disease and matched reference individuals from the general population. Statistically significant estimates are highlighted in bold. Abbreviations: IR = incidence rate, PY = person-years, sHR = subdistribution hazard ratio.

	n/N, Wilson	n/N, controls	IR/1000 PY, Wilson	IR/1000 PY, reference individuals	sHR (95%CI)	p value
Liver-related death	1/151	1/1441	0.85 (0.12–6.06)	0.08 (0.01–0.58)	9.54 (0.60–151.89)	0.11
Liver transplantation	14/141	1/1441	11.94 (7.07–20.17)	0.08 (0.01–0.58)	**137.15 (17.94–1048.58)**	**<0.001**
Cardiovascular disease	26/122	92/1111	32.23 (21.95–47.34)	10.26 (8.36–12.59)	**2.90 (1.85–4.53)**	**<0.001**
Hepatocellular carcinoma	1/150	1/1432	0.86 (0.12–6.10)	0.08 (0.01–0.58)	9.22 (0.55–154.79)	0.12
Psychiatric diagnoses	24/115	106/988	30.29 (20.30–45.19)	12.79 (10.57–15.47)	**2.11 (1.36–3.29)**	**0.001**
Neurologic diagnoses	23/125	102/1120	25.12 (16.70–37.81)	10.91 (8.99–13.25)	**2.12 (1.34–3.35)**	**0.001**

12.7% (95%CI = 7.0–22.5) in patients with Wilson's disease, compared to 3.3% (95%CI = 2.2–5.0) in reference individuals. Higher risks of several secondary outcomes in patients with Wilson's disease were identified (Table 1).

Conclusion: In this large, population-based cohort study, patients with Wilson's disease had an almost 4-fold increased rate of death, as well as increased risks for several clinically important outcomes, compared to matched individuals from the general population.

THU-276

Risk of cirrhosis and hepatocellular carcinoma in hemochromatosis: a Swedish nationwide cohort study

Hanne Åström[1], Axel Wester[1], Linnea Widman[1], Per Stal[1,2], Hannes Hagström[1,2]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Sweden;* [2]*Karolinska University Hospital, Division of Hepatology, Department of Upper Gi, Sweden*
Email: hanne.astrom@ki.se

Background and aims: Hereditary hemochromatosis (HH) is a common genetic disorder of iron metabolism characterized by excessive absorption and accumulation of dietary iron. Patients with HH are thought to be at increased risk of severe liver disease (SLD) and hepatocellular carcinoma (HCC) but current research have produced conflicting results. In this study, we aimed to establish the rates of SLD and HCC in a nationwide cohort study of patients with HH.

Method: Patients with administrative coding for HH (n = 7711) in the Swedish National Patient Register between years 1969–2016 were included. Patients with HH were matched for age, sex and municipality with 74089 controls. Patients were stratified into groups based on age, sex and year of diagnosis. Cox proportional hazards regression was used to determine the rates of SLD and HCC and cumulative incidence was illustrated using Kaplan Meier curves.

Results: In the entire cohort, SLD was diagnosed in 862 persons (HH: 393 [5.1%], vs. Controls: 469 [0.6%]) and HCC was diagnosed in 224 persons (HH: 133 [1.7%], vs. Controls: 91 [0.1%]). During the entire study period, patients with HH had a higher rate of SLD and HCC compared to matched controls (adjusted hazard ratio [aHR] 8.2; 95% CI 7.1–9.5 and aHR 14.1; 95%CI 10.4–19.2 respectively). The rate of SLD development decreased over time with highest rates in 1969–1980 (aHR 19.3; 95%CI 7.4–50.3) and lowest in 2001–2010 (aHR 6.8; 95%CI 5.5–8.4). Men experienced a higher rate of SLD development when compared to women (aHR 8.8; 95%CI 7.4–10.4, vs. aHR 7.1; 95%CI 5.3–9.4) and this was additionally reflected in rate of HCC development (aHR 17.3; 95%CI 12.2–24.7 vs. aHR 6.2; 95%CI 3.0–12.6). Patients older than 66 years of age experienced the highest rate of SLD development (aHR 10.4; 95%CI 8.0–13.6) compared to younger subgroups where rates were observed to be similar (51–65: aHR 7.4; 95%CI 6.0–9.2 and <50: aHR 7.8; 95%CI 5.6–10.9).

Conclusion: In this nationwide cohort study, patients with HH experienced an increased rate of SLD and HCC compared to matched controls from the general population. Over time, the rate of SLD and HCC development in patients with HH seemed to decrease; possibly owing to improved diagnostic techniques and change in management over time. We identified a few subgroups of patients with diverging risk estimates of liver-related outcomes that may require different clinical follow-up strategies. Thus, further studies are warranted to optimize the management of patients with hemochromatosis.

THU-277

Association of circulating Z-polymer with adverse clinical outcomes and liver fibrosis in adults with the PiZZ alpha-1 antitrypsin deficiency genotype

Malin Fromme[1], Laura Rademacher[1], Samira Amzou[1], John Ripollone[2], Christi Cook[2], Isabel Zacharias[2], Yang Chen[2], Bing Han[2], Pavel Strnad[1]. [1]*University Hospital RWTH Aachen, Aachen, Germany;* [2]*Vertex Pharmaceuticals, Boston, United States*
Email: pstrnad@ukaachen.de

Background and aims: The PiZ variant is the most clinically relevant variant in alpha-1 antitrypsin deficiency (AATD), leading to impaired AAT secretion from the liver and Z-polymer formation. To improve the limited knowledge about the biological role of circulating Z-polymers, we studied its association with adverse clinical outcomes, and with liver fibrosis.

Method: PiZZ adults from the European Alpha-1 Liver Cohort, recruited between 2015 and 2020, were included. Serum circulating Z-polymer was measured via an immunoassay method specific for the polymeric form of AAT. Time-to-event analyses were conducted for PiZZ adults followed for adverse clinical outcomes over a median of approximately 4 years. Cox proportional hazards models were used to describe the association between binary circulating Z-polymer (>versus ≤analytic sample median circulating Z-polymer) and adverse clinical outcome (composite of first instance of liver-related hospitalization, listed/realized liver transplant, or all-cause mortality). Cross-sectional associations between circulating Z-polymer and baseline liver fibrosis (FibroScan stiffness) were evaluated using the Spearman correlation (rho). Analyses were stratified by augmentation therapy status because augmentation therapy may infuse polymer, leading to inflated Z-polymer levels.

Results: There were 431 PiZZ adults (baseline: average age of 55 years, 46% female, average body mass index [BMI] of 25.1 kg/m^2; 59% reported augmentation therapy use). Baseline mean circulating Z-polymer was higher among PiZZ adults on augmentation therapy (26.0 mg/L, n = 254) than those not on augmentation therapy (19.3 mg/L, n = 173). Of 292 PiZZ adults followed for adverse clinical outcomes, 28 (9.6%) had adverse clinical outcomes (4 liver-related hospitalizations, 4 listed/realized liver transplants, 20 deaths [6 liver-related, 4 lung-related, 10 other/unknown]). Higher circulating Z-polymer (median circulating Z-polymer = 21.5 mg/L) was associated with increased risk of adverse clinical outcome in an age-adjusted model (hazard ratio [HR]: 1.96, 95% confidence interval [CI]: 0.78–4.94, n = 289). Similar associations were observed after stratification by baseline augmentation therapy status (augmented HR: 2.97, 95% CI: 0.95–9.33, n = 182; non-augmented HR: 3.52, 95% CI: 0.73–17.1, n = 106). At baseline, among those not on augmentation therapy, circulating Z-polymer was positively correlated with FibroScan stiffness (rho: 0.29; n = 138).

Conclusion: Higher circulating Z-polymer was associated with shorter time to adverse clinical outcome, and positively correlated with FibroScan stiffness, in PiZZ adults. Circulating Z-polymer may identify patients at risk for rapid liver disease progression in AATD.

THU-278

Blood markers of immune activation help distinguish paediatric activated T-cell hepatitis from other causes

Tamir Diamond[1,2], Catherine Chapin[3,4], Adriana Perez[1,2], Kathleen M. Loomes[1,2], Edward Behrens[1,2], Estella Alonso[3,4].
[1]*University of Pennsylvania, Pediatrics, Philadelphia, United States;* [2]*Children's Hospital of Philadelphia, Pediatrics, Philadelphia, United States;* [3]*Northwestern University, Feinberg School of Medicine, Pediatrics, Chicago, United States;* [4]*Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, United States*
Email: diamondt@chop.edu

Background and aims: Paediatric acute liver failure (PALF) and acute severe hepatitis of unknown cause has recently attracted increased attention due to reports since late 2021 of a possible worldwide increase in cases which may be related to adenovirus infection. To date, a direct viral cause has not been identified in most patients with indeterminate PALF. Instead, recent studies support that many cases of indeterminate acute hepatitis and PALF are driven by an overactive immune response involving effector memory CD8 T-cells, designated activated T-cell hepatitis. Here we describe a multicentre cohort of children with acute hepatitis and PALF presenting between March 2020 and August 2022 and demonstrate how patients can be differentiated by immune phenotype.
Method: Retrospective chart review to identify patients aged 3 months-18 years with acute severe hepatitis and PALF at Ann and Robert H. Lurie Children's Hospital of Chicago and Children's Hospital of Philadelphia. Patients with biochemical evidence of severe liver injury within 8 weeks of onset of illness measured by alanine aminotransferase (ALT) above 500 were included. PALF was defined per the PALF Study Group criteria as previously published. Patients with evidence of chronic liver disease or non-hepatic intrinsic causes for hepatitis were excluded. Demographic, clinical, laboratory, and pathology data were collected by chart review. Patients were classified as activated T-cell hepatitis based on liver biopsy with moderate-dense CD8+ T-cell inflammation (if available) and/or development of severe aplastic anaemia with negative evaluation for other causes. Patients were labelled unknown (IND-hep) if no aetiology of the liver injury was identified.
Results: 124 patients met inclusion criteria: 83 patients with known diagnoses (23 with PALF) (fig. 1A), 14 with activated T-cell hepatitis (3 PALF), and 27 with IND-hep (11 PALF) (fig 1B). Most patients (97%) had recovery with native liver. Total serum bilirubin and soluble IL-2 receptor at presentation were higher in activated T-cell hepatitis patients compared to IND-hep (fig 1C and 1D). Clinical T- and B-cell flow cytometry studies noted increased percentage of CD8+ T-cells (fig. 1E) and increased HLA-DR+ (activated) T-cells (fig. 1F) in the activated T-cell hepatitis compared to IND-hep group. An increase in CD8 T-cell perforin and granzyme B expression was only seen in patients with activated T-cell hepatitis (figure 1G).
Conclusion: In a multicenter cohort of children with acute liver injury we found that patients with activated T-cell hepatitis have distinctive differences in clinically available peripheral blood immune biomarkers compared to patients with IND-hep which can be used help to identify this diagnostic group. Better characterization of this group will facilitate additional understanding of the underlying pathophysiology, and development of targeted therapies, to improve transplant-free survival.

THU-279

Incidence of hemochromatosis in HFE p.H63D homozygote and p.C282Y/H63D compound heterozygote individuals

Lorenz Michael Pammer[1], Benedikt Schaefer[1], Bernhard Pfeifer[2,3], Sabrina Neururer[2], Claudia Lamina[4], Florian Kronenberg[4], Herbert Tilg[1], Heinz Zoller[1]. [1]*Medizinische Universität Innsbruck, Dept. of Internal Medicine I, Innsbruck, Austria;* [2]*Landesinstitut für Integrierte Versorgung Tirol, Innsbruck, Austria;* [3]*University for Health Sciences, Medical Informatics and Technology, Hall in Tirol, Austria;* [4]*Medizinische Universität Innsbruck, Institute of Genetic Epidemiology, Innsbruck, Austria*
Email: heinz.zoller@i-med.ac.at

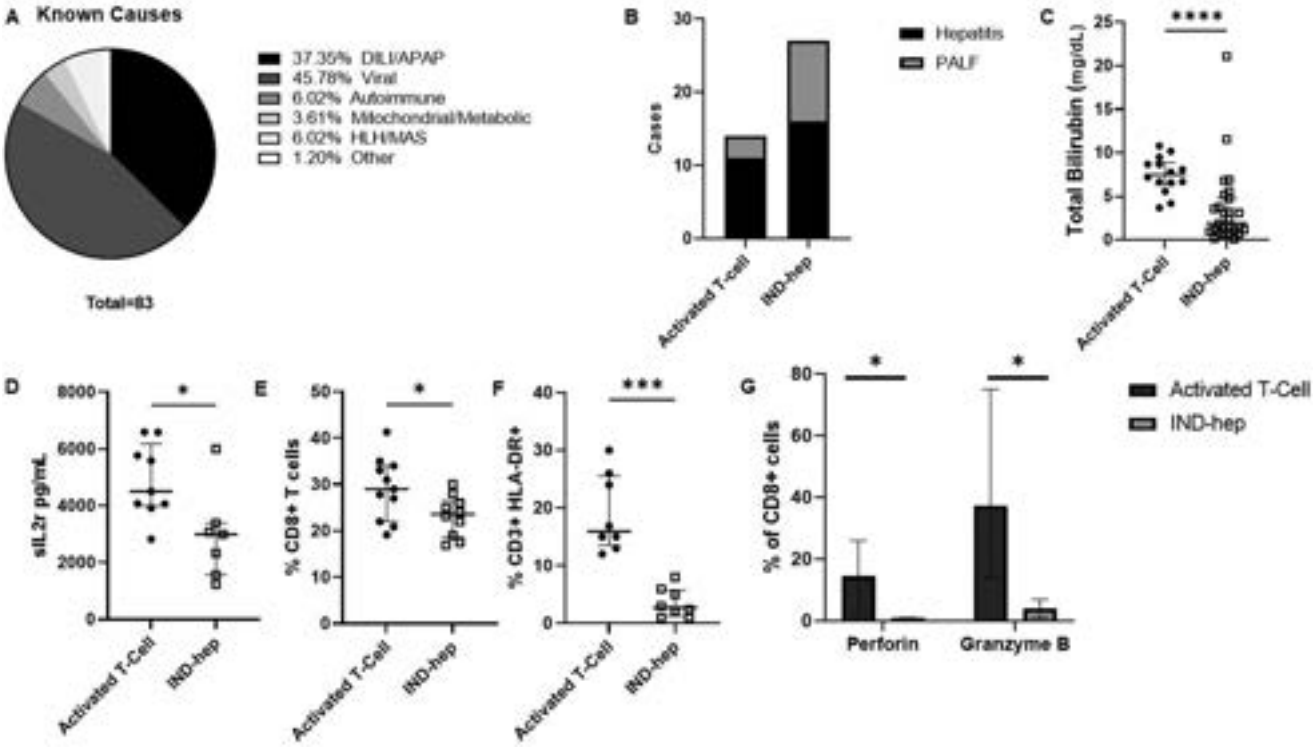

Figure: (abstract: THU-278).

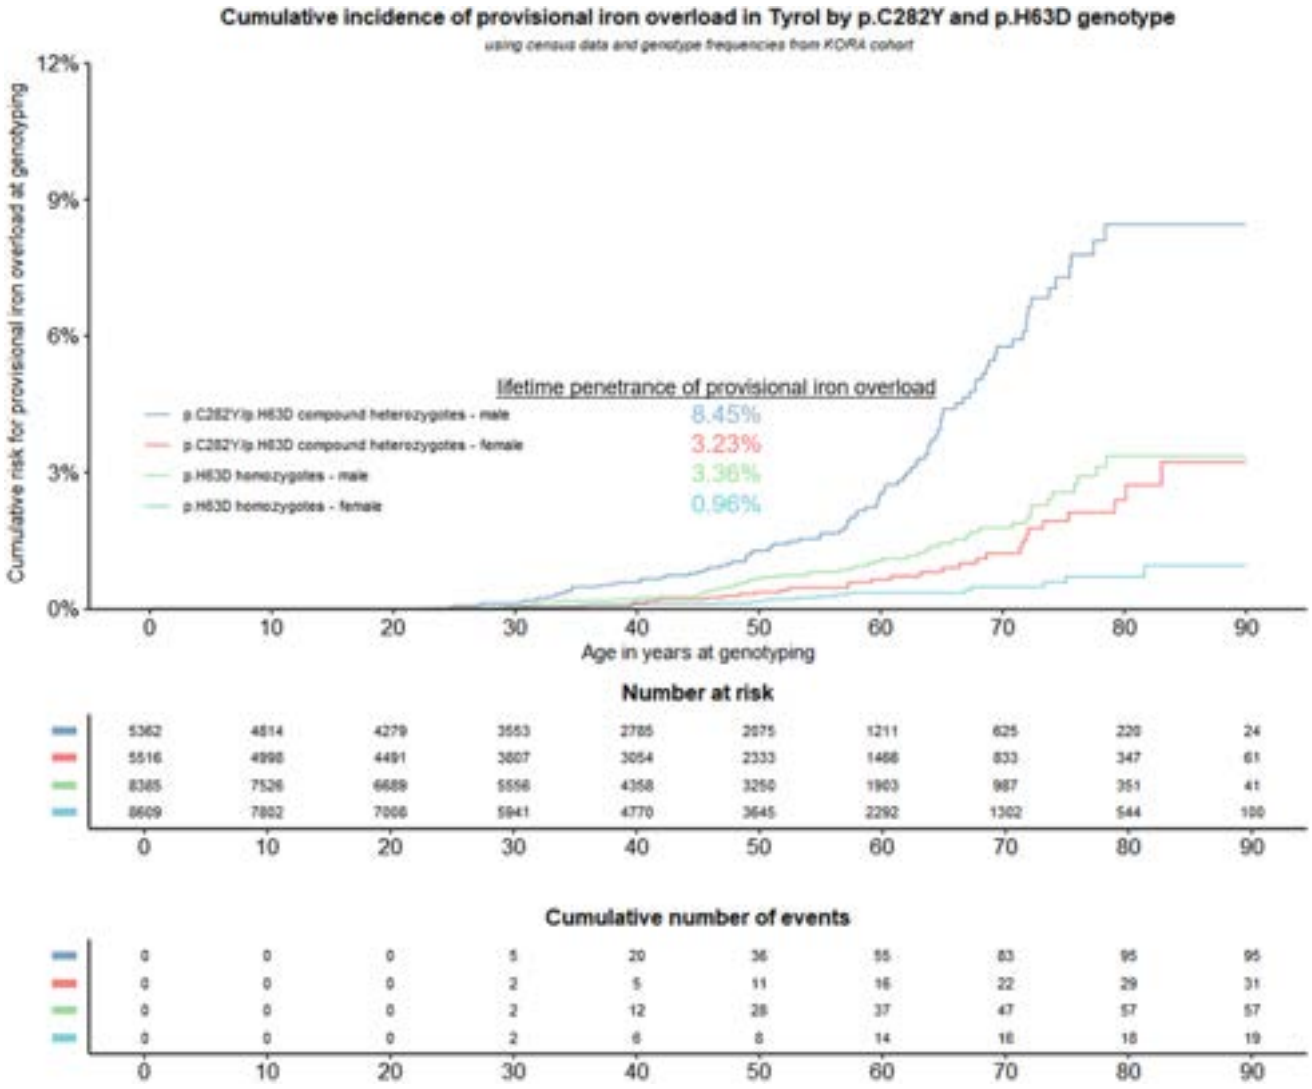

Figure: (abstract: THU-279).

Background and aims: Hemochromatosis is a genetic disease characterized by increased transferrin saturation and liver iron overload. The most common disease-associated genotype is p.C282Y homozygosity in *HFE*. The reported incidence of iron overload in patients who are compound heterozygous for p.C282Y and p.H63D as well as for those patients who are homozygous for p.H63D varies widely between studies. The present study assesses disease penetrance in a large European cohort with a median follow-up of 10.6 years/follow-up of up to 25.1 years

Method: We included 8839 patients, referred for *HFE* genotyping from Tyrol, Austria over a period of 25 years. Penetrant disease was defined as the presence of provisional iron overload (ferritin >300 µg/L for men and postmenopausal women, >200 µg/L for premenopausal women in association with transferrin saturation >55% for men and >45% for women). Using genotype frequencies from a health research database and general population data from Tyrol, expected number for both genotypes were calculated.

Results: In total, we identified 301 p.H63D homozygotes (3.41% of referred patients) and 507p.C282Y/p.H63D compound heterozygotes (5.73% of referred patients). Lower bounds of lifetime disease penetrance were established at 8.45% for males and 3.23% for females in p.C282Y/p.H63D compound heterozygotes. For p.H63D homozygotes, male lifetime penetrance was 3.36% and female lifetime penetrance was 0.96%. The p.C282Y/p.H63D confers a higher risk of lifetime provisional iron overload. Compound heterozygous females have comparable lifetime risk to p.H63D homozygous males. Age at diagnosis/genotyping and sex are the strongest modifiers of disease penetrance.

Conclusion: The absolute life-time risk of developing provisional iron overload for p.C282Y/H63D compound heterozygotes and p.H63D homozygotes individuals is low, suggesting that environmental and behavioral risk factors determine disease penetrance.

THU-280

Does earlier introduction of azathioprine result in a reduced cumulative dose of corticosteroid therapy in the treatment of autoimmune hepatitis (AIH) and does this result in the same degree of biochemical response?

Sital Shah[1], Yooyun Chung[2], Maura Morrison[2], Catherine McKenzie[3], Michael Heneghan[2]. [1]*Kings College Hospital NHS Foundation Trust, Institutue of Liver Studies, London, United Kingdom;* [2]*King's College Hospital, United Kingdom;* [3]*2.University Hospital Southampton, Pharmacy and Critical Care, Southampton, United Kingdom*
Email: sitalshah@nhs.net

Background and aims: Patients with autoimmune hepatitis (AIH) often receive variable steroid and azathioprine regimens. The purpose of this study was to determine whether earlier introduction

Figure: Table 1: Prednisolone exposure over 5 year follow-up period

Months	Prednisolone dose, mg median (IQR)				Cumulative prednisolone dose, mg, median (IQR)				Cumulative prednisolone dose, mg/kg, median (IQR)

Figure: (abstract: WED-280).

of azathioprine for the treatment of AIH allows for reduced cumulative steroid burden in AIH.

Method: We performed a retrospective single centre cohort study. Two hundred and twenty six patients were divided into 2 groups: those who had received azathioprine therapy within 8 weeks of initiation of steroid therapy (early group) and those who had received azathioprine more than 8 weeks after steroid initiation (late group).

Results: The dose and cumulative dose of predniso (lo)ne (mg/kg) in the early group was lower compared to the late group at all time-points but this did not reach statistical significance (table 1). The number of patients continuing on steroids was higher in the late group (62%) compared to the early group (52%) at the end of the 5-year follow-up but did not reach statistical significance (p = 0.33). The proportion of patients achieving biochemical remission (normal AST and IgG) from induction therapy was 59.1% at 3 months, 71.7% at 6 months and 82% at 12 months. Serum ALT level was normalised in 80% of patients in the early azathioprine group compared to 64.5% in the late group (p = 0.01) at 6 months. IgG levels were normalised in 68% of patients in the early group compared to 54% of patients in the late group (p = 0.05) at 1-year. Over the 5-year follow-up, more patients in the early group achieved biochemical remission although this was not statistically significant. Within the first 12 months of commencing steroid therapy, 70% of patients experienced steroid related side effects. The odds of experiencing an infection, visual disturbances, fatigue, changes to bone health, weight gain and hyperglycaemia was higher in the late group.

Conclusion: Earlier introduction of azathioprine does not result in a reduced cumulative dose of predniso (lo)ne during the first five years of treatment for AIH. However earlier introduction does result in a faster rate of normalisation of AST at 6 months and IgG at 12 months. The odds of experiencing steroid related side effects were higher in late azathioprine group.

Email: mfromme@ukaachen.de

Background and aims: Alpha-1 antitrypsin deficiency (AATD) arises from mutations in the alpha1-antitrypsin (AAT) gene and predisposes to liver cirrhosis. However, the liver phenotype is variable and modifying factors are poorly understood. We studied the impact of alcohol intake on liver-related parameters in individuals with the characteristic heterozygous/homozygous Pi*Z variant (Pi*MZ/PI*ZZ genotype) found in the community-based United Kingdom Biobank (UKB) and the European Alpha1 liver consortium.

Method: Anamnestic data on alcohol consumption were evaluated in 17 145 Pi*MZ and 141 Pi*ZZ subjects as well as 425 002 non-carriers (Pi*MM) from the UKB. 561 Pi*ZZ individuals from the European Alpha1 liver consortium without concomitant liver disease were assessed and a measurement of carbohydrate deficient transferrin (CDT) was performed. Non-transgenic and Pi*Z mice were subjected to Lieber-DeCarli (LDC) diet containing 3–4% alcohol for 8 weeks.

Results: >80% of individuals reported no/low alcohol intake, while harmful consumption (women ≥40 g/d, men ≥60 g/d) was rare (~1% in most groups). In UKB participants with Pi*MM/Pi*MZ genotype, significant alcohol consumption (women 12–39 g/d, men 24–59 g/d) resulted only in a <30% increase in transaminases above the upper limit of normal (ULN), while the effect on GGT was more pronounced (Pi*MM: 15.0% vs. 23.0%; Pi*MZ: 15.7% vs. 22.5%), but comparable in both groups. In both genotypes, harmful alcohol intake led to an at least twofold increase in the proportion of Pi*MM and Pi*MZ subject with elevated transaminases, GGT serum levels as well as elevated AST-to-platelet ratio indices (APRI) that were used as a surrogate of liver fibrosis. While liver-related death was >3times more common in Pi*MM/Pi*MZ subjects with harmful alcohol consumption, the difference was not statistically significant in Pi*MZ subjects. In Pi*ZZ individuals from both cohorts, moderate alcohol consumption had no obvious impact on transaminase serum levels, although GGT levels were numerically more frequently elevated. In the European

cohort, Pi*ZZ subjects with moderate alcohol consumption tended to have higher continuous attenuation parameters (CAP) suggestive of liver steatosis, while liver stiffness measurement (LSM) as a surrogate of liver fibrosis did not differ. In addition, 14% of individuals had elevated CDT serum levels (≥1.7%). In univariable analysis, Pi*ZZ subjects with elevated CDT levels displayed higher GGT serum levels (72.5 vs. 60.0% ULN, p = 0.011) as well as higher APRI scores (0.36 vs. 0.30 units, p = 0.006). No differences in LSM, but a trend towards higher CAP results was noted. LDC diet did not increase AAT accumulation in Pi*Z mice, while its impact on collagen mRNA was similar in both genotypes.
Conclusion: Moderate alcohol consumption seems to be tolerated in the majority of Pi*MZ and Pi*ZZ subjects.

Email: lgarciavillarreal@gmail.com

Background and aims: We had no wide study about mutations (MUT) and clinical data on Wilson Disease (WD) in Spain. Recently, a National Registry for WD (SWR) was started by the AEEH (Spanish Association for the Study of the Liver). We aimed to study WD mutations and its association with clinical phenotypes and the different use of genetic evaluation among regions.
Method: Multicentre study including genetic and clinical data from patients (pt) from the SWR during the first year. Ethical approval and informed consent was obtained for all cases.
Results: The SWR includes data from 29 hospitals (from 1 to 71 pt) of 13/17 regions (85% nation population). Genetics were available in 233/320 pt with a Leipzig score>2; with data of 2 alleles in 206/233 pt (homozygous 27%). More than 130 MUT were registered, the majority in less than 4 alleles, being the most prevalent: M645R (17.3% alleles, mainland and Canaries), L708P (12.6%, only Canaries) and H1069Q (6.5%, only mainland). Only 15 MUT were in homozygosis and 3 in more than 3 pt: L708P (24 pt), c.1708–1G>A (5 pt, restricted to gipsy ethnicity), M645AR (4 pt). Among regions, genetic data ranged from 0% to 100% pt (in 3 regions under 40% and in 4 regions above 85% of their pt). In regions with several centers, the difference among them was higher than 50%. Among the most prevalent MUT, we found differences in the proportion of cirrhosis at diagnosis (higher for L708P p = 0.002), asymptomatic pt (higher in H1069Q, p = 0.027), clinical presentation (chronic hepatic higher for M645R, recent neurological higher in c.1708–1G>A, chronic neurological higher in L708P, p < 0.001). In homozygous pt, we only found differences in recent neurological cases (higher in c.1708-1G>A; p < 0.05) and age at diagnosis after 40 yo (low in L708P and high for M645R; p < 0.001). In the absence of genetic data up to 45% of pt would not have reached Leipzig score >3. In screening cases, genetics were used in 49/58 (85%); without genetics, two thirds would not have reached Leipzig>3 (33/49).
Conclusion: We got the first genetic map for WD in Spain, with a great variability of MUT (except in Gran Canaria and the gipsy community, probably with higher inbreeding). The use of genetic testing in WD is very heterogeneous among regions and even within them. Its use is high for screening cases, saving time and costs to both patients and the health care system. The most frequent MUT (M645R) seems to associate with a milder phenotype (lower penetrance), while the Gran Canaria mut (L708P) seems to present earlier and with more severe cases. The MUT of the gipsy ethnicity is associated with recent neurological cases. These data will be confirmed and expanded with further data in the Spanish Wilson Registry.

THU-283

Myeloproliferative neoplasms and splanchnic vein thrombosis: results of a long-term UK prospective cohort study

Rupen Hargreaves[1], Anicee Danaee[1], David Patch[2], Salil Karkhanis[3], Israa Kaddam[4], Jin Un Kim[1], Hayder Hussein[4], Frederick Chen[4], Dominic Yu[1], Mallika Sekhar[1], Dhiraj Tripathi[3]. *[1]Royal Free Hospital NHS Foundation Trust, Department of Haematology, United Kingdom; [2]Royal Free Hospital NHS Foundation Trust, Sheila Sherlock Liver Centre, United Kingdom; [3]University Hospitals Birmingham NHS Foundation Trust, Liver Unit, United Kingdom; [4]University Hospitals Birmingham NHS Foundation Trust, Department of Haematology, United Kingdom*
Email: rupen.hargreaves@nhs.net

Background and aims: Myeloproliferative neoplasms (MPN) confer an increased risk of thrombosis, including splanchnic vein thrombosis (SVT). SVT comprises porto-mesenteric-splenic axis thrombosis (PMVT) and hepatic vein thrombosis (HVT, Budd-Chiari syndrome). MPN-SVT carries a significant morbidity and clinical management is challenging, requiring surgical and radiological intervention in addition to aggressive anticoagulation. Long term prospective studies of this patient population are lacking. We report the results of a 5-year prospective cohort study assessing outcomes in MPN-SVT patients.

Method: The primary end point was a composite comprised of change in morbidity or portal circulation over 18 months. Secondary end points included 5 year outcome data and antithrombotic and cytoreductive usage, amongst others. Splanchnic thrombotic burden was assessed using cross sectional imaging in line with international standards.
34 patients with MPN-SVT were recruited from two UK specialist centres to an observational study that lasted between 2014 and 2021.
Results: 34 patients with MPN-SVT were recruited from two UK specialist centres to an observational study that lasted between 2014 and 2021. Median age at diagnosis was 45 (range 22–72) and 59% were female. Median time from SVT to registration was 34 months (range 1–167). There were 3 deaths, two were disease-related. 94% had a *JAK2 V617F* mutation. The underlying MPN was Polycythaemia vera in 44% and Essential thrombocythaemia in 35%. At 5 years, 39% of patients were taking hydroxycarbamide, 17% interferon, 28% ruxolitinib and 17% no cytoreduction. 28/34 (82%) were on anticoagulation at study recruitment, of whom 89% were on warfarin. 9/34 (26%) were taking an antiplatelet at registration. At 5 years, 28/29 (97%) were on anticoagulation, 68% were on warfarin and 21% on DOACs. HVT accounted for 21% of thrombosis and PMVT for 79%. Cavernoma formation was seen in 19/34 (56%). Imaging outcome data were obtained at 18 months and 60 months. At 18 months, 17/34 (50%) had unchanged abdominal thrombotic appearances, 13/34 (38%) had recanalization, 1 patient (3%) had extension and there were no recurrences. A reduction in thrombotic load was seen in 3 patients (8.8%). At 5 years, 25/29 (86%) had unchanged abdominal thrombotic appearances, 3/29 (10%) had further recanalization and 1/29 (3.4%) had recurrence despite therapeutic anticoagulation. Spleen size increased in 6/29 (21%), reduced in 14/29 (48%) and remained unchanged in 9/29 (31%).
Conclusion: To our knowledge, this is the first prospective study of MPN-SVT. The data show sustained recanalization and low recurrence rates over 5 years, which is a novel finding. Our data provide a contemporary perspective on the natural course of this rare disease entity treated at specialist centres and pave the way for future studies in MPN-SVT.

THU-284

Efficacy and safety outcomes with odevixibat treatment: Pooled data from the phase 3 ASSERT and ASSERT-EXT studies in patients with Alagille syndrome

Email: novchins@montefiore.org

Background and aims: Cholestasis in Alagille syndrome (ALGS) is associated with accumulation of bile acids (BAs) and other biliary components in the liver with spill-over into the systemic circulation, as well as severe pruritus that can impair sleep. In the phase 3 ASSERT and ASSERT-EXT trials, odevixibat, an ileal BA transporter inhibitor, improved pruritus and sleep parameters and reduced BAs in patients with ALGS. Using pooled data from these studies, we describe efficacy and safety outcomes with odevixibat in patients with ALGS.
Method: In the completed 24-week ASSERT study, patients with ALGS with history of significant pruritus and elevated serum BAs were randomised 2:1 to odevixibat 120 µg/kg/day or placebo, respectively. Patients who completed ASSERT could enter ASSERT-EXT, an ongoing, 72-week open-label extension study in which all patients receive odevixibat 120 µg/kg/day. This pooled analysis included all odevixibat-treated patients from ASSERT and/or ASSERT-EXT and spans from patients' first dose of odevixibat to a data cut-off of 9 September 2022. Assessments through 36 weeks of treatment included change in observer-reported scratching scores and sleep parameters as well as levels of serum BAs, autotaxin (a proposed mediator of pruritus), and plasma 7-alpha-hydroxy-4-cholesten-3-one (p-C4; a marker of reduced BA reabsorption). Safety evaluations included monitoring liver function parameters and treatment-emergent adverse events (TEAEs).
Results: At the data cut-off, 52 odevixibat-treated patients (mean age, 6.5 years; 48% female) comprised the pooled population. Compared with baseline, odevixibat treatment resulted in rapid (by week 4) and significant mean improvements in pruritus and reductions in BA levels, as well as significant mean decreases in autotaxin and increases in p-C4 levels (Figure). There were significant decreases from baseline to weeks 33–36 ($n = 21$) in multiple sleep parameters, including mean percentage of days seeing blood due to scratching, needing help falling asleep, needing soothing, and sleeping with caregiver (-30%, –60%, –59%, and –44%, respectively; all $p < 0.001$). No patients had concurrent elevations in alanine aminotransferase or total bilirubin that were indicative of drug-induced liver injury. TEAEs were reported in 43 of 52 (83%) odevixibat-treated patients. The most common drug-related TEAE

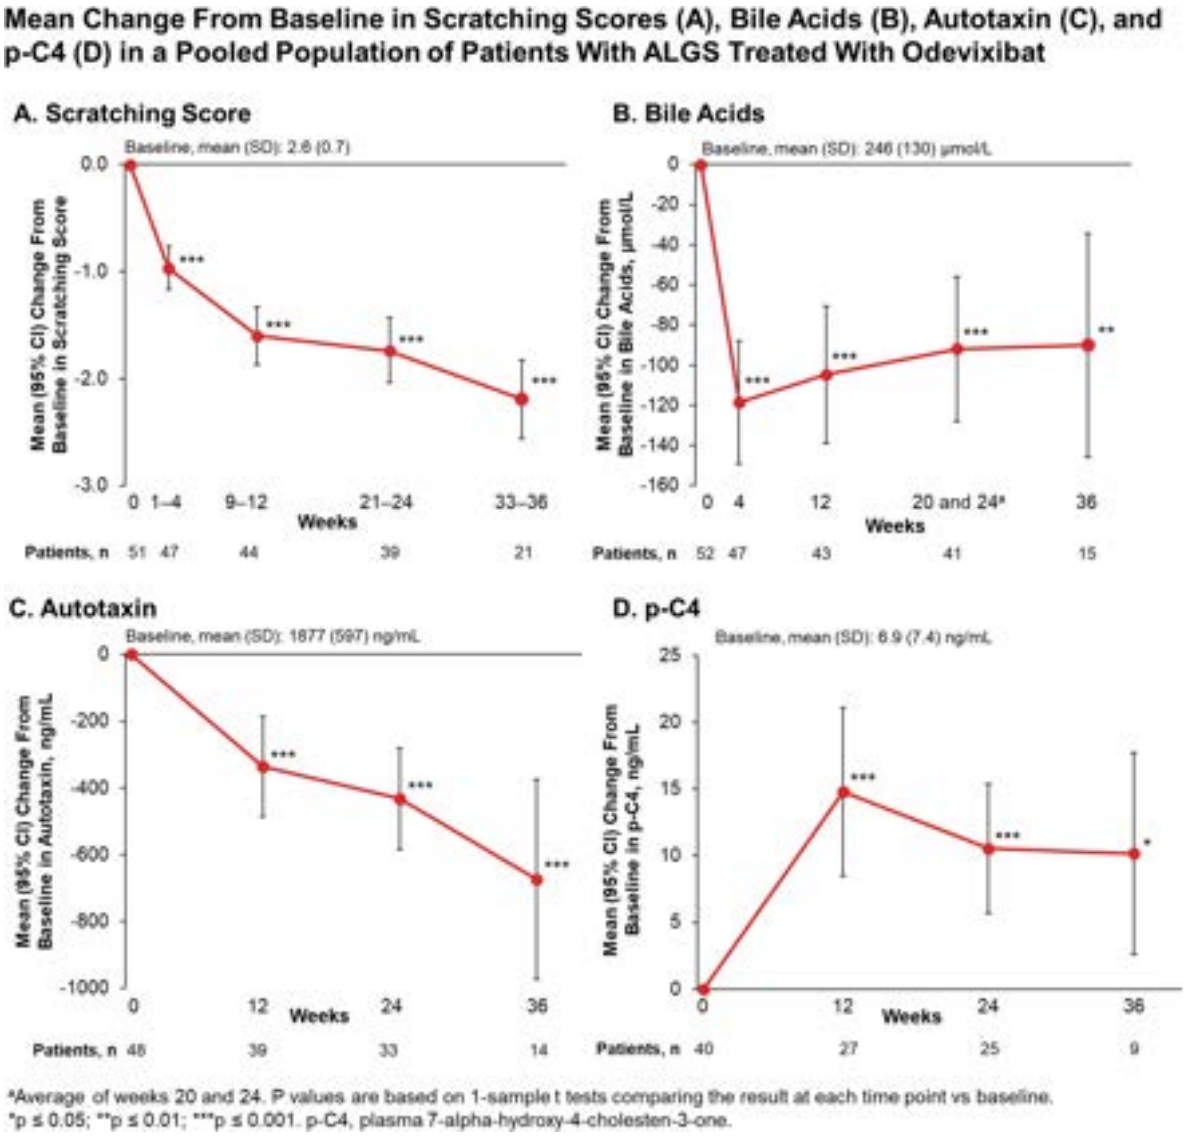

Figure: (abstract: THU-284).

was diarrhoea (n = 6/52 [12%]). At the data cut-off, no patient had TEAEs that led to study discontinuation.

Conclusion: In patients with ALGS, odevixibat treatment for up to 36 weeks led to significant and sustained improvements in pruritus and sleep and significant reductions in BA levels. Consistent with effects on pruritus and BA levels, there were significant changes in autotaxin and p-C4 levels with odevixibat. Odevixibat treatment was generally well tolerated in patients with ALGS.

THU-285

Clinical features, histology and outcome of pediatric porto-sinusoidal vascular disease

Angelo Di Giorgio[1], Lorenza Matarazzo[1], Aurelio Sonzogni[2], Emanuele Nicastro[1], Andrea Pietrobattista[3], Mara Cananzi[4], Paola Gaio[4], Marco Sciveres[5], Grazia Di Leo[6], Raffaele Iorio[7], Antonio Marseglia[8], Giuseppe Maggiore[3], Maria Guido[9], Lorenzo D'Antiga[1]. Email: adigiorgio@asst-pg23.it

Background and aims: in paediatrics, porto-sinusoidal vascular disease (PSVD) is likely an underdiagnosed and misdiagnosed condition. We report data of a large cohort of children diagnosed with PSVD.

Method: retrospective, multicentre study of children with PSVD diagnosed by histological criteria in the last 15 years.

Results: 62 children with PSVD (M/F = 36/26, median age 6.6 years, range 3.3–10.6), from 7 centres, were included. Two expert liver pathologists reviewed histological features blindly. Thirty-six patients presented with non-cirrhotic portal hypertension, PH, (PH-PSVD Group = 58%) while 26 had a liver biopsy because of chronic elevation of transaminases without PH (noPH-PSVD Group = 42%). On histology review, the two groups differed for the prevalence of

obliterative portal venopathy (more prevalent in PH-PSVD, p = 0.005), and hypervascularised portal tract (more common in noPH-PSVD, p = 0.039). At multivariate analysis, platelet count ≤185.000/mm3 was the only independent determinant of PH (p < 0.001). Linear regression analysis showed a significant reduction in platelet count with increasing age at time of diagnosis and at last follow-up (Pearson coefficient – 0.4876, p = 0.02 at diagnosis; 0.4209; p value = 0.04 at last follow-up). After a median follow-up of 7 years (range 3.0–11.2), in PH-PSVD group 3/36 (8%) required TIPS placement, 5/36 (14%) developed pulmonary vascular complications of PH, and 7/36 (19%) required liver transplantation. In noPH-PSVD none progressed to PH nor had complications. At last follow-up 60/62 patients (97%) were alive.

Conclusion: PSVD present with two different clinical phenotypes, one characterised by PH and one by chronic elevation of transaminases without PH. PSVD should be included among the conditions causing isolated hypertransaminasemia. There is a clear trend to decreased platelet count by age and follow-up at linear regression. On histology, the differences between the two groups are subtle. Medium-term outcome is favourable in patients without PH; progression of the disease is observed in those with PH.

THU-287

High-dose oral thiamine was not superior to placebo in reducing fatigue in patients with primary biliary cholangitis: a randomised, double-blinded, placebo-controlled crossover trial

Palle Bager[1], Lars Bossen[1], Rasmus Hvidbjerg Gantzel[1], Henning Grønbæk[1]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus N, Denmark*
Email: pallbage@rm.dk

Background and aims: Fatigue in primary biliary cholangitis (PBC) is highly frequent and associated with reduced quality of life. The causes of fatigue are multifactorial and have led to a variety of interventions. Despite the impact of fatigue in PBC, only a few interventions have demonstrated clinical effects. However, in patients with inflammatory bowel disease, high-dose thiamine given for 4 weeks showed significant effects on fatigue. We aimed to investigate the effects of high-dose thiamine on fatigue in patients with PBC and conducted a randomised, double-blinded, placebo-controlled crossover trial.
Method: Patients with PBC and significant fatigue, normal renal function, and no obvious other reasons for fatigue were included. Patients were allocated 1:1 to Group 1 (high dose oral thiamine for 4 weeks, a 4 weeks wash-out period, followed by 4-week oral placebo) or Group 2 (oral placebo for 4 weeks, a 4 weeks wash-out period, followed by 4 weeks high dose oral thiamine). The doses of thiamine ranged between 600 and 1800mg/day, based on gender and body weight. Fatigue was measured using the PBC-40 questionnaire. A subscale including 11 questions measures the severity of fatigue (range 11–55). We defined significant fatigue as a score >32, based on data from the general population. The primary end point was a decrease of ≥5 points on the PBC-40 fatigue-subscale. The study adhered to the principles for Good Clinical Practice.

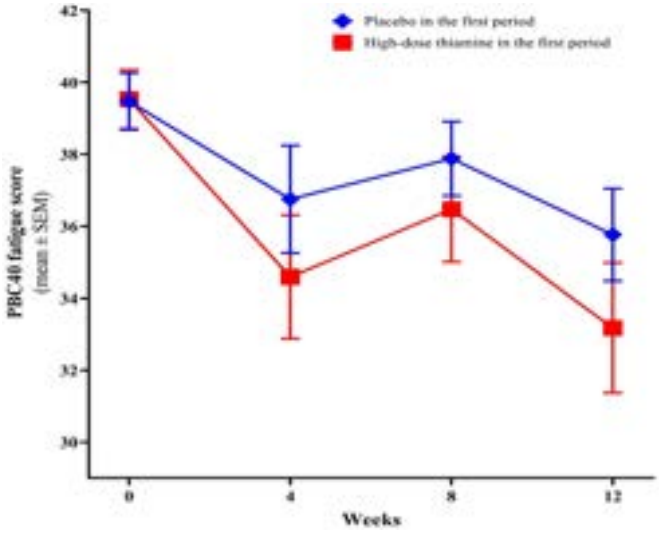

Figure:

Results: Of 36 patients included and randomised, 32 completed the study. Of these, 30 participants (94%) showed >80% adherence to thiamine treatment and were included for further analysis. We observed no statistical differences between the groups at baseline and no carryover effect. At the end of study (week 12), 14 patients (47%) had a reduction ≥5 points in fatigue. The overall mean reduction of fatigue was 5.4 points (95% CI 2.8–8.0; $p < 0.001$). A delayed treatment model was assessed, showing a 3.7 points (95% CI 1.2–6.2) reduction in fatigue after thiamine treatment, compared to a 3.7 points (95% CI 1.9–5.6) reduction in fatigue after placebo ($p = 0.98$). Furthermore, 44% of Group 1 and 25% of Group 2 showed an improvement of more than 5 points while on thiamine treatment compared with 44% of Group 1 and 31% of Group 2 while on placebo (Figure 1). No serious adverse events were detected. Adverse events were sparse, temporary, and included sore throat and cold symptoms.
Conclusion: The treatment was well tolerated and safe for the patients. However, the effect of four weeks high-dose oral thiamine was not superior to placebo in PBC patients with significant fatigue. The overall effect could be ascribed to a convincing effect of placebo.

THU-288

Cancer incidence and survival in HFE hemochromatosis-A population-based cohort study

Benedikt Schaefer[1], Lorenz Michael Pammer[1], Bernhard Pfeifer[2,3], Sabrina Neururer[2,3], Maria Troppmair[1], Marlene Panzer[1], Sonja Wagner[1], Elke Pertler[1], Christian Gieger[4,5], Florian Kronenberg[6], Claudia Lamina[6], Herbert Tilg[1], Heinz Zoller[1]. Email: heinz.zoller@i-med.ac.at

Background and aims: Hemochromatosis is characterized by progressive iron overload affecting the liver and can cause cirrhosis and hepatocellular carcinoma. Most hemochromatosis patients are homozygous for p.C282Y in *HFE*, but only a minority of individuals with this genotype will develop the disease. The aim was to assess the penetrance of iron overload, liver fibrosis, hepatocellular carcinoma and life expectancy in hemochromatosis patients.
Method: A total of 8839 individuals from the Austrian region of Tyrol were genotyped for the p.C282Y variant between 1997 and 2021. Demographic, laboratory parameters and causes of death were assessed from health records. Survival and cancer incidence were ascertained from the national health insurance and cancer registry. Outcomes were compared to a propensity score matched control population.
Results: Median age at diagnosis in 542 p.C282Y homozygous individuals was 47.8 years (64% male) and the prevalence of biochemical iron overload was 55%. Among all expected Tyrolean residents with p.C282Y homozygosity, biochemical iron overload was confirmed in 15.8% of men as compared to 8.9% of women aged 60 years. The proportion of p.C282Y homozygotes in whom significant fibrosis could be excluded by a FIB-4 score <1.3 decreased with age and was 95.6% in males and 97.3% in females at the age of 60 years. Median life-expectancy was reduced by 6.8 years in individuals homozygous for p.C282Y when compared with population-matched controls ($p = 0.001$). No difference could be found in cancer incidence, including hepatocellular carcinoma.
Conclusion: Penetrance of iron overload in p.C282Y homozygotes is low, but survival is reduced when compared to a matched control population.

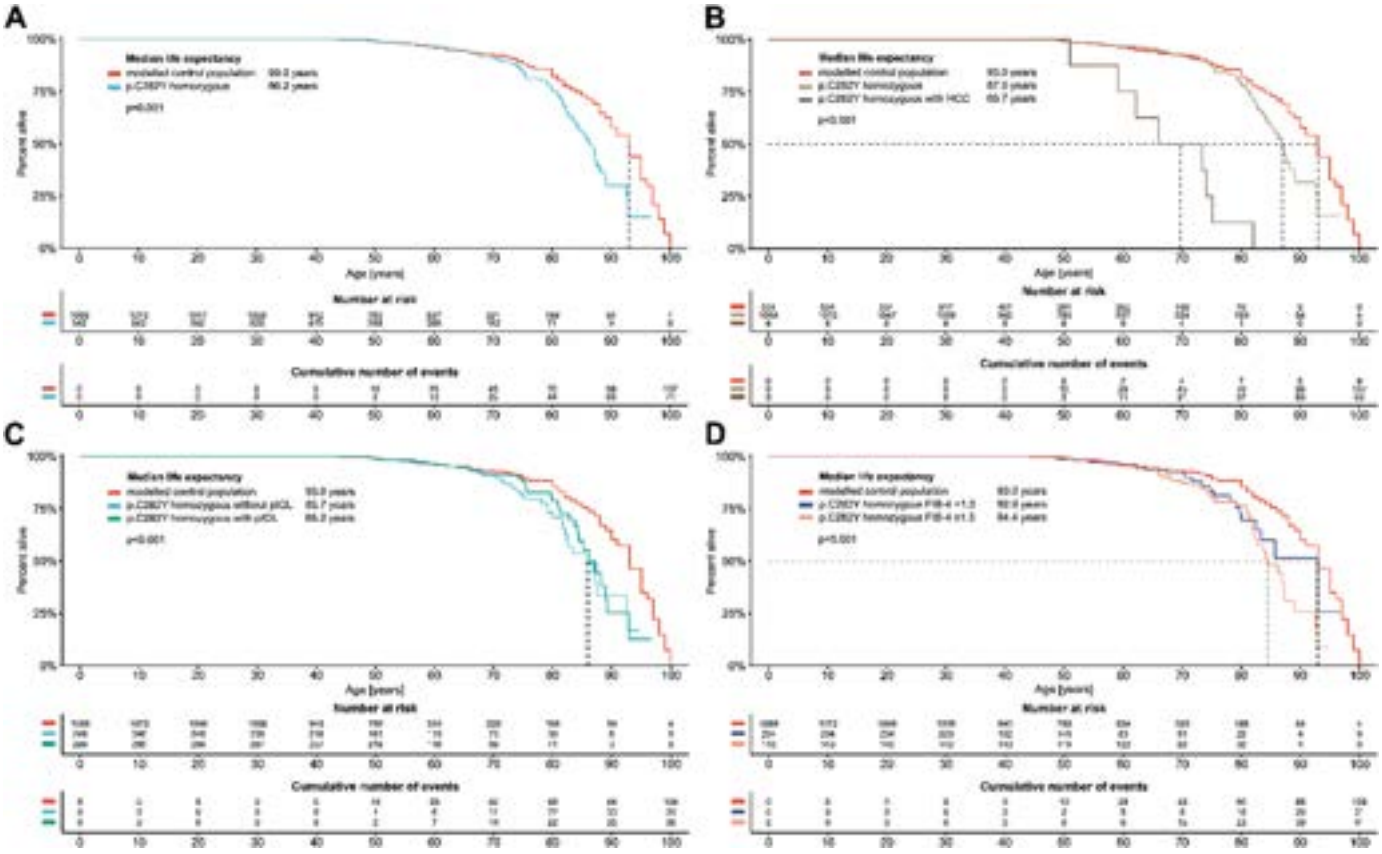

Figure: (abstract: THU-288): (A) Life expectancy of p.C282Y homozygotes (B) with and without hepatocellular carcinoma (C) with and without provisional iron overload (pIOL) and (D) FIB-4 score <1.3 or ≥1.3 compared to a modelled propensity score-matched control population.

Background and aims: Progressive familial intrahepatic cholestasis (PFIC) is a group of rare cholestatic liver diseases characterized by intractable pruritus, elevated serum bile acids (sBAs), and progressive liver damage. NAPPED (NAtural course and Prognosis of PFIC and Effect of biliary Diversion) is a large retrospective database investigating the natural history of PFIC. Odevixibat, an ileal bile acid transporter inhibitor, reduced sBAs and pruritus in patients with PFIC in the phase 3 PEDFIC 1 and PEDFIC 2 studies. We compared clinical outcomes of surgical biliary diversion (SBD), liver transplantation (LT), and death in patients from NAPPED (not treated with odevixibat) with odevixibat-treated patients from the PEDFIC studies.
Method: The analysis population comprised odevixibat-naive patients from NAPPED and odevixibat-treated patients from PEDFIC 1 and/or PEDFIC 2. BSEP3 patients were excluded in both groups. Eligibility criteria were aligned across cohorts and included genetically proven diagnosis of PFIC1 or PFIC2, sBAs ≥100 µmol/L, alanine aminotransaminase and total bilirubin ≤10 × the upper limit of normal, and no prior SBD or LT. Propensity scores, inverse probability of treatment weighting, and matching methods were used to identify and balance baseline covariates, including PFIC type 1, PFIC2-BSEP1 or PFIC2-BSEP2. The primary end point was event-free survival (EFS; time to first event of SBD, LT, or death); secondary end points included native liver survival (NLS), SBD-free survival (DFS), and overall survival (OS). Survival outcomes were measured from study day 1; treatment differences were evaluated by weighted log-rank tests and Cox regression.
Results: A cohort of 80 NAPPED patients (controls) was compared with 69 odevixibat-treated patients. The median study duration in the odevixibat cohort was 22.6 months (range: 1.9–39.2 months). The follow-up duration in the NAPPED cohort was truncated accordingly. Odevixibat-treated patients showed significantly higher EFS and DFS than controls (hazard ratio [HR]: 0.20 and 0.13, respectively); numerical improvements in NLS and OS were also observed **(Table)**. Results were consistent when different sensitivity analyses were performed. Additional subgroup analyses indicated that EFS was higher in odevixibat-treated patients with PFIC1 (HR [95% CI] = 0.10 [0.02, 0.55]) and PFIC2 (HR [95% CI] = 0.34 [0.12, 1.00]) vs controls.
Conclusion: Odevixibat treatment is associated with higher EFS in patients with PFIC without prior SBD, upon comparison to matched, non-odevixibat-treated patients from the NAPPED registry.

Email: vihernandez@clinic.cat

Background and aims: Patients with vascular liver diseases (VLD) are at considerable risk for thromboembolic events and are at higher risk of infection by SARS-CoV-2 and a severe course of COVID-19 disease. The immune response to the SARS-CoV-2 vaccination in patients with VLD is unknown. The effectiveness and safety of CoVID-19 vaccines, especially the potential risk of thromboembolic events has not been investigated in these individuals. We thus, aimed to determine the efficacy of vaccination against CoVID-19, incidence of adverse reactions and outcome post-vaccination in a large cohort of patients with VLD.
Method: International multicentre prospective observational study in patients with VLD. Patients were included at the time of vaccination, with a mean follow-up of 47 weeks (13–71 weeks). We analyzed the incidence of CoVID-19 infection after vaccination, severity of side effects, occurrence of thromboembolic events and hepatic decompensation. In a subgroup of patients, the humoral and cellular responses to vaccination were analyzed.
Results: A total of 909 patients from 14 European centers were included, 524 non-cirrhotic-non-malignant-splanchnic vein thrombosis (NCPVT), 234 Portosinusoidal Vascular Disorder (PSVD) and 140 Budd-Chiari Syndrome (BCS). A total of 151 patients were previously infected by CoVID-19. A total of 883 patients (97%) received two vaccine doses (fully vaccinated: FV), 681 (75%) also a third dose. In the 755 naïve FV, primary CoVID-19 infection occurred in 52 (6.9%), a

Table: (abstract: THU-289): Survival Outcomes

	Odevixibat-Treated Cohort n = 69	NAPPED Control Cohort n = 80
Event-Free Survival (EFS)		
Events, n (%)	6 (9%)	44 (55%)
p value	0.0016	
HR (95% CI)	0.20 (0.09, 0.45)	
Native Liver Survival (NLS)		
Events, n (%)	4 (6%)	21 (26%)
p value	0.0900	
HR (95% CI)	0.33 (0.11, 1.03)	
Diversion-Free Survival (DFS)		
Events, n (%)	2 (3%)	31 (39%)
p value	0.0023	
HR (95% CI)	0.13 (0.04, 0.39)	
Overall Survival (OS)		
Events, n (%)	0 (0%)	4 (5%)
p value	0.0845	
HR (95% CI)	0 (0, NE)	

Sample sizes and events are unweighted. HRs are generated using PS-weighted + covariate-adjusted Cox regression. P values are generated using PS-weighted + covariate-stratified log-rank tests. HR, hazard ratio; NAPPED, NAtural course and Prognosis of PFIC and Effect of biliary Diversion; NE, not estimable; PS, propensity score.

rate lower than reported for the un-vaccinated VLD population of 14%. Four FV patients required hospitalization including 2 ICU admissions, and two died from CoVID-19. Incidence of primary CoVID-19 infection after receiving a 3rd dose was 31/600 (5.2%). Prevalence of re-infection was 9/151 (6%), 3 after one dose of vaccination, 4 after two doses, and 2 after a third dose. At least one adverse event was reported in 42.6% patients, 40.6% after the first dose, and 74.9% after the second and third dose. The most frequently reported adverse events were local side effects at the injection site. Systemic side effects were asthenia (15%) and fever (9.4%). No serious adverse events were reported. Thirty-two (3.5%) thromboembolic events were identified, 28 SVT/PVT (23 re-thrombosis and 5 de-novo) and 4 extra-splanchnic. Two after the first dose (23- and 43-days post-vaccination), 23 (71.9%) after the second dose (median 52-days, 12–270), and 7 after a third dose (median 36-days, 19–270). No case of immune-thrombotic-thrombocytopenia (ITP) occurred. Twenty-two (2.4%) patients developed decompensations (median 25-weeks, range 13–42): ascites in n = 11, hepatic encephalopathy in n = 7 and portal hypertensive bleeding in n = 5 in VLD patients. Vaccine immunogenicity was longitudinally assessed in 36 patients receiving an mRNA vaccine. Immune responses were robust in this subgroup, with 36/36 (100%) of patients mounting detectable antibody and T-cell responses after two vaccine doses with comparable levels to those previously reported in healthy populations.

Conclusion: Patients with VLD present an adequate immune response to COVID-19 vaccines, and seem to be effectively protected from serious COVID-19 courses. No cases of vaccine-induced ITP were reported in this large cohort of VLD patients after repeated COVID19 vaccine doses.

Background and aims: Alagille syndrome (ALGS) is a rare, autosomal dominant multisystem disorder characterized by cholestasis and extrahepatic manifestations. Given the current era of ileal bile acid transporter (IBAT) inhibitor therapies that reduce serum bile acid (SBA) levels, the aim of this study was to determine whether SBA are a predictor of clinical outcomes in ALGS.
Method: Patients were ascertained from the GALA cohort, an international multicentre study including clinically and/or genetically diagnosed children with ALGS. Those with neonatal cholestasis and at least one SBA measurement during follow-up were eligible for inclusion and those with biliary diversion were excluded. An established SBA threshold in progressive familial intrahepatic cholestasis (PFIC) (102 mmol/L) was assessed as a time-dependent covariate in Cox regression analyses for native liver survival (NLS); liver transplantation and death as end points), overall and while adjusting for total bilirubin (TB) levels and stratified by geographical region. Patients who did not meet one of these end points were truncated at the time of Kasai procedure, or their last follow-up, up to a maximum of 18 years of age.
Results: 565 patients from GALA were included, of whom 349 (61.8%) were male with a median year of birth of 2012 (IQR 2007–2016). Rates of NLS at 1, 5 and 18 years were 93.5%, 63.5%, and 50.3%, respectively. The SBA threshold of 102 mmol/L was a significant predictor of outcome (HR = 3.40, 95% CI 2.28–5.06, p < 0.001) and there was no significant difference in the impact of SBA between the first year of life and thereafter (p = 0.90). SBA remained a significant factor for NLS while adjusting for TB clearance at 1 year (HR = 1.87, 95% CI 1.04–3.33, p = 0.03), where clearance is defined as TB <2 mg/dL. There was no significant interaction between the SBA threshold and clearance of TB.
Conclusion: SBA is an independent predictive factor for NLS in children with ALGS and neonatal cholestasis. Of note, SBA is associated with NLS in children with ALGS who clear their bilirubin i.e. those with anicteric cholestasis. This is relevant in the context of IBAT inhibitors that promote a reduction in SBA and are currently indicated for pruritus but may also impact additional important clinical outcomes.

THU-292

Deep tissue exposure of antibiotics at the target site of infection in patients with cystic liver disease: a randomized pharmacokinetic trial

Lucas H.P. Bernts[1,2], Roger Brüggemann[3], Anouk M.E. Jansen[3], Nynke Jager[3], Heiman Wertheim[2], Joost P.H. Drenth[1], Marten A. Lantinga[1,4]. [1]Radboud University Medical Center, Department of Gastroenterology and Hepatology, Netherlands; [2]Radboud University Medical Center, Department of Medical Microbiology, Netherlands; [3]Radboud University Medical Center, Department of Pharmacy, Netherlands; [4]University Medical Centers Amsterdam, Department of Gastroenterology and Hepatology, Amsterdam Gastroenterology and Metabolism, Netherlands
Email: martenlantinga@gmail.com

Background and aims: Successful antibiotic therapy for liver (cyst) infection depends on adequate exposure of the drug at the site of infection. Available pharmacokinetic (PK) data of antibiotics in liver cyst fluid is limited, but such knowledge is critical to manage patients with cyst infections. This study aims to analyse deep tissue exposure of antibiotics using an in vivo human liver cyst model and explore influencing factors.
Method: We performed an explorative, randomized, single-dose, PK study. Patients (≥18 years, intact liver and renal function) eligible for percutaneous drainage of liver cysts were, after providing written informed consent, randomized between receiving intravenous (iv) ciprofloxacin and piperacillin/tazobactam (group 1), or trimethoprim/sulfamethoxazole (group 2). Antibiotics were administered as a single iv dose prior to the cyst drainage procedure. Blood samples were drawn at three time-points within 12 hours following administration of antibiotics. The cyst fluid sample was collected during liver cyst drainage. Antibiotic concentrations were measured with liquid chromatography-tandem mass spectrometry using a validated assay for plasma and liver cyst fluid. Primary outcome was deep tissue exposure, expressed as liver cyst to plasma concentration ratio (%). Individual plasma exposure was described by area under the concentration-time curve (AUC). AUC and maximum plasma concentration (Cmax) were calculated by post hoc estimation based on existing population PK models using non-linear mixed effect modelling. Deep tissue exposure estimates were calculated as cyst concentration to AUC or Cmax ratio. For exploratory analyses, we used linear regression to assess whether the time interval between antibiotic administration and cyst drainage (minutes), cyst location (left or right liver lobe) or cyst volume (ml) were correlated with deep tissue exposure.
Results: We included 20 patients (90% female, median age 61 years, median eGFR 88 ml/min/1.73 m2, median BMI 23.7 kg/m2). Twenty-one liver cysts were drained (group 1: n = 11 cysts, left lobe: n = 5, right lobe: n = 6 and group 2: n = 10 cysts, left lobe: n = 3, right lobe:

n = 7). Median drained volume was 700 ml [IQR 375–1200 ml]. Deep tissue exposure for ciprofloxacin was 4.2% [IQR 1.6–8.9%], piperacillin 0.3% [IQR 0.1–1.3%], tazobactam 0.2% [IQR 0.0–1.3%], trimethoprim 12.2% [IQR 6.3–16.1%] and sulfamethoxazole 0.4% [IQR 0.2–3.8%], respectively (Figure 1). Cyst concentration to AUC and Cmax ratios showed comparable distributions. Time between iv administration and cyst drainage increased deep tissue exposure for trimethoprim (R-square 0.63, $p < 0.01$). Deep tissue exposure was numerically higher in left lobe located cysts, except for sulfamethoxazole (Figure 1). Individual cyst volume did not correlate with deep tissue exposure.

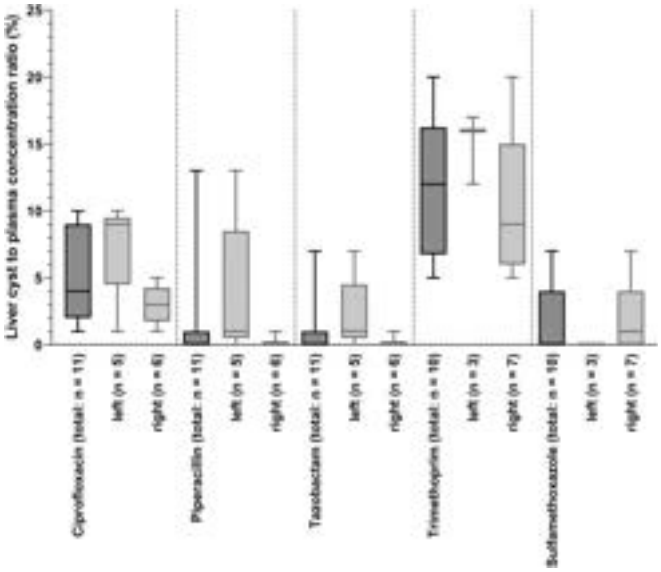

Figure:

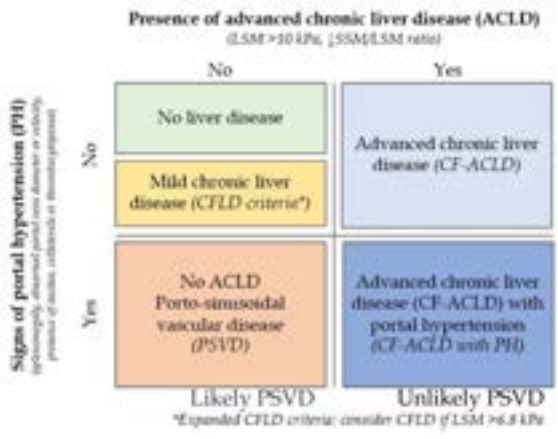
Conclusion: Deep tissue exposure of antibiotics in liver cysts was overall low after a single iv dose. Highest exposure in both liver lobes was seen for trimethoprim. Due to low sulfamethoxazole penetration, the synergistic combination with trimethoprim (co-trimoxazole) might be less effective. Exploratory analyses show that complex time-dependent pharmacokinetics and hepatic lobar differences could influence antibiotic exposure at the target site of infection.

THU-293

The non-invasive evaluation of vascular liver disease in patients with cystic fibrosis: a prospective cross-sectional study

Elton Dajti[1,2,3], Federico Ravaioli[1,3], Giulia Paiola[2], Sonia Volpi[2], Luigi Colecchia[1], Alberto Ferrarese[2], Luigina Vanessa Alemanni[1], Caterina Cusumano[2], Annarita Di Biase[4], Giovanni Marasco[1], Amanda Vestito[5], Davide Festi[1], Pierre-Emmanuel Rautou[6], Marco Cipolli[2], Antonio Colecchia[2,3]. *[1]University of Bologna, Italy; [2]Borgo Trento University Hospital of Verona, Italy; [3]University of Modena and Reggio Emilia, Dipartimento Chirurgico, Medico, Odontoiatrico e di Scienze Morfologiche con interesse Trapiantologico, Oncologico e di Medicina Rigenerativa, Italy; [4]University of Modena and Reggio Emilia, Department of Pediatrics, Italy; [5]IRCCS S. Orsola Hospital, Bologna, Italy; [6]Université de Paris, AP-HP, Hôpital Beaujon, Service D'Hépatologie, France*
Email: e_dajti17@hotmail.com

Background and aims: Porto-sinusoidal vascular disease (PSVD) has recently been described as the prominent pathology in liver explants of patients with cystic fibrosis (CF), but data outside the transplant setting are lacking. We aimed to investigate the prevalence of portal hypertension in cystic fibrosis-associated liver disease (CFLD) and develop a non-invasive algorithm to classify liver involvement in CF patients.
Method: This is a cross-sectional study of consecutive CF patients followed at our tertiary center between 2018 and 2019, who underwent ultrasound examination, liver (LSM), and spleen stiffness (SSM) measurement by transient elastography (TE). CFLD was defined according to abnormal physical examination, liver tests, and ultrasound findings. PSVD was likely if there were portal hypertension (PH) signs in the absence of advanced chronic liver disease (CF-ACLD, LSM <10 kPa).
Results: CFLD was found in 50 (27.5%) of the 182 included patients. At least one sign of PH was found in 47 (26%) patients, but the majority (38/47, 81%) had low LSM (<10 kPa) and were likely to have PSVD, whereas only 9 (5%) had CF-ACLD. PSVD and "mild" CFLD (LSM <10 kPa) co-existed in most (23/36) cases. SSM/LSM ratio could accurately distinguish between likely PSVD and CF-ACLD patients (AUROC = 0.863). In a historical cohort of 599 patients (pre-TE era), survival progressively decreased among patients with no PH, patients with likely PSVD, and patients with CFLD + PH signs (log-rank <0.0001).
Conclusion: PSVD seems to be the prevailing cause of portal hypertension in patients with CF. We developed a new diagnostic



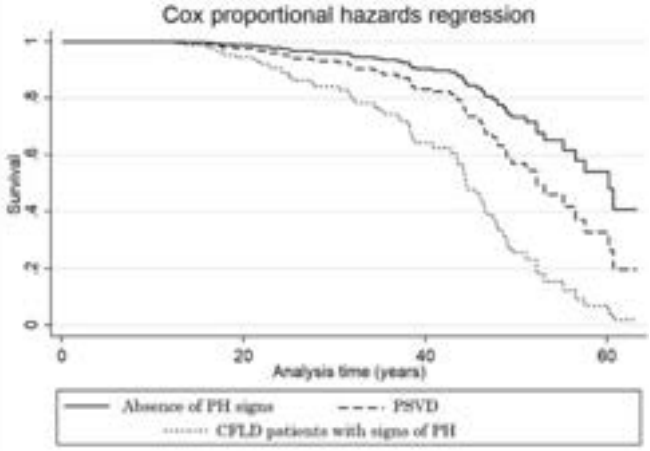


Figure: (abstract: THU-293).

algorithm based on ultrasound, clinical criteria, and TE to classify liver involvement in patients with CF.

THU-294

Monitoring, dosing and clinical outcomes of CFTR modulator triple combination therapy in children with CF post liver transplantation

Dana Cerminara[1], Daniel Leung[2]. [1]*Texas Children's Hospital, Pharmacy, United States;* [2]*Baylor College of Medicine, Pediatrics, Houston, United States*
Email: dhleung@texaschildrens.org

Background and aims: Triple combination therapy with elexacaftor/tezacaftor/ivacaftor (E/T/I) has revolutionized the lives of people with CF by restoring CF transmembrane regulator (CFTR) function in pulmonary, pancreatic and intestinal tissue, leading to drastically improved lung and nutritional health. There is a known risk of hepatotoxicity and drug interactions with transplant immunosuppressive agents.
Method: This was a retrospective review of 8 patients with CF who were candidates for E/T/I. We describe the protocolized dosing, monitoring, and clinical outcomes of E/T/I use in 8 children with CF post liver transplantation (LT) transplanted between 2014 and 2022. Data was analyzed using descriptive statistics.
Results: From January 2014-December 2022, a total of 14 children with CF received LT at Texas Children's Hospital (TCH) for the indication of portal hypertension. Of these, 8 (25% female) were alive and initiated E/T/I 17.5 months (median) post LT with a mean follow-up of 26 months. Tacrolimus trough (TAC) and liver labs were collected at baseline, 7 days, 14 days, and 28 days post-initiation. Five out of 8 (63%) patients required a TAC dose decrease within the first 2 months; 0 patients required a TAC dose increase. 1–2 TAC dose adjustments were needed in 63% to achieve goal levels and a 20–30% reduction in TAC while on E/T/I was most common. Adverse effects while on E/T/I included mild elevations (>1.5x baseline) in AST (43%), ALT (43%), GGT (29%), and subjective abdominal pain (29%). No elevations in bilirubin or INR. Only 14% discontinued E/T/I due to intolerance (abdominal pain and diarrhea) and was not liver related. Lung function measured by median FEV_1% improved from 85% to 93% over 13 months (expected 3% decline/year) while on E/T/I. Median BMI pre-E/T/I was 16.6 and increased to 19 post-E/T/I over 12 months but no change in BMI z-score (−0.99, −1.02, $p > 0.05$).

Conclusion: While our single center experience appears small, it represents 20% of the US CF pediatric population that received LT during this time period. Treatment with E/T/I post-LT in children with CF appears safe and requires protocolized lab monitoring. 1–2 dose adjustments of tacrolimus (primarily reductions) was most common. E/T/I associated hepatitis was mild with no cholestasis or liver dysfunction. E/T/I was associated with clinically meaningful improvement in lung function and BMI post-LT.

Background and aims: While Sars-Cov-2 infection is a well-known prothrombotic disorder, whether it is a risk factor for splanchnic vein thrombosis (SVT) is unknown. We aimed to assess the impact of Sars-Cov-2 infection on the presentation and prognosis of recent SVT and to assess if the disease profile of these patients differs from patients with recent SVT without Sars-Cov-2 infection.
Method: Retrospective study collecting health-related data of 27 patients presenting with recent SVT in the context of Sars-Cov-2 infection in 12 hospital centers belonging to VALDIG network and comparison to 494 patients with recent SVT prospectively included in a database before the Sars-Cov-2 pandemics.

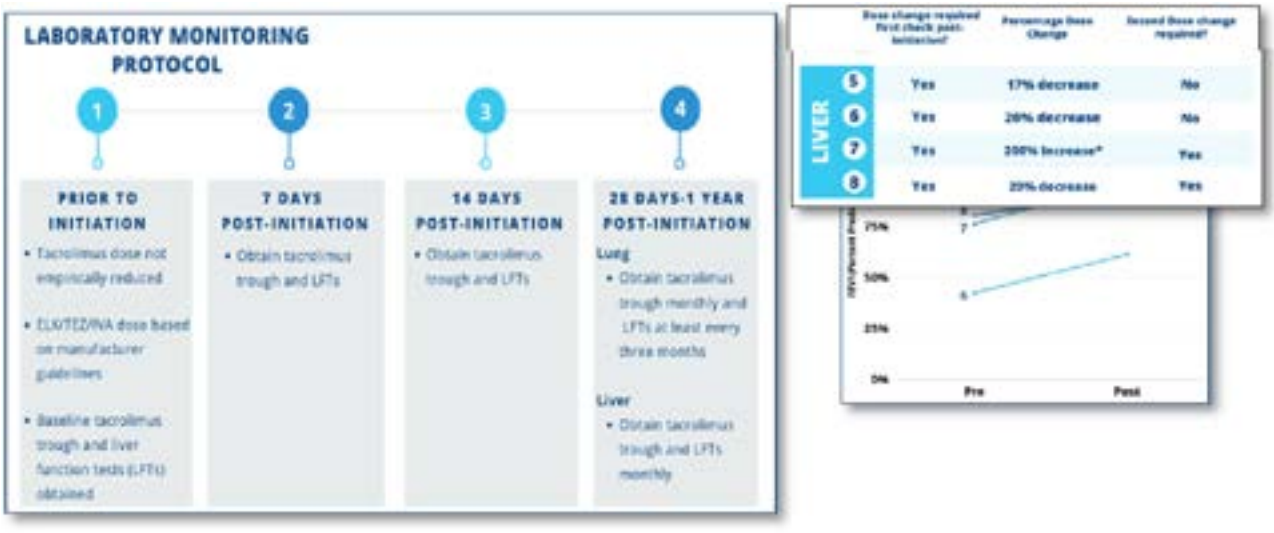

Figure: (abstract: THU-294): (placeholder)

Results: Among the 27 patients with recent SVT and Sars-Cov-2 infection (18 males, median age 51 years), 21 had portal vein thrombosis with or without thrombosis of another splanchnic vein, 2 had isolated superior mesenteric vein thrombosis, 1 isolated splenic vein thrombosis and 3 isolated hepatic veins thrombosis. Diagnosis of SVT was made 10 days (95% CI: 0–24) after the diagnosis of Sars-Cov-2 infection. Extension of SVT did not differ between patients with and without Sars-Cov-2 infection. No difference was observed in terms of

Table: (abstract: THU-295).

Table. Characteristics of patients with recent SVT with and without Sars-Cov-2 infection

Characteristics	Patients with Sars-Cov-2 infection (n = 27)	Patients without Sars-Cov-2 infection (n = 494)	p-value
Age, years	51 (36-53)	47 (45-49)	0.9
Male sex, n (%)	18 (67%)	298 (61%)	0.7
BMI	26.7 (24.3-29.3)	NA	NA
Fever, n (%)	14 (52%)	74 (15%)	<0.001
Respiratory symptoms, n (%)	12 (44%)	0 (0%)	<0.001
Dyspnea, n (%)	8 (30%)	0 (0%)	<0.001
Anosmia, n (%)	6 (25%)	0 (0%)	<0.001
Ageusia, n (%)	6 (25)	0 (0%)	<0.001
Abdominal pain, n (%)	24 (89%)	404 (82%)	0.6
Ascites, n (%)	7 (26%)	105 (22%)	0.4
CRP, mg/dL	42 (14-106)	35 (21-45)	0.5
D-dimers, ng/mL	3298 (850-10000)	NA	NA
White blood cells (10^3/mm^3)	6.1 (4.0-10.0)	7.0 (6.6-7.2)	0.5
Polymorphonuclear neutrophils (10^3/mm^3)	3.8 (2.7-6.2)	4.1 (3.9-4.4)	0.8
Lymphocytes (10^3/mm^3)	1.1 (0.9-1.5)	1.6 (1.5-1.7)	0.04
Eosinophils (10^3/mm^3)	0.03 (0-0.10)	0.10 (0.10-0.10)	0.002
Platelets (10^3/mm^3)	220 (178-301)	257 (240-273)	0.6
ASAT, IU/mL	38 (24-43)	32 (30-34)	0.3
ALAT, IU/mL	41 (25-52)	40 (37-43)	0.7
Alkaline Phosphatase, IU/mL	90 (75-134)	83 (79-88)	0.4
Bilirubin, mg/dL	0.9 (0.6-1.1)	0.6 (0.6-0.7)	0.03
INR	1.2 (1.1-1.3)	1.1 (1.0-1.1)	0.01
Creatinine (mg/dL)	0.9 (0.7-1.0)	0.8 (0.8-0.8)	0.3

Abbreviations: ALAT, alanine amino-transferase; ASAT, aspartate amino-transferase; BMI, body mass index; CRP, C-reactive protein; INR: international normalized ratio; NA, not available; SVT, splanchnic vein thrombosis

Continuous variables are presented as median (interquartile range)

age, sex ratio and liver blood tests between patients with and without Sars-Cov-2 infection. Seventeen of Sars-Cov-2 patients (59%) had fever and/or respiratory symptoms (dyspnea, ageusia and/or anosmia). Fever (52% vs. 15%, $p < 0.001$) and respiratory symptoms (44% vs. 0%, $p < 0.001$) were more frequent, and the median count of lymphocytes was lower (1.1 10^3/mm^3 [95% CI: 0.9–1.5] vs. 1.6 10^3/mm^3 [95% CI: 1.5–1.7], $p = 0.043$) in patients with than in those without Sars-Cov-2 infection. A prothrombotic condition was identified in 44% patients of Sars-Cov-2 patients and in 52% of non-Sars-Cov-2 patients ($p = 0.5$). No difference was observed regarding associated prothrombotic conditions. Four Sars-Cov-2 patients required ventilation support. All Sars-Cov-2 patients were treated with anticoagulation, including 25 in whom anticoagulation was initiated on the day of SVT diagnosis. During a median follow-up of 250 days (95% CI: 83–394 days), no patient suffered from gastro-intestinal bleeding or from another liver-related event and no patient died. Three patients (11%) required intestinal resection for infarction 1 to 3 months after the diagnosis of SVT, which was significantly more frequent than in the control group (n = 13 [2.6%], $p = 0.044$). At the end of the follow-up period, partial or complete recanalization of the thrombosed splanchnic vein was observed in 33% of Sars-Cov-2 patients.

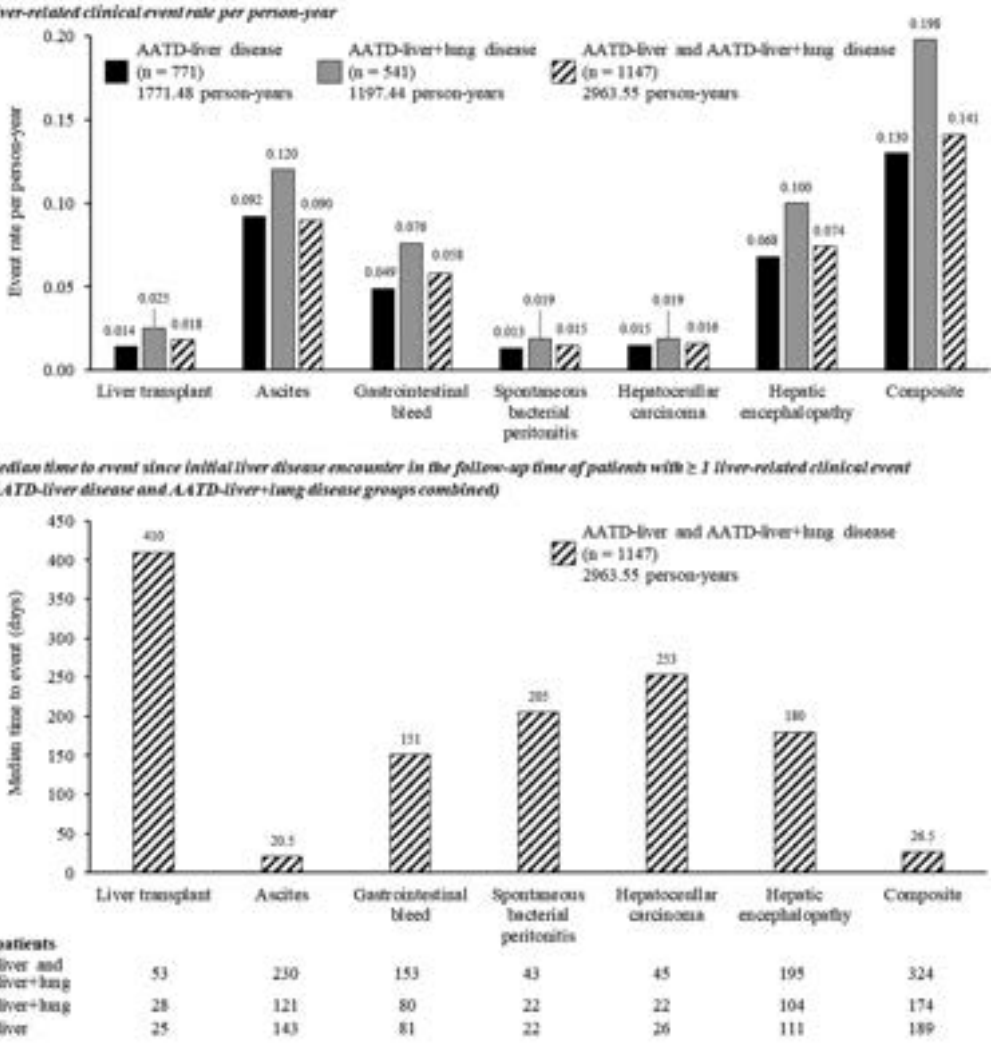
Conclusion: Sars-Cov-2 infection can be associated with recent SVT. SVT occurring during Sars-Cov-2 infection is characterized by a higher frequency of respiratory symptoms and a lower lymphocytes count. Intestinal ischemia leading to delayed intestinal resection seems more frequent in Sars-Cov-2 patients. In this cohort study in which all Sars-Cov-2 patients received anticoagulation therapy early on after the diagnosis of SVT, partial or complete recanalization was observed in one third of patients.

THU-296

Liver-related clinical events among adult patients with alpha-1 antitrypsin deficiency-associated liver disease: a longitudinal retrospective study using linked insurance claims data and electronic medical records in the United States

May Hagiwara[1], Victoria Divino[2], Swapna Munnangi[2], Mark Delegge[2], Suna Park[1], Ed G. Marins[1], Kaili Ren[1], Charlton Strange[3]. *[1]Takeda Development Center Americas, Inc., Cambridge, MA, USA, United States; [2]IQVIA Inc., Falls Church, VA, USA, United States; [3]Medical University of South Carolina, Charleston, SC, USA, United States*
Email: ed.marins@takeda.com

Figure 1. Liver-related clinical events in the follow-up time of adult patients in the AATD-liver disease and AATD-liver+lung disease groups



No. of patients							
AATD-liver and AATD-liver+lung	53	230	153	43	45	195	324
AATD-liver+lung	28	121	80	22	22	104	174
AATD-liver	25	143	81	22	26	111	189

AATD, alpha-1 antitrypsin deficiency.

Figure: (abstract: THU-296).

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disorder occurring in ~1 per 3000–5000 people in the USA. It is characterized by low levels of serum alpha-1 antitrypsin (AAT) and accumulation of misfolded AAT in hepatocytes, which can lead to liver and/or lung disease. Patients with AATD and the protease inhibitor (Pi) ZZ genotype are at increased risk of both diseases. The burden of liver-related clinical events among adult patients with AATD was investigated using large US claims and Ambulatory Electronic Medical Records (AEMR) databases.
Method: This was a retrospective analysis of administrative claims data from the IQVIA PharMetrics® Plus database linked to the IQVIA AEMR database (selection period: January 2012 to October 2021). PharMetrics Plus comprised 142 million enrollees with medical and pharmacy benefits and ≥1-month enrolment during the selection period. Inclusion criteria were: (1) at least one inpatient or at least two outpatient medical claims ≥90 days apart with a diagnosis of AATD in PharMetrics Plus, or (2) with a PiZZ/PiMZ genotype in AEMR and with linkage to PharMetrics Plus; (3) a liver disease diagnosis. A person-time approach was used to maximize the use of data. Follow-up time was assigned to the AATD-liver disease group (for time with liver disease only) and the AATD-liver+lung disease group (for time with both liver and lung disease). Liver-related clinical events of interest (identified by International Classification of Diseases-Ninth/Tenth Revision codes) included liver transplantation, ascites, gastrointestinal bleeds, spontaneous bacterial peritonitis, hepatocellular carcinoma, and hepatic encephalopathy. These were evaluated separately and as a composite (defined as the occurrence of ≥1 of the six clinical events).
Results: In total, 771 and 541 adults aged ≥18 years contributed their time to the AATD-liver disease and AATD-liver+lung disease groups, respectively (combined 1147 patients). The median age was 49 and 55 years, 58% and 51% were male, and the median duration of observation was 22 and 21 months, respectively. Liver-related clinical event rates per person-year among all patients and median time to event for those with liver-related clinical events are shown in Figure 1.
Conclusion: Among adult patients with AATD and liver disease, ascites was the most frequently observed and earliest encountered of the liver-related clinical events studied, followed by gastrointestinal bleeds and hepatic encephalopathy. These rates were higher when patients had both liver and lung disease involvement than liver disease only, possibly related to the higher median age of patients with both diseases. The number of patients with a confirmed PiZZ/PiMZ genotype was very low (AATD-liver disease: n = 11; AATD-liver+lung disease: n = 5), restricting further analysis.

Hepatobiliary malignancies in Wilson Disease: data from an Italian national reference centre

Lorenzo Canova[1], Pier Maria Battezzati[1], Greta Trevisi[1], Elisabetta Boga[1], Emanuela Bertolini[1], Paola Zermiani[1], Sara Monico[1], Massimo Giovanni Zuin[1]. [1]*ASST Santi Paolo e Carlo, S.C. Gastroenterologia ed Epatologia, Milano, Italy*
Email: lorenzo.canova@unimi.it

Background and aims: Wilson disease (WD) is a rare genetic disorder of copper transport leading to its accumulation mainly in the liver and the brain. Clinical course is frequently complicated by development of liver cirrhosis, a recognized risk factor for liver cancer (LC). Data on the risk of LC in WD is limited and controversial. Hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC) have been regarded as a rare complication of WD. In the largest available study (130 patients), a 1.2% prevalence (incidence rate, 0.28 cases per 1,000 person years) has been estimated (van Meer S., 2015). Conversely, HCC estimates in Saudi Arabia (71 patients) were 7.0% and 9.1 cases per 1, 000 person years, respectively (Al Fadda M., 2012). We investigated LC risk in a cohort of WD from a single tertiary referral center for liver diseases.
Method: We enrolled all the patients who were consecutively diagnosed WD (Leipzig score >3) between 1975 and 2022. First line therapy was Penicillamine, while intolerant patients received trientine or zinc salts. Patients underwent liver US examinations yearly. Cirrhosis was diagnosed on the basis of histology (if available), clinical, laboratory and US criteria. At time of first evidence of cirrhosis, LC surveillance was started (6-month US scan, alpha-fetoprotein testing). End of follow-up was date of LC diagnosis, liver transplantation (OLT), death, or last visit. 24 h urinary copper excretion was used to monitor treatment adequacy. Cox modeling was used to analyze survival.
Results: Overall, 189 WD patients (52% males) were included. Median age was 17 yr (2–74) on diagnosis and 40 yr (11–74) at time of enrollment. Median follow-up was 11.1 yr (0–47). 158 patients (83%) had hepatic or neurologic symptoms at presentation and 32 (17%) were diagnosed by family screening. On diagnosis, cirrhosis was present in 85 (45%) patients, of whom 11 (13%) had decompensated cirrhosis. At the end of follow-up, 95/189 patients had cirrhosis (3 decompensated, 1 waiting OLT for end-stage liver disease). LC was detected in 8 patients (75% M; age at LC diagnosis, 49–60 yr): 5 had HCC (4 transplanted and alive, 1 died), 2 CC (1 transplanted and alive, 1 died); 1 patient with HCC underwent tumor resection and subsequently developed CC (transplanted and alive). Of the 8 patients diagnosed WD when aged 30+ yr, 6 developed LC (4 HCC, 1 CC, 1 HCC +CC). In 2 patients HCC was diagnosed at time of WD recognition (57, 58 yr). In the remaining 6 patients, 24 h urinary copper excretion was in the therapeutic target. No relationship with mode of presentation or treatment emerged during the treatment period. The incidence of LC was 2.8 cases per 1,000 person years since birth (3 cases per 1,000 person years since time of WD diagnosis) with a prevalence of 4.2%.
Conclusion: The incidence of LC in WD is higher than formerly estimated, but still lower than other chronic liver diseases. CC represents a substantial part of LC.

Email: alexandra61@med.uoa.gr

Background and aims: In cystic fibrosis (CF), liver disease (CFLD) is the third leading cause of mortality. A combination of modalities including physical examination, biochemical and imaging were utilized in the conventional Debray criteria. New drugs have been approved for the treatment of CF patients who have at least one copy

of the F508del mutation in the CF transmembrane conductance regulator (CFTR) gene. These modulators were reported to improve lung function and symptoms as well as decrease CF exacerbations. However, the drug efficacy and tolerability on CFLD need further investigation.

Method: Longitudinal data were collected from a cohort of genetically confirmed CF adult patients. CFLD was diagnosed by Debray criteria.

Results: Thirty patents with CF [66.7% male, median age at diagnosis 6 (interquartile range 1.83–36) months, median age 27.5 (23–33) years] were included. Nine (30%) met the Debray criteria at first assessment. Seventeen patients (treatment group) treated for ≥12 months were compared with 13 treated for <12 months or untreated (non-treatment group). The median period of drug administration was 45 (21–69) months. Seven patients were receiving from the beginning elexacaftor/tezacaftor/ivacaftor (ELX/TEZ/IVA) while 10 initiated TEZ/IVA or lumacaftor/IVA and continued with ELX/TEZ/IVA. Mild fluctuations in LFTs occurred in 58.8% but did not lead to therapy discontinuation. Only one patient with CFLD received the drug in reduced dose. At the reassessment, 60.5 (57–65.25) months following first assessment, 11 (36.7%) of total patients met the Debray criteria. Two (15.4%) of the non-treatment group were classified as CFLD at first assessment and 6 (46.2%) in the reassessment. Seven (41.2%) in treatment group were classified as CFLD at first assessment and were reduced in 5 (29.4%) at the reassessment. Liver stiffness decreased in the treatment group from 6.8 kPa (5.05–11.95) to 5 kPa (4.15–6.35), ($p = 0.001$). The median time elapsing between two liver stiffness determinations were 87 (57–95) months. Liver stiffness values did not demonstrate a significant alteration in the non-treatment group between the two assessment points ($p = 0.972$).

Conclusion: In a case series of adult patients with CF, some patients from non-treatment group developed CFLD during investigation period while others treated with CFTR modulators were de-classified from CFLD and re-classified in non-CFLD group. Liver stiffness was also improved in treated patients. However, more patients and longer follow-up are needed for solid conclusions to be drawn.

THU-299

Genetic findings and magnetic resonance imaging of multiple biliary hamartomas

Juliana Goediker[1], Philipp Schindler[2], Judit Horvath[3], Julius Heidenreich[4], Jonel Trebicka[1], Carsten Bergmann[5], Bernhard Schlevogt[1]. *[1]University Hospital Muenster, Internal Medicine B, Germany; [2]University Hospital Muenster, Department of Radiology, Germany; [3]University Hospital Muenster, Department of Human Genetics, Germany; [4]University Hospital of Würzburg, Department of Diagnostic and Interventional Radiology, Germany; [5]Medical Center-University of Freiburg, Department of Medicine IV, Germany*
Email: juliana.goediker@ukmuenster.de

Background and aims: Biliary hamartomas (BH), which are also known as "von Meyenburg complexes," are benign and asymptomatic malformations of dilated bile ducts embedded in fibrous stroma, usually smaller than 10 mm. BH are usually incidental findings in liver imaging and there is a risk of misdiagnosis as malignomas. BH are part of a wider spectrum of ductal plate malformations, which are generally presumed to have a genetic basis. However, the specific genetic cause of BH is unknown. This study aims to provide a structured genetic and magnetic resonance imaging (MRI) analysis of BH.

Method: 6 patients with multiple biliary hamartomas (MBH) were identified in a large cohort of a tertiary center. Customized next-generation sequencing was used to identify the underlying genetic cause of MBH. This panel contained more than 650 genes with a known association with ciliopathies. High-resolution contrast-enhanced hepatobiliary MRI was performed in all subjects to provide a structured report of the imaging features of MBH. Quantitative analysis of cystic liver volume was performed with an artificial-intelligence augmented approach at baseline and follow-up MRI.

Results: In all patients, a heterozygous missense change, truncating or frameshift mutation was found in PKHD1, which encodes for multidomain integral membrane protein fibrocystin. Biallelic mutations are causative for autosomal recessive polycystic kidney disease (ARPKD). Laboratory and clinical abnormalities were missing and acoustic radiation force elastography (ARFI) displayed no signs of liver fibrosis in these patients. MRI showed innumerable small liver cysts without communication with the biliary tree, which allowed diagnosis of MBH. Longitudinal MRI studies revealed that total hepatic cystic volume remained stable over time (mean volume: 104.8 ml; mean proportion of total liver volume: 8.1%, mean follow-up: 3.8 years).

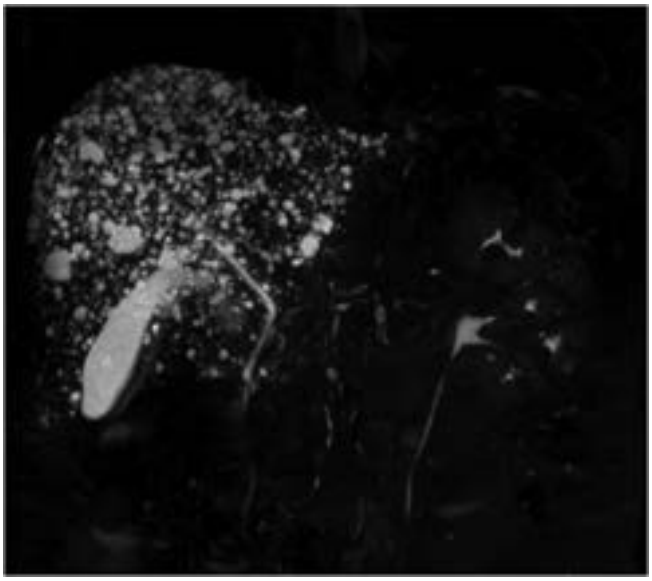

Figure: 3D magnetic resonance cholangiopancreatography (MRCP) showing multiple cystic lesions within the liver, but without communication of the lesions with the biliary ducts.

Conclusion: This case series delivers evidence that MBH and PKHD1-associated polycystic liver disease may belong to the same disease entity, caused by monoallelic mutations in PKHD1. Clinically they share a similar phenotype with innumerous liver cysts within the range of a few millimeters, which remain stable over time.

THU-300

Performance of blood based non-invasive tests for liver fibrosis prediction by transient elastography in Alpha-1 antitrypsin deficiency

Hassaan Yousuf[1,2], Tobias Maharaj[1,2], Daniel Fraughen[1,2], Tomas Carroll[1,2], Noel G. McElvaney[1,2], John Ryan[1,2]. *[1]Beaumont Hospital, Dublin, Ireland; [2]Royal College of Surgeons in Ireland, Ireland*
Email: Hassaanmyousuf@hotmail.com

Background and aims: Alpha-1 Antitrypsin Deficiency (AATD) is an inherited disorder characterised by lung and/or liver injury. The most severe form is seen in individuals with the homozygous PiZZ variant, while heterozygous (PiMZ; PiSZ) variants are associated with milder disease. Progressive liver fibrosis may lead to cirrhosis in some cases. In chronic liver disease, liver biopsy is used less often as a staging tool; instead blood-based fibrosis scores such as the NAFLD fibrosis score (NFS), AST to platelet ratio index (APRI) or the Fibrosis-4 (Fib-4) score, or Transient Elastography (TE) by liver stiffness measurement (LSM) may be used to determine fibrosis stage.

Method: Clinical data, blood tests and TE measurements were taken on adult patients presenting to a dedicated AATD clinic over a 18-month period. LSM cutoffs used were were >7.1kPa for significant

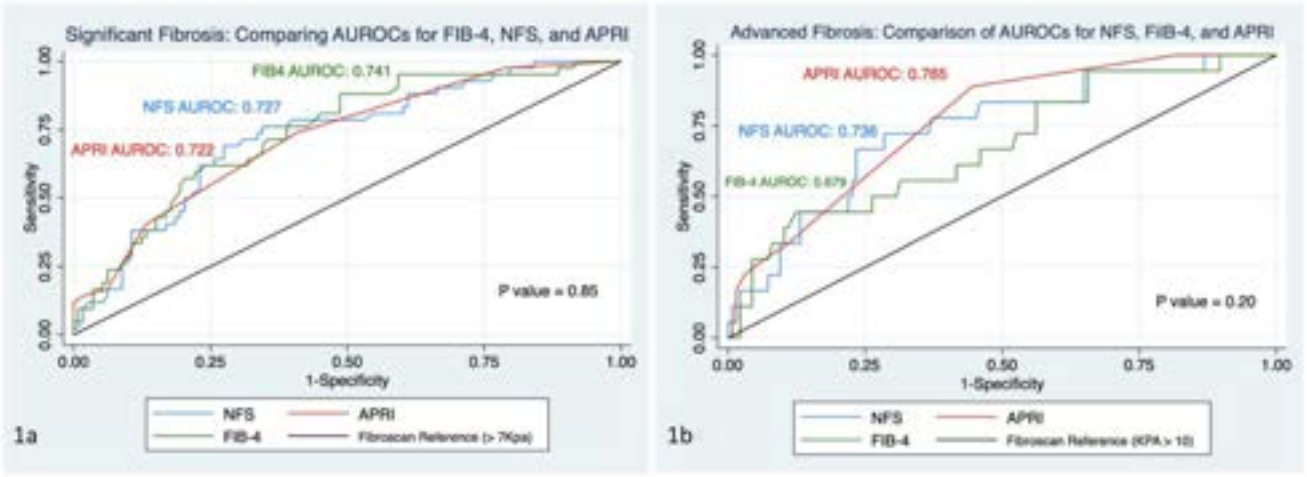

Figure: (abstract: THU-300).

fibrosis, and >10kPa for advanced fibrosis/cirrhosis. Statistics were performed using Stata software.

Results: 155 patients were assessed. Of them, 55% were female, mean age was 52.6 (± 16). Regarding AATD phenotype, 69 (44.5%) were PiZZ, and 62 PiMZ and 15 PiSZ. Of the overall cohort, 40 (25.8%) had significant fibrosis based on TE measurement, while 17 (11%) had advanced fibrosis. Of patients with the PiZZ phenotype, 20 (28.9% of PiZZ) had significant fibrosis, while 10 (14.4%) had advanced fibrosis. Of patients with the PiMZ phenotype, 12 (19% of PiMZ) had significant fibrosis, while 4 (6.4%) had advanced fibrosis. NAFLD fibrosis score (NFS), AST to platelet ratio index (APRI) and the Fibrosis-4 (Fib-4) score were compared with liver fibrosis stage as determined by TE. The AUROC curves from significant and advanced fibrosis are outlined in Fig 1. For both stages of fibrosis, these scores showed a modest ability to predict fibrosis stage without significant differences between scores; NFS (r = 0.72), APRI (r = 0.72) and Fib-4 (r = 0.74) for significant fibrosis (Fig1a), and NFS (r = 0.73), APRI (r = 0.76) and Fib-4 (r = 0.67) for advanced fibrosis (Fig1b).

Conclusion: In patients with AATD, existing blood-based, non-invasive markers of liver fibrosis have a modest ability to predict fibrosis. Reliable disease-specific tools are needed to accurately stage liver disease in AATD.

Email: zmarino@clinic.cat

Background and aims: Wilson disease (WD) is characterized by a high clinical heterogenicity. In Spain, a National Wilson Registry (supported by the Spanish Association for the Study of the Liver, AEEH) was created in Nov/2021, with the aim of updating clinical information and promote consciousness and interest on the disease. In this first analysis of the global database, we aimed at describing the main baseline characteristics, therapy and long-term clinical events of WD patients.

Method: Multicentric national study including patients from the Wilson AEEH-Registry up to November 2022. Ethical approval from the participant centers and a signed informed consent was required for all cases.

Results: During the first year, 352 patients were registered and 320 had enough data to be analyzed (final cohort): 315 (95.3%) were

adults at inclusion (mean age 42, IQR_{25-75} 29–53), 228 (71.3%) were *index* cases, 167 were male (52.2%), age at WD diagnosis: 16 years (10–27.8), Leipzig score at diagnosis: 7 (5–9) points (93.4% had score ≥3), baseline ceruloplasmin <0.2 g/L in 265 (83%), urinary copper >100 µg/24 hours in 148 (46.3%), intrahepatic copper >250 µg/g in 152 (47.5%). Genetics were performed in 242 patients (75%); among them, 85% were compound heterozygote. One third (32.2%) reported a positive family history. Most of the patients (78%) were diagnosed after being studied from a liver disease. Predominant phenotype at diagnosis was chronic liver disease (n = 158, 49%), followed by presymptomatic cases (n = 66, 20.6%), neurological presentations (n = 32, 10.1%), mixed phenotypes (n = 29, 9.1%) and acute liver disease (n = 29, 9.1%). This last group included 7 cases who required an early liver transplantation (in the first month after diagnosis). Cirrhosis was present in 62 patients (19.4%) at diagnosis. The main initial therapy was based on chelators (n = 213, 67%), mainly with D-penicillamine (91.3%). Up to 30% suffered early adverse events (AE). In patients with AE, the therapeutical decision (available in 222) was to remain unchanged in 62%, changed in 32.4% and dose-adjusted in 5.9%. WD treatment is currently different to the initial one in 56% of the cohort. Mean follow-up from diagnosis is 18 years (9–26). Elastography was performed at least once in 203 (64%) cases [mean 6.1KPa (5–8.7)]. Evolutionary events were available from 170 patients (53%): 42 (24.7%) developed *de novo* cirrhosis, 7 (16%) presented hepatic decompensation (mainly ascites), 1 (0.6%) had liver cancer, 5 (2.9%) required liver transplantation within time and 16 (9.4%) patients died (15 deaths were WD-related).

Conclusion: During the first year of the Wilson AEEH-Registry we have recorded data from 320 patients. The hepatic phenotype was predominant in this cohort, as it has been promoted from the Hepatology scientific community. Up to 25% of the patients in Spain still lack from a confirmatory genetic analysis.

THU-302

Endoscopic ultrasound direct portal pressure measurement in patients with porto-sinusoidal vascular disorder and clinically significant portal hypertension: a comparison with hepatic venous pressure gradient measurement

Lucia Giuli[1], Francesco Santopaolo[1], Francesca Ponziani[1], Maria Pallozzi[1], Alberto Larghi[1], Gianenrico Rizzatti[1], Giulia Venturini[1], Andrea Contegiacomo[1], Brigida Eleonora Annicchiarico[1], Antonio Gasbarrini[1]. [1]*Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy*
Email: lucia.giuli92@gmail.com

Background and aims: Hepatic venous pressure gradient (HVPG) represents the gold standard for the evaluation of portal hypertension (PH). HVPG >10 mmHg defines clinically significant portal hypertension (CSPH), a condition that is independently associated with the occurrence of decompensation events. Portal pressure measurement is of fundamental importance for prognostic stratification and assessment of response to therapies. Indeed, a decrement of HVPG by 20% and/or <10 mmHg reduces the decompensation risk. HVPG, however, indirectly measures PH and it may underestimate portal pressure gradient (PPG) in patients with pre-sinusoidal forms of PH, as in porto-sinusoidal vascular disorder (PSVD). Endoscopic ultrasound (EUS)-guided PPG measurement has recently become available. This technique allows measurement of portal pressure directly in the portal vein system and theoretically overcomes HVPG limitations. We investigated the safety and accuracy of EUS measurements as compared to HVPG in evaluating PPG in a cohort of patients with PSVD and CSPH. In patients naïve to non-selective beta-blockers (NSBBs) hemodynamic response to therapy was also evaluated.

Method: Consecutive outpatients with PSVD diagnosed according to Valdig criteria and who presented specific sign (s) of CSPH (gastro-oesophageal varices and/or portosystemic collaterals) underwent HVPG and EUS-guided PPG measurements. In patients naive to NSBBs, treatment was started and after its titration EUS-PPG measurement was repeated. Definition and severity of adverse events (AEs) were based on classification of Cotton et al.

Results: Between March 2022 and December 2022, ten patients (mean age 59 ± 16; 67% males) were enrolled. Mean platelet count was 64.000 U/microliter with 30% of patients having platelet count <50.000 U/microliter. A total of 13 EUS-guided PPG and 10 HVPG measurements were performed. EUS-PPG was technically successful in all cases, without any AEs and requirement for platelet transfusion. EUS-PPG mean value was 19.3 ± 3.2 mmHg versus 8.3 ± 1.3 mmHg of HVPG ($p < 0.0001$) (figure 1). In three patients naive to NSBBs we repeated a new EUS-PPG measurement after drug titration. The average PPG value in these patients before and after NSBBs titration was respectively 19.3 (± 3.8) and 16.3 (± 2.9) mmHg, with one patient out of three who achieved a decrement of PPG >20%.

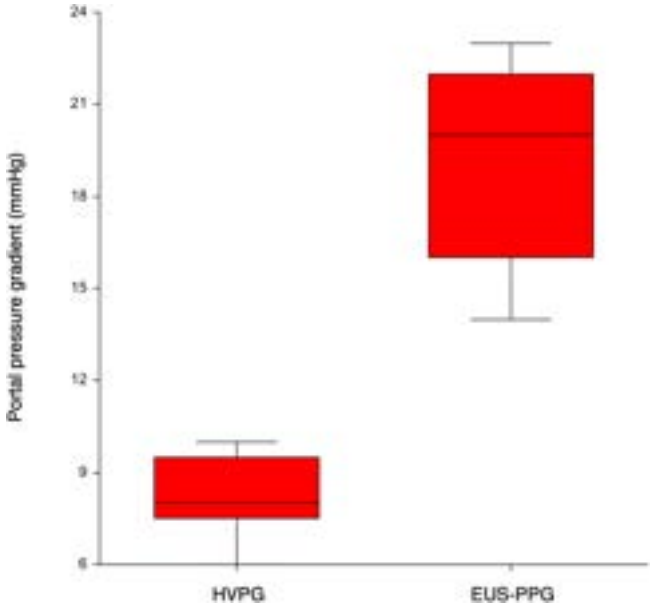

Figure 1:

Conclusion: Direct EUS-guided PPG measurement is safe and significantly more reliable than HVPG in the evaluation of PH in patients with PSVD and CSPH. This technique could be also used to assess hemodynamic response to therapy in pre-sinusoidal forms of PH.

Email: manon.evain@hotmail.fr

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is one of the most common genetic diseases in Europe. It mainly causes pulmonary emphysema. Although it is also responsible for liver fibrosis, AATD is not always diagnosed, even in the most severe patients who are candidates for liver transplantation (LT). The aims of this study was to determine when the diagnosis was made for patients tranplanted for AATD, to describe their clinical characteristics and the outcome on the transplant waiting list.

Method: We performed a multicenter retrospective study between May 2019 and June 2021 in 9 French and Canadian centers by including all liver transplant patients for AATD. The selection of patients was made or confirmed on the explant analysis with PAS+, diastase-resistant inclusions within hepatocytes. A control group (n = 305) to study the evolution on the transplant waiting list was selected from an existing monocentric cohort of liver transplant patients for decompensated cirrhosis.
Results: We included 58 liver transplant patients with AATD between 1996 and 2020, with a mean age of 55.6 ± 9.9 years at LT, mostly men (78%). Indication of LT was AATD in only 31% of cases whereas excessive alcohol consumption, NASH, cryptogenic cirrhosis represented 43%, 14% and 12% of patients respectively. The diagnosis of AATD was made before LT in only 40% of cases, after LT in 15% of cases. For 45% of patients, the diagnosis was never confirmed before the retrospective analysis. Among them, 62% was diagnosed with cirrhosis due to excessive alcohol consumption. Only 46% of patients in the cohort had confirmation of AATD by phenotyping or genotyping before or after LT. Only 60% of patients had a pre-LT serum AAT assay, which was significantly lower in homozygous versus heterozygous patients (0.36 vs. 0.82 mg/ml, $p < 0.01$). Moreover, 25% of the patients had non-specific pulmonary symptoms, 8% had pulmonary emphysema and 7% had an obstructive syndrome. Compared to the control group, patients transplanted for AATD had a higher MELD score at listing for transplant (21.9 vs 14.2, $p < 0.001$) and a shorter waiting time on the transplant waiting list (4.7 months vs 8.3 months, $p < 0.001$). They were also significantly more often hospitalized in intensive care before transplantation (22 vs. 4.3%, $p < 0.001$), and had more pre-LT sepsis (29 vs. 5.1%, $p < 0.001$).
Conclusion: Our study demonstrates that although patients with AATD are more severe, AATD is largely under-diagnosed in the context of LT. AAT dosage is not sufficient to screen the disease on the waiting list patient. Regarding recent advances and development of curative treatments, systematic phenotype/genotype screening of patients on waiting list could be suggested as well as raising awareness of transplant physician to achieve better management of the patients and their relatives.

Email: Romee.Snijders@radboudumc.nl

Background and aims: Autoimmune hepatitis (AIH) is a rare, chronic liver disease. A complete biochemical response (CBR) is a desired end point in the treatment of AIH. Data suggest that CBR improves the prognosis, but the impact on health-related quality of life (HRQoL) in AIH patients is unclear. The aim of this study is to characterize the relationship between CBR and HRQoL in an international multicentre cohort.
Method: A cross-sectional cohort study was performed in adult patients with AIH who were recruited between July 2020 and December 2022 from 12 European tertiary centres. Patients with a history of liver transplantation or hepatocellular carcinoma were excluded. HRQoL was evaluated using the EQ-5D visual analogue scale (VAS), ranging from 0 (worst imaginable health) to 100 (best imaginable health). The cohort was divided into two groups according to their CBR, which was defined as normal alanine aminotransferase, aspartate aminotransferase, and immunoglobulin G levels. Clinical data were obtained from patient records at the time of HRQoL evaluation. A linear mixed regression analysis was used to explore the relationship between CBR and EQ-5D VAS score.
Results: A total of 748 patients with AIH (mean age: 49.7 years (standard deviation (SD) 17.2); 73.8% female) were evaluated. A total of 25.6% had compensated cirrhosis. The median disease duration was six years (interquartile range (IQR) 2–11). In this cohort, 44.8% had a CBR at the time of HRQoL evaluation. The median EQ-5D VAS score was 80 (IQR 65-90) in the patients with a CBR and 70 (IQR 50–85) in the patients without a CBR. Patients with a CBR used fewer corticosteroids (48.0% vs. 65.4%, $p < 0.001$) and were older (mean (SD) 51.9 (17.1) vs. 48.0 (17.1), $p = 0.002$), while sex and the prevalence of cirrhosis were similar. After controlling for age, sex and corticosteroid use, patients with a CBR reported significantly higher mean EQ-5D VAS scores than those without a CBR ($\beta = 6.71$; 95% CI 2.23, 11.20). We did not observe any association between corticosteroid use and EQ-5D VAS score.
Conclusion: Achieving a CBR in patients with AIH is an important factor associated with improved HRQoL, independent of corticosteroid use, age and sex.

THU-305

Impact of extrahepatic portal vein obstruction on fertility and pregnancy outcomes- a tertiary center experience

Ankita Singh[1], Sidharth Harindranath[2], Karan Muzumdar[2], Aditya Kale[2], Akash Shukla[1]. [1]*King Edward Memorial Hospital, Gastroenterology, Mumbai, India;* [2]*King Edward Memorial Hospital, Mumbai, India*
Email: drakashshukla@yahoo.com

Background and aims: Pregnancy in patients with portal hypertension (PHT) presents a major challenge in terms of management due to plasma volume expansion and increased cardiac output which increases portal pressure and risk of variceal bleeding. PHT is associated with poor pregnancy outcomes in mother and foetus. We aim to study the outcomes of pregnancy (maternal and neonatal) in patients with EHPVO.

Method: This was a single center retrospective analysis of pregnancy outcomes in patients with EHPVO who were registered in the department of Gastroenterology at KEM Hospital between January 2006 to December 2022. All patients underwent endoscopy with prophylactic EVL (for high-risk varices) during second trimester and beta blockers were continued during pregnancy. Second stage of labour was shortened as per obstetric indications. Control group consisted of healthy females without comorbidities and with low-risk pregnancies.

Results: Complete data was available for 100 pregnancies in 45 patients, of which 98 were spontaneous and 2 assisted. There was no maternal mortality. 82 (82%) pregnancies had successful fetal outcomes. Of the 18 unsuccessful pregnancies, 13 (72.2%) were spontaneous abortions, 2 (11.1%) were intra uterine fetal deaths, and 3 (16.7%) were neonatal deaths. 3 (6.7%) patients presented with acute variceal bleed (AVB) for the first-time during pregnancy. Only one of the 17 patients with history of UGIB prior to pregnancy, had repeat hematemesis during pregnancy. During pregnancy, 24 (53.3%) patients were treated with combination (endoscopic with non-selective beta blockers) therapy, 10 (22.3%) with NSBB alone and 11 (24.4%) did not receive any treatment. Anemia was observed in 37 (82.2%) patients; 73% patients had mild, 21.6% moderate and 5.4% severe anemia. 10 (22.2%) patients had thrombocytopenia (platelet count <1L). Infertility was diagnosed in 10 (13.3%) patients, 3 (50%) of them underwent treatment for same and 1 patient had conceived. Of the pregnancies with successful outcomes, 4 (4.9%) were delivered preterm and 19 (23.1%) required Caesarean section; Low birth weight was seen in 23 (28%) and small for gestational age in 9 (10.9%) pregnancies. 105 pregnancies in 45 healthy females formed the control group. 86 (81.9%) successful pregnancies were recorded with 15 (14.28%) low birth weight and 7 (6.66%) small for gestational age births. Neonatal outcomes in patients with EHPVO did not differ significantly from healthy controls ($p > 0.05$). Pregnancy outcomes were also similar between the two groups, with around 82% successful pregnancies. None of the patients were on anticoagulants before or during pregnancy.

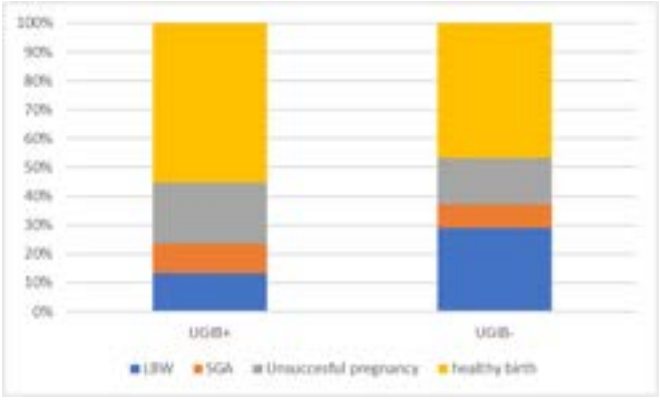

Figure:

Conclusion: Pregnancy in patients with EHPVO has good maternal and neonatal outcomes irrespective of history of variceal bleed before or during pregnancy.

THU-306

Extrahepatic iron loading and disease complications in HFE haemochromatosis

John Olynyk[1,2], Tim St Pierre[3], Louise Ramm[4], Grant Ramm[4]. [1]*Fiona Stanley Hospital, Murdoch, Australia;* [2]*Edith Cowan University Joondalup Campus, Joondalup, Australia;* [3]*The University of Western Australia, Physics, Crawley, Australia;* [4]*QIMR Berghofer Medical Research Institute, Herston, Australia*
Email: john.olynyk@health.wa.gov.au

Background and aims: Arthritis and advanced hepatic fibrosis (AHF) are complications of HFE haemochromatosis (HH), more likely at higher degrees of iron overload especially in men. Iron overload is quantified by calculation of mobilizable iron (Fe) stores or the hepatic iron concentration (HIC). Whilst there is a linear relationship between HIC and Fe stores, there is substantial variance, the cause of which is unclear. We aimed to determine if the variance in relationship between HIC and Fe stores may be due to extrahepatic iron load occurring in the presence of arthritis or AHF.

Method: We recorded data on arthritis, liver-biopsy fibrosis, HIC, and Fe stores in 77 male HH subjects. We calculated the hepatic iron index (HII, HIC/age), Fe stores (number of phlebotomies × 250 mg to reduce ferritin to 50ug/L), and Fe/HIC ratio (a marker of body iron relative to liver iron). To determine if liver volume could confound the relationship between HIC and Fe, we measured liver volume by MRI in an independent group of 17 HH subjects. We conducted linear regression analysis for groups dichotomized for arthritis or AHF and compared HII, HIC, Fe and Fe/HIC relationships.

Results: AHF and arthritis were associated with increased HIC and Fe stores (Table 1). HII was similar across the groups, indicating the rate of hepatic iron loading is independent of arthritis or AHF. Linear regression analysis showed distinctly different relationships between Fe stores and HIC for subjects with arthritis or AHF compared with those without, with less than a 0.01% (for arthritis) or 4% (for AHF) probability of a single relationship being present. Median Fe/HIC values were 50% higher in subjects with arthritis and AHF (0.062 g/(umol/g)) compared with those without (0.040 g/ (umol/g), $p = 0.027$). The upper and lower 95% limits of liver volumes varied by a factor of 2.3 (CI 2.1–2.7) which is significantly lower than the factor of 6.7 (CI 5.1–8.7) observed between the 95% limits of Fe for a given HIC, indicating that variability in liver volume does not explain the variability of Fe at a given HIC.

(n)	No AHF No arthritis (36)	No AHF Arthritis (21)	AHF No arthritis (3)	AHF Arthritis (17)
HIC (umol/g)	110 (34–399)	188 (41–361)	384 (295–510)*	228 (57–675)*
HII (HIC/age)	3.7 (1.0–17.4)	4.4 (1.3–10.8)	6.1 (6.0–12.4)	4.9 (1.3–19.3)
Fe (g)	4.8 (1.2–20.0)	7.5 (2.5–19.5)	11.0 (10.0–11.25)	14.0 (4.8–50.0)***
Fe/HIC (g/[umol/g])	0.041 (0.016–0.088)	0.042 (0.023–0.133)	0.029 (0.022–0.034)	0.062 (0.026–0.171)*+

All values-Median (range); *$p < 0.05$, ***$p < 0.001$ vs no AHF/no arthritis group, +$p < 0.05$ vs AHF/no arthritis group.

Conclusion: HH subjects with AHF and arthritis exhibit substantially greater Fe/HIC not explained by variations in hepatic iron deposition or liver volume, raising the possibility of greater extrahepatic iron loading.
