Ming-Lung Yu[1], Chung-Feng Huang[2]. *[1]Kaohsiung Medical Univeristy, Kaohsiung, Taiwan; [2]Kaohsiung Medical Univeristy Hospital, Kaohsiung, Taiwan*
Email: fengcheerup@gmail.com

Background and aims: Recent nomenclature of steatotic liver disease (SLD) stratify subjects based on the cardiometabolic risk factors (CMRFs) and alcohol consumption. SLD subjects carrying CMRFs and with moderate alcohol consumption are named as MetALD, whereas those with heavy alcohol consumption are viewed as having alcoholic liver disease (ALD) regardless CMRF carriage. The study aims to address the prevalence, liver disease severity and cardiovascular risk in SLD patients with different alcohol exposures and CMRF carriage in Taiwan.
Method: Eligible subjects were those retrieved from a nationwide-based health check-up system in Taiwan from 1997 to 2019. SLD was evaluated by sonography and/or having hepatic steatosis index greater than 36. Alcohol consumption was judged by questionnaires and transformed into daily exposure. Liver disease severity was evaluated by fibrosis-4 index (FIB-4) and the cardiovascular risk was calculated by Framingham risk score (FRS).
Results: A total of 501,863 subjects were recruited, and 162,689 (32.4%) subjects had SLD (mean age 44.0 years, male: 63.6%). Of the SLD subjects, the proportion of subjects without alcohol use or with social drinking (Group A), moderate alcohol consumption (Group B) and heavy alcohol consumption (ALD, Group C) was 93.3% (n = 151,747), 4.0% (n = 6,597) and 2.7% (n = 4,345), respectively. The proportion of CMRF carriage was 96.0% (MASLD), 98.1% (Met-ALD) and 97.9% among the 3 groups, respectively. The FIB-4 value progressively increased from Group A (0.85 ± 0.58), Group B (0.96 ± 0.80) to Group C (1.20 ± 1.13) (Ptrend <0.001). While subjects were divided by the CMRF carriage, those with CMRF carriage had a significantly higher FIB-4 than those without in each subgroup (All P value <0.001). Group A subjects without CMRF had the lowest FIB-4 value (0.71 ± 0.36) whereas Group C subjects with CMRF had the highest FIB-4 value (1.21 ± 1.14). Logistic regression analysis revealed that factors independent associated with significant fibrosis (FIB-4 > 2.6) included alcohol exposure (Odds ratio [OR]/95% confidence intervals [CI]: 2.00/1.91–2.11, P < 0.01 for Group B; OR/CI: 2.61/2.46–2.77, P < 0.01 for Group C, compare to Group A) and CMRF carriage (OR/CI: 4.94/4.27–5.71, P < 0.01 for 1–2 CMRF carriage; OR/CI:27.78/24.03–32.09, P < 0.01 for >3 CMRF carriage, compared to no any CMRF carriage). Coincidently, FRS progressively increased from Group A (6.95 ± 7.08), Group B (9.60 ± 8.56) to Group C (10.79 ± 9.33) (Ptrend <0.001). Alcohol exposure was independently associated with a higher cardiovascular risk (OR/CI: 1.64/1.53–1.75, P < 0.01 for Group B; OR/CI: 1.74/1.60–1.90, P < 0.01 for Group C, compared to Group A).
Conclusion: Despite the classification of Met-ALD and ALD takes CMRF carriage into consideration, almost all the SLD subjects with moderate or heavy alcohol consumption carried at least one CMRF. Both alcohol exposure and CMRF carriage were independently associated with liver disease severity and cardiovascular risk in Taiwanese SLD subjects.

THU-404

Genome-wide association study of noninvasive scores of fibrotic MASLD in an italian population

Email: francesco.malvestiti@unimi.it

Background and aims: Metabolic Associated Steatotic Liver Disease (MASLD) is the most prevalent chronic liver disease. It can progress to metabolic steatohepatitis (MASH), resulting in cirrhosis and hepatocellular carcinoma. A large fraction of MASLD heritability remains unexplained, and few genomic data are available in the Italian population. Genome-wide association studies (GWAS) offer a powerful method to identify genetic risk variants for risk stratification and therapeutic strategies.
Method: The Milano BioBank is a multi-center effort which is gathering genomic and phenotypic data of Italian individuals enriched for the presence of metabolic dysfunction and MASLD (currently n = 5,875). Global Screening Array 3.0 (Illumina) and Michigan Imputation Server (GRCh38 TOPMed freeze 5) were used for SNP detection and imputation. We considered as main outcome the Fibrosis-4 Index (FIB-4) and secondary the Fibrotic NASH Index (FNI) and liver enzymes, as first-line clinical tests to identify at-risk MASLD (quantitative traits) adjusting the REGENIE regression models for age, sex, BMI, ethnicity.
Results: We confirmed a genome-wide significant association of *PNPLA3* locus with FIB-4 and FNI (rs738409 p.I148M; beta = 0.132, p = 3.06*10–22 and beta = 0.233, p = 3.59*10–16 respectively) and with circulating ALT (rs3747207; beta = 0.145, p = 2.64*10–16), AST (rs738408; beta = 0.186, p = 1.48*10–23), and GGT (rs738409; beta = 0.109, p = 1.28*10–11) levels. Additionally, *HAPLN4-TM6SF2* locus was associated with FNI (current top hit rs150641967 intronic variant; beta = 0.374, p = 5.55*10–10), *ERLIN1* locus was associated with circulating ALT (rs10883451; beta = -0.099, p = 2.64*10–9) while *GGT1* (rs2073397, beta = 0.157, p = 4.21*10–22), *RORA* (rs339969, beta = 0.108, p = 5.84*10–11) and *EXOC3L4* (rs944002, beta = 0.108, p = 8.22*10–10) loci associated with GGT.

Conclusion: We confirmed that single nucleotide polymorphisms in genes involved in hepatic lipid retention are the main genetic determinants of at risk of MASLD in the Italian population. These findings reinforce the role of *PNPLA3* as a key genetic determinant of MASLD, suggest the possible presence of additional contributors to liver disease at the *TM6SF2* locus and support the use of FNI to detect fibrosing MASH.

THU-405

Impact of ultra processed foods on metabolic dysfunction-associated steatotic liver disease: limitations of the NOVA classification

Franziska Beck[1], Lina Jegodzinski[2], Hans Benno Leicht[1], Florian P. Reiter[1], Friedhelm Sayk[2], Ina Bergheim[3], Jens U. Marquardt[2], Andreas Geier[1], Monika Rau[1]. *[1]Division of Hepatology, Department of Internal Medicine II, University Hospital Würzburg, 97080 Würzburg, Germany; [2]Department of Medicine I, University Hospital Schleswig-Holstein, Lübeck, Germany; [3]Department of Nutritional Sciences, Molecular Nutritional Science, University of Vienna, Vienna, Austria*
Email: franziska.beck@stud-mail.uni-wuerzburg.de

Background and aims: The rise in consumption of ultra-processed foods (UPFs) has become an increasing concern in facilitating the metabolic syndrome. Subsequently, the relationship between MASLD and UPFs needs to be explored. The NOVA classification system categorizes foods into four groups based on their level of processing. This study aims to investigate UPF consumption, as classified by NOVA, in MASLD patients, and examine the impact of UPF intake on disease severity.
Method: A total of 315 MASLD patients were prospectively included (01/21–09/24) in a multi-center study. At baseline, all patients completed a food frequency questionnaire including 53 food groups to assess UPF consumption using the NOVA system. Clinical data, including controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) were available for each patient. Follow-up (FU) nutritional and clinical data were obtained for 42 patients. Statistical analyses were performed using SPSS.
Results: Slightly more men (54%) than women (46%) were included with a mean age of 54y and a mean BMI of 32.5 kg/m². UPFs (NOVA 4) accounted for a significant proportion (34.7%) of total caloric intake in MASLD patients. Gender-specific dietary patterns were observed, with men consuming a significantly higher percentage of UPFs (37.2% ♀ vs 30.4% ♂, $p < 0.001$). Although no overall associations were found between UPF consumption (NOVA 4) and liver enzymes, CAP, or LSM, specific UPFs showed notable effects. Soft drink consumption was significantly associated to higher LSM, particularly in men, regardless of sugar content. Fast-food intake correlated with higher ALT levels, again more prominently in men. Conversely, patients consuming more unprocessed foods (NOVA 1) had significantly lower CAP levels (326 dB/m vs. 346 dB/m; $p < 0.024$). A reduction in processed meat intake during follow-up was associated with significantly lower CAP values, while increased consumption of salty fast foods correlated with higher LSM over time.
Conclusion: UPFs contribute to a large component of the diet in MASLD patients, particularly in men. While the NOVA food classification system offers a framework for categorizing UPFs, it provides limited insights into the effects of specific UPFs on MASLD. This study underscores the importance of dietary interventions to improve liver health, promoting increased consumption of unprocessed or minimally processed foods and reduced intake of soft drinks, fast foods, and processed meats.

Email: geier_a2@ukw.de

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects more than 18 million individuals in Germany. Life-style choices including alcohol, coffee and smoking are frequent among these patients but prospective data on the combinatorial effects are rare. Real-world data help to better characterize the natural history of disease and to guide targeted lifestyle intervention.
Method: The German SLD-Registry aims to describe clinical characteristics and observe outcomes in secondary and tertiary care. Detailed data on life-style choices are prospectively collected. Advanced fibrosis was defined as liver stiffness (LS) >9.6 kPa.
Results: Baseline data of 903 patients were analysed. 40% (363/903) reported low grade alcohol consumption (mean 1.4 g/day, 60% male). The alcohol subgroup had higher levels of ferritin (152 vs. 205 ng/ml) but less frequently high-risk fibrosis scores (FIB-4 > 2.67 8.5 vs. 15%; NFS > 0.675 9.3 vs. 17%) or LS values > 9.6 kPa (25 vs. 73%; OR 0.546 [0.41–0.73], $p < 0.001$). Smokers (current 83/544, former 136/544) were more frequently male than never smokers (325/544) and had a trend towards higher CAP values (326 and 314 vs. 305 dB in never smokers). No association of smoking to LS > 9.6 kPa or cirrhosis stage could be observed (OR 0.94 [0.62–1.43], $p = 0.78$). Former smokers had more frequently coronary heart disease, hypercholesterolemia and hypertension. Coffee consumers (1–2 cups/day 229/464, 3–4 cups/day 117/464, > 5 cups/day 36/464) more frequently had high-risk fibrosis scores compared to non-consumers (FIB-4 > 2.67 17, 16, 14% vs. 9.8%; NFS > 0.675 18, 13, 19 vs. 7.9%). LS > 9.6 kPa tended to be more frequent in non-consumers (45% vs. 36, 23 and 28%). CAP values were not different between these groups. The OR for coffee drinkers was reduced (0.58 [0.97–0.34]; $p = 0.04$) with a significant dose dependency ($p < 0.003$). Physical activity was associated with a decreased risk of LS > 9.6 kPa (OR 0.63 [0.42–0.96], $p = 0.031$). No interaction of alcohol, coffee consumption and smoking could be detected.
Conclusion: Alcohol and coffee consumption is frequent among MASLD patients. Low grade alcohol and any degree coffee consumption were associated with a decreased risk of advanced liver fibrosis. For smoking, no such association to fibrosis but a trend towards

higher steatosis grade could be detected. Our data may confirm the beneficial effects of coffee and indicate that very low alcohol consumption may at least not exert relevant unfavourable effects of fibrosis progression.

Assessing muscle function in non-cirrhotic patients with steatotic liver disease : a cross-sectional study

Guillaume Henin[1,2], Alexis Goffaux[1], Salomé Declerck[1], Stéphanie André-Dumont[1,2], Etienne Pendeville[3], Maxime Valet[4], Thierry Lejeune[5], Géraldine Dahlqvist[2], Audrey Loumaye[6], Peter Stärkel[1,2], Nicolas Lanthier[1,2]. *[1]Laboratory of Hepato-Gastroenterology (GAEN), Institut de Recherche Expérimentale et Clinique (IREC), UCLouvain, Brussels, Belgium; [2]Department of Hepato-Gastroenterology, Cliniques universitaires Saint-Luc, UCLouvain, Brussels, Belgium; [3]Department of physiotherapy and ergotherapy, Cliniques universitaires Saint-Luc, UCLouvain, Brussels, Belgium; [4]Neuro Musculo Skeletal Lab (NMSK), Institut de Recherche Expérimentale et Clinique (IREC), UCLouvain, Brussels, Belgium; [5]Department of Physical medicine and Rehabilitation, Cliniques universitaires Saint-Luc, UCLouvain, Brussels, Belgium; [6]Department of Endocrinology, Diabetology and Nutrition, Cliniques universitaires Saint-Luc, UCLouvain, Brussels, Belgium*
Email: ghenin1993@gmail.com

Background and aims: Muscle function decay and frailty are prevalent in cirrhosis whatever the cause. However, muscle function evaluation in non-cirrhotic patients is lacking, as well as data by etiology, including steatotic liver disease (SLD). Our aim is to determine if muscle function already decays in non-cirrhotic SLD and if the SLD subtype impacts muscle function.

Method: SLD patients were prospectively recruited and classified according to the recent SLD subtype categories. Liver disease was assessed by transient elastography (Fibroscan®). Cirrhotic patients were excluded. Controls were defined by the absence of liver steatosis on controlled attenuation parameter (<215 dB/m). Muscle function was assessed by isokinetic dynamometer (Cybex®). All patients and controls also underwent the three tests used to calculate the liver frailty index (LFI): handgrip strength, sit-to-stand test and balance test. SLD patients and controls were classified based on the LFI as robust (LFI <3) or pre-frail/frail (LFI ≥3). Results are expressed as means ± SD.

Results: One hundred and thirty-seven patients with SLD were included: 69 with alcohol-related liver disease (ALD) and 66 with metabolic dysfunction-associated steatotic liver disease (MASLD), and compared to 30 healthy controls matched for sex and age (controls: 47.8 years ± 14.1, ALD: 50.2 ± 10.8, MASLD: 52.5 ± 10.4; p = 0.16). The groups differed for several parameters, such as alanine aminotransferase (controls: 18.4 IU/L ± 10.2, ALD: 74.8 ± 53.2, MASLD: 48.3 ± 29.5; p < 0.0001), liver stiffness (controls: 4.4 kPa ± 1, ALD: 8.9 ± 3.5, MASLD: 9 ± 3.9; p < 0.0001) and body mass index (controls: 22.1 kg/m² ± 2, ALD: 26.3 ± 5, MASLD: 33.3 ± 6.4; p < 0.0001). LFI negatively correlated with right knee extension evaluated by isokinetic dynamometer in all SLD patients (N = 137, r = –0.53; p < 0.0001). LFI was higher in all SLD subgroups compared to controls (controls: 2.2 ± 0.8, ALD: 3.2 ± 0.8, MASLD 3.1 ± 0.7; p < 0.0001) without any difference between MASLD and ALD patients (p = 0.67). 56.5% of ALD patients and 58.5% of MASLD patients were considered pre-frail or frail (p = 0.81) compared to only 10% of control patients (p < 0.0001). LFI negatively correlated with right knee extension evaluated by isokinetic dynamometer in all SLD patients (N = 137, r = –0.53; p < 0.0001).

Conclusion: LFI is an accurate method to assess muscle function. Muscle function assessed by the LFI declines in non-cirrhotic SLD patients compared to age-matched controls. Frailty severity is not influenced by the SLD subtype. This highlights the concept of a muscle-liver axis already in the early stages of SLD.

THU-408

The impact of first and further decompensation in patients with metabolic-dysfunction associated compensated advanced chronic liver disease

Email: graziapennisi901@gmail.com

Background and aims: The first and further decompensation mark the natural history and the risk of mortality in patients with cirrhosis. We assessed the cumulative incidence of first and further (acute and non-acute) decompensation and evaluated their impact on both liver-related death (LR-D) in patients with compensated advanced chronic liver disease (cACLD) due to metabolic dysfunction-associated steatotic liver disease (MASLD).

Method: Consecutive patients with clinical (LSM > 10 kPa) or biopsy-proven (F3-F4 fibrosis) diagnosis of cACLD due to MASLD were included. First and further decompensation were defined according

to Baveno VII criteria. Competing risk analysis and cumulative incidence functions were assessed by Fine and Gray. Cause-specific Cox models with baseline and time-dependent variables were applied. Multistate model was built to better assess the clinical course of cACLD due to MASLD.
Results: The cumulative incidence of the first decompensation was 3.5% at 5 years, increasing 20-fold the risk of LR-D at cause-specific Cox analysis; the cumulative incidence of further decompensation was 44% at 5 years among patients with first decompensation, additionally increasing 1.6-times the risk of LR-D. Ascites, followed by variceal bleeding, were the most common events in both first and further decompensation. Hepatocellular carcinoma (HCC) further independently increased the risk of LR-D of 3.2-times and 1.6-fold, respectively, in the whole cohort of cACLD due to MASLD and in those who experienced first decompensation.
Conclusion: The first and further decompensations represent tipping points in the clinical course of patients with cACLD due to MASLD, increasing 20-times and additionally 1.6-times the risk of LR-D. HCC is an independent predictor of LR-D in patients with cACLD due to MASLD, resulting in an additional risk of LR-D when associated with both first and further decompensation.

THU-413
Metabolic-dysfunction associated steatotic liver disease in inflammatory bowel disease: prevalence and progression
Grazia Pennisi[1], Emanuele Bracciamà[1], Francesca Di Giorgio[1], Piera Melatti[1], Livia Amato[1], Ivan Alberto Salerno[1], Roberto Ajovalasit[1], Lavinia Di Prima[1], Simone Scalia[1], Domenico Gambadauro[1], Salvatore Petta[1], Maria Cappello[1]. *[1]Section of Gastroenterology and Hepatology, Dipartimento Di Promozione Della Salute, Materno Infantile, Medicina Interna e Specialistica Di Eccellenza (PROMISE), University of Palermo, Italy, Palermo, Italy*
Email: graziapennisi901@gmail.com

Background and aims: Prevalence of MASLD in patients with Inflammatory Bowel Disease (IBD) has been reported 24.4% in a recent metaanalysis and 21.6% in a previous cross-sectional study from our center. However, data on the progression of MASLD in IBD patients are scanty. We aimed to investigate the prevalence and the progression of MASLD, diagnosed by non-invasive tools, in a homogeneous cohort of patients with IBD followed in our referral center.
Method: Consecutive IBD patients without known chronic liver disease were retrospectively enrolled and prospectively followed between 2020 and 2024. MASLD was defined as Controlled Attenuation Parameter (CAP) according to EASL criteria. Significant fibrosis was defined as Liver Stiffness (LSM) ≥8 kPa by FibroScan. Demographic, metabolic and biochemical data were collected at baseline and at the last follow-up visit. All patients were genotyped for PNPLA3 rs738409 C > G by Taqman assay. Univariate logistic regression analysis was performed to identify risk factors associated with the prevalence of MASLD and its progression.
Results: 230 patients (mean age was 46.1 ± 13.4 years, 49.2% were males, 50.8% had Crohn's disease, mean disease duration was 9.4 ± 7.5 years) were recruited. 14.8% of them were obese (BMI > 30 kg/m^2), 9.8% diabetic. 49.2% were PNPLA3 rs738409 CG/GG. 62 out of 230 patients had complete metabolic and biochemical assessment at follow-up. Mean follow-up time was 4 years. At baseline, according to EASL criteria, 31.1% (19/62) had MASLD. 19.1% (8/42) of patients without steatosis at baseline, developed steatosis at follow-up; while 42.1% of those having steatosis at baseline, did not show steatosis at follow-up. Two patients without fibrosis assessed by LSM at baseline developed significant fibrosis, while two patients with fibrosis at baseline experienced fibrosis regression. 13.5% developed obesity. Obesity was significantly associated with the prevalence of MASLD both at baseline ($p = 0.01$) and on follow-up ($p = 0.01$) and was a predictor of steatosis progression ($p = 0.01$); no association was found in relation to sex, PNPLA3 polymorphism, disease characteristics and the use of biologics. Diabetes was not significantly associated with MASLD in our cohort, but the number of patients was low.
Conclusion: One third of IBD patients had MASLD and obesity was the main predictor of its prevalence and progression, highlighting the relevance of active surveillance of MASLD and appropriate nutritional and lifestyle counselling especially in obese IBD patients. The use of biologics to control inflammation seems to have no influence on MASLD progression but data need further confirm in larger cohorts.

THU-414
Rising prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD)-associated hepatocellular carcinoma: a comparative analysis of clinical features and outcomes
Gupse Adali[1], Fırat Oyman[2], Mehmet Ali Saruhan[2], Berkay Dertsiz[2]. *[1]University of Health Sciences Istanbul Umraniye Training and Research Hospital Department of Gastroenterology, Istanbul, Türkiye; [2]University of Health Sciences Istanbul Umraniye Training and Research Hospital, Istanbul, Türkiye*
Email: gupseadali@gmail.com

Background and aims: The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) has been increasing worldwide. The prevalence of hepatocellular carcinoma (HCC) caused by MASLD is also increasing. Studies have shown that the clinical features and outcomes of MASLD-associated HCC differ from those of HCC due to viral and other etiologies; however, the results are conflicting. We aimed to compare the clinical features and outcomes of MASLD-associated HCC with those of other non-MASLD HCC.
Method: Between 1/1/2009 and 1/1/2024, we retrospectively identified patients (n = 174) diagnosed with HCC in our hospital and divided them into two groups: MASLD HCC and non-MASLD HCC. (1) Patient demographic and clinical characteristics, (2) tumor characteristics, (3) treatment modalities, and overall survival outcomes were compared between the two groups.
Results: The primary etiology was MASLD in 34 (19.5%) of the 174 patients with HCC included in the study. Most patients had a viral etiology (n = 121, 69.5%). The MASLD HCC group was less likely to be male than the non-MASLD HCC group (61.8% vs. 78.6%, $p = 0.042$), the median BMI was higher (31.5 kg/m^2 vs. 27.7 kg/m^2, $p < 0.001$), and the prevalence of diabetes was higher (91.2% vs. 32.9%, $p < 0.001$). The median alpha-fetoprotein levels, FIB-4 scores, ALBI scores, ECOG scores, BCLC stages, maximum tumor diameters, and baseline cirrhosis percentages were similar between the groups. Patients were divided into two groups according to their primary etiological diagnosis: before and after January 2019, a significantly higher proportion of MASLD HCC patients (88.2%) was diagnosed after January 2019 than non-MASLD HCC patients (67.9%) ($p = 0.018$). The median overall survival (OS) of non-MASLD HCC median OS was 46 and 41 months, respectively. MASLD HCC compared to non-MASLD HCC, hazards ratio was 0.98 (95% CI: 0.56–1.71, $p = 0.938$). There was no significant difference in the OS between the two groups.
Conclusion: The prevalence of HCC in the MASLD setting has significantly increased in recent years. There was no difference in overall survival between patients with HCC due to MASLD and HCC due to other etiologies.

THU-415
Comparison of clinical characteristics and outcome of HCC patients with and without MASLD underwent surgical resection – experience from an asian tertiary center
Chia Jung Ho[1], Chun-Ting Ho[1], Yi-Chen Lin[1], Gar-Yang Chau[2], Yi-Hsiang Huang[3], Ming-Chih Hou[3], Jaw-Ching Wu[4], Chien-Wei Su[1]. *[1]Division of General Medicine, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan; [2]Division of General Surgery, Department of Surgery, Taipei Veterans General Hospital, Taipei, Taiwan; [3]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan; [4]National Yang Ming*

Chiao Tung University, Taipei, Taiwan
Email: cwsu2@vghtpe.gov.tw

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) may influence the outcomes of patients with hepatocellular carcinoma (HCC). This study aimed to compare the clinical characteristics and outcomes of HCC patients with and without MASLD who underwent surgical resection and identify risk factors associated with poor overall survival (OS) and recurrence-free survival (RFS).
Method: This retrospective study included 946 HCC patients who underwent surgical resection as their initial treatment at Taipei Veterans General Hospital between 2016 and 2022. Patients with combined HCC and cholangiocarcinoma (n = 35) and those with insufficient pathological data (n = 5) were excluded, leaving 906 patients for analysis. Based on the latest MASLD diagnostic criteria, patients were categorized into the MASLD group (n = 410) and the non-MASLD group (n = 496). The primary endpoint was OS, while the secondary endpoint was RFS. Baseline demographics, serum biochemistry, imaging features, and pathological findings from hepatectomy specimens were analyzed. Independent risk factors for poor OS and RFS were identified using Cox proportional hazards models. Kaplan-Meier survival analyses were performed to compare outcomes between groups.
Results: HCC Patients with MASLD were less likely to have cirrhosis, and had earlier tumor stages, lower histological grades, lower rates of microvascular invasion, and lower serum alpha-fetoprotein (AFP), aspartate aminotransferase (AST) levels and lower platelet counts, and higher serum albumin levels, compared to the non-MASLD cohort. After a median follow-up of 59.2 months, 195 patients died, and 385 experienced recurrences. The 5-year OS rate was significantly higher in the MASLD group (78.3%) than in the non-MASLD group (67.1%) (p = 0.006). Similarly, the 5-year RFS rate was higher in the MASLD group (50% vs. 45%, p = 0.019). Cox proportional hazards models identified age, serum albumin, serum creatinine, serum AST, serum AFP, tumor size, and histological grade, but not MASLD, as independent risk factors for poor OS.
Conclusion: HCC patients with MASLD demonstrated better OS and RFS compared to non-MASLD patients. However, MASLD itself was not an independent risk factor for poor OS or RFS.

THU-416

Risk assessment for carotid atherosclerosis in asymptomatic patients with metabolic dysfunction-associated steatotic liver disease

Hana Park[1], Ji Young Lee[1], Sungwon Park[1], Hyo Jeong Lee[1], Jaeil Kim[1], Hye-Sook Chang[1], Jaewon Choe[1], Hye Won Park[1], Ju Hyun Shim[1].
[1]Asan Medical Centre, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South
Email: hnpark80@gmail.com

Background and aims: Cardiovascular disease remains a leading cause of mortality in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). This study evaluated the association between subclinical carotid atherosclerosis (SCA) and MASLD or MASLD and increased alcohol intake (MetALD) in asymptomatic individuals.
Method: This cross-sectional study analyzed 56,889 adults who underwent health check-ups at a tertiary hospital in South Korea between January 2015 and December 2020. Hepatic steatosis was diagnosed via sonographic findings, and SCA was assessed using duplex ultrasound to measure carotid intima-media thickness or detect plaques. Liver fibrosis was evaluated using the Fibrosis-4 index and point-shear wave elastography. The study population included 13,969 patients with MASLD and 3,854 with MetALD.
Results: Among the participants, 7,679 (13.5%) were diagnosed with SCA. MASLD was significantly associated with SCA after adjustment (adjusted odds ratio [aOR] 1.26; 95% confidence interval [CI] 1.19–1.33, p < 0.001), as was MetALD (aOR 1.43 [1.30–1.58], p < 0.001). The association between MASLD and SCA increased with the severity of hepatic steatosis and liver fibrosis. MASLD patients with a hepatic steatosis index ≥36, Fibrosis-4 ≥1.3, and liver stiffness ≥5.6 kPa had adjusted odds ratios of 1.70 [1.53–1.88], 1.23 [1.14–1.33], and 1.78 [1.05–3.01], respectively, for SCA risk compared to individuals without MASLD. A similar trend was observed for MetALD, with adjusted odds ratios of 1.83 [1.51–2.23], 1.49 [1.30–1.70], and 1.29 [0.52–3.19], respectively.
Conclusion: MASLD and MetALD are strongly associated with an elevated risk of SCA, particularly in the presence of liver fibrosis. These findings underscore the importance of carotid ultrasound screening in patients with MASLD and MetALD accompanied by liver fibrosis.

THU-417

Influence of cardiometabolic risk factors and alcohol consumption on liver stiffness in MASLD patients: a multicenter study in Colombia

Ismael de Jesus Yepes Barreto[1], Pablo Osorio[2], Nicole Chamorro[3], Yohana Poveda[4], Clara Caez[2], Juan Carlos Restrepo[5], Jorge Ortiz[6], Santiago Pino[7]. *[1]Universidad de Cartagena, Gastropack SAS, Cartagena, Colombia; [2]Universidad de Cartagena, Cartagena, Colombia; [3]Universidad de Cartagena, Cartagena, Colombia; [4]Gastropack SAS, Cartagena, Colombia; [5]Universidad de Antioquia, Hospital Pablo Tobon Uribe, Cartagena, Colombia; [6]IMAT, Monteria, Colombia; [7]Universidad de Antioquia, Medellin, Colombia*
Email: ismayep@yahoo.com

Background and aims: To better characterize steatotic liver disease, a new nomenclature has recently been proposed, aiming to group patients based on the disease's etiology. The metabolic dysfunction-associated steatotic liver disease (MASLD) category includes all patients with steatosis who present at least one cardiometabolic risk factor (CMRF). However, significant differences exist in how each factor influences disease progression. Alcohol consumption thresholds for MASLD diagnosis were arbitrarily chosen, risk of chronic liver disease seems to increase even with values below current limits. It is possible that alcohol's interaction with different cardiometabolic risk factors, or even the interaction between the risk factors themselves, could contribute to disease progression. This study aims to compare elastographic values in MASLD patients based on the number of CMRF and determine the effect of interactions between CMRF themselves and these risk factors and alcohol consumption on liver stiffness.
Method: Patients diagnosed with MASLD from four cities in Colombia who underwent transient elastography were included. Other causes of chronic liver disease were ruled out. Patients with significant alcohol consumption were excluded. Cardiometabolic risk factors were defined according to ATP III criterio. Alcohol consumption was calculated using the number of standard drink units per week. Interaction terms between CMRF themselves, and between CMRF and alcohol consumption were included in a multivariate linear regression analysis where liver stiffness was the dependent variable.
Results: A total of 284 patients were included, 57.4% were female. The prevalence of hypertension, diabetes, dyslipidemia, and overweight was 50.4%, 27.1%, 64.8%, and 92.3%, respectively. Patients with 1, 2, 3, and 4 cardiometabolic risk factors represented 25.4%, 27.8%, 33.8%, and 13%, with progressively increasing elastographic values of 6.4 KPa, 6.9 KPa, 7.9 KPa, and 8.5 KPa, respectively. However, there were no statistically significant differences in elastographic values between patients with 1 or 2 (3.5 KPa vs. 4.7 KPa; p = 0.47), 2 or 3 (6.9 KPa vs. 7.9 KPa; p = 0.39), or 3 or 4 (7.9 KPa vs. 8.5 KPa; p = 0.66) CMRF. Multivariate linear regression analysis identified diabetes (b = 0.2, 95% CI: 1.1 to 4.3; p = 0.001) and the interaction between diabetes and dyslipidemia (b = –0.32, 95% CI: –7.8 to –1.7; p = 0.003) as the only independent predictors of liver stiffness. Diabetic patients had higher elastographic values than their counterparts (9.6 KPa vs. 6.7 KPa, p = 0.017). No interaction terms between alcohol

consumption and cardiometabolic risk factors were associated with elastographic values.
Conclusion: The MASLD category encompasses a heterogeneous spectrum of disease severity. Diabetes and its interaction with dyslipidemia appear to be the main determinants of liver stiffness but this data needs further validation. No association was found between mild alcohol consumption and elastographic values.

THU-418
The effect of a fast-food meal on endothelial function in people with metabolic dysfunction-associated steatotic fatty liver desease
Sam Dugdale[1], Meegan Walker[1], Chris Askew[1,2], Hattie Wright[1], Fraser Russell[1], Suzanne Broadbent[1], James O'Beirne[2]. [1]*University of the Sunshine Coast, Sippy Downs, Australia;* [2]*Sunshine Coast Hospital and Health Service, Birtinya, Australia*
Email: sdugdale8@gmail.com

Background and aims: For people with metabolic dysfunction-associated steatotic fatty liver disease (MASLD), cardiovascular disease (CVD) is the leading cause of death. Although the association between the two diseases is strongly established, the underpinning mechanisms are not clearly defined. Elevated consumption of dietary fat combined with metabolic dysfunction may contribute to the burden of CVD on people with MASLD by inducing endothelial dysfunction. Therefore, this study aimed to investigate the acute response in endothelial function and circulating blood lipids and glucose to a fast-food meal (breakfast burger) in participants with and without MASLD.
Method: Participants with (n = 8, 68 ± 7 years, 50% male) and without MASLD (n = 9, 62 ± 8 years, 44% male) attended two experimental sessions separated by at least 7 days. The participants with MASLD were non-cirrhotic and had a liver stiffness between 8–12 kPa. During experimental sessions, participants consumed either a fast-food meal (3579 kj, 45 g of fat) or a 50 mL glass of water (control) in a randomized cross-over design. Outcome measures included brachial artery flow mediated dilation (FMD) for analysis of endothelial function and venous blood samples for blood glucose and lipid concentrations, taken prior to meal/water consumption and then hourly for six hours.
Results: During the water control visit, there was no change in FMD, blood triglycerides, or blood glucose concentration for either group, however, after consumption of the meal there was a reduction in FMD in both groups. When expressed relative to baseline, the percentage change in FMD was greater in the MASLD group after the test meal compared with the healthy control group (−61 ± 12% vs −41 ± 23%, p = 0.046). Blood triglyceride concentrations were elevated after the test meal for both groups. However, the absolute change in triglyceride levels from baseline to peak elevation was greater in the MASLD group compared with the healthy control group (+1.41 ± 0.58 mmol·L^{-1} vs +0.72 ± 0.56 mmol·L^{-1}, p = 0.043). Blood glucose concentration was elevated after the test meal in the MASLD group, while it did not change in the healthy control group.
Conclusion: The novel finding from this study is that postprandial endothelial dysfunction is exacerbated in people with MASLD compared with sex- and age-matched healthy participants. In MASLD, exaggerated elevations in blood triglycerides and blood glucose postprandially may aggravate endothelial dysfunction. These findings suggest that reducing intake of dietary fats and glucose should be a treatment target to decrease both the risk and the burden of CVD on the MASLD population.

THU-419
Differences in quality of life and coping strategies between patients with metabolic dysfunction-associated steatotic liver disease and liver transplant recipients. A comparison with the general spanish population
Jesús Funuyet-Salas[1], María Ángeles Pérez-San-Gregorio[2], Agustín Martín-Rodríguez[2], Miguel Ángel Gómez-Bravo[3], Manuel Romero-Gómez. [1]*Department of Psychology, Loyola University Andalusia, Seville, Spain;* [2]*Department of Personality, Assessment, and Psychological Treatment, Faculty of Psychology, University of Seville, Seville, Spain;* [3]*Hepatic-Biliary-Pancreatic Surgery and Liver Transplant Unit, Virgen del Rocío University Hospital, Seville, Spain*
Email: jfunuyet1@us.es

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and liver transplantation are closely associated with a psychosocial risk profile, including impaired quality of life (QoL) and maladaptive coping strategies. However, evidence of differences in QoL and coping strategies between these two groups of patients has not yet been reported. We therefore sought to analyze the differences in QoL and coping strategies between MASLD patients and liver transplant recipients, using QoL data from the general Spanish population in (GSP), and determine the coping strategies predicting QoL in these two groups.
Method: The total sample of 480 patients was evaluated using the SF-12 and Brief COPE and divided into two groups balanced for age and gender: 240 biopsy-proven MASLD patients (G_1) and 240 liver transplant recipients (G_2). The independent samples *t*-test was used to compare QoL and coping strategies between these two groups and with the GSP. Stepwise multiple linear regression was used in both groups of patients to analyze what coping strategies predicted QoL. Cohen's d was used to measure effect size.
Results: Patients with MASLD (G_1) had better scores in physical functioning ($p < 0.006$, $d = 0.25$), role-physical ($p < 0.001$, $d = 0.36$), social functioning ($p < 0.001$, $d = 0.46$) and role-emotional ($p = 0.011$, $d = 0.23$), and worse scores in general health ($p < 0.001$, $d = –0.62$) and vitality ($p = 0.008$, $d = -0.24$) than liver transplant recipients (G_2). Both MASLD patients (G_1) and liver transplant recipients (G_2) had worse scores in physical functioning ($p < 0.001$, $d = –0.56$, G_1; $p < 0.001$, $d = –0.82$, G_2), role-physical ($p < 0.001$, $d = –0.38$, G_1; $p < 0.001$, $d = –0.74$, G_2), bodily pain ($p < 0.001$, $d = –0.25$, G_1; $p = 0.002$, $d = –0.21$, G_2), vitality ($p < 0.001$, $d = –0.50$, G_1; $p < 0.001$, $d = –0.26$, G_2), role-emotional ($p < 0.001$, $d = –0.31$, G_1; $p < 0.001$, $d = –0.55$, G_2) and physical component summary ($p < 0.001$, $d = –0.47$, G_1; $p < 0.001$, $d = –0.47$, G_2) than the GSP. Lastly, active coping ($p < 0.001$, beta = 0.31), denial ($p < 0.001$, beta = –0.24), positive reframing ($p = 0.004$, beta = 0.20), self-blame ($p < 0.001$, beta = –0.21) and acceptance ($p = 0.024$, beta = 0.16) predicted QoL in MASLD patients (G_1). Self-distraction ($p < 0.001$, beta = –0.23), acceptance ($p = 0.004$, beta = 0.19), active coping ($p < 0.001$, beta = 0.27), self-blame ($p = 0.009$, beta = –0.17) and religion ($p = 0.015$, beta = –0.15) predicted QoL in liver transplant recipients (G_2).
Conclusion: QoL was mostly lower in liver transplant recipients than MASLD patients, although self-perceived health was worse in MASLD. Both groups of patients showed greater decline in QoL, mainly physical, than the GSP. Coping strategies such as active coping, positive reframing or acceptance predicted better QoL, while denial, self-blame, self-distraction and religion predicted worse QoL. QoL and coping strategies should be considered important at all stages of liver disease, from MASLD to liver transplantation.

THU-420

10 years progression of metabolic risk factors, diet quality and degree of steatosis and fibrosis in a general population cohort - ECOR liver study

Joana Estrabocha[1], Sara Policarpo[2], Maria do Mar Orey[1], Sofia Carvalhana[3], Ana Craciun[3], Juliana Serrazina Pedro[3], Helena Cortez-Pinto[4]. [1]*Associação para Investigação e Desenvolvimento da Faculdade de Medicina (AIDFM), Lisbon, Portugal;* [2]*Laboratório de Nutrição, Faculdade de Medicina Universidade de Lisboa, Serviço de Dietética e Nutrição, ULS Santa Maria, Lisbon, Portugal;* [3]*Serviço de Gastroenterologia, ULS Santa Maria, Lisbon, Portugal;* [4]*Clínica Universitária de Gastroenterologia, Faculdade de Medicina Universidade de Lisboa, Lisbon, Portugal*
Email: joanaestrabocha.cic@gmail.com

Background and aims: Relationship between diet quality, inflammation, and metabolic health is key to understanding non-communicable diseases such as Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD). This study evaluates dietary patterns, anthropometric parameters, and the degree of steatosis and fibrosis in a Portuguese cohort over 10 years, correlating outcomes with the Healthy Eating Index (HEI).
Method: Assessments were conducted at two time points, with a mean 10-year interval. Participants consulted with a hepatologist, dietitian, nurse and underwent physical exams, blood tests, liver elastography (Fibroscan®) measuring CAP (steatosis), LSM (liver stiffness), and nutritional parameters (BMI, waist circumference - WC, dietary intake). HEI was calculated based on consumption of specific food groups. Higher consumption of dairy, protein foods, fruits, whole fruits, whole grains, vegetables, greens, beans and seafood/plant proteins contributed positively to the score, while higher intake of refined grains, sodium, added sugars, and saturated fats contributed negatively. HEI was analyzed as a continuous variable and by quartiles based on the sample distribution.
Results: The cohort of 92 individuals (53.3% male, baseline age 47.5 ± 16.2 years) showed a significant increase in steatosis prevalence from 29.3% to 47.8% ($p = 0.014$). Mean LSM decreased slightly from 5.1 ± 1.4 to 4.9 ± 1.8 kPa (NS), while moderate fibrosis (> 8 kPa) rose from 3.3 to 5.6% (NS). Weight (73.7 ± 14.1 to 77 ± 15.9 kg, $p < 0.001$), BMI (26.7 ± 3.6 to 28.2 ± 4.4 kg/m², $p < 0.001$), and WC (89.1 ± 12.5 to 93.9 ± 14.1 cm, $p < 0.001$) increased significantly. Caloric intake reduced from 2469 ± 805 to 1874 ± 672 kcal ($p < 0.001$), with reductions in protein (110.8 ± 34.7 to 88.1 ± 31.8 g, $p < 0.001$), carbohydrates (292.5 ± 111.6 to 194.9 ± 78.9 g, $p < 0.001$), and fiber (29.1 ± 12.1 to 20.4 ± 8.6 g, $p < 0.001$). Total HEI improved from 53.1 ± 7.9 to 59.8 ± 9.7 ($p < 0.01$). Significant HEI decreases for whole grains ($p < 0.01$), saturated fats ($p < 0.01$), greens and beans ($p = 0.027$), and whole fruits ($p < 0.01$). HEI for added sugar ($p = 0.001$) and sodium ($p < 0.01$) improved. Individually, HEI inversely correlated with BMI ($r = -0.297$, $p < 0.01$) and weight ($r = -0.267$, $p < 0.05$). Lower HEI quartiles link to poorer fatty acid profiles, while higher quartiles show better refined grain scores ($p < 0.03$ to $p < 0.001$). Whole grains, vegetables, fruits, and greens and beans intake improves with higher HEI scores ($p < 0.05$ to $p < 0.001$).
Conclusion: Despite improvements in diet quality, including reduced added sugar, sodium intake and lower caloric consumption, these changes did not significantly reduce weight, WC, or steatosis prevalence. Liver stiffness remained stable, suggesting reduced caloric expenditure, lower physical activity, or reporting bias. Nutritional interventions are crucial to further improving diet quality and promote weight control.

THU-421

10 year progression of metabolic risk factors - correlation with steatosis and fibrosis degree in a general population cohort

Joana Estrabocha[1], Sara Policarpo[2], Sofia Carvalhana[3], Ana Craciun[3], Juliana Serrazina Pedro[3], Helena Cortez-Pinto[4]. [1]*Associação para Investigação e Desenvolvimento da Faculdade de Medicina (AIDFM), Lisbon, Portugal;* [2]*Laboratório de Nutrição, Faculdade de Medicina Universidade de Lisboa, Serviço de Dietética e Nutrição, ULS Santa Maria, Lisbon, Portugal;* [3]*Serviço de Gastroenterologia, ULS Santa Maria, Lisbon, Portugal;* [4]*Clínica Universitária de Gastroenterologia, Faculdade de Medicina Universidade de Lisboa, Lisbon, Portugal*
Email: joanaestrabocha.cic@gmail.com

Background and aims: There is evidence that aging is associated with an increase in the number of metabolic risk factors potentially increasing prevalence and degree of hepatic steatosis. Aiming to evaluate which factors could predominantly be associated, we studied a group of individuals from the general population that had been previously evaluated, comparing risk factors, as well as hepatic steatosis and fibrosis grade after a 10-year interval.
Method: From 220 participants initially included, it was possible to re-evaluate 92 with a similar methodology, single visit to a multidisciplinary consultation: hepatologist, dietitian and nurse. A physical examination, blood panel and liver elastography (Fibroscan®) with assessment of CAP (for steatosis), LSM (for liver stiffness) and a nutritional evaluation (BMI, waist circumference-WC, dietary intake) were carried out.
Results: 53.3% of the participants were male, with an average baseline age of 47.5 ± 16.2years. Steatosis prevalence increased from 29.3 to 47.8% ($p = 0.014$). Prevalence of moderate fibrosis increased from 3.3 to 5.6% (NS), but none of the current fibrotic patients presented fibrosis at baseline. Eighty percent of those with steatosis at baseline, now had moderate fibrosis. Average weight was 73.7 ± 14.1 kg at baseline vs. 77.6 ± 15.9 kg ($p < 0.001$) currently, implicating an increase in the average BMI from 26.7 ± 3.6 at baseline to 28.2 ± 4.4 kg/m² ($p < 0.001$). Average WC also increased: (89.1 ± 12.5 vs. 93.92 ± 14.1 cm: $p < 0.001$). The proportion of overweight participants has risen from 69.7% to 81.4% ($p = 0.035$), obese prevalence increased from 15.7 to 27.9% ($p = 0.001$). Mean systolic blood pressure increased from 122.9 ± 18.6 mmHg to 130.9 ± 20.7 mmHg ($p < 0.001$). Participants with steatosis, had higher BMI: 28.1 ± 3.2 vs. 25.6 ± 3.4 kg/m² ($p = 0.001$) and WC: 94.8 ± 10.6 vs. 84.4 ± 11.8 cm ($p < 0.001$) compared to baseline. From univariate analysis, the BMI ($p = 0.002$), ALT ($p = 0.012$), GGT ($p < 0.001$) and HDL ($p = 0.010$), at baseline significantly correlate with the presence of steatosis 10 years later. However, in multivariate analysis only GGT remained significantly associated (OR: 1.043 [1.002–1.086]: $p = 0.038$).
Conclusion: We confirmed aging to associate with increased prevalence of overweight/obesity as well as waist circumference, with potential increase in visceral fat, a significant risk factor for metabolic diseases. As expected, the prevalence of steatosis and moderate fibrosis also increased. These findings highlight the need for interventions with an emphasis on preventing weight gain, that besides promoting cardiovascular and metabolic health, can mitigate the progression of liver diseases. Interestingly, elevation of GGT in the baseline was the best predictor of steatosis development.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease, which can progress to life-threatening cirrhosis and liver failure. Clinical studies have shown that the severity of MASLD associates with a high plasma beta-hydroxybutyrate-to-acetoacetate ratio (bOHB/AcAc), a well-established marker of hepatic mitochondrial reductive stress. Here, we aimed to investigate whether bOHB/AcAc predicts major adverse liver-related outcomes (MALO) in a large prospective cohort. Additionally, we sought to identify medications and dietary factors that associate with bOHB/AcAc.
Method: In the UK Biobank data (~500,000), plasma bOHB and AcAc concentrations were determined using the Nightingale NMR metabolomics platform. We excluded participants with liver disease at baseline or chronic viral hepatitis at any time, and constructed registry-based prospective models restricted to a 15-year follow-up. We conducted multivariable Cox regression analyses to evaluate the associations between baseline bOHB/AcAc and MALO. The analyses were adjusted for age, sex, waist-to-hip ratio, BMI, and alcohol consumption. We utilized linear regression to evaluate the associations of bOHB/AcAc with self-reported medication use and dietary factors based on repeated 24-hour dietary recalls. We validated medication associations in vitro by assessing their effects on HepG2 cell viability after 24-hour incubations in 300 uM palmitate.
Results: High baseline bOHB/AcAc predicts the risk of hospitalization due to both non-alcohol-related and alcohol-related cirrhosis (K70.3 or K74.6) and chronic hepatitis (K73) (HR = 1.12–1.51 per 1-SD, $p < 0.05$, for all). Furthermore, bOHB/AcAc predicts mortalities related to cirrhosis (K70.3 and K74.6) and liver failure (K70.4 and K72) (HR = 1.24–1.50 per 1-SD, $p < 0.05$ for both). Multiple commonly used medications associated with bOHB/AcAc, including statins, whose users had 10.8% lower bOHB/AcAc compared to non-users (FDR <0.0001). Atorvastatin and simvastatin improved HepG2 viability dose-dependently ($p \leq 0.0001$, for both). Regarding dietary factors, high fat intake was associated with high bOHB/AcAc (effect size 2.4% per 1-SD, FDR <0.01). Conversely, intakes of vitamins B1, B2, B3, B5, B6, B9, and B12, as well as zinc, exhibited an inverse association with bOHB/AcAc (effect sizes ranging from −1.7% to −2.5% per 1-SD, FDR <0.01).
Conclusion: Plasma bOHB/AcAc predicts both metabolic dysfunction-associated and alcohol-related MALO. High dietary fat intake associates with increased bOHB/AcAc, while statin use and intake of nutrients necessary for mitochondrial energy metabolism, such as B vitamins and zinc, associate with decreased bOHB/AcAc. These data suggest that mitochondrial reductive stress contributes to the development of MALO, and may be modifiable by medications and dietary factors.

THU-423

All-cause and disease-specific mortality in young adults with metabolic dysfunction-associated steatotic liver disease: a nationwide cohort study

Jeayeon Park[1], Goh Eun Chung[2], Eun Ju Cho[1], Su Jong Yu[1], Yoon Jun Kim[1], Jung-Hwan Yoon[1]. *[1]Seoul National University College of Medicine, Seoul, Korea, Rep. of South; [2]Seoul National University Hospital Healthcare System Gangnam Center, Seoul, Korea, Rep. of South*
Email: creatioex@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has become a major cause of chronic liver disease globally, particularly among young adults. This study aimed to analyze all-cause and disease-specific mortality in young adults with MASLD.
Method: In this nationwide cohort study, we analyzed data from the Korean National Health Insurance Service, focusing on individuals aged 20 to 39 years who underwent health screenings between 2009 and 2012. The participants were categorized into two groups: those with MASLD and those without steatotic liver disease (SLD). SLD was defined by a fatty liver index ≥30. Mortality risk was analyzed via Cox proportional hazards models.
Results: MASLD was present in 25.3% of the study participants. During a median follow-up of 10.6 years (interquartile range, 9.5–11.2), individuals with MASLD had a significantly greater risk of all-cause mortality than did those without steatosis (adjusted hazard ratio [aHR], 1.17; 95% confidence interval [CI], 1.13–1.21). The MASLD group also had an increased risk of mortality related to cardiovascular disease, liver cancer, and liver disease, whereas the risk of extrahepatic cancer related mortality did not significantly differ between the two groups. Compared with men with MASLD, women with MASLD had higher risks of all-cause mortality, cardiovascular mortality, extrahepatic cancer mortality, and liver disease-related mortality, although the risk of liver cancer-related mortality was similar between the sexes.
Conclusion: Young adults with MASLD are at a significantly increased risk of all-cause and disease-specific mortality. These findings underscore the importance of early detection and intervention to mitigate the long-term outcomes of MASLD in young adults.

THU-424

Patient preferences for metabolic-dysfunction associated steatotic liver disease: moving towards patient centred care

Katie Williams[1], Rhiannon Latham[1], Daniel Cuthbertson[1,2], Michael Merrimen[3], Cyril Sieberhagen[2], Helen Jarvis[4], Ian Rowe[5], Bryn Williams[6], Deirdre Lane[1], Louise Roper[1], Theresa Hydes[1,2]. *[1]Institute of Life Course and Medical Sciences, University of Liverpool, Liverpool, United Kingdom; [2]University Hospital Aintree, Liverpool University Hospital NHS Foundation Trust, Liverpool, United Kingdom; [3]Millbrook Medical Centre, Southdene Primary Care Resource Centre, Liverpool, United Kingdom; [4]Population and Health Sciences Institute, Newcastle University, Newcastle, United Kingdom; [5]University of Leeds, Leeds, United Kingdom; [6]Patient Co-Applicant, Liverpool, United Kingdom*
Email: theresa.hydes@liverpool.ac.uk

Background and aims: Considerable variability exists among MASLD care pathways. There is an important, unmet need to identify patient preferences for MASLD care for prevention, screening, risk stratification, follow-up and management. Understanding patient preferences is integral to the improvement and innovation process and can optimise clinical outcomes, improve engagement and treatment adherence. This study aimed to explore patient preferences for MASLD care.
Method: In-depth qualitative interviews and focus groups were conducted with adults in the UK who have MASLD, managed in primary or secondary care, and with those at risk of MASLD. An interview guide was co-developed by the multidisciplinary research team and patient and public involvement representatives and was updated in an iterative manner. Thematic analysis of the data was performed.
Results: Thirty-three adults aged between 31 and 78 years participated (30% male, 70% female; 85% White, 12% Black, 3% Asian). Twelve participants were managed in primary care, twelve in secondary care and nine were identified as being at risk of MASLD. The absence of MASLD public health campaigns negatively influenced participants understanding of its importance. This was compounded by the lack of information provided by healthcare professionals at diagnosis. All participants wished to be screened for MASLD, primarily as they felt a diagnosis would encourage lifestyle changes. Emphasis was placed on clear communication of the diagnosis, including information about disease stage, trajectory and reversibility. Participants were receptive to multiple non-invasive testing to determine disease stage and were not concerned by potential false positive results providing the possibility was clearly explained. Participants strongly desired more information on weight

management and suggested that individualised support would be most effective. When asked to rank preferences of care, clear explanation of liver disease stage and test results was deemed a priority, compared to access to clinical trials and treatment for weight loss.
Conclusion: In this first qualitative study to explore patient preferences for MASLD care, clear communication emerged as the dominant theme across the patient journey for people at risk of, and living with, MASLD. Incorporating such patient preferences into MASLD care pathways will potentially improve patient satisfaction and clinical outcomes.

Clinical and genetic predictors of steatotic liver disease in lean individuals: a cohort study of risk factors and fibrosis prediction
Angela Sato Espinoza[1], Filippo Pinto e Vairo[2], Perapa Chotiprasidhi[1], Shulan Tian[3], Robert Vierkant[4], Jun Ma[5], Daniel O'Brien[3], Konstantinos N. Lazaridis[6], Alina M. Allen[1], Kirk Wangensteen[1].
[1]Department of Medicine, Division of Gastroenterology, Mayo Clinic, Rochester, United States; [2]Department of Clinical Genomics, Mayo Clinic, Center for Individualized Medicine, Mayo Clinic, Rochester, United States; [3]Department of Quantitative Health Sciences, Division of Computational Biology, Mayo Clinic, Rochester, United States; [4]Department of Quantitative Health Sciences, Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, United States; [5]Department of Quantitative Health Sciences, Division of Computational Biology, Rochester, United States; [6]Department of Medicine, Division of Gastroenterology, Mayo Clinic, Center for Individualized Medicine, Mayo Clinic, Rochester, United States
Email: wangensteen.kirk@mayo.edu

Background and aims: Steatotic liver disease (SLD), characterized by fat accumulation exceeding 5% in the liver, can progress to cirrhosis due to cardiometabolic conditions, genetic predisposition, or alcohol consumption. Lean SLD, a rare phenotype, presents unique challenges as the balance of metabolic and genetic risk factors remains unclear. Although non-invasive tools like the Fib-4 score and polygenic risk score are validated for the general population, their utility in lean individuals is underexplored. This study aimed to characterize clinical and genetic factors influencing SLD and advanced fibrosis in lean patients (BMI ≤25 kg/m²).
Method: We used natural language processing, search tools, and manual chart review to identify lean SLD patients and match lean controls without SLD from two large healthcare biobanks. We also performed cross-sectional comparisons with overweight/obese SLD patients (BMI > 25 kg/m^2). SLD diagnosis was confirmed through radiology, pathology, or biopsy review. Data on clinical variables, laboratory values, and genetic variants (in *PNPLA3, TM6SF2, GCKR*, and *MBOAT7*) were analyzed using univariate and multivariate statistical methods.
Results: Among 188 lean SLD patients, 694 lean controls, and 3090 overweight/obese SLD patients, lean SLD patients had fewer metabolic comorbidities than their overweight/obese counterparts but more than lean controls. Diabetes emerged as the strongest predictor of lean SLD (OR 2.42, 95% CI 1.43–4.08, p < 0.001). Coronary artery disease and hypertension showed a trend without reaching statistical significance. Genetic variants in the main genes associated with SLD polygenic score were not significantly associated with SLD or fibrosis in lean patients. The Fib-4 score demonstrated moderate accuracy in identifying advanced fibrosis in lean individuals (AUC 0.76, 95% CI 0.64–0.89, p < 0.001).
Conclusion: Metabolic factors, particularly diabetes, are primary predictors of SLD in lean individuals, while genetic variants did not contribute significantly to disease risk or progression. The Fib-4 score proved to be an effective tool for assessing advanced fibrosis risk in this population, supporting its role in early diagnosis and targeted management strategies for lean SLD patients.

THU-429
Volatile organic compound metabolites in urine are associated with MASLD and fibrosis: an environmental health study
Laurens A. van Kleef[1], Jesse Pustjens[1], Marike Wabbijn[2], Geert Bezemer[3], Pengfei Li[1], Harry L.A. Janssen[1], Willem Pieter Brouwer[1]. *[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Center, Rotterdam, Netherlands; [2]Department of Internal Medicine, Ikazia Hospital, Rotterdam, Netherlands; [3]Department of Gastroenterology and Hepatology, Ikazia Hospital, Rotterdam, Netherlands*
Email: l.vankleef@erasmusmc.nl

Background and aims: Exposure to volatile organic compounds (VOCs) through inhalation, ingestion, and dermal contact has increased over the past decades, raising concerns about their impact on environmental health. VOCs are mostly metabolized by the liver into various compounds which are subsequently excreted in urine. While VOC exposure has been linked to impaired metabolic health, the associations between VOCs and metabolic dysfunction-associated steatotic liver disease (MASLD) as well as fibrosis due to steatohepatitis or a direct toxic effect remains unclear.
Method: We used data from the NHANES 2017–2020 cycle, a United States population-based cohort with data on controlled attenuation parameter (CAP) and liver stiffness measurements (LSM). Participants with viral hepatitis, excessive alcohol consumption or missing data on urine creatinine were excluded. MASLD was defined as CAP ≥275 dB/m together with metabolic dysfunction and fibrosis as LSM ≥8 kPa. To account for co-linearity between the 15 individual urine VOC metabolites, least absolute shrinkage and selection operator (LASSO) analysis was used to identify urine VOC metabolites that were most associated with MASLD and fibrosis. Weighted quantile sum (WQS) analysis was performed to quantify the associations of the LASSO-selected parameters. Analyses were adjusted for age, sex, smoking and alcohol consumption.
Results: The cohort included 2,279 participants (median age 51 [34–64], 48% male), with 41.4% having MASLD and 9.6% fibrosis. LASSO identified CEMA, MA, 3HPMA and DHBMA as a predictor of increased steatosis and/or fibrosis risk, while PGA, SBMA, CYMA, 2-HPMA and ACTA were linked to reduced steatosis and/or fibrosis risk. WQS analysis generated weighted quantile mixtures of the LASSO-selected VOCs both in positive and negative directions of effect. For steatosis, a non-significant increased risk was observed (aOR 1.13 per quartile, 95%CI 0.97–1.32; 75% accounted for by CEMA), while a significant decreased risk was found (aOR 0.66 per quartile, 95%CI 0.53–0.83; 38% by PGA, 33% by CYMA). For fibrosis, a non-significant increased risk (aOR 1.37 per quartile, 95%CI 0.86–2.17; 31% by MA, 25% by DHBMA, 24% by 3-HPMA) and a significant decreased risk (aOR 0.61 per quartile, 95%CI 0.40–0.93; 48% by PGA, 21% by 2-HPMA) were found.
Conclusion: Urinary metabolites of VOCs are associated with MASLD and fibrosis in the general population. Both positive and negative associations were observed. Notably, MA, a metabolite of styrene and ethylbenzene, is further metabolized by alcohol dehydrogenase into PGA. In this study, higher levels of MA were linked to an increased risk of fibrosis, while higher levels of PGA were associated with a decreased risk of fibrosis. These contrasting associations raise the possibility that impaired metabolism of ethylbenzene and styrene could lead to intra-organic accumulation, potentially contributing to fibrosis risk.

THU-430
Weight loss was associated with risk reduction of MASLD, at-risk MASH and fibrosis with ongoing effects beyond the current recommendations
Laurens A. van Kleef[1], Jesse Pustjens[1], Mesut Savas[2], Harry L.A. Janssen[1], Elisabeth van Rossum[2], Willem Pieter Brouwer[1].
[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Center, Rotterdam, Netherlands; [2]Department of

Internal Medicine, Erasmus MC, University Medical Center, Rotterdam, Netherlands
Email: l.vankleef@erasmusmc.nl

Background and aims: Weight loss varying between 3–10% is recommended in individuals with MASLD, dependent on whether there is only steatosis or also signs of metabolic dysfunction associated steatohepatitis (MASH) or fibrosis. These recommendations originate from experiences post gastric bypass surgery. However, improved insulin resistance is observed in individuals after gastric bypass even before substantial weight loss has occurred. We therefore investigated the associations between weight loss and risk of MASLD, MASH and fibrosis in a general population setting.
Method: A United States population-based cohort, NHANES 2017–2020, was used. Participants aged 18–80 years, with data on controlled attenuation parameter (CAP) and/or liver stiffness measurements (LSM) were selected. Exclusion criteria were BMI <18.5, excessive alcohol consumption, viral hepatitis, ALT > 100 and missing data on weight history. Weight change was based on self-reported weights. Current MASLD status was defined as CAP ≥275 dB/m together with metabolic dysfunction, at-risk MASH based on the Fibroscan AST (FAST) score ≥0.35 and fibrosis as LSM ≥8 kPa. Risk reduction attributed to weight loss was quantified using logistic regression analysis, adjusted for age, sex, race, education, smoking, alcohol consumption and BMI (either 10 years or 1 year ago, depending on the analysis). Non-linearity was assessed by restricted cubic splines among those with either weight loss or stable weight.
Results: We included 6753 individuals (aged 48 yr [33–62], 48.7% male), of whom 29% gained >3% weight, 44% remained stable, and 28% gained >3% weight over the last year. Weight change was between −14% and +14% for 90% of the population. At the current study visit, 42.0% had MASLD, 5.9% at-risk MASH and 8.9% fibrosis. Compared to stable weight, weight increase was associated with an increased risk of MASLD (OR 1.76; 95%CI 1.52–2.04), at-risk MASH (OR 1.96; 95%CI 1.48–2.58) and fibrosis (OR 1.55; 95%CI 1.23–1.96). Similarly, weight loss was associated with reduced risk for MASLD (OR 0.52; 95%CI 0.45–0.61), at-risk MASH (OR 0.73; 95%CI 0.54–0.98) and fibrosis (OR 0.59; 95%CI 0.46–0.75). Among those with stable weight or weight loss, each 5% reduction in weight was associated with lower risk of MASLD (OR 0.66; 95%CI 0.62–0.70), at-risk MASH (OR 0.85; 95%CI 0.74–0.95) and fibrosis (OR 0.79; 95%CI 0.71–0.90). There was no evidence of significant non-linearity for these outcomes. Results were consistent for 10-years weight change or when focusing on BMI changes.
Conclusion: In this general population study, the observed risk of MASLD, MASH and fibrosis decreased with self-reported weight loss. Higher reported weight loss was associated with lower observed risks in a linear fashion, indicating that weight loss beyond the currently recommended targets could further reduce the risk of advanced liver disease.

THU-431

Influence of cardiometabolic risk factors on HCC risk in patients with metabolic dysfunction-associated steatotic liver disease

Ho Soo Chun[1,2], Minjong Lee[1,2], Hye Ah Lee[3], Tae Hun Kim[1,2], Seung Up Kim[4]. *[1]Department of Internal Medicine, Ewha Womans University College of Medicine, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Ewha Womans University Medical Center, Seoul, Korea, Rep. of South; [3]Clinical Trial Center, Ewha Womans University Seoul Hospital, Seoul, Korea, Rep. of South; [4]Department of Internal Medicine, Institute of Gastroenterology, Yonsei University College of Medicine, Seoul, Korea, Rep. of South*
Email: minjonglee2@naver.com

Background and aims: Emerging data suggest that cardiometabolic risk factors (CMRFs) are major risk factors for hepatocellular carcinoma (HCC). However, it is unclear that which CMRFs are significantly associated with HCC development in metabolic dysfunction-associated steatotic liver disease (MASLD). We investigated the influence of five CMRFs, the criteria of MASLD definition, on the risk of HCC development in patients with MASLD.
Method: Between 2004 and 2023, this multicenter retrospective cohort study recruited 73,599 patients with MASLD from 5 medical centers in South Korea. The index date was defined as the date of the first diagnosis of MASLD and the primary outcome was HCC development. A time-varying Cox proportional analyses was performed for risk factor of HCC development, which handled the duration of each CMRF in each patient as a time-dependent variable. Significant liver fibrosis was defined as the fibrosis-4 index (FIB-4) > 2.67 or liver stiffness (LS) by vibration-controlled transient elastography ≥8 kPa.
Results: The mean age was 53.3 years, and male gender predominated (n = 43,440, 59.0%). During a median follow-up period of 5.0 years (interquartile range, 2.5–9.0 years), 142 (0.2%) patients developed HCC (0.32 per 1,000 person-years). Among fiver CMRFs, Overweight/obesity or central obesity (CMRF 1; adjusted hazard ratio [aHR] = 2.20, 95% CI = 1.26–3.85, p = 0.006) and pre-diabetes/diabetes (CMRF 2; aHR = 1.90, 95% CI = 1.20–3.00, p = 0.006) were independently associated with the risk of HCC development in time-varying Cox multivariable analysis, along with age, gender, platelets. Patients with CMRFs 1 and 2 had a significantly higher risk of HCC development than those with other CMRFs in the subgroup with FIB-4 <2.67 (aHR = 3.18, 95% CI = 1.46–6.93, p = 0.004). In contrast, the risk of HCC development was statistically similar between patients with CMRFs 1 and 2 and those with CMRFs 1 and 2 who additionally had other CMRFs (p = 0.119). Similar results were identified in the subgroups with FIB-4 ≥2.67, LS <8 kPa, and LS ≥8 kPa. Among patients with MASLD having CMRFs 1 and 2 at baseline (n = 29,453), the risk of HCC development was significantly lower in those who improved CMRF 2 at 2 years (n = 7,453 [25.3%], p = 0.004) compared to that in patients who consistently had CMRFs 1 and 2 (n = 18,930, 64.3%). No HCC developed in patient who improved both CMRFs 1 and 2 at 2 years (n = 1,319, 4.5%).
Conclusion: The influence of five CMRFs on the HCC risk significantly differed in MASLD. Overweight/obesity or central obesity and pre-diabetes/diabetes with fibrotic burden were significantly associated with the increased risk of HCC development in patients with MASLD.

THU-432

Impact of metabolic dysfunction-associated steatotic liver disease on post-surgical outcomes in HBV-related hepatocellular carcinoma

Younghyeon Ahn[1], Ji Won Yang[1], Jonggi Choi[1], Danbi Lee[1], Ju Hyun Shim[1], Kang Mo Kim[1], Young-Suk Lim[1], Han Chu Lee[1], Won-Mook Choi[1]. *[1]Department of Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South*
Email: dr.choi85@gmail.com

Background and aims: The impact of metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic risk factors on post-surgical outcomes for hepatitis B virus (HBV)-related hepatocellular carcinoma (HCC) remains unknown.
Method: A retrospective cohort study was conducted on 2,485 consecutive patients with very early or early-stage HBV-related HCC who underwent curative resection between 2010 and 2018 at a tertiary center in Korea. We collected baseline data on the presence of histologic steatosis and metabolic risk factors, including obesity, hypertension, dyslipidemia, and diabetes. The risks of intrahepatic HCC recurrence and overall mortality were analyzed based on MASLD status and metabolic risk profile.
Results: Among the 2,485 patients, 1,050 (42.3%) had MASLD. Patients with MASLD had more metabolic comorbidities, a higher prevalence of cirrhosis, lower alpha-fetoprotein levels, and less microvascular invasion compared to those without MASLD. During a median follow-up of 4.9 years, 1,087 (43.7%) cases of recurrence and 475 (19.1%) deaths were recorded. Patients with MASLD showed a

significantly higher risk of intrahepatic HCC recurrence compared to those without MASLD (adjusted hazard ratio [aHR], 1.16; 95% confidence interval [CI], 1.03–1.32), with a clear trend of increasing risk as the number of metabolic risk factors increased, ranging from 8% for one factor to 24% for three or more factors. However, MASLD was not significantly associated with overall mortality (aHR: 1.07; 95% CI: 0.88–1.30). Subgroup analysis revealed that the impact of MASLD on the risk of intrahepatic HCC recurrence was more pronounced in non-obese patients (aHR, 1.55; 95% CI, 1.15–2.09) compared to obese patients (aHR, 1.11; 95% CI, 0.95–1.28; *P* for interaction = 0.02), implying that the interplay between MASLD and metabolic risk factors may vary depending on obesity status.
Conclusion: MASLD is associated with an increased risk of intrahepatic HCC recurrence following curative resection for HBV-related HCC, particularly among non-obese patients and those with multiple metabolic risk factors, underscoring the need for tailored post-surgical surveillance and management strategies based on obesity status and metabolic risk profiles.

THU-433-YI

The impact of cardiopulmonary fitness on metabolic dysfunction-associated steatotic liver disease in a combined lifestyle intervention for adolescents with obesity

Maarten Buytaert[1], Ilse Coomans[2], Ellen Dupont[3], Kristof Vandekerckhove[1], Sander Lefere[4], Ruth de Bruyne[1]. *[1]Ghent University, Ghent University Hospital, Ghent, Belgium; [2]Ghent University Hospital, Ghent, Belgium; [3]Zeepreventorium, De Haan, Belgium; [4]Ghent University, Ghent, Belgium*
Email: maarten.buytaert@ugent.be

Background and aims: The interplay between liver and muscle health is incompletely understood, especially in adolescents. Cardiopulmonary exercise testing (CPET) evaluates cardiopulmonary fitness. Its association with metabolic dysfunction-associated steatotic liver disease (MASLD) and MASLD evolution during a lifestyle intervention is poorly characterized.
Method: Adolescents aged 12–18 years old living with (severe) obesity who received a structured, combined lifestyle intervention in a residential setting were prospectively followed for 6 months. CPET was performed at the start using a step-wise load increasing protocol. Raw data were analyzed, and the maximal parameters were obtained. Lean mass was obtained by DEXA scanning. MASLD was defined as a CAP value > 248 dB/m, and resolution as a CAP <248 dB/m at 6 months when baseline CAP values were > 248 dB/m.
Results: 119 adolescents (60 boys) with obesity were included, with a median (interquartile range) age of 16 (15–17) years. The median (IQR) BMI z-score was 2.87 (2.51–3.17). 85 adolescents (71.4%) had MASLD, of which 58.8% were boys. Maximal cardiopulmonary fitness (expressed as the percentage of the predicted VO2max; VO2max%) was significantly lower in adolescents with MASLD, with a median (IQR) of 42.8 (35.7–52.1) vs. 53.5 (46.1–58.5) % in adolescents without MASLD ($p < 0.001$). Strikingly, VO2max/kg did not differ between groups, whereas VO2max on lean mass was significantly lower in patients with MASLD: 35.5 (30.3–40.3) vs. 39.5 (33.9–44.8) ml/kg/min ($p = 0.036$). This highlights the importance of fat-free mass on cardiopulmonary fitness and MASLD. Next, data on resolution of baseline MASLD after 6 months intervention were available for 66 patients, of whom 33 (50.0%) had resolution. Interestingly, a higher VO2max/kg and VO2max% at baseline were associated with steatosis resolution, respectively 19.7 (16.6–22.1) vs. 16.1 (13.9–19.2) ml/kg/min ($p < 0.001$) and 45 (41–54) vs. 36 (29–52) % ($p = 0.006$). Moreover, this was also observed for VO2max on lean mass: 37.7 (33.8–43.6) vs. 32.9 (27.8–37.2) ml/kg/min ($p = 0.003$). These results remained significant when including weight z-scores at 6 months and gender in a binary logistic regression model. As a sensitivity analysis, MASLD was defined by the presence of liver steatosis on ultrasound, and the results remained significant.
Conclusion: Cardiopulmonary fitness is associated with liver health. Baseline cardiopulmonary fitness, independent from (fat) mass, in adolescents with obesity is associated with MASLD and could be an important contributor to MASLD resolution during a combined lifestyle intervention.

THU-434

Liver phenotypes in a multicentric PCOS cohort: prospective analysis including steatotic liver disease-associated genetic variants

Email: marcinjan.krawczyk@uk-essen.de

Background and aims: Polycystic ovary syndrome (PCOS) is frequently associated with advanced steatotic liver disease (SLD). However, there are numerous knowledge gaps in our understanding of genetic architecture of MASLD and its severity in women with well characterized PCOS. In this study, we aim to evaluate the role of genetic variants in shaping SLD phenotypes in women with PCOS, using non-invasive methods for quantification of hepatic fibrosis and steatosis.
Method: A total of 797 females with PCOS were recruited from Poland (n = 343), Germany (n = 42), USA (n = 264), and Brazil (n = 148). Liver status was assessed using SWE for patients from Poland, and Fibroscan with CAP for patients from Germany, the USA, and Brazil. All participants were genotyped for SLD-related variants, including *PNPLA3* p.I148M, *MBOAT7* p.G17E, *HSD17B13 rs72613567*: TA, *MTARC1* p.A165 T, *PIS*, *PIZ* and *PSD3* p. L186 T, using TaqMan assays. Steatosis was defined as CAP > 285 db/m, clinically significant fibrosis (CSF) as LSM > 8.5 kPa, and advanced fibrosis (AF) as LSM > 10.3 kPa.
Results: Among recruited patients with liver stiffness measurements (median: 4.8 kPa, range: 2.1–66.3 kPa), 8.3% had CSF and 4.8% met criteria for AF. CAP > 285 db/m was observed in 46.5% of patients with available CAP data (median: 279, range: 100–400 db/m). The median ALT was 17 I/UL (range: 4–253 I/UL), the median AST was 19 IU/l (range: 9–238 IU/L), and the median bilirubin was 0.5 mg/dl (range: 0.1–4.3 mg/dl). Only two patients had bilirubin levels exceeding 2 mg/dl. Minor allele frequencies (MAF) for genotyped variants were: *PNPLA3* p.I148M - 0.24, *MBOAT7* p.G17E - 0.40, *HSD17B13 rs72613567*: TA - 0.23, *MTARC1* p.A165 T - 0.26, *PIS* - 0.02, *PIZ* - 0.01 and *PSD3* p.

L186 T - 0.29. The *PNPLA3* polymorphism significantly modulated serum ALT (P = 0.002), AST (P = 0.049), CAP (P = 0.033) and liver stiffness (P = 0.013), with the highest values detected among carriers of the *PNPLA3* p.148MM genotype. Heterozygotes for the *PIS* had higher liver stiffness (P = 0.032). Carriers of the *PNPLA3* p.148M allele were at increased risk of CAP > 285 db/m (OR 1.71, 95% CI 1.16–2.52, P = 0.006).
Conclusion: SLD is common among females with PCOS, whereas advanced liver fibrosis is less frequent. Common genetic variants, particularly the *PNPLA3* p.I148M, significantly influence liver status in females with PCOS.

THU-435
Obesity-related cognitive problems are not related to liver disease severity and remain unchanged after metabolic restoration
Charlotte Wernberg[1], Elise Jonasson Nielsen[1], Birgitte Jacobsen[1], Lea Ladegaard Grønkjær[1], Mette Lauridsen[1]. [1]*Liver Research Group, University Hospital of Southern Denmark, Esbjerg, Denmark*
Email: charlotte.wilhelmina.wernberg@rsyd.dk

Background and aims: Obesity with metabolic dysfunction is associated with cognitive impairments in up to 40% of cases, primarily affecting reaction time stability, short-term, and long-term memory. The etiology of these cognitive issues is unclear, possibly linked to metabolic dysfunction associated steatotic liver disease and steatohepatitis (MASLD and MASH), or resulting from premature brain aging due to neuroinflammation, oxidative stress, and neurodegeneration. This study investigates whether cognitive dysfunction improves with weight loss post-bariatric surgery, suggesting a metabolic origin.
Method: Individuals with obesity (BMI > 35 kg/m²) underwent evaluations including liver biopsies, biometric assessment, and multidomain cognitive tests: the Continuous Reaction Time Test (CRT), Portosystemic Encephalopathy Syndrome Test (PSE), and Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). Abnormal results were defined using validated cut-offs: CRT (<1.9), PHES (<-4), RBANS (<79). One-third underwent bariatric surgery (BS) after baseline visit, and all participants, including controls, had serial liver biopsies. Changes in test scores and their correlation with weight or liver histology improvements were analysed.
Results: Among 110 patients (67% female, age 48 ± 13 years, weight 126 kg ± 23), 24% had type 2 diabetes. At baseline, 19% had no-MASLD, 51% had MASLD, 30% had MASH, fibrosis staging was 74% (F0-F1), 19% F2, and 7% F3-F4. At follow-up (2.7 years ± 0.43 years), BS patients (n = 35) lost 40.7 kg (±14.5), while the no-surgery group (n = 73) remained weight stable (−2.8 kg, SD 8.4). No significant changes were observed in the proportions of participants with abnormal CRT, PHES, and RBANS performances: 68% vs. 68%, 11% vs. 8%, and 39% vs. 30% respectively. Cognitive improvements occurred in both groups, with no significant changes in CRT index (0.17 ± 0.67 vs. 0.03 ± 0.52), PHES score (0.52 ± 1.5 vs. 0.79 ± 2.9), or RBANS index (9.2 ± 16.3 vs. 7.8 ± 14.9). Improvements in liver histology (≥1 grade fibrosis or inflammation/ballooning) did not correlate with cognitive improvements.
Conclusion: Cognitive impairments, affecting reaction time and memory, were present in 40% of this obese cohort at baseline and persisted nearly 3 years post-bariatric surgery despite MASLD and metabolic improvements. These deficits may be congenital or indicate irreversible damage, potentially reflecting premature brain ageing.

THU-436
Histologic severity on liver biopsy is identical between normal weight and overweight adults with metabolic dysfunction associated steatotic liver disease: is it time to revise the definition of lean MASLD?
Kaela Miller[1], Laura Wilson[2], Eduardo Vilar Gomez[1], Niharika Samala[1], Liyun Yuan[3], Veeral Ajmera[4], David E. Kleiner[5], Naga Chalasani[1]. [1]*Indiana University School of Medicine, Indianapolis, United States;* [2]*Johns Hopkins University, Baltimore, United States;* [3]*Keck School of Medicine of USC, Los Angeles, United States;* [4]*University of California San Diego, San Diego, United States;* [5]*National Cancer Institute, Bethesda, United States*
Email: nchalasa@iu.edu

Background and aims: While higher body weight is closely associated with histologic severity in MASLD, lean MASLD (i.e., MASLD in normal weight individuals) is a distinct phenotype which has received considerable attention. However, there are knowledge gaps in our understanding of the interplay among weight categories, *PNPLA3* genotype, and severity of liver histology. We examined clinical, *PNPLA3* genotypic, and histological characteristics of MASLD across several BMI categories in adult participants of the NASH CRN.
Methods: We categorized MASLD in the adult NASH CRN participants into normal weight (BMI <25 kg/m^2), overweight (BMI 25–29.9 kg/m^2), class 1 obesity (BMI 30–34.9 kg/m^2) and ≥ class 2 obesity (BMI ≥35 kg/m^2). These weight categories were adjusted for Asian participants according to the WHO criteria. Definite NASH, NAFLD Activity Score (NAS), advanced fibrosis (≥ F3) and cirrhosis (F4) were histological outcomes of interest.
Results: There were 107 adults with normal weight (mean BMI 23.2 kg/m^2), 744 with overweight (mean BMI 27.7 kg/m^2), 1128 with class 1 obesity (mean BMI 32.3 kg/m^2), and 1407 with class ≥2 obesity (mean BMI 40.5 kg/m^2) MASLD. The prevalence of metabolic syndrome increased across 4 weight groups - normal weight: 25%, overweight: 45%, class I obesity: 64%, and ≥ class 2 obesity: 72% ($p < 0.001$). The prevalence of *PNPLA3* G-allele did not differ - normal weight: 74%, overweight: 75%, class I obesity: 70%, and class ≥2: 73%. The mean NAS increased across categories: normal weight: 4.1, overweight: 4.1, class 1 obesity: 4.4, and class ≥2 obesity: 4.4 ($p < 0.001$), as did the proportion of definite NASH: normal weight: 50%, overweight: 50%, class 1 obesity: 59%, and class ≥2 obesity: 63% ($p < 0.001$). The prevalence of advanced fibrosis increased across 4 weight groups: normal weight: 24%, overweight: 24%, class 1 obesity: 30%, and class ≥2 obesity: 37% ($p < 0.001$), as did cirrhosis: normal weight: 8%, overweight: 8%, class 1 obesity: 10%, and class ≥2 obesity: 13% ($p < 0.001$). When normal weight MASLD with and without advanced fibrosis were compared, individuals with normal weight with advanced fibrosis were older (58.5 vs 49.8 years, $p = 0.005$), more likely to have diabetes (48% vs 19%, $p = 0.003$) and metabolic syndrome (46% vs 19%, $p = 0.009$) and be homozygous for *PNPLA3* G allele (44% vs 17%, $p = 0.02$). The histologic severity was identical between normal and overweight MASLD groups (mean NAS 4.1, 50% definite NASH, 24% advanced fibrosis, and 8% cirrhosis in both groups).
Conclusion: One in 4 normal weight adults with MASLD have advanced fibrosis and one in 12 normal weight adults with MASLD have cirrhosis. Interestingly the rates of advanced fibrosis and cirrhosis are similar in patients with normal weight and overweight MASLD, and their histological severity worsens only after BMI > 30 kg/m^2. These data call for revising definition of lean MASLD as a distinct entity.

THU-437

Association of alpha-1 antitrypsin Pi*Z allele and disease severity in metabolic dysfunction-associated steatotic liver disease

Kaela Miller[1], Eduardo Vilar Gomez[1], Niharika Samala[1], Tiebing Liang[1], Raj Vuppalanchi[1], Samer Gawrieh[1], Rohit Loomba[2], Naga Chalasani[1]. [1]*Indiana University School of Medicine, Indianapolis, United States;* [2]*University of California San Diego, San Diego, United States*
Email: nrsamala@iu.edu

Background and aims: Alpha-1 antitrypsin deficiency is a known cause of cirrhosis specifically in Pi*Z allele homozygotes (serpin family A member 1 [*SERPINA1*] rs28929474). However, studies have suggested that patients with Z allele heterozygosity have increased risk of liver injury and cirrhosis as well. The impact of Pi*Z allele in metabolic dysfunction-associated steatotic liver disease (MASLD) is unclear; therefore, we aimed to evaluate the frequency of *SERPINA1* Pi*Z allele in an ongoing prospective registry of patients with well characterized MASLD cohort and examine its association with disease severity.
Methods: A total of 915 patients in the Indiana University MASLD cohort who underwent SERPINA1 genotyping and Vibration Controlled Transient Elastography (VCTE) assessment were included in this analysis. *SERPINA1* rs28929474 was genotyped via TAQMAN genotyping assay (C is the ancestral allele whereas T is the minor allele). The outcomes of interest were liver stiffness measurement (LSM) and CAP measurement by VCTE in all patients and NAFLD Activity Score (NAS 0–8) and fibrosis score (F0–4) in patients with liver histology available (n = 419).
Results: There were 864 patients (94%) with CC genotype (65% female, 93% Caucasian, mean BMI 35.6 kg/m^2) and 51 patients (6%) with CT genotype (53% female, 96% Caucasian, mean BMI 35.2 kg/m^2). There were no individuals with homozygosity for T allele. There appears to be an enrichment of *SERPINA1* rs28929474 T allele in this cohort relative to population controls (6% in our cohort vs 2–3% in general population). The mean CAP measurement in the CC genotype group was 319 dB/m and it was 310 dB/m in the CT genotype group (p = 0.28). The mean LSM was 14 kPa in CC group and 15 in CT group (p = 0.77). The prevalence of LSM ≥12 kPa was 36% CC group and 37% CT group (p = 0.87). Of the 915 patients included in this analysis, 419 patients had liver histology assessment on biopsy. The mean NAS score was 3.7 ± 1.6 in both CC and CT genotype groups (p = 0.94) with a NAS score ≥4 in 56% of CC genotype and 65% of CT genotype participants (p = 0.45). The mean fibrosis score was 2.1 ± 1.4 in the CC group and 2.0 ± 1.3 in the CT group. The prevalence of advanced fibrosis (F≥3) was 42% and 35% respectively in CC and CT groups (p = 0.52). The prevalence of cirrhosis was 20% and 15% respectively in CC and CT groups (p = 0.56).
Conclusion: The minor allele frequency for *SERPINA1* rs28929474 (Pi*Z) in a large cohort of Caucasian individuals with well characterized MASLD was 6%. While this MAF is higher than in general population, Pi*Z carriers did not have worse liver disease by VCTE or by liver histology.

Email: miriam.duell@uk-erlangen.de

Background and aims: Sensory neuropathic symptoms are frequently overlooked in patients with metabolic syndrome (MetS), especially compared to Type 2 Diabetes Mellitus (T2DM). The mechanisms underlying small nerve fiber damage in MetS remain poorly understood. Reactive carbonyl species (RCS), such as methylglyoxal (MGO), by-products of glucose and lipid metabolism, are implicated in diabetic peripheral neuropathy, neuropathic pain, and liver steatosis-associated damage. This study evaluates small nerve fiber function in hepatological patients with MetS, including metabolic-associated steatotic liver disease (MASLD), and T2DM, correlating findings with RCS levels, nerve histopathology, and microneurography.
Method: Patients were recruited from a tertiary hepatology outpatient clinic. Clinical assessments included liver ultrasound, elastography, neuro-electrophysiology, pain/neuropathy questionnaires, and systemic MGO measurements. Small nerve fiber function was evaluated via quantitative sensory testing (QST) and selective C-fiber electrical stimulation. Skin biopsies from upper and lower legs were analyzed for intraepidermal nerve fiber density (IENFD) and MGO-derived glycation markers (MG-H1). Direct C-fiber recordings via microneurography were performed to objectively assess the extent of pathological C-fiber changes.
Results: MetS patients showed significant alterations in skin nerve fiber function compared to healthy controls, despite the absence of overt clinical neuropathy. Reduced IENFD correlated with elevated MG-H1 and MGO levels and diminished pain responses to C-fiber stimulation. Electrical stimulation induced dose-dependent pain in both groups, but MetS patients demonstrated a lack of pain adaptation during longer-lasting sinusoidal wave stimulation, a pattern typically seen in healthy controls. Women reported overall higher pain ratings than men. Direct microneurography recordings revealed abnormal C-fiber activity in MetS patients, indicating early pathological changes in peripheral nerve function.
Conclusion: Small nerve fiber dysfunction, including altered C-fiber functionality, is detectable in Mets/MASLD patients even in the absence of clinically evident neuropathy, highlighting the need for early diagnostic and preventive strategies. These findings suggest potential interactions between small nerve fibers and other MetS-affected organ systems, such as the liver or vasculature, possibly mediated by neuropeptides facilitating bidirectional signaling. Correlation of RCS levels with C-fiber changes may reveal early metabolic and functional biomarkers for neuropathy development.

THU-439-YI

Impact of a multidisciplinary clinic for metabolic dysfunction-associated steatotic liver disease on cardiovascular risk and liver health

Mirko Zoncapè[1,2], Anna Mantovani[1,3], Davide Roccarina[1,4], Amy Teague[1], Sau Yee Chan[5], Wing Sum Shin[5], Atul Goyale[1], Emmanuel Tsochatzis[1]. University of Hong Kong, Hong Kong, China
Email: mirko.zonky@yahoo.it

Background and aims: Cardiovascular disease (CVD) is the leading cause of mortality in metabolic dysfunction-associated steatotic liver disease (MASLD) patients. Guidelines recommend a multidisciplinary approach, but real-world data are limited. This study aimed to assess the efficacy of a multidisciplinary MASLD clinic in optimising control of metabolic comorbidities and liver injury markers.
Method: We conducted a retrospective analysis of 465 patients seen in a multidisciplinary MASLD clinic from June 2014 to June 2024. All participants were evaluated by both a hepatologist and an expert in cardiovascular disease. Patients were referred directly from primary care or through the Camden and Islington MASLD Pathway (London, UK), which involved a FIB-4 and, if needed, an ELF score. Each patient received a comprehensive hepatological assessment, cardiovascular risk assessment and management, and, where required, dietary counselling by a dietician. Diagnostic criteria for comorbidities, including hypertension, type II diabetes, dyslipidaemia, and obesity, were based on recognised clinical guidelines. Cardiovascular risk was assessed using the QRISK-3 Score, with statins recommended for patients with a ≥10% 10-year CVD risk or a history of cardiovascular events. Baseline and follow-up data on anthropometry, blood pressure, and laboratory values were collected. Primary endpoints were changes in liver injury markers (transaminases, LSM) and metabolic comorbidities (e.g., blood pressure, HbA1c, lipid profile, and QRISK-3 Score).
Results: The mean age of 465 patients was 57 ± 12 years, 56% were males, and 54% Caucasian. Hypertension, diabetes, and dyslipidaemia were present in 66%, 56%, and 84% of patients, respectively. At baseline, 65% had abnormal ALT, while LSM, measured in 95% of patients, had a median of 7.9 kPa. Of 190 liver biopsies, 79% showed steatohepatitis, with bridging fibrosis in 29% and cirrhosis in 14%. At a 15-month median follow-up, 61% of patients remained under secondary care, with significant improvements observed in ALT ($p < 0.001$), AST ($p < 0.001$), GGT ($p < 0.001$), total cholesterol ($p < 0.001$), LDL-c ($p < 0.001$), TG ($p = 0.007$), systolic and diastolic blood pressure ($p < 0.001$ and $p = 0.001$), weight ($p < 0.001$), BMI ($p < 0.001$), LSM ($p = 0.020$), and QRISK-3 Score ($p = 0.002$). Waist circumference decreased significantly in obese patients, with 12% achieving ≥10% weight loss. Therapy adjustments improved metabolic markers, notably HbA1c, blood pressure, and lipid profile in patients with diabetes, hypertension, and dyslipidaemia, respectively.
Conclusion: A multidisciplinary approach to MASLD effectively improves liver and CV risk markers. Long-term collaboration between primary and secondary care is crucial to achieve and maintain these health improvements.

THU-440
The paradox of low hepatic fat content in steatotic liver disease: insights from an MRI-PDFF study

Atsushi Nakamura[1]. [1]*Nippon Koukan Hospital, Kawasaki, Japan*
Email: naka2722@gmail.com

Background and aims: The pathophysiological mechanisms of hepatic fat loss in late steatotic liver disease (SLD) are enigmatic, and the impact of low hepatic fat content (LHF) on prognosis in advanced chronic liver disease (ACLD) is remains unclear. Proton density fat fraction (PDFF) measured by MRI can non-invasively and accurately quantify hepatic fat content. In the present study, we investigated these issues using MRI-PDFF measurements.
Method: This is a single-center retrospective study of 657 patients with CLD excluding alcohol-related liver disease in which MRI-PDFF and liver stiffness (LS) on MRE were measured. 46 patients with HCC were included. Patients were divided into two groups according to the etiology of their disease: SLD (group S) and other etiologies (group O). We examined the trends and interrelationships of PDFF, ALT, and ALBI score in five stages of LS progression (<2.5, 2.5–3.5, 3.5–4.5, 4.5–5.5, and ≥5.5 kPa). We defined LHF as PDFF ≤2.7%, and analyzed the relationships between variables using multivariate analysis and the prognosis of ACLD patients using the Cox proportional hazards model.
Results: 1) Analysis of PDFF: There was a significant difference in the mean PDFF (12.8% and 5.3%) between Group S (n = 232) and Group O (n = 425) ($P < 0.05$). In the multivariate analysis, Group S ($\beta = 0.26$), BMI (0.25), ALT (0.22), triglyceride (0.14) and ALBI score (-0.18) were independent associated factors of hepatic PDFF (each $P < 0.01$). 2) Analysis of the five groups (without HCC): In the group S, the PDFF was 12, 14, 15, 18, 7 (%) and the ALT was 45, 69, 85, 73, 49 (U/l), and it turned from an increase to a decrease at 5.5 kPa. Then, the ALBI score (−2.95, −2.97, −2.96, −2.73, −2.18) significantly worsened at ≥5.5 kPa ($P < 0.01$). In addition, in Group O, there was a significant correlation between the progression of LS and the ALBI score, and the PDFF (5, 6, 7, 6, 3%) decreased at ≥5.5 kPa ($P < 0.05$). 3) Study in ACLD (LS ≥3 kPa): In both the S and O groups, a significant inverse correlation was observed between the ALBI score and PDFF ($r = -0.588$ and -0.341, $P < 0.01$). In addition, the incidence of LHF increased with progression of ALBI grade ($P < 0.01$). In the prognosis analysis with a median observation period of 36 months and 33 cases of liver-related death, ALBI score (HR: 4.3), HCC (4.4), and LHF (6.2) were independent associated factors ($P < 0.01$).
Conclusion: This study showed that the increase in hepatic PDFF, a factor in liver inflammation and fibrosis in SLD, begins to decrease at 5.5 kPa and is associated with worsening liver reserve function. Hepatic PDFF may serve as a dynamic biomarker reflecting liver pathophysiology, and LHF is an important independent factor that predicts the prognosis in all ACLD patients. These results suggest that a decrease in liver fat content in the advanced stage of SLD does not necessarily indicate a good prognosis, and it is important to continuously monitor hepatic fat content in patient management.

THU-445
Subgroup definition and monitoring of liver fibrosis evolution in patients with MASH bridging fibrosis based on objective measurements of septa parameters using digital pathology with artificial intelligence analyses

Nikolai Naoumov, Elaine Chng[1], Yayun Ren[1], Dominique Brees[2], Chandra Saravanan[3], Dean Tai[1], David E. Kleiner[4], Arun J. Sanyal[5]. [1]*HistoIndex, Singapore, Singapore;* [2]*Novartis Pharma AG, Basel, Switzerland;* [3]*Novartis Institute of Biomedical Research, Cambridge, MA, United States;* [4]*Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, United States;* [5]*Stravitz-Sanyal Institute of Liver Disease and Metabolic Health, Virginia Commonwealth University School of Medicine, Richmond, Virginia, United States*
Email: nikolainaoumov@yahoo.com

Background and aims: Metabolic Dysfunction-Associated Steatohepatitis (MASH) with bridging fibrosis (stage F3) is a critical, yet very broad category, in steatotic liver disease encompassing subjects with potential progression to cirrhosis or regression to milder stages. Second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy with artificial intelligence (AI) provides sensitive and objective quantification of liver fibrosis. This study aimed to identify subsets of the MASH F3 population by quantitative septa evaluation.
Method: Paired liver biopsies from 57 patients, all with bridging fibrosis, part of the FLIGHT-FXR trial (NCT02855164): placebo (PLB, n = 17), tropifexor (TXR, n = 40) were included. Unstained sections were analyzed by SHG/TPEF microscopy with quantification of 12 septa parameters at baseline (BL) and end of treatment (EOT) biopsies. Septum width measurement of 93 randomly selected septa was used to differentiate thick (mean width 167 µm) from thin septa (mean width 41 µm) with a cutoff of 88.5 µm, as determined by the Youden's index. The ratio between the thick septa area to total septa area per biopsy identified 2 subgroups: predominantly thin septa

(F3a) (mean ratio 13%, range 0–48%) or predominantly thick septa (F3b) (mean ratio 71%, range 51–97%).
Results: At BL, 27 of 57 F3 patients were categorised as F3a (PLB, n = 9; TXR, n = 18) and 30 were F3b (PLB, n = 8; TXR, n = 22). The average septa area in F3b patients was 3-fold larger (21820 ± 3383 μm²) than in F3a patients (6752 ± 7219 μm², p < 0.001). Importantly, septa area measurements revealed significant imbalance between those randomised to receive PLB or TXR (p = 0.027). From BL to EOT, intra-stage changes F3a to F3b and vice versa were observed in 5 of 11 PLB and 10 of 28 TXR cases with unchanged F3 stage by the ordinal scoring. The placebo cohort showed no consistent trend in septa area dynamics across F3a or F3b subgroups, while the TXR cohort, especially F3b subgroup, showed a notable reduction in the septa area, though not statistically significant.
Conclusion: SHG/TPEF microscopy with AI offers precise insights into fibrosis dynamics in MASH F3 patients, revealing details not detectable by conventional methods. Its use in clinical trials can optimise patients' selection and stratification, as well as dose-response analyses. These findings highlight the potential of digital pathology for an objective subgroup separation of F3 stage, informing future studies.

THU-446

Risk stratification of liver-related complications through unsupervised partitioning clustering of alanine aminotransferase (ALT) levels and trajectories in patients with type 2 diabetes (T2D)

Nana Peng[1,2], Sherlot Juan Song[1,2], Mary Yue Wang[1,2], Jimmy Lai[1,2,3], Grace Lai-Hung Wong[1,2], Vincent Wai-Sun Wong[1,2], Terry Cheuk-Fung Yip[1,2,3]. *[1]Medical Data Analytics Center, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China; [2]State Key Laboratory of Digestive Disease, Institute of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, China; [3]Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong, China*
Email: nnpeng@link.cuhk.edu.hk

Background and aims: ALT is commonly used in clinical practice to screen for and monitor liver disease in patients with T2D. We aimed to characterise common ALT levels and trajectories and examine their impact on the risk of liver-related complications including hepatic decompensation, hepatocellular carcinoma, and liver-related death in T2D.
Method: A territory-wide retrospective cohort of patients with T2D from 2000–2016 was identified in Hong Kong. Patients with type 1 diabetes, chronic viral hepatitis, excessive alcohol use, or liver-related complications before baseline or follow-up <5 years were excluded. Unsupervised partitional clustering was applied to identify trajectories by testing the number of clusters (k) from 1 to 6. Various distance measures with centroid calculation were employed, including Euclidean distance, dynamic time wrapping (DTW) and move-split-merge (MSM) with arithmetic mean, DTW with DTW barycenter averaging (DBA), and MSM with MSM barycenter averaging (MBA). Cluster validity indices were summarised to determine the optimal k and the best-performing algorithm. The association between ALT levels and trajectories with liver-related complication risk was evaluated using cause-specific hazard models, with non-liver-related death as competing risk. ALT trajectories were quantified by linear mixed models.
Results: Of 240,076 patients with T2D (age 61 ± 13 years, 48.7% females, 1.9% cirrhosis, HbA_{1c} 8.0 ± 2.2%, ALT 23 [17–35] U/L), 2,859 (1.2%) developed liver-related complications at a median follow-up of 12.0 (9.3–15.0) years. MSM-MBA identified 4 robust ALT trajectories in the first 5 years after T2D diagnosis: U-shaped, inverted U-shaped, increasing and decreasing. Considering the limited clinical significance and shallow pattern differences between the U-shaped and inverted U-shaped trajectories, the two groups were merged, resulting in 3 trajectories: stable (n = 149,520 [62.3%]), increasing (n = 54,593 [22.7%]) and decreasing (n = 35,963 [15.0%]). Compared to a stable trend, patients with decreasing ALT had a lower risk (adjusted hazard ratio [aHR], 0.63 [95% CI, 0.55–0.71]), while those with increasing ALT had a higher risk (aHR, 1.15 [95% CI, 1.05–1.27]). Compared to a stable trajectory with ALT <upper limit of normal (ULN; 35 U/L for male and 25 U/L for female), patients with baseline ALT <ULN with an increasing trend or 1–2×ULN with either a stable or increasing trajectories had higher risks of liver-related complications (aHR [95% CI], 1.12 [1.01–1.24], 1.36 [1.22–1.51], and 1.84 [1.49–2.28], respectively); while patients with baseline ALT ≥2×ULN demonstrated higher risks across all trajectories: decreasing (aHR, 1.29 [95% CI, 1.09–1.52]), stable (aHR, 2.69 [95% CI, 2.28–3.17]), and increasing (aHR, 3.76 [95% CI, 2.46–5.75]). Higher HbA_{1c}, older age and cirrhosis were associated with higher liver risk.
Conclusion: Lower ALT levels and decreasing ALT over time are associated with a lower risk of liver-related complications in T2D.

THU-447

Impact of metabolic dysfunction-associated steatotic liver disease on fatigue and pruritus in primary sclerosing cholangitis: a U.S. single-center cross-sectional study

Natalia Rojas-Amaris[1], Ana Marenco-Flores[1], Carmen Lara-Romero, Manuel Romero-Gómez, Michelle Lai[1], Vilas Patwardhan[1], Alan Bonder[1]. *[1]Harvard Medical School, Beth Israel Deaconess Medical Center, Boston, United States*
Email: nrojasam@bidmc.harvard.edu

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common cause of liver disease in the United States and frequently coexists with other liver diseases, including viral hepatitis, autoimmune hepatitis, and primary sclerosing cholangitis (PSC). Despite growing interest in MASLD overlap syndromes, the presence of MASLD in PSC patients remains underexplored. Consequently, data on patient-reported outcomes, particularly pruritus and fatigue, are limited. This study aimed to assess the prevalence and characteristics of the MASLD-PSC overlap syndrome, with a specific focus on patient-reported outcomes such as pruritus and fatigue.
Method: A cross-sectional study used data from a single visit of PSC patients enrolled between January 2018 and November 2024 in the Autoimmune Liver Diseases Registry at Beth Israel Deaconess Medical Center (Boston, MA, USA). Steatosis was defined as: (i) > 5% hepatocyte steatosis on liver biopsy per NASH CRN criteria, (ii) CAP (controlled attenuation parameter) > S1 (248 dB/m), or (iii) hyperechogenic liver parenchyma on ultrasound. Patient-reported outcomes, including fatigue and pruritus, were assessed using the Chronic Liver Disease Questionnaire (CLDQ) and 5D Itch Scale. Ordinal logistic regression evaluated the association between MASLD overlap and fatigue severity. Continuous variables were analyzed with the Wilcoxon rank-sum test, categorical variables with Fisher's exact test, and results were summarized as medians (IQR) or percentages. Statistical significance was defined as p < 0.05.
Results: A total of 103 patients with PSC were included in this analysis, 33% of whom had overlap with MASLD. Patients with PSC/MASLD were significantly older (median age: 55 vs. 46 years, p < 0.006), had a higher body mass index (BMI) (median: 30 vs. 25 kg/m², p < 0.001), and were more likely to have bile duct involvement (43% vs. 12%, p = 0.002) compared to those with PSC alone. No significant differences were observed in gender, race, or inflammatory bowel disease prevalence. In the ordinal logistic regression analysis, pruritus intensity (odds ratio [OR]: 2.64; 95% CI: 1.51–4.61, p = 0.001), DM (OR: 4.48; 95% CI: 1.05–19.10, p = 0.043), and BMI (OR: 1.08; 95% CI: 1.01–1.16, p = 0.018) were associated with higher fatigue levels. MASLD overlap was linked to lower fatigue intensity (OR: 0.37; 95% CI: 0.16–0.85, p = 0.020).
Conclusion: PSC patients with MASLD overlap present with distinct clinical features, including older age, higher BMI, and greater bile duct involvement. Interestingly, MASLD overlap is associated with reduced fatigue intensity, suggesting a possible influence of altered

inflammatory or metabolic pathways. Further research is needed to elucidate the mechanisms underlying this relationship and its clinical implications.

THU-448

Impact of anthropometric and body composition on response to lifestyle intervention in patients living with MASLD

Paloma Carrillo[1], Miguel Angel Fernández[2], Ignacio Torrescusa-Buzo[2], Lucía López-Bermudo[3], Carmen Lara-Romero[4], Rocío Aller[5], Rocío Munoz-Hernández[6], Javier García-Rioja[5], Blanca Escudero-López[3], Genoveva Berná[3], Jesús Funuyet-Salas[7], Raquel Millan[6], Isabel Fernández-Lizaranzu[6], Rocío Gallego-Durán[6], Douglas Maya-Miles[6], Franz Martin-Bermudo[3], Javier Castell[8], Manuel Romero-Gómez[6]. *[1]SeLiver Group, Instituto de Biomedicina de Sevilla, IBiS/Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Sevilla, Spain; [2]Sports Activity Service, University of Sevilla, Sevilla, Spain; [3]Andalusian Center of Molecular Biology and Regenerative Medicine-CABIMER- University Pablo Olavide-University of Seville-CSIC, Biomedical Research Network on Diabetes and Related Metabolic Diseases-CIBERDEM, Instituto de Salud Carlos III, Sevilla, Spain; [4]SeLiver Group, Instituto de Biomedicina de Sevilla, IBiS/Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, CIBEREHD, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas, Digestive Unit, Virgen del Rocío University Hospital, Sevilla, Spain; [5]Valladolid University Hospital, Valladolid, Spain; [6]SeLiver Group, Instituto de Biomedicina de Sevilla, IBiS/Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, CIBEREHD, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas, Sevilla, Spain; [7]Department of Psychology, Loyola University, Seville, Spain, Sevilla, Spain; [8]Department of Radiology, Virgen del Rocío University Hospital, Sevilla, Spain*
Email: mromerogomez@us.es

Background and aims: Weight loss intervention often raise concerns about the preservation of muscle mass given its critical role in preventing sarcopenia. This study evaluates the relationship between anthropometric and body composition on response to lifestyle intervention combining exercise and a Mediterranean Diet.

Method: Patients with MASLD (n = 96) underwent a 6-month lifestyle intervention. Baseline and a 6-month follow-up with MRI including PDFF and MRE, VCTE, liver ultrasound and assessments of metabolic and liver function. Muscle function was assessed by muscle elastography and stiffness at external Vastus in leg. Data were reported as delta between baseline and six months intervention. Statistical analyses included t-student, U-Mann-Whitney and logistic regression performed with SPSS 29.0.

Results: Regarding to MASLD responses, fibrosis regression correlated with an increase in muscle stiffness (7.31 ± 5.50 in responders vs −4.68 ± 9.64 in non-responders, n = 23) and a decrease in fat-free mass (−4.48 ± 5.93 vs −1.59 ± 3.24, n = 47), muscle mass (−4.69 ± 6.21 vs −1.59 ± 3.10, n = 47) and basal metabolism (−122.34 ± 156.70 vs −42.79 ± 85.07, n = 47), but not with delta BRI and delta BMI. after multivariate analysis, no variable remains as independent associated to fibrosis. MASH resolution was associated with an increase in muscle stiffness (0.10 ± 7.86 vs −6.70 ± 12.72, n = 44) and a decrease in BMI (−1.60 ± 1.35 vs. −0.73 ± 1.75, n = 89). Age (p = 0.042; OR 1.06; CI95% 1.00–1.13) and muscle stiffness (p = 0.085, OR 1.08, CI95% 0.99–1.17) remained as independent variables associates to MASH resolution after a backward LR analysis. Steatosis response correlated with a decrease in BMI (−1.76 ± 1.73 vs −0.61 ± 1.62, n = 65); in fat-free mass (−4.62 ± 5.07 vs −1.11 ± 2.62, n = 65); in muscle mass (−4.14 ± 5.24 vs −1.41 ± 2.71, n = 65) and in basal metabolism (−111.19 ± 132.98 vs −39.36 ± 75.45, n = 65). Backward LR identified free-fat mass as the only independent variable associated to steatosis response (p = 0.003, OR 0.254, CI95% 0.575–0.892).

Conclusion: Weight loss correlated with steatosis response and MASH resolution. Increased muscle stiffness and decreased muscle mass correlated with fibrosis regression and MASH resolution. Future interventions should prioritize not just weight loss but also muscle preservation to mitigate sarcopenia risks and optimize metabolic health outcomes.

THU-449-YI

Steatosis in cirrhosis: a prognostic marker for liver related outcomes in metabolic-dysfunction associated steatotic liver disease

Yiying Pei[1], Yayun Ren[2], Dean Tai[2], Wei Qiang Leow[1], Chee-Kiat Tan[1], Jason Pik Eu Chang[1], Mark Chang-Chuen Cheah[1], Kevin Kim Jun Teh[1], George Boon Bee Goh[1]. *[1]Singapore General Hospital, Singapore, Singapore; [2]HistoIndex Pte Ltd, Singapore, Singapore, Singapore*
Email: pei.yiying@singhealth.com.sg

Background and aims: The association between fibrosis and liver-related outcomes is well established. However, the predictive utility of histological components have not been well studied. We aim to study the utility of the qFIBs and its components (qfibrosis, qInflammation, qBallooning, qSteatosis) in predicting risk of Liver Related Events (LRE) in Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD).

Method: 108 liver biopsy images were retrieved and the composite LREs of liver-related death, hepatic encephalopathy (HE), ascites and hepatocellular carcinoma (HCC) were studied with the Non-alcoholic Steatohepatitis Clinical Research Network (NASH-CRN) score and qFIBs. Firth-corrected Cox regression was performed due to the occurrence of few events, together with log-rank tests and Kaplan-Meier analysis.

Results: LREs (liver-related deaths = 5, HE = 4, HCC = 4, ascites = 8) occurred in 12% of the cohort (n = 13/108). There was a median follow up of 7.83 years. Patients with more advanced fibrosis had a six-fold risk of developing LREs (qF3/4 vs qF0/1/2, HR 6.41, 95% CI 1.10–37.23), compared to a seven-fold risk with NASH-CRN (F3/4 vs F0/1/2, HR 7.19, 95% CI 1.74–29.82). A lower qSteatosis showed a twenty-three fold increased risk of developing LREs (HR 23.51, 95% CI 1.23–448.16). On further analysis, it was found that majority of the patients with lower steatosis were also cirrhotic. Interestingly, among the cirrhotic group (n = 33), a lower steatosis grade, rather than being a protective factor, correlated with poorer outcomes (qS0/1 = 24 vs qS2/3 = 9, 100% of LREs occurred in the qS0/1 group), likely due to the reduction of steatosis in dynamic fat changes in end stage liver disease. This is further substantiated by the finding that samples with lower percentages of macrovesicular steatosis had a significantly higher risk of developing LREs compared to samples with more macrovesicular steatosis (18% vs 30%, p = 0.013). In addition, patients with lower zone 2 steatosis had higher risk of LREs (HR 6.86, p = 0.001, 95% CI 1.79–26.33). Though the difference was not significant, fat distribution was also more azonal in the LRE group (zone 3: 18%, p = 0.886; azonal 64%, p = 0.901). Ballooning was positively associated with higher risk of LREs (HR 3.20, p = 0.042, 95% CI 1.02–10.03).

Conclusion: Lower steatosis and inflammation grades in cirrhosis correlate with the occurrence of LREs and reiterates the natural history of MASLD - as fibrosis progresses, steatosis regresses. On histology, steatosis was less likely to be macrovesicular and more likely to be azonal in distribution. Our findings open up exciting new channels for validation with larger cohorts and exploration of the process of steatosis fluxes and how it reflects the underlying pathogenesis of MASLD progression to decompensation and LREs.

THU-450

Cryptogenic cirrhosis in Brazil: much beyond burned-out metabolic associated steatohepatitis

Paulo Bittencourt[1], Elodie Hyppolito[2], Ludmila Guedes[3], Natalia Trevizoli[4], Débora Terrabuio[5], Yasmin Amorim[6], Marina Queiroz[6], Jose Telmo Valenca Valenca, Jr [2], José Huygens Parente Garcia[2], Francisco Guilherme Cancela Penna[3], Daniel Terra[3], Henrique Rocha[4], Priscila Campos[4], Marcus Gomes[5],

Matheus Aires[5], Liana Codes[1], Clebia de Lima[2], Paula Vidigal[3], Andre Watanabe[4], Luiz C. D'Albuquerque[5]. [1]*Bahiana School of Medicine and Public Health, Unit of Gastroenterology and Hepatology, Portuguese Hospital of Salvador, Bahia, Salvador, Brazil;* [2]*Federal University of Ceara, Fortaleza, Brazil;* [3]*Federal University of Minas Gerais, Belo Horizonte, Brazil;* [4]*Gastroenterology and Hepatology Unit at Base Hospital, Institute of Cardiology and Transplantation of the Federal District (ICTDF), Brasilia, Brazil;* [5]*University of Sao Paulo School of Medicine, Sao Paulo, Brazil;* [6]*Bahiana School of Medicine and Public Health, Salvador, Brazil*
Email: plbbr@uol.com.br

Background and aims: Cryptogenic cirrhosis is now considered a consequence of metabolic associated steatohepatitis (MASH) in European and North-American centers. Little is known about the frequency of MASH in subjects with cryptogenic cirrhosis from other populations. The purpose of the present study was to evaluate clinical and histological signs of MASH as well as traditional histological markers of other liver diseases in patients submitted to liver transplantation (LT) due to cryptogenic cirrhosis (CC) in Brazil.
Method: All patients who underwent LT in four different Brazilian centers due to CC were retrospectively reviewed. Type 2 diabetes and/or overweight or obesity were arbitrarily defined as clinical risk factors for MASH. Only patients with histopathological findings of the explants were included in the study. Burned-out MASH was considered in the presence of cirrhosis without proper histological markers in subjects with clinical risk factors for MASH.
Results: 3775 patients were included in the study. Only 511 (14%) (309 males, mean age: 56+14 years) had a diagnosis of CC before LT. After analysis of explants and clinical and/or laboratory reassessment, diagnosis of MASH and burned-out MASH were observed in 147 (29%) and 111 (22%) patients, respectively. Diagnosis of CC remained unchanged in 129 (25%) patients. Other diagnoses were elicited in the 124 remaining patients including biliary cirrhosis compatible with adult-onset familiar progressive intrahepatic cholestasis (PFIC) (n = 34), porto-sinusoidal vascular disorder (PSVD) and/or schistosomiasis (n = 23) and non-HFE hemochromatosis (n = 19).
Conclusion: MASH or burned-out MASH was shown to be responsible for at least ½ of the cases of CC requiring LT in Brazil, but other diagnosis could be elicited in ¼ of the remaining patients including biliary cirrhosis resembling adult-onset PFIC and PSVD.

THU-451

Long-term outcomes of metabolic dysfunction associated steatotic liver disease (MASLD) patients in a prospective, german real-world cohort

Monika Rau[1], Johanna Kestel[1], Sara De Monte[1], Hans Benno Leicht[1], Florian P. Reiter[1], Heike Hermanns[1], Andreas Geier[1]. [1]*Division of Hepatology, Departement of Internal Medicine II, University Hospital Würzburg, Würzburg, Germany*
Email: rau_m@ukw.de

Background and aims: Metabolic Dysfunction-associated steatotic liver disease (MASLD) is the most frequent liver disease, but longitudinal data of clinical outcomes in Germany are lacking. Aim of this study is to analyse long-term outcomes in a prospective, German real-world cohort.
Method: A total of 310 MASLD patients, diagnosed via histology or liver stiffness/CAP, were prospectively included and followed from 2012 to 2023. Liver-related outcomes and mortality were analyzed using SPSS.
Results: 310 MASLD patients were followed for a median of 36 ± 16 months (56.8% male, mean age 52.3 years, mean BMI 32.5 ± 6.4 kg/m²), 40% had T2DM, 58% arterial hypertension and 36% hypercholesterinemia. 36% were diagnosed histologically (of those 36.9% F2-F4) and 59% staged by elastography (12% LS 8–12 kPa, 21% > 12 kPa). Long-term follow-up showed that patients with cirrhosis had significantly more liver-related outcomes compared to those without (HR 3.501 (95% CI 1.835–6.682)) and a higher mortality (HR 11.572 (95% CI 3.030–44.194)). Patients with F2–F3 in histology had a higher rate of liver-related outcomes compared to F0–F1 (HR 3.638 (95%-CI 1.345–9.840)). Stratified by liver stiffness, the highest rate of liver-related outcomes was detected for > 12 kPa (HR 11.738 (95% CI 4.421–31.167)) followed by 8–12 kPa (HR 4.630 (95% CI 1.514–14.160)), both compared to <8 kPa. Mortality was similarly increased for > 12 kPa (HR 13.489 (95% CI 1.622–112.152)) and 8–12 kPa (HR 6.044 (95% CI 0.546–66.876)). In the longitudinal study 3.5% (n = 11) of patients died, three due to liver-related complications.
Conclusion: In this first German longitudinal MASLD cohort, patients with significant fibrosis or cirrhosis have the highest risk for liver-related outcomes and overall mortality. This underscores the need for regular monitoring of at-risk-patients.

Email: panu.luukkonen@helsinki.fi

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease, but the underlying pathophysiology remains unclear. Recent studies have shown that the severity of MASLD associates with a high plasma beta-hydroxybutyrate-to-acetoacetate ratio (bOHB/AcAc), a well-established marker of hepatic mitochondrial reductive stress. Here, we investigated whether intravenous administration of fatty acids and ethanol – two key risk factors of SLD – induce hepatic mitochondrial reductive stress in humans. Furthermore, we tested whether the stable isotope tracer ^{13}C-alpha-ketoisocaproate (^{13}C-KIC), whose catabolism in hepatic mitochondria produces $^{13}CO_2$ and isovaleryl-CoA in a redox-dependent manner, is applicable for studying hepatic mitochondrial reductive stress.
Method: On three separate days after an overnight fast, 8 healthy volunteers (4 female, 4 male, age 29.6 ± 4.7 years, BMI 25.2 ± 2.0 kg/m^2, liver fat 2.4 ± 1.3%) received, in a random order, volume-controlled 240-minute infusions of either: a) a lipid emulsion (Intralipid 20% with heparin, IL/Hep), b) 6% ethanol (EtOH), or c) saline. Breath alcohol concentration (BrAC) was clamped to 60 mg/dl using a breathalyzer and a physiologically based pharmacokinetic model-based algorithm. After 60 minutes from starting the infusions, the participants ingested a tracer dose of ^{13}C-KIC (1 mg/kg) and L-leucine (20 mg/kg). Breath samples were collected for determination of $^{13}CO_2$ production using isotope ratio mass spectrometry. Cumulative $^{13}CO_2$ areas under the curve (AUC) were calculated using the trapezoidal rule. Arterialized plasma samples were taken for colorimetric determination of bOHB/AcAc and for targeted metabolomics using liquid-chromatography mass spectrometry.
Results: IL/Hep infusion increased circulating fatty acid concentration from 0.47 ± 0.06 to 1.47 ± 0.19 mmol/l at 60 minutes and 1.51 ± 0.16 mmol/l at 240 minutes. EtOH infusion increased BrAC to 60 mg/dl in 30 minutes, remaining at a steady state of 61.1 ± 0.3 mg/dl between 30 and 240 minutes. No significant differences in glucose, insulin, pH or bicarbonate were detected during IL/Hep or EtOH compared to saline infusion. Plasma bOHB/AcAc increased by 59%

during IL/Hep (p = 0.002) and by 109% during EtOH infusion (p = 0.01). Compared to saline infusion, $^{13}CO_2$ AUC was 34% lower during IL/Hep (p = 0.0006) and 26% lower during EtOH (p = 0.0028). Both IL/Hep (–24%) and EtOH (–25%) decreased plasma concentration of isovalerylcarnitine, a breakdown product of KIC.
Conclusion: Physiological increases in circulating fatty acids and ethanol induce hepatic mitochondrial reductive stress, as determined by increased plasma bOHB/AcAc and decreased $^{13}CO_2$ production after ingestion of ^{13}C-KIC. ^{13}C-KIC breath test is a useful noninvasive method for the study of hepatic mitochondrial reductive stress.

Evaluation of liver steatosis and advanced fibrosis assessed by transient elastography in general population: a prospective study from north-eastern Romania
Robert Nastasa[1], Carol Stanciu[1], Ermina Stratina[1], Sebastian Zenovia[1], Remus Stafie[1], Adrian Rotaru[1], Horia Minea[1], Irina Girleanu[1], Cristina-Maria Muzica, Cojocariu Salloum[1], Catalin Sfarti[1], Laura Huiban, Ana-Maria Singeap[1], Anca Trifan. *[1]Department of Gastroenterology, Grigore T. Popa University of Medicine and Pharmacy, 70015 Iasi, Romania, "St. Spiridon" Emergency Hospital, Institute of Gastroenterology and Hepatology, 700111, Iasi, Romania, Iasi, Romania*
Email: robertnastasa948@gmail.com

Background and aims: Cirrhosis is considered the final stage of liver fibrosis, and it is the leading cause of liver disease-related death worldwide. Viral hepatitis B (VHB) and C (VHC), alcohol-related liver disease (ALD), and metabolic dysfunction-associated steatotic liver disease (MASLD) have been found to have a major impact on the development of chronic advanced liver disease. Our study's goal was to ascertain the prevalence of liver steatosis and advanced fibrosis and steatosis in Northeastern Romania's general population.
Method: One thousand one hundred and twenty-three adult asymptomatic participants of apparently healthy subjects from Northeastern region of Romania, were selected for this study. Each participant's demographic, clinical, and physiological information was documented once informed consent was obtained. The AUDIT-C questionnaire was filled out by each participant. Transient elastography (TE) was used to evaluate liver fibrosis, controlled atenuation parameter (CAP) was used to assess liver steatosis, and rapid blood tests were used to check presence of VHB and VHC.
Results: We found that 56.7% of the screened participants were males, 48.5% had a smoking habit, and 1.4% had a history of blood transfusions, tattooing, drug use or imprisonment over the years. Moreover, 44.2% of the patients had a body mass index above the normal limit, 3.5% of the participants were positive for the presence of HBs antigen, while 2.1% exhibited HCV antibody positive titer. In addition, approximately one-third of the subjects (35.1%) were diagnosed with metabolic syndrome and according to Audit-C questionnaire we found that 4.8% of the individuals had a history of alcohol consumption. Regarding the prevalence of liver steatosis, 60.5% of subjects included in our study was found with liver steatosis according with CAP values (≥274 dB/m). Advanced liver fibrosis was found in 7.6% of the participants, and liver cirrhosis in 5.3% of the cohort. Furthermore, we observed that more than one-third of the participants with advanced fibrosis or cirrhosis (35.4%) from general population had the criteria for MASLD.
Conclusion: We discovered that a significant portion of Romanians have severe liver fibrosis by screening a cohort of individuals who appeared to be clinically healthy and lived in North-Eastern Romania. These individuals had significant risk factors, including tattooing, increased alcohol consumption, and blood transfusions. This should raise concerns for public health organizations and physicians.

THU-454
Coagulation imbalance is associated with hepatic and vascular complications in patients with MASLD and diabetes: key role of factor VIII
Rosa Lombardi[1,2], Roberta Forlano[3], Gabriele Maffi[1], Annalisa Cespiati[1,2], Felice Cinque[1,2], Daniela Bignamini[1], Paola Dongiovanni[1], Paolo Francione[4], Marica Meroni[1], Giordano Sigon[3], Jian Huang[3], Pinelopi Manousou[5], Flora Peyvandi[2,6], Armando Tripodi[6], Anna Ludovica Fracanzani[1,2]. *[1]SC Medicina Indirizzo Metabolico, Fondazione IRCCS Ca' Grande Ospedale Maggiore Policlinico di Milano, Milan, Italy; [2]Department of Pathophysiology and Transplantation University of Milan, Milan, Italy; [3]Liver Unit, Section of Hepatology and Gastroenterology, Division of Digestive Diseases, Department of Metabolism, Digestion and Reproduction, Faculty of Medicine, Imperial College London, London, United Kingdom; [4]UO di Medicina, Azienda Ospedaliera "Card. G. Panico" di Tricase, Tricase, Italy; [5]Liver Unit, Section of Hepatology and Gastroenterology, Division of Digestive Diseases, Department of Metabolism, Digestion and Reproduction, Faculty of Medicine, Imperial College London, London, Italy; [6]Angelo Bianchi Bonomi Hemophilia and Thrombosis Centre, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Milan, Italy*
Email: rosa.lombardi@unimi.it

Background and aims: Metabolic-dysfunction associated steatotic liver disease (MASLD) promotes fibrosis and vascular complications, especially if associated to type 2 diabetes (T2DM), and both diseases present a procoagulant imbalance. Aim: to evaluate the association between hypercoagulability, hepatic and vascular damage in a cohort of MASLD diabetic patients.
Method: 185 MASLD patients with T2DM (mean age 62 ± 11 ys, 59% males) underwent assessment of coagulation factors (fibrinogen, FII, FVIII, protein C and antithrombin; FVIII/PC considered a hypercoagulability index), FibroScan® (LSM > 8 kPa), and assessment of macro/microvascular complications. In 96 patient genotyping for PNPLA3 and thrombin generation assay,) which directly measures thrombin production over time (peak-thrombin: greatest amount of generated thrombin; endogenous thrombin potential (ETP):total amount of generated thrombin), expressed as ratio in presence/absence of added trombomodulin-TM as index of procoagulant imbalance) were also available. In addition, 192 healthy controls were tested for all the coagulation parameters.
Results: MASLD diabetic patients presented higher FVIII/PC (1.36 ± 0.58 vs 1.08 ± 0.31, p < 0.001) and ETP-TM ratio (0.68 ± 0.22 vs 0.60 ± 0.17, p = 0.003) compared to controls. In patients, ETP-TM ratio and FVIII/proteinC increased over LSM quartiles (from 1 to 4: 0.63 ± 0.12 to 0.89 ± 0.42, pANOVA = 0.012; 1.18 ± 0.35 to 1.57 ± 0.68, pANOVA = 0.003) and independently associated with increasing LSM values (b-coefficient, 6.11; CI 95% 3.59–8.64; b-coefficient, 4.80; CI 95% 2.28–7.32). Antithrombin and proteinC independently inversely correlated to LSM > 8kpa (OR 0.92, CI 95% 0.88–0.97; OR 0.97, CI 95% 0.94–0.99). Added to the model, PNPLA3 hampered these associations and remained independently associated with increased peak thrombin ratio (b-coefficient 0.063; CI 95% 0.001; 0.126) and decreased antithrombin (b-coefficient –6.14; CI 95% –11.82; –0.46). Finally, FVIII and fibrinogen levels were independent risk factors for microvascular complications (OR 1.01, CI 95% 1.00–1.02; OR 1.01; CI 95% 1.00–1.01).
Conclusion: MASLD diabetic patients display a procoagulant profile which seems mainly associated with increased FVIII levels and which is independently related to the severity of hepatic fibrosis by Fibroscan and to microvascular complications. A possible interplay between coagulation and PNPLA3 in determining fibrosis has emerged, however further studies are warranted to elucidate this mechanism.

THU-455

Real-world assessment of clinical burden and healthcare resource utilisation among patients with metabolic dysfunction-associated steatohepatitis with additional cardiovascular, renal and metabolic comorbidities in France, Italy, Germany and Canada

Jens U. Marquardt[1], Giada Sebastiani[2], Riku Ota[3], Eliza Smith[4], Hayley Wallinger[4], Kathryn Tebbs[4], Elisabetta Bugianesi[5]. [1]*University Hospital Schleswig-Holstein, Lübeck, Germany;* [2]*McGill University Health Centre, Montreal, Canada;* [3]*Novo Nordisk A/S, Sobørg, Denmark;* [4]*Adelphi Real World, Bollington, United Kingdom;* [5]*University of Torino, Torino, Italy*
Email: RQXO@novonordisk.com

Background and aims: Cardiovascular, renal and metabolic comorbidities are common, clinically relevant conditions associated with metabolic dysfunction-associated steatohepatitis (MASH). As data are limited on the impact of these comorbidities, we aimed to describe the clinical burden and healthcare resource utilisation (HCRU) in patients with MASH.
Method: Data were drawn from the Adelphi Real World MASH Disease Specific Programme™, a cross-sectional survey of physicians and their patients with MASH in France, Germany, Italy, and Canada from January–May 2024. Physicians reported patient demographics, clinical characteristics and HCRU. Patients were grouped by physician-stated fibrosis stage and presence of cardiovascular, renal and metabolic comorbidities: early fibrosis without comorbidities (EFnoC); early fibrosis with ≥1 comorbidity (EFwC); and advanced fibrosis with ≥1 comorbidity (AFwC). EFwC and AFwC groups were compared using pairwise statistics against the EFnoC control group after entropy balancing on patient age and sex.
Results: Overall, 247 physicians reported data for 2675 patients. For EFnoC (n = 170), EFwC (n = 1575) and AFwC (n = 478), respectively, mean ± standard deviation patient age was 50.6 ± 10.8, 54.7 ± 11.3 and 60.4 ± 11.6 years, 46.5%, 40.9% and 37.2% were female. Body mass index was higher for EFwC and AFwC than EFnoC ($p < 0.001$). Compared to EFnoC, AFwC patients had a higher number of symptoms at data collection (1.5 ± 1.8 vs 3.0 ± 3.0; $p < 0.001$) and EFwC and AFwC had more comorbidities (including non-cardiovascular, renal and metabolic; 3.5 ± 2.2 and 4.4 ± 3.1 vs 1.6 ± 1.0; $p < 0.001$). EFwC and AFwC patients also had more diagnostic tests (19.7 ± 11.3 and 23.8 ± 11.9 vs 17.4 ± 10.1; $p < 0.01$). Monitoring required more blood/urine tests in EFwC than EFnoC (3.5 ± 2.5 vs 2.8 ± 1.4; $p < 0.001$), and both EFwC and AFwC had more liver composite tests (2.3 ± 2.0 and 2.9 ± 3.3 vs 1.9 ± 1.3; $p < 0.01$). In the last 12 months, EFwC and AFwC patients visited more healthcare professionals then EFnoC (4.5 ± 3.9 and 4.8 ± 4.0 vs 4.0 ± 3.4; $p < 0.05$). More AFwC patients required ≥1 hospitalisation compared to EFnoC (10.4% vs 24.4%; $p < 0.001$), with a higher mean number of hospitalisations in the last 12 months (0.1 ± 0.4 vs 0.5 ± 2.3; $p < 0.01$). More EFwC and AFwC patients required a caregiver than EFnoC (18.9% and 28.0% vs 7.9%; $p < 0.001$).
Conclusion: Additional cardiovascular, renal and metabolic comorbidities in patients with MASH increased the clinical and HCRU burden of MASH, highlighting the critical need for improved recognition of comorbidities, and appropriate intervention, to improve patient outcomes.

THU-456

The impact of chronic hepatitis B on fibrosis progression in metabolic dysfunction-associated steatotic liver disease

Fajuan Rui[1], Yixuan Zhu[1], Liang Xu[2], Jing Zhang[3], Qi Zheng[4], Ming-Hua Zheng[5], Haijun Huang[6], Yongfeng Yang[7], Youwen Tan[8], Chao Wu[1], Yuemin Nan[9], Qing Xie[10], Junping Shi[11], Jie Li[1]. Email: lijier@sina.com

Background and aims: With the increasing prevalence of obesity and changes in dietary lifestyle, the overlap between chronic hepatitis B (CHB) and metabolic dysfunction-associated steatotic liver disease (MASLD) has been growing. Our study aimed to explore the impact of HBV infection on liver fibrosis progression in patients with MASLD.
Method: We enrolled MASLD patients who underwent liver biopsy at 16 medical centers across China between April 2004 and April 2024. Both univariable and multivariable logistic regression analyses were conducted to examine the association between CHB and significant fibrosis, advanced fibrosis, and cirrhosis. Propensity score matching (PSM) was used to adjust for potential confounders, ensuring a balanced comparison between patients with and without CHB.
Results: A total of 2,787 MASLD patients (Median age 43.5years, 58.9% male) were included in the study, with 1,811 (65.0%) having DM. Multivariate regression analysis suggested that the combination of CHB was an independent risk factor for significant fibrosis (before PSM: OR 1.83, 95% CI: 1.52–2.20, $p < 0.01$; after PSM: OR 1.64, 95% CI: 1.26–2.15, $p < 0.01$), advanced fibrosis (before PSM: OR 1.63, 95% CI: 1.20–2.23, $p < 0.01$; after PSM: OR 1.75, 95% CI: 1.20–2.57, $p < 0.01$), and cirrhosis (before PSM: OR 2.18, 95% CI: 1.32–3.61, $p < 0.01$; after PSM: OR 2.46, 95% CI: 1.40–4.66, $p < 0.01$) in patients with MASLD. In addition, sensitivity analyses were performed in different levels of HBeAg and HBV DNA and in HBV patients not receiving antiviral treatment previously, the conclusions were consistent with previous findings.
Conclusion: Our study demonstrated evidence that the combined CHB was an independent risk factor for significant fibrosis, advanced fibrosis and cirrhosis in patients with MASLD.

THU-461-YI

Genetic risk score correlates with Cytokine expression and risk of HCC and cirrhosis in MASLD patients from Latin America

Background and aims: Genetic Risk Score (GRS) and cytokine dysregulations have been separately associated with the development of hepatocellular carcinoma (HCC) and cirrhosis in the context of Metabolic Associated Steatotic Liver Disease (MASLD). Latin Americans have elevated rates of HCC attributed to MASLD. However, the relationship between GRS, cytokine expression, and the progression of MASLD-related liver disease has not been explored in this population.
Method: We assessed the SNPs of *PNPLA3* rs738409, *TM6SF2* rs58542926, *MBOAT7* rs641738, and *HSD17B13* rs72613567 in a cohort of 983 individuals from 6 countries in Latin America, consisting of 267 HCC and 716 non-HCC. The four genetic variants were combined to create a genetic risk score for MASLD-related liver disease, including 142 HCC and 364 non-HCC cases. A total of 43 cytokines were measured in a sub-group of these samples (HCC = 107, cirrhosis = 111), categorized by low (0–4) and high (5–8) GRS within each group. Logistic regression was performed to calculate the odds ratios for individual SNPs and the combined GRS. The Mann-Whitney U test was utilized to compare cytokine levels between the low and high GRS groups.
Results: In Latin America, *PNPLA3* GG genotype was associated with a significantly increased risk of MASLD-related cirrhosis (OR: 6.157, 95% CI: 2.997–12.648, $p < 0.0001$) and HCC (OR: 2.629, 95% CI: 1.086–6.368, $p = 0.032$), whereas *HSD17B13* TATA was only associated with MASLD-related cirrhosis (OR: 0.108, 95% CI: 0.022–0.532, $p = 0.006$). No correlation between the SNPs of *TM6SF2* and *MBOAT7* and MASLD-related liver disease was found. When the four SNPs were combined into a GRS, patients with GRS 6–8 had a substantially higher risk of developing MASLD-related cirrhosis (OR: 12.25, 95% CI: 2.125–70.58, $p = 0.005$) and cirrhotic HCC (OR: 4.205, 95% CI: 1.205–14.67, $p = 0.024$) compared to those with GRS 0–2. In MASLD-related cirrhotic HCC, patients with GRS 5–8 exhibited lower expression of CXCL9, TNF, CCL13, CXCL10, CXCL16, CCL2, IFNγ, and CCL8 compared to those with GRS 0–4 ($p < 0.05$). Conversely, in MASLD-related cirrhosis, patients with GRS 5–8 showed higher expression of CCL1, CXCL8, and MMP2 compared to those with GRS 0–4 ($p < 0.05$).
Conclusion: In Latin America, GRS is strongly associated with an increased risk of MASLD-related cirrhosis and cirrhotic HCC, accompanied by opposing and distinct pro-inflammatory cytokine profiles across GRS groups. These findings emphasize the potential of genetic and immune profiling in understanding and stratifying MASLD-related liver disease.

THU-462
The association of Ferritin with subclinical coronary artery calcification is an expression of underlying cardiometabolic risk

Sophie Gensluckner[1], Bernhard Wernly[2], Julian Eberhardt[1], Mathias Ausserwinkler[3], Florian Koutny[4], Stephan Zandanell[1], Bernhard Paulweber[1], Bernhard Iglseder[5], Eugen Trinka[6], Vanessa Frey[6], Patrick Langthaler[6], Christian Datz[7], Elmar Aigner[1].

Email: s.gensluckner@salk.at

Background and aims: Observations of an association of serum ferritin (SF) and coronary artery calcification (CAC) have revealed conflicting results in the past. The aim of this study was to analyze the impact of SF on risk of subclinical artery disease in a population-based, Central-European cohort with a focus on cardiometabolic risk factors and genetic risk using a polygenic risk score (PRS).
Method: A subset of 1516 individuals of the Paracelsus 10.000 cohort was analyzed. Elevated SF-levels, defined by SF > 200 ng/ml for women and > 300 ng/ml for men, and the association with subclinical CAC were assessed univariate and using multiple regression models adjusted for sex, age, metabolic syndrome (MetS), SCORE 2 and PRS and compared to a model for MetS and CAC adjusted for age, sex and PRS.
Results: In 1516 patients, 12% (n = 182) had hyperferritinemia and 51% (n = 779) were male. Univariate analysis showed a significant association of CAC for ferritin with sex and age (IRR: 1.0003, 95% CI: 1.0000–1.0006, $p = 0.028$), sex and age combined with PRS (IRR: 1.0003, 95% CI: 1.000–1.004, $p = 0.044$), SCORE2 (IRR: 1.0006, 95% CI: 1.0002–1.0009, $p = 0.001$) and SCORE2 combined with PRS (IRR: 1.0006, 95% CI: 1.0003–1.0009, $p = 0.000$). The association was abolished after adjustment for MetS (IRR: 1.0001, 95% CI: 0.9999–1.0005, $p = 0.366$) and MetS combined with PRS (IRR: 1.0001, 95% CI: 0.9998–1.0005, $p = 0.262$). A comparison of the models of SF or MetS with CAC revealed a better fit for the MetS model.
Conclusion: Elevated SF levels and CAC are not independently associated after adjustment for MetS. The higher risk for CAC in people with elevated SF is very likely explained by underlying metabolic disease.

THU-463
Coexistence of fatty acid desaturase 2 (FADS2) and PNPLA3 risk alleles contributes to fibrosis progression in MASLD

Shunsuke Ikejima[1], Kazuyoshi Kon[1], Kumiko Arai[1], Akira Uchiyama[1], Hiroo Fukada[1], Kyoko Fukuhara[1], Reiko Yaginuma[1], Shunhei Yamashina[1], Kenichi Ikejima[1]. [1]*Department of Gastroenterology, Juntendo University Graduate School of Medicine, Tokyo, Japan*
Email: ikejima@juntendo.ac.jp

Background and aims: Metabolic-associated steatotic liver disease (MASLD) is triggered by genetic predispositions combined with acquired factors such as overnutrition, aging, and lack of physical activity. A subset of MASLD patients develops liver fibrosis, which can progress to cirrhosis. While the involvement of PNPLA3 single-nucleotide polymorphism (SNP) in MASLD development is well established, the combined effects of multiple genetic factors remain unclear. Our previous animal study suggested that alterations in the expression of fatty acid desaturase (FADS) may influence the progression of steatohepatitis. This study aimed to evaluate the impact of risk alleles of FADS-related SNPs on the progression of MASLD.
Method: This study included 48 biopsy-proven MASLD patients diagnosed between January 2021 and September 2024. Patients were categorized into two groups: non-progressive fibrosis (stage 0–2, n = 32) and progressive fibrosis (stage 3–4, n = 16). DNA was extracted from blood cells, and SNPs of PNPLA3 (rs738409), MBOAT7 (rs641738), TM6SF2 (rs58542926), FADS1 (rs174556), and FADS2 (rs174583) were determined using TaqMan PCR. Group comparisons were performed using chi-square tests or Student's t-tests, and multivariate analysis was conducted using logistic regression.
Results: The mean age tended to be higher in the progressive fibrosis group (60 ± 2 years) compared to the non-progressive group (55 ± 2 years), but the difference was not significant. The male-to-female ratio was 12:20 in the non-progressive group and 8:8 in the progressive group. Comparing SNP frequencies, the PNPLA3 G/G allele was observed in 43.8% vs. 62.5%, the MBOAT7 C/C allele in 43.8%

vs. 43.8%, the TM6SF2 C/T allele in 25% vs. 6.3%, the FADS1 T/T allele in 28.1% vs. 25.0%, and the FADS2 T/T allele in 40.6% vs. 56.3%, indicating that the PNPLA3 G/G and FADS2 T/T alleles tended to be more frequent in the progressive fibrosis group. The proportion of patients carrying both risk alleles (PNPLA3-GG/FADS2-TT) was significantly higher in the progressive group compared to the non-progressive group (12% vs. 43.8%; p = 0.027). Logistic regression analysis, adjusting for age and sex, identified PNPLA3-GG/FADS2-TT as an independent risk factor for fibrosis progression, with an odds ratio of 7.171 (95% CI: 1.284–40.047).
Conclusion: The coexistence of PNPLA3 and FADS2 risk alleles was identified as an independent and significant risk factor for fibrosis progression in MASLD, suggesting a potential synergistic effect. These findings demonstrate the importance of considering combined genetic risk factors, with SNP analysis of PNPLA3 and FADS2 providing a valuable tool for identifying high-risk patients with progressive MASLD.

THU-464
Type 2 diabetes increases the risk of progression to metabolic dysfunction-associated steatohepatitis-related cirrhosis in a real world setting

Sabine Kahl[1], Eddison Godinez Leiva[2], Karen Corbin[3], Heather Morris[4], Derek Gazis[4], Andrea Mospan[4], Michael Roden[1], Kenneth Cusi[2]. [1]*German Diabetes Center, Department of Endocrinology and Diabetology, Medical Faculty and University Hospital Düsseldorf, Heinrich-Heine-University Düsseldorf, German Center for Diabetes Research (DZD e.V.), Düsseldorf, Germany;* [2]*Division of Endocrinology, Diabetes & Metabolism, Department of Medicine, University of Florida, Gainesville, United States;* [3]*AdventHealth Translational Research Institute, Orlando, United States;* [4]*Target RWE, Durham, United States*
Email: michael.roden@ddz.de

Background and aims: In metabolic dysfunction-associated steatotic liver disease (MASLD), type 2 diabetes (T2D) confers a higher risk for disease progression, but limited prospective data are available. Thus, we examined the relationship between T2D and the development of cirrhosis in a longitudinal observational study of people with MASLD.
Method: TARGET-NASH is a longitudinal observational cohort comprised of people who are managed for MASLD in hepatology and endocrinology practices in the US. TARGET-NASH previously developed definitions were applied to identify metabolic dysfunction-associated steatohepatitis (MASH) and cirrhosis. Diagnosis of T2D was derived from medical history, medication use or HbA1c ≥ 6.5%. People without MASH, with decompensated cirrhosis at index or with other diabetes types than T2D were excluded from the analyses. The index was defined as the earliest date within a 3-year period prior to enrollment when evidence of MASH or cirrhosis was observed. Fibrosis-4 (FIB-4) and NAFLD Fibrosis Score (NFS) were calculated to assess fibrosis risk category (low, indeterminate, high). Results for continuous variables are given as median. Hazard ratios were derived from multivariable modeling.
Results: A total of 2415 individuals (1211 with and 1204 without T2D) with MASH (n = 1748) and compensated cirrhosis (n = 667) were included in the analysis. People with T2D were older (58 vs. 55 years), more frequently female (64 vs 54%) and had a higher body mass index (34.3 vs. 30.8 kg/m^2) as well as HbA1c (7.0 vs 5.6%; all p < 0.001) than participants without T2D. At index, people with T2D were more likely to have advanced disease by FIB-4 (high risk category: 33.4% vs 20.9%, p < 0.001) and NFS (44.4% vs 10.2%; p < 0.001). In those with available liver biopsy on or prior to index (n = 402), T2D was associated with a higher prevalence of any fibrosis or advanced (F3/F4) fibrosis (both p < 0.05). People with MASH and T2D had higher hazard ratio (HR) for progression to compensated cirrhosis compared to those without T2D (HR; 95% confidence interval, CI; 2.12 (1.69–2.66)), which remained after adjustment for age and sex (2.05 (1.62–2.58)) and also in the subgroups of different fibrosis risk (high: 1.72 (1.11–2.66); low: HR 2.17 (1.39–3.40)). In contrast, risk of progression from compensated to decompensated cirrhosis was independent of the presence of T2D at index in all individuals (1.15 (CI 0.87–1.52)) and across fibrosis risk groups (high: 1.16 (0.78–1.72); low: 0.92 (0.18–4.67)).
Conclusion: Among people with MASH, the presence of T2D is associated with a higher risk of progression from MASH to cirrhosis, whereas the risk of progression from compensated to decompensated MASH cirrhosis is independent of diabetes status. This underlines the importance of early screening for MASH in people with T2D to reduce the growing individual and societal burden of MASLD-related severe liver disease.

THU-465
Long term outcomes of liver transplantation for patients with metabolic dysfunction and alcohol associated/related liver disease (MetALD) versus alcohol associated liver disease (ALD)

Swapnil Dhampalwar[1], Neeraj Saraf[1], Kunwar Ashish Singh[1], Narendra S. Choudhary[1], Arvinder Singh Soin[1]. [1]*Institute of Liver Transplantation & Regenerative Medicine, Medanta The Medicity, Gurugram, India*
Email: swapnildhampalwar@gmail.com

Background and aims: As per the new nomenclature of steatotic liver disease (previously fatty liver disease), the subcategory of metabolic dysfunction and alcohol associated/related liver disease (MetALD) denotes the co-existence of metabolic and alcohol-associated risk factors. Existing literature shows better post-transplant outcomes after alcohol associated liver disease (ALD) compared to non-alcoholic steatotic liver disease. We assessed the metabolic outcomes & survival of patients of MetALD and ALD who underwent Living donor liver transplantation (LDLT) as there is no existing literature on the same.
Method: This is a retrospective analysis of a prospectively maintained database of LT recipients. 319 patients who underwent LDLT for Alcohol associated liver disease from July 2018 to August 2023 were included in this study. Patients who had at least one Cardio-metabolic risk factor as per the new definition such as Diabetes mellitus, hypertension, and obesity (BMI ≥23 kg/m^2) were reclassified as MetALD. Their pre-transplant characteristics and post-transplant outcomes were compared with patients with ALD.
Results: Of 319 patients, 202 patients had MetALD and 117 had ALD. Patients with MetALD were older [50(25–74) versus 47(25–70) years] and had higher BMI [26.10(18.8–40.8) versus 21.25(15.5–26.6) kg/m^2]. Larger proportion of patients with ALD had weight gain (>10% body weight at 1-year) than MetALD [45 (38%) versus 26 (12%), p = 0.001]. Patients with MetALD had higher incidence of post-transplant steatotic liver disease (SLD) [62(30%) versus 23(19%)]. Incidence of CKD (eGFR <60 ml), post-transplant metabolic risk factors (DM, HTN, Dyslipidemia), coronary artery disease and recidivism were similar in both the groups. There was a trend towards lower survival in patients with MetALD as compared to ALD (1-year survival was 84.2% vs 91.5%), although not statistically significant.
Conclusion: Survival after liver transplantation for patients with MetALD and ALD is comparable. The incidence of post-transplant weight gain is higher in ALD group, probably due to reversal of alcohol & disease associated malnutrition. This group also had equal proportion of metabolic risk factors as of MetALD group.

Email: tslim21@yuhs.ac

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is strongly linked to cardiovascular disease (CVD), the leading cause of death in this population. However, traditional CVD risk models fail to account for MASLD-specific factors such as liver fibrosis and sarcopenia. This study aimed to develop a machine learning model that incorporates these unique characteristics to improve 10-year CVD risk prediction using data from the UK Biobank.
Method: A total of 39,758 participants with MASLD were included in this study. MASLD was defined as the presence of hepatic steatosis, determined by fatty liver index ≥60 in combined with at least one cardiometabolic criterion. CVD outcomes were identified using International Classification of Diseases-10 codes. Predictors included liver-related test results and handgrip strength, alongside established CVD risk factors. Model development and internal validation were performed on the England cohort with an 8:2 training-validation split. The XGBoost algorithm was selected for its superior performance. The Scotland and Wales cohorts served as test sets.
Results: Among study participants, 35,871 individuals from the England cohort and 3,887 from the Scotland and Wales cohorts were diagnosed with MASLD. The mean age was 56.2 years in the England cohort and 55.2 years in the Scotland and Wales cohorts, with male participants comprising 62.2% and 63.6% of each cohort, respectively. The 10-year CVD incidence was 9.4% in the England cohort and 8.1% in the Scotland and Wales Cohorts, respectively. The machine learning model exhibited robust predictive performance for 10-year CVD risk in MASLD participants, an achieving area under the receiver operating characteristic curve (AUROC) values of 0.81 (95% confidence interval [CI]: 0.801–0.821), 0.71 (95% CI: 0.685–0.731), and 0.75 (95% CI: 0.712–0.779) in the training, internal validation, and test sets, respectively. Notably, the model significantly outperformed traditional CVD risk scores such as the atherosclerotic cardiovascular disease (ASCVD) risk score (AUROC 0.69 in the test sets) and the Framingham risk score (AUROC 0.58 in the test sets).
Conclusion: This study indicates that integrating liver-related test results and muscle strength parameters with conventional CVD risk factors improves cardiovascular risk prediction in MASLD participants. Further validation in diverse populations is warranted to confirm its clinical applicability.

THU-467-YI
MASLD and FIB4 are independent predictors of major adverse liver outcomes and cardiovascular events in type 2 diabetes: findings from a single-center cohort using AI-driven machine learning

Valentin Calvez[1], Chiara Dachena[2], Lucrezia Petrucci[1], Anna Rita Barberio[3], Laura Antenucci[2], Carlotta Masciocchi[2], Antonio Liguori[1], Angela Sciarra[1], Linda Tartaglione[3], Stefano Paternello[2], Antonio Gasbarrini[1], Dario Pitocco[3], Luca Miele[1].
[1]Fondazione Policlinico Universitario "A. Gemelli" IRCCS, Catholic University of Rome, Department of Translational Medicine and Surgery, Rome, Italy; [2]Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy; [3]Diabetes Care Unit, Fondazione Policlinico Universitario A. Gemelli Istituto di Ricerca e Cura a Carattere Scientifico (IRCCS), Rome, Italy
Email: valentino.calvez@gmail.com

Background and aims: MASLD and liver fibrosis are common in type 2 diabetes (T2D), and the FIB-4 index is a widely used non-invasive marker of liver fibrosis. However, data on the specific predictive role of FIB-4 in identifying the risk of major adverse liver outcomes (MALOs) in T2D remain limited.
The primary objective of this study was to evaluate whether the presence of MASLD and elevated FIB-4 predict an increased incidence of MALO in a cohort of patients with T2D, utilizing AI-driven data extraction for analysis. Secondary objectives included assessing whether MASLD and FIB-4 serve as predictors of MACE, and identifying any additional variables associated with MALO and MACE.
Method: This was an observational retrospective cohort study conducted at the outpatient diabetes clinic of the Gemelli Polyclinic in Rome, Italy, from Jan-2016 to Jan-2022. Data were extracted using an AI driven system, which collected comprehensive clinical information. The cohort consisted of adult patients with T2D. MASLD was identified by imaging or the Hepatic Steatosis Index (HSI) and the FIB-4 was calculated. A FIB-4 greater than 2.67 was considered indicative of a high probability of advanced liver fibrosis. The primary outcome was the occurrence of MALO, while a secondary outcome was MACE. To evaluate the predictive role of MASLD and FIB-4 for MALO and MACE, multivariable logistic regression models were developed. Each model was adjusted for clinically relevant covariates, with statistical significance defined as $p < 0.05$.
Results: A total of 1,711 patients were included, of whom 67 (3.9%) experienced a MALO and 203 (11.86%) a MACE. Patients with MASLD had significantly higher odds of experiencing MALO (OR 2.03, 95% CI 1.10–3.77, $p = 0.024$) and MACE (OR 1.40, 95% CI 1.01–1.95, $p = 0.042$). A FIB-4 > 2.67 was strongly associated with an increased risk of both MALO (OR 6.92, 95% CI 4.01–11.96, $p < 0.001$) and MACE (OR 2.39, 95% CI 1.67–3.42 $p < 0.001$). In the second multivariable model, which excluded patients with cirrhosis at baseline, MASLD remained a significant predictor of MALO (OR 2.51, 95% CI 1.04–6.04, $p = 0.040$), and a FIB-4 > 2.67 continued to be associated with an increased risk of MALO (OR 3.02, CI 1.34–6.77, $p = 0.007$). Additionally, HbA1c was a significant predictor in both models (OR 1.02, 95% CI 1.01–1.04, $p = 0.009$).
Conclusion: This study demonstrated that MASLD and elevated FIB-4 are independent predictors of MALOs and MACE in patients with T2D. The findings underscore the importance of routine non-invasive screening for liver fibrosis and MASLD in diabetic populations, as well as the role of HbA1c in predicting adverse outcomes. Early detection and optimal glycemic control could help reduce the risk of both liver and cardiovascular complications. Furthermore, the use of AI-driven data extraction demonstrates the potential for enhancing clinical research and improving patient management in real-world settings.

THU-468
Adverse outcomes and HBsAg seroclearance of chronic hepatitis B complicated with metabolic dysfunction-associated steatotic liver disease: a cohort study

Jialan Wang[1], Airong Hu[2], Suwen Jiang[2], Ying Fan[3], Ken Lin[4], Menghan Jin[3], Haojin Zhang[4], Shiyang Fang[4], Shiqi Yang[1]. *[1]Graduate School, Wenzhou Medical University, Wenzhou, China; [2]Liver Diseases Center, Ningbo Institute of Liver Diseases, Ningbo No. 2 Hospital, Ningbo, China; [3]Ningbo University Health Science Center, Ningbo, China; [4]School of Medicine, Shaoxing University, Shaoxing, China*
Email: huairong@ucas.edu.cn

Background and aims: To explore the influence of MASLD on the risks of adverse events, including cirrhotic complications and hepatocellular carcinoma, and on the HBsAg clearance among patients with CHB.
Method: From January 2015 to January 2024, consecutive patients with CHB and had undergone liver biopsy were enrolled at Ningbo No. 2 Hospital, Ningbo, China. Upon enrolment, participants underwent blood, imaging tests and physical examinations. To assess the presence of MASLD, metabolic dysfunction, steatohepatitis and steatosis in relation to the cumulative incidence of related adverse events (cirrhotic complications and hepatocellular carcinoma) and serum HBsAg clearance.

Results: Our cohort were included 827 patients. The median follow-up time for adverse events as an outcome was 4.62 years (3.08–6.76), and for HBsAg seroclearance, it was 4.72 years (3.23–7.10). There were 81 adverse events, including 13 of hepatocellular carcinoma (HCC) and 68 of hepatic dysfunction, as well as 33 HBsAg antigen-clearance events. The cumulative incidence of 1-, 3-, and 5-year adverse events was 3.3%, 6.1%, and 15%, respectively, in the with MASLD group and 0.7%, 3.9%, and 7.1%, respectively, in the without MASLD group. In multivariable Cox regression models, baseline cirrhosis (corrected hazard ratio [aHR], 9.87; $P < 0.001$), antiviral therapy (aHR, 8.48; $P = 0.031$), lower baseline ALB (aHR, 0.90; $P < 0.001$), higher AST levels (aHR, 1.01; $P = 0.049$), higher ALP levels (aHR, 1.01; $P < 0.001$), and the presence of MASLD (aHR, 2.22; $P = 0.002$) were associated with the incidence of adverse events, whereas a reduction in baseline HBV DNA (aHR, 0.79; $P < 0.001$) was related to adverse events. In the PSM analysis, the presence of MASLD in 151 patients was associated with increased adverse outcomes (PSM-adjusted HR, 2.095), and HBsAg clearance (PSM-adjusted HR, 3.475). In patients with MASLD, the presence of steatohepatitis and metabolic burden ($P > 0.65$) was not associated with adverse outcomes. Compared with the steatosis, activity, fibrosis (SAF) scores <5 group (42.38%), the SAF ≥5 group (57.62%) was significantly associated with adverse event rates (HR: 6.812). Multifactorial analysis demonstrated that aspartate aminotransferase (AST) and gamma-glutamyl transferase (GGT) were independent risk factors for disease progression in CHB patients with MASLD ($P < 0.05$). The non-invasive diagnostic models, with AST and GGT, developed accordingly were more effective than the aspartate aminotransferase to platelet ratio index (APRI) and fibrosis-4 (FIB-4) in predicting adverse events in patients with MASLD combined with CHB (AUC = 0.700).
Conclusion: The existence of MASLD was related to higher rates of adverse events and HBsAg seroclearance in patients with CHB. In addition to MASLD, metabolic dysfunction can also increase the incidence of adverse events in CHB patients, but there is no cumulative effect. Non-invasive models based on AST and GGT had good accuracy in predicting the risk of adverse events in this population.

THU-469

Long-term clinical outcomes across biopsy-confirmed steatotic liver disease categories: a multicenter prospective cohort study using merged data

Won Kim[1], Gi-Ae Kim[2], Heejoon Jang[3], Moon Young Kim[4], Seul Ki Han[4], Jung Gil Park[5], Eun Young Cho[6], Jae Yoon Jeong[7], Soo Young Park[8], Sang Gyune Kim[9]. *[1]Seoul Metropolitan Government Seoul National University Boramae Medical Center, Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea, Rep. of South; [2]Kyung Hee University Hospital, Seoul, Korea, Rep. of South; [3]Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, Korea, Rep. of South; [4]Yonsei University Wonju College of Medicine, Wonju, Korea, Rep. of South; [5]Yeungnam University College of Medicine, Daegu, Korea, Rep. of South; [6]Wonkwang University College of Medicine, Iksan, Korea, Rep. of South; [7]Ewha Womans University, Seoul, Korea, Rep. of South; [8]8Kyungpook National University Hospital, Kyungpook National University, Daegu, Korea, Rep. of South; [9]9Soonchunhyang University Hospital Bucheon, Soonchunhyang University College of Medicine, Bucheon, Korea, Rep. of South*
Email: wonshiri@yahoo.com

Background and aims: Little has been explored about the long-term outcomes of biopsy-confirmed steatotic liver disease (SLD) and its subcategories. We aimed to investigate the risks of all-cause mortality, liver-related events (LREs), cardiovascular disease, and extrahepatic cancers in biopsy-confirmed metabolic dysfunction-associated steatotic liver disease (MASLD), MetALD, and alcohol-related liver disease (ALD).
Method: This multicenter prospective cohort study included patients who had liver biopsies between 2010 and 2023 at 8 tertiary hospitals in South Korea. SLD was defined as ≥5% macrovesicular steatosis in biopsy specimens. Adjusted hazard ratios (aHRs) for all-cause mortality, LREs, cardiovascular disease, and extrahepatic cancers were estimated using multivariable Cox proportional hazards regression models.
Results: During the median follow-up of 4.8 years, 106 deaths, 118 LREs, 55 cardiovascular diseases, and 94 extrahepatic cancers occurred in 2,543 study populations including MASLD (n = 1,929), MetALD (n = 132), ALD (n = 269), and no SLD (n = 213). Compared with no SLD, MetALD (aHR 8.50; 95% CI, 2.12–33.99) and ALD (aHR 6.93; 95% CI, 1.89–25.42) had higher risks of all-cause mortality. MASLD (aHR 3.64; 95% CI, 1.12–11.87) and ALD (aHR 10.04; 95% CI, 2.82–35.71) had an increased risk of LREs. No significant differences were observed in the risk of cardiovascular diseases or extrahepatic cancers among the subcategories of SLD. Of patients with MASLD, metabolic-associated steatohepatitis (MASH) had an increased risk of all-cause mortality (aHR 2.70; 95% CI, 1.31–5.60) and LREs (aHR 5.02; 95% CI, 2.35–10.74) compared to those without MASH. At-risk MASH (MASH with ≥ F2) showed an increased risk of all-cause mortality (aHR 2.90; 95% CI, 1.52–5.53) and LREs (aHR 9.81; 95% CI, 4.75–20.26) compared to those without.
Conclusion: Using a biopsy-confirmed SLD cohort, this study showed MASLD, MetALD, and ALD had increased risks of all-cause mortality or LREs while little differences were observed with cardiovascular disease and extrahepatic cancers. These findings contribute to deepening the insight into the long-term outcomes of SLD and devising more customized management strategies by the differential risk.

THU-470-YI

Liver-related events are uncommon in patients meeting AASLD criteria for Resmetirom and are not seen in those with a liver stiffness measurement <10 kPa

Hua Xuan Yeow[1], Ewan H. Forrest[1], Adrian Stanley[1], Stephen T. Barclay[1]. *[1]Glasgow Royal Infirmary, Department of Gastroenterology, Glasgow, United Kingdom*
Email: yeowhuaxuan@gmail.com

Background and aims: Resmetirom, a selective thyroid hormone receptor beta agonist, has been licensed for treatment of MASLD in the USA. AASLD guidelines recommend consideration of Resmetirom for those with a liver stiffness measurement (LSM) between 8 and 15 kPa. Several studies suggest that the risk of liver related events (LRE) is low when LSM <10 kPa, and only moderately increased when between ≥10 kPa and <15 kPa. We sought to evaluate rates of LRE, non-liver related deaths, progression and regression of LSM, amongst MASLD patients meeting AASLD LSM criteria for Resmetirom.
Method: Patients undergoing Fibroscan in a single centre from April 2012 to February 2019 with LSM ≥8 kPa and <15 kPa were identified from an electronic database. Those with an indication recorded as "NAFLD" or "Under Investigation" were selected for case note review. Using recorded alcohol history, patients were included and assigned as having MASLD or MetALD according to current definitions. Those with alternative causes of liver disease were excluded. Data collected included demographic, clinical, and laboratory information. Case notes were reviewed to identify dates of LRE (ascites, jaundice, variceal bleeding, encephalopathy, HCC). Dates of death were identified, and death categorised as liver related if occurring after an LRE. Kaplan-Meier analysis was performed to determine cumulative rates of LRE, censored 01/04/2024. Follow-up LSMs were categorised as improved (<8 kPa), static (≥8 and <15 kPa) or progression (≥15 kPa).
Results: On case note review, 213 of 450 patients meeting LSM and indication criteria were confirmed suitable for inclusion (177 MASLD,

36 MetALD). Median age was 63 (±17) years, with 109 (51.2%) being male. Median follow up was 7.1 (±2.2) years. 179 (84%) patients were obese and 34 (16%) overweight. Hypertension (133, 62.4%), diabetes (107, 50.2%) were the most common metabolic comorbidities. 4 (1.88%) patients experienced LRE (2 HCC and 2 ascites), 2 (0.94%) of whom died. A further 17 (7.98%) experienced non-liver related mortality. No LRE occurred in the 88 (41.3%) of patients with LSM <10 kPa. Cumulative rates of LRE were 0.94% at 5 years and 1.88% at 10 years. Of 127 (61%) patients with a follow up scan, 67 (52.76%) improved, 49 (38.58%) were static, and 11 (8.66%) progressed.
Conclusion: LRE are uncommon in patients meeting AASLD criteria for Resmetirom therapy and were not seen with a LSM <10 kPa. Non liver related mortality was predominant. In an era predating specific drug therapy, a majority of patients undergoing follow up LSM demonstrated improvement. It is likely that a high number of patients would require treatment to prevent one medium term LRE in the suggested treatment population.

THU-472

Sarcopenia is an independent risk predictor for all-cause mortality in individuals with a body mass index less than 25

Wang Zilong[1], Huiying Rao[1]. [1]*Peking University Hepatology Institute, Beijing, China*
Email: zeelomwang@bjmu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a prevalent chronic liver metabolic disease characterized by excessive lipid accumulation in the liver. Sarcopenia, a progressive condition involving the decline of muscle mass and function, was traditionally associated with aging. However, recent studies have elucidated a strong connection between sarcopenia and metabolic disorders. Existing literature indicates that MASLD patients with sarcopenia experience more severe disease progression and a higher mortality risk. Nonetheless, there is a paucity of research on the specific subtype known as lean MASLD.
Method: This study included participants from the Third National Health and Nutrition Examination Survey (NHANES III) database who had bioelectrical impedance analysis (BIA) data, with mortality followed up until 2019. MASLD was diagnosed using liver ultrasound data and the presence of overweight, hypertension, diabetes, hyperlipidemia, and low high-density lipoprotein cholesterol. Lean MASLD refers to patients with MASLD and a body mass index (BMI) less than 25. Skeletal muscle mass was calculated and divided by body weight to derive the skeletal muscle index, defined as less than 37% in men and less than 28% in women. Logistic and Cox regression models were used for statistical analysis, with $P < 0.05$ considered statistically significant.
Results: Of the 12316 subjects, 3989 met the MASLD diagnostic criteria. Compared with the MASLD patients without sarcopenia (n = 1709), those with sarcopenia (n = 2,280) had a lower proportion of males but higher BMI, waist circumference, ALP, and triglyceride levels ($P < 0.01$). Multivariate Logistic regression analysis showed that MASLD patients had an increased risk of sarcopenia (OR = 1.14, 95% CI: 1.00–1.29, $P < 0.05$) compared to non-MASLD patients. Among participants, 701 (13.12%) were classified as having sarcopenia in the lean MASLD group, while 3,288 (54.85%) were classified in the non-lean MASLD group. In participants with BMI≥25, sarcopenia was associated with an increased risk of MASLD (OR = 1.28, 95% CI: 1.12–1.46, $P < 0.01$), but not all-cause mortality ($P = 0.89$). Conversely, in participants with BMI<25, sarcopenia was linked to an increased risk of all-cause mortality (HR = 1.27, 95% CI: 1.08–1.49, $P < 0.01$), but not MASLD ($P = 0.49$).
Conclusion: In a nationally representative sample of U.S. adults, MASLD is associated with an increased risk for developing sarcopenia. Among participants with a BMI<25, sarcopenia was linked to an increased risk of all-cause mortality, but not MASLD. Conversely, in participants with a BMI≥25, sarcopenia was associated with MASLD risk, but not all-cause mortality.

Email: zhengmh@wmu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has become a significant global public health challenge, with liver fibrosis serving as a critical determinant of clinical prognosis. qFibrosis is an automated fibrosis quantification system that combines artificial intelligence with second harmonic/two-photon excitation fluorescence (SHG/TPEF) microscopy imaging. Previous studies suggested that with changes in fibrosis area in the periportal region observed via qFibrosis, we could potentially distinguish patients receiving routine or strengthened lifestyle interventions in the placebo group in the MASH clinical trial. To build on these findings, we expanded the sample size and employed qFibrosis to observe subtle pathological changes in paired liver biopsy specimens.
Method: We initiated an international multicenter study. To date, we have enrolled 308 MASLD patients with paired liver biopsies from 9 medical centers across China, Egypt, India, Italy, Japan, Malaysia, Saudi Arabia and Australia. These patients were managed through lifestyle intervention during follow-up and did not receive resmetirom. Clinical data collation has been completed, while unstained scanning and quantitative fibrosis assessment of their paired liver biopsy samples are ongoing. For comparison, 75 patients from the placebo cohorts in two failed MASLD clinical trials were analyzed.
Results: In the lifestyle intervention group, after a median follow-up of 13 months, 31.5% (97/308) of MASLD patients exhibited fibrosis regression, with significant improvements in fibrosis stage (Δ: -0.1 ± 1.0, $p = 0.011$). Additionally, improvements were observed in steatosis (Δ: -0.3 ± 0.9, $p < 0.001$), lobular inflammation (Δ: -0.2 ± 0.8, $p < 0.001$) and hepatocyte ballooning (Δ: -0.2 ± 0.7, $p < 0.001$). In the placebo group from the clinical trials, 21.3% (16/75) showed fibrosis regression after 24 to 48 weeks of treatment. Significant improvements were observed in the fibrosis stage (Δ: -0.2 ± 0.6, $p = 0.012$) and hepatocyte ballooning (Δ: -0.2 ± 0.6, $p = 0.018$). No significant

difference in fibrosis changes was observed between the two groups (p = 0.687).
Conclusion: Preliminary clinical data analysis revealed significant improvements in liver histological features in both the lifestyle intervention and placebo groups. And the lifestyle intervention group was considered analogous to a placebo group in the real world. We plan to conduct a standardized unstained scan and quantitative fibrosis analysis of paired liver biopsy samples collected globally. Ongoing quantitative fibrosis analysis, focusing on periportal fibrosis dynamics, will further elucidate the differentiation between routine and strengthened lifestyle intervention patients, providing novel insights into fibrosis dynamics and placebo effects.

THU-476
Rising trends in preventable premature MASLD-related deaths: disparities across urban and rural U.S. counties (2011–2021)
James M. Paik[1,2], Annette Paik[1,2], Yusuf Yilmaz[1,3], Mohamed El-Kassas[1,4], Saleh Alqahtani[1,5,6], Zobair Younossi[1,2,7]. *[1]The Global NASH Council, Washington DC, United States; [2]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, United States; [3]Department of Gastroenterology, School of Medicine, Recep Tayyip Erdoğan University, Rize, Türkiye; [4]Endemic Medicine and Hepatology Department, Faculty of Medicine, Cairo, Egypt, Helwan University, Cairo, Egypt; [5]Division of Gastroenterology & Hepatology, Weill Cornell Medicine, New York, NY, United States, Weill Cornell Medicine, New York, United States; [6]Liver, Digestive, and Lifestyle Research Section, and Organ Transplant Center of Excellence, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; [7]Center for Outcomes Research in Liver Diseases, Washington DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: Many MASLD-related deaths in the US occur prematurely and may be preventable. We aimed to evaluate preventable premature MASLD-related deaths and identify associated disparities in the US.
Method: Data from the U.S. National Vital Statistics System (2011–2021) were used to estimate premature preventable death (PPD) defined as deaths exceeding expected numbers based on the death rates of the three states with the lowest premature death (age ≤75 at death) rates. Counties were classified using the Center for Disease Control's (CDC's) urban-rural framework, and county-level demographic, healthcare access, and lifestyle data were obtained from the PLACES dataset. Annual percent changes (APC) were calculated using joinpoint regression models. Mixed-effects linear regression (MELR) models evaluated associations between county-level factors and PPD.
Results: MASLD-related death rates in the U.S. rose from 15.33 to 24.13 per 100,000 between 2011 and 2021 (APC: +4.21%). Of these deaths, ≥84% could be considered PPDs which increased from 13.09 to 20.33 per 100,000 (APC: +3.97%). Rural counties in the US consistently had higher premature MASLD-death rates (16.40 per 100,000 in 2011 to 30.03 in 2021, APC: +6.23%) compared to urban counties (11.56 per 100,000 in 2011 to 16.45 in 2021, APC: +3.48%). The proportion of PPD from MASLD increased more sharply in the urban counties of the US (16.95% in 2011 to 41.49% in 2021, APC: +8.28%) than in rural counties (41.62% in 2011 to 68.41% in 2021, APC: +4.82%). Interestingly, PPD from MASLD in the urban counties in the US surged after 2019 (APC: +18.16%), surpassing rural increases (APC: +6.94%). In fully adjusted MELR models, higher rates of routine checkups (beta = –0.0136 to –0.0138) and cholesterol screenings (beta = –0.0034 to –0.0459) were associated with a lower proportion of PPD from MASLD in both urban and rural counties. Conversely, food insecurity (beta = 0.0154 to 0.0281) and lack of physical activity (beta = 0.0143 to 0.0281) were linked to higher PPD from MASLD. Obesity (beta = 0.0212) contributed to higher PPD in urban counties, while food deserts (beta = 0.0030) were associated with higher PPD in rural counties.
Conclusion: Preventable premature MASLD-related deaths are rising in the U.S. While the rural areas were mostly affected, there is an increase in preventable deaths from MASLD in urban areas since 2019. Components of healthcare access, food insecurity, and physical inactivity are critical drivers of PDP from MASLD in the US.

THU-477
Serum bile acid is associated with clinically significant pruritus in patients with metabolic dysfunction-associated steatotic liver disease
Zobair Younossi[1,2,3], James M. Estep[1,2], Brian Lam[1,2], Andrei Racila[1,2], Fatema Nader[1,2,3], Maria Stepanova[1,2,3]. *[1]The Global NASH/MASH Council, Washington, District of Columbia, United States; [2]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, United States; [3]Center for Outcomes Research in Liver Diseases, Washington, District of Columbia, United States*
Email: zobair.younossi@cldq.org

Background and aims: Although pruritus has been reported in metabolic dysfunction-associated steatotic liver disease (MASLD), its association with serum bile acids is less well established. We assessed the associations of serum bile acids with pruritus in patients with MASLD.
Method: We analyzed clinical, laboratory (including serum bile acid) and CLDQ-NASH data available in MASLD database. All study-related variables were collected after informed consent. The severity of pruritus was assessed using the itch item of CLDQ-NASH, and pruritus was defined as the item score ≤4 on a 1–7 scale (patient troubled by itch at least "some of the time"). In those with follow-up CLDQ-NASH and serum bile acid data available, a significant change in bile acids was defined as a change of ≥20% from baseline; a significant change in pruritus was defined as a change in CLDQ-NASH itch score of ≥2 points from baseline.
Results: We included 2154 subjects: mean (SD) age 57.7 (10.0) years, 42% male, BMI 33.4 (6.8), 66% type 2 diabetes, 25% pruritus. Patients with pruritus had significantly lower HRQL scores in all domains of CLDQ-NASH: up to –1.2 on a 1–7 scale, all p < 0.0001. The correlation of higher serum bile acids with lower itch score was significant (r = –0.12, p < 0.0001), and patients with pruritus had higher levels of bile acids: 12.2 (14.6) µmol/L vs. 10.1 (12.6) µmol/L (p < 0.0001). Among N = 1627 patients with 12-week follow-up data, 14% had their pruritus worsened, 12% improved, and 74% unchanged. Patients with improved pruritus more commonly had a significant decrease in bile acids (34% vs. 24% in pruritus unchanged and 18% pruritus worsened, p = 0.0006). On the other hand, patients with worsened and unchanged pruritus had similar rates of significant bile acids increase (33% vs. 30%, p > 0.05). Among patients with a significant bile acid decrease, there were 17% who had pruritus improved vs. 12% in unchanged bile acids, 9% in increased bile acids groups (p = 0.0009) while no similar association was observed for significant bile acids increase and pruritus worsening (p > 0.05). In multivariate regression analysis, a significant decrease in bile acids was independently associated with higher odds of pruritus improvement (OR = 2.0 (1.3–3.0), p < 0.0001; adjusted for age, sex, BMI, diabetes, history of skin and psychiatric disorders, cirrhosis, baseline history of itch and bile acids levels, baseline ALP, GGT and bilirubin and changes in those). In a round of post hoc cutoff search, significant worsening of pruritus was found to be associated with at least 200% increase in serum bile acids: cross-sectional rates 38% vs. 13%, adjusted OR = 3.70 (1.80–7.59), p = 0.0004.
Conclusion: Among MASLD, higher serum bile acid level is associated with more pruritus. A decrease of ≥20% in bile acids is independently associated with improvement of pruritus, and a three-fold increase in bile acids is associated with pruritus worsening.

THU-478

Metabolic dysfunction-associated steatotic liver disease (MASLD) screening according to EASL guideline is cost-effective

Zobair Younossi[1,2,3], James M. Paik[1,2,3], Linda Henry[1,2,3], Maria Stepanova[1,2,3], Jillian Price[1,2], Leyla de Avila[1,2], Fatema Nader[1,2,3]. [1]*The Global NASH/MASH Council, Washington, DC, United States;* [2]*Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, United States;* [3]*Center for Outcomes Research in Liver Diseases, Washington, DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: EASL 2024 guidelines recommend screening individuals with type 2 diabetes (T2D), medically complicated obesity, and elevated liver enzymes to identify those as risk for MASLD. The screening algorithms begin with Fibrosis-4 index (FIB-4), followed by vibration-controlled transient elastography (VCTE) with enhanced liver fibrosis (ELF) as an alternative where VCTE is unavailable. We applied screening algorithm according to 2024 EASL guideline to the primary care setting in the United States.
Method: A Markov-based cost-utility model was developed to evaluate screening strategies. The prevalence of T2D, medically complicated obesity, and elevated liver enzymes in primary care was estimated using nationally representative data. Transition probabilities were aligned with the available national data on liver outcomes (HCC, cirrhosis, and liver transplants) and were adjusted for T2D and obesity. Treatment of co-morbidities (T2D, obesity, etc.) were considered as per standard of care. For those who qualified, treatment with resmetirom was provided according to the FDA approval. Costs for screening, staging, follow-up testing, treatment, and long-term care were sourced from public and private payer data. Incremental cost-effectiveness ratios (ICERs) were calculated over a 20-year horizon, comparing screening strategies to no screening. Sensitivity analyses evaluated the robustness of findings across key parameters.
Results: Screening algorithm recommended by EASL guideline was cost-effective in the U.S., with ICERs ranging from $23,265 to $26,949 per quality-adjusted life year (QALY). Screening reduced the prevalence of advanced fibrosis (24.89%–33.11% vs. 46.70%–48.84%) and cumulative mortality (50.86%–79.60% vs. 61.23%–85.59%) compared to no screening. Sensitivity analyses highlighted treatment effectiveness, fibrosis progression rates, and non-invasive test (NIT) performance as critical determinants of cost-effectiveness. When VCTE access was limited, using ELF as an alternative maintained the cost-effectiveness of screening.
Conclusion: Screening for MASLD following EASL guidelines is cost-effective in the U.S., reducing advanced fibrosis, mortality, and long-term healthcare costs.

MASLD – Diagnostics and non-invasive assessment

Background and aims: With the advent of approved MASLD therapies, there remains a critical need for non-invasive tests to accurately triage patients with MASLD for therapy. This study aims to identify proteomic signatures that distinguish between fibrosis stage and disease activity, and to leverage machine learning approaches to develop simple, well-performing models that detect advanced fibrosis and at-risk MASH.
Method: The European SLD Registry (formerly European NAFLD Registry) LITMUS Study Cohort comprises a prospectively recruited histologically characterised international multicentre cohort covering the complete spectrum of MASLD severity. All biopsies were centrally read by expert hepatopathologists using the NASH-CRN system. To assess changes in protein levels across the MASLD spectrum, these were integrated with serum proteomics from a SomaScan panel comprising approximately 7,000 human proteins. Logistic regression models were trained on the prospective LITMUS Study Cohort (1,088 samples). Feature selection utilised XGBoost and recursive feature elimination; best-fitting models were chosen based on AIC. Cases from the LITMUS Metacohort (275 samples) were used

for hold-out independent validation. Additionally, the Cox proportional hazards model was used on a sub-group of 332 patients who had multiple FibroScan-VCTE measurements to identify the proteins linked to fibrosis progression.
Results: Proteomic signatures defining (1) advanced fibrosis and (2) MASLD activity, were identified and used to establish accurate predictive models for clinical application. LiMITT-Fibrosis (comprising ADAMTSL2, COLEC11, CLSTN2, C7, and GDF15) to predict advanced fibrosis (F0-2 vs F3+) when categorised dichotomously, while LiMITT-MASH (comprising ADAMTSL2, AKR1B10, ME1, and UGDH) defined at-risk MASH (MAS ≥4 + F≥2). For LiMITT-Fibrosis, in the training/validation sets respectively, the AUC was 0.92/0.90 (Youden index provided Sensitivity 0.85/0.87, Specificity 0.86/0.80) and outperformed FibroScan-VCTE (AUC of 0.79/0.84 in training/validation sets), FIB-4 (AUC 0.77/0.75), and ELF (AUC 0.81/0.76). For LiMITT-MASH, in training/validation sets respectively, the AUC was 0.83/0.84 (Sensitivity 0.81/0.83, Specificity 0.73/0.72) and outperformed AST (AUC 0.74/0.70 in training/validation sets). Additionally, time-to-event analysis uncovered 92 proteins linked to fibrosis progression, 44 of which overlapped with the fibrosis proteomic signature.
Conclusion: Circulating protein analysis has enabled the development and validation of the LiMITT suite of accurate, non-invasive predictive models for diagnosing advanced fibrosis and at-risk MASH. Furthermore, proteins associated with future fibrosis progression have been identified, providing insights into the mechanisms driving the disease and supporting the prognostic utility of this approach.

Dynamics in lab-based non-invasive tests predict the development of liver-related outcomes in tertiary care

Georg Semmler, Katrine Lindvig, Lucie Simonis, Katharina Stopfer, Lorenz Balcar, Benedikt Hofer[1], David Bauer[1], Benedikt Simbrunner[1], Lukas Hartl[1], Mathias Jachs, Peter Andersen[2,3], Katrine Thorhauge[2,3], Michael Trauner, Aleksander Krag, Thomas Reiberger, Mattias Mandorfer, Maja Thiele. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark; [3]Institute of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark*
Email: georg.semmler@meduniwien.ac.at

Background and aims: Non-invasive tests (NITs) are essential tools to identify individuals at risk of developing complications associated with steatotic liver disease (SLD), and to direct patient pathways. While conventional algorithms only consider one-time assessments, longitudinal trajectories of NITs might provide unexploited additional information. We aimed to assess the prognostic value of longitudinal trajectories of NITs in predicting liver-related outcomes.
Method: This retrospective cohort study included 3399 outpatients with suspected SLD characterized at the time of first referral to a tertiary hospital. All available labs from hospital records were used to model trajectories of NITs including FIB-4, APRI, CORE score (%) and LiverPRO (%), generating the best-fitting line per patient indicating the direction and degree of change over time. These dynamics were linked to liver-related endpoints including the development of compensated advanced chronic liver disease (cACLD, defined as reliable liver stiffness measurement ≥10 kPa), hepatic decompensation, and liver-related death retrieved from national death registries, using a joint modelling approach.
Results: We included 2712 (80%) patients with SLD, 136 (4%) with cryptogenic and 551 (16%) without chronic liver disease. Prevalence of cACLD was 845 (25%) at first referral.
A total of 74,907 lab timepoints were used to model lab-trajectories over a median period of 9.4 years (median time from the first lab prior to referral: 1.9 years [IQR: 8.6–0.1]). 118 (4%) patients developed hepatic decompensation, 268 (8%) died including 80 (2%) liver-related deaths during a median follow-up of 5.4 years from first referral.
Adjusting for age and sex, dynamics in LiverPRO (adjusted hazard ratio [aHR] per logit-change: 1.28 [95% CI: 1.18–1.39], FIB-4 (aHR per log-change: 2.84 [95% CI: 1.54–4.45] and CORE (aHR per logit-change: 1.29 [95% CI: 1.08–1.50]), but not APRI, were independently associated with development of cACLD, indicating a direct relationship between an averaged increase in these scores and an increased subsequent risk of cACLD. Results for hepatic decompensation were similar [aHR LiverPRO: 1.61 [1.25–1.86], FIB4: 3.04 [2.10–4.45], CORE: 1.31 [1.06–1.59]). However, only LiverPRO (aHR: 1.78 [95% CI: 1.51–1.99]) and FIB-4 (aHR: 4.17 [95% CI: 2.37–12.66]) were associated with liver-related death.
Notably, when considering dynamics within the previous 5 years to predict outcomes in the subsequent 5 years, discrimination was numerically highest for LiverPRO, with an area under the curve (AUC) of 0.716 for cACLD, 0.889 for hepatic decompensation and 0.904 for liver-related death, as compared to FIB-4 (0.691/0.869/0.882) and CORE (0.665/0.812/0.837).
Conclusion: Dynamics in LiverPRO, FIB-4 and CORE score yield early prognostic information for subsequent development of liver-related outcomes in tertiary care.

Untargeted lipidomic profiling in pediatric metabolic dysfunction-associated steatohepatitis: insights from youth enrolled in NASH CRN studies

Gahyun Lim[1], Helaina Huneault[1], Chih-Yu Chen[2], Grey Won[3], Cristian Sanchez-Torres[4], Kristal Maner-Smith[3], Miriam Vos[5]. *[1]Nutrition & Health Sciences Program, Laney Graduate School, Emory University, Atlanta, GA, United States; [2]2Emory Integrated Metabolomics and Lipidomics Core, Emory School of Medicine, Atlanta, GA, United States; [3]Emory Integrated Metabolomics and Lipidomics Core, Emory School of Medicine, Atlanta, GA, United States; [4]Department of Pediatrics, Division of Gastroenterology, Hepatology, and Nutrition, Emory University, Atlanta, GA, United States; [5]Nutrition & Health Sciences Program, Laney Graduate School, Emory University, Department of Pediatrics, Division of Gastroenterology, Hepatology, and Nutrition, Emory University, Children's Healthcare of Atlanta, Atlanta, GA, United States*
Email: gahyun.lim@emory.edu

Background and aims: Disruptions in lipid metabolism play a significant role in the pathogenesis of metabolic dysfunction-associated steatohepatitis (MASH). Lipidomics offers a comprehensive approach to identifying lipid alterations contributing to disease mechanisms and potential biomarkers or therapeutic targets. However, research on the lipidomic profile of pediatric MASH remains limited. This cross-sectional study applied lipidomic profiling to identify lipid alterations associated with biopsy-confirmed pediatric MASH using data from youth in NASH CRN studies (TONIC, DB1) and healthy controls.
Method: Untargeted lipidomics was performed on fasting serum samples from 160 pediatric participants using ultra-high-performance liquid chromatography-mass spectrometry (UHPLC-MS/MS). Clinical assessments included anthropometrics, lipid and liver enzyme levels, and glucose metabolism markers. MASLD/MASH status was determined by liver biopsy for NASH CRN participants and MRI for controls. Lipidomics data were processed using MS-DIAL (v4.9) and analyzed with MetaboAnalyst 6.0. Statistical methods included partial least squares discriminant analysis (PLS-DA), differential expression, and lipid class enrichment analysis.
Results: The cohort included 102 participants with MASH (29% Zone 1 pattern, 19% Zone 3 pattern, 52% definite MASH) and 58 non-MASH participants. The age range was 7–18 years, 77% male, with a mean BMI z-score of 2.01 ± 0.77, and 58% were Hispanic. Participants with

MASH demonstrated significantly higher BMI z-scores, waist circumference, ALT, AST, insulin, HOMA-IR, triglycerides, total cholesterol, LDL, and lower HDL than non-MASH ($p < 0.05$). Lipidomics analyses revealed distinct metabolic profiles between MASH and non-MASH participants. Key metabolites driving group separation included hexosylceramides Hex2Cer 28:2;2O, HexCer 39:4;3O, and HexCer 29:1;4O, indicating disruptions in ceramide metabolism. Altered lipid species included phospholipids (PC 33:4) and triglycerides (TG 58:8), reflecting changes in lipid homeostasis. Differential expression identified Hex2Cer 28:2;2O and HexCer 39:4;3O as significantly elevated in MASH participants ($p < 0.05$). Lipid class enrichment revealed significant alterations in HexCer and TG classes, driven by these ceramide species.

Conclusion: These findings highlight significant alterations in ceramide and TG pathways, potentially contributing to pediatric MASH through mechanisms involving inflammation and apoptosis. Elevated hexosylceramides may reflect deranged sphingolipid metabolism and serve as potential biomarkers of disease severity. These results align with previous studies suggesting that targeting ceramide metabolism could offer a promising therapeutic strategy. Longitudinal studies are needed to validate these findings and assess their implications for treatment.

Gemelli, IRCCS, Rome, Italy; [2]Università Cattolica del Sacro Cuore, Rome, Italy*
Email: lig.antonio91@gmail.com

Background and aims: Liver fibrosis is the primary prognostic factor in MASLD. Liver biopsy is the gold standard for staging fibrosis, although it is invasive and expensive procedure. Currently, non-invasive methods are available to stratify the degree of fibrosis.
The aim of this study is to validate liver stiffness as a prognostic factor both at baseline and in its variation over time during follow-up.

Method: This is a retrospective single-center cohort study including 389 patients who underwent at least two Fibroscan liver stiffness measurements, with a minimum 6-month interval between scans, from January 2011 to December 2023. They were stratified into 3 risk groups according to Baseline liver stiffness measurements (LSM) (<10, 10–20, > 20 kPa). Primary outcome was a composite of Liver Related Events (LRE), death or liver transplantation.
Kaplan-Meier curves were generated for time to primary outcome stratified by Baseline LSM and Δ% Fibroscan categories (worsening: LSM increase > 20%, stable, improved: LSM decrease > 20%). Multivariable Cox regression analysis, adjusted for age, gender, BMI and type 2 diabetes, was used to assess the association of baseline LSM and Δ% fibroscan with primary outcome event. Cumulative incidence curves and incidence rates have been assessed and compared for each risk subgroup.

Results: During a median follow-up of 28 months (IQR 14.4–43.4), 29 (7.5%) patients experienced the composite primary endpoint. These patients were older and had a higher LSM at baseline (median 23.3 vs 6.2 kPa, $p < 0.01$) and higher Δ% fibroscan (16.9% vs −3.5%, $p < 0.01$) than patients who did not experienced a LRE. Baseline LSM show a good predictive performance for the composite endpoint events with an AUC of 0.897 (95% CI 0.845–0.948). Compared to patients with an LSM <10, patients with LSM between 10 and 20 kPa had a 9.7 fold higher risk for the primary outcome (HR 9.7 [2.05–45.79], $p \leq 0.01$) and those with LSM > 20 had a 55.6-fold higher risk (HR 55.63 [12.15–254.74], $p \leq 0.01$).
Multivariate Cox regression analysis also revealed significantly lower risk of developing LRE for high-risk patients (>20 kPa) who showed longitudinal improvements (Δ%LSM ≥20%) on fibroscan results (HR 0.16, 95%CI 0.04–0.68, $p = 0.01$), and a significantly higher risk of developing LRE in intermediate patients (10–20 kPa) who showed worsening longitudinal changes (Δ%LSM > 20%) on fibroscan results (HR 6.66, 95%CI 1.69–26.23, $p < 0.01$). Incidence rate of composite outcome per 1000 person-year was 15.5, 19.7, 81.4 for LSM improved, stable or worsened groups respectively.

Conclusion: Our study strengthens the use of LSM both at baseline and during follow up as reliable prognostic factors in MASLD able to identify the subgroups of patients with MASLD at risk of LREs. In patients with intermediate or high risk of events at baseline, elastography surveillance should be encouraged.

Liver stiffness as a predictor of major adverse cardiac events in metabolic dysfunction-associated steatotic liver disease

Nirbaanjot Walia[1,2], Stuart Roberts[3], Ammar Majeed[3], John Lubel[3], Jirayut Prompen[3], Anouk Dev[1], William Sievert[1], Stephen Bloom[4], Paul Gow[2], William Kemp[3], Michael Braude[1]. *[1]Department of Gastroenterology and Hepatology, Monash Health, Melbourne, Australia; [2]Gastroenterology and Liver Transplant Unit, Austin Health, Melbourne, Australia; [3]Department of Gastroenterology and Hepatology, Alfred Health, Melbourne, Australia; [4]Department of Gastroenterology and Hepatology, Eastern Health, Melbourne, Australia*
Email: nirbaanwalia@gmail.com

Background and aims: There is a growing burden of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) globally. Given the risk factors MASLD shares with cardiovascular disease, patients with MASLD are prone to major, adverse cardiac events (MACE). Several studies evaluate an individual's risk of MACE, however they seldom assess the impact of liver fibrosis. The aim of this study was to assess whether liver stiffness measurement (LSM), as measured by Vibration controlled Transient Elastography (VCTE), is associated with incident MACE in patients with MASLD.

Method: This was a retrospective study of patients with MASLD and VCTE conducted at four major hospital networks in Victoria, Australia. The primary outcome was the 5-point MACE, a composite of acute myocardial infarction, stroke, cardiovascular death, unstable angina and heart failure. LSM by VCTE was categorized using a rule of five (10, 15, 20 and 25 kPa) for analysis. The risk of incident MACE was assessed using a Cox regression model, with adjustment for age, sex, diabetes, obesity, dyslipidemia, hypertension, chronic kidney disease and smoking status. Discriminatory performance of the model was evaluated using C-index, and compared to a model without LSM using the likelihood ratio test.

Results: Among 6,088 patients with VCTE, 292 experienced MACE (23,408 person-years, median follow-up 3.84 years). Univariable Cox regression demonstrated significant, stepwise increases in the risk of MACE across each LSM category compared to LSM <10 (HRs 1.71, 2.23, 2.77, 5.23, all $p < 0.001$). This trend persisted with multivariable Cox regression, with a significantly higher risk of MACE for the LSM 20–25 (HR 1.64, 95% CI:[1.01, 2.70], $p = 0.048$) and LSM > 25 (HR 2.52, 95% CI: [1,83, 3.46], $p < 0.001$) categories. When LSM was treated as a continuous variable, each 5kPa increase was independently associated with a 10.4% increased risk of MACE (HR 1.104, 95% C:[1.07, 1.139], $p < 0.001$). The model demonstrated good discriminatory performance and outperformed a model without LSM as a predictor (C-index 76.7 vs 75.4%, $p < 0.001$).

Conclusion: Higher LSM, as measured by VCTE, is independently associated with increased risk of MACE in patients with MASLD, and may improve existing risk stratification tools. Further research is required to build on these findings.

TOP-394

Comprehensive analysis of biomarker performance targeting "advanced fibrosis" and "at-risk" metabolic-dysfunction associated steatotic liver disease (MASH) – primary analysis of the LITMUS study cohort

Background and aims: The advent of regulatory approved pharmacological treatments for metabolic dysfunction associated steatotic liver disease (MASLD) calls for precise, non-invasive biomarkers that facilitate early diagnosis, support patient selection for therapy, and aid clinical trial enrolment. The European multi-center LITMUS Study evaluated >30 non-invasive biomarkers, assessing their performance in identifying patients with at-risk MASH or advanced fibrosis.
Method: In this diagnostic accuracy analysis we used data from adult patients with biopsy-confirmed MASLD prospectively recruited across 13 countries in Europe and the US (2018–2023). The reference standard was centrally scored liver histology conducted by the LITMUS Histopathology Group according to the NASH-CRN system. We focused on detecting at-risk MASH, defined by a MASLD activity score (MAS) ≥4, with at least one point in each component + significant fibrosis (F≥2); and advanced fibrosis (F≥3). We assessed 12 single markers (AST, ALT, CK18-M30, CK18-M65, GDF15, GGT, PROC3, PROC6, PROC4, thrombospondin-2 [TSP2], YKL-40, Fibroscan-VCTE) and 18 multi-marker panels (ABC3D, ADAPT, APRI, Agile 3+, Agile 4, ELF, FAST, FIB-4, FIBC3, FibroMeter-VCTE, FNI, MACK-3, NFS, NIS2+, NIS4, OWLiver [two models], and SomaSignal). Performance was evaluated by area under the receiver operating characteristic curve (AUC), with a target AUC > 0.80 to indicate potential replacement of biopsy for detecting at-risk MASH.

Results: Of the 1,557 participants analysed, single markers exhibited AUCs ranging from 0.52 to 0.76 for at-risk MASH detection and from 0.53 to 0.84 for advanced fibrosis (with the best-performing marker being TSP2 with AUCs of 0.76 and 0.84 for at-risk MASH and advanced fibrosis, respectively). Multi-markers performed better overall, with AUCs ranging from 0.65 to 0.83 for at-risk MASH and 0.58 to 0.92 for advanced fibrosis with SomaSignal outperforming single markers in detecting both target conditions; AUCs of 0.83 and 0.92, respectively. Considering biomarkers adopted in clinical practice guidelines, ELF and Fibroscan-VCTE had AUCs of 0.80 and 0.79 respectively for advanced fibrosis. Two other multi-markers, FibroMeter-VCTE and Agile 3+, however showed acceptable AUC values in detecting advanced fibrosis (0.87 and 0.84, respectively).
Conclusion: The LITMUS Study is the largest and most comprehensive biomarker validation study performed to date in liver disease. Single biomarkers alone are unlikely to replace liver biopsy; however, multi-marker panels have great potential, with panels like SomaSignal showing high diagnostic performance. Although non-invasive detection of steatohepatitis remains challenging, biomarkers for fibrosis are better performant. These results support the development of reliable, non-invasive diagnostic panels to reduce the need for invasive liver biopsies and enhance patient care.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is highly prevalent worldwide. We evaluated the global performance of non-invasive tests (NITs) and mortality predictors in MASLD.
Method: This GNC collaboration enrolled MASLD patients with liver biopsies and NITs [FIB-4, ELF, liver stiffness measurement (LSM) by transient elastography]. FAST, Agile-3+ and Agile-4 were calculated. NITs' performance to predict ≥F2 (significant fibrosis, SF), ≥F3 (advanced fibrosis, AF) or cirrhosis (F4) was determined by assessing area under the ROC curve (AUC). In those with follow-up, predictors of mortality were assessed.
Results: 17,561 MASLD patients from 41 countries [30% North America (NA), 30% Europe (EU), 24% Southeast Asia (SEA), 7% MENA, 6% South Asia (SA), 3% Latin America (LA)] were included [age 51 ± 13 years, 48% male, BMI 33 ± 8 kg/m^2, 46% type 2 diabetes (T2D), 53% SF, 36% AF, 14% F4]. SF and AF were most prevalent in NA (68% and 49%), lowest in SA (33% and 21%) ($p < 0.001$). The NIT performance showed variability across regions [AUC of FIB-4 for AF: 0.80 (95% CI 0.79–0.81), lowest in LA (0.72 (0.67–0.77)), highest in MENA (0.84 (0.82–0.87)), $p < 0.001$]. AUC of ELF: 0.77 (95% CI 0.76–0.79), lowest in EU (0.72 (0.69–0.75)), highest in NA (0.80 (0.78–0.82)), $p < 0.001$. AUC of LSM: 0.84 (0.83–0.85), similar across regions ($p > 0.05$). AUC of FAST: 0.76 (0.74–0.77), similar (up to 0.79) in all regions except NA (0.70 (0.67–0.73)), $p < 0.01$. AUC of Agile-3+ for AF: 0.87 (0.86–0.88), similar (≥0.85) in all regions ($p > 0.05$). AUC for predicting SF were similar for all NITs: 0.76 (0.76–0.77) for FIB-4, 0.77 (0.75–0.78) for ELF, 0.81 (0.80–0.81) for LSM, 0.75 (0.74–0.76) for FAST, 0.82 (0.81–0.83) for AGILE-3+. AUC of Agile-4 for predicting cirrhosis was 0.90 (0.89–0.91), lowest in NA (0.85 (0.83–0.87)), highest in MENA (0.96 (0.94–0.98)), $p < 0.001$. Presence of T2D and age ≥65 years reduced AUC of FIB-4 and ELF by 0.05–0.08 ($p < 0.01$) but not LSM ($p > 0.05$). N = 7285 subjects had follow-up (mean (SD) 6.6 (7.2) years) with 7% deaths. In adjusted (age, sex, T2D) Cox proportional hazards models, fibrosis severity by histology or NITs (regardless of modality) was associated with higher mortality: adjusted hazard ratio (aHR) (95% CI) for ≥F2 = 1.61 (1.33–1.94), ≥F3: 2.2 (1.8–2.7), F4: 3.1 (2.4–3.9); FIB-4 ≥1.30: 1.5 (1.2–1.8), FIB-4 ≥2.67: 2.0 (1.6–2.5), FIB-4 ≥3.25: 2.1 (1.6–2.8); LSM ≥10 kPa: 2.6 (1.8–3.7), LSM ≥15 kPa: 3.2 (2.2–4.6), LSM ≥20 kPa: 3.7 (2.5–5.4); Agile-3+ ≥0.678: 3.4 (2.1–5.4); Agile-4 ≥0.251: 3.5 (2.4–5.2); Agile-4 ≥0.842: 6.3 (3.6–11.2) (all $p < 0.001$). Other predictors of mortality were older age, male sex, history of hypertension ($p < 0.05$).
Conclusion: NIT diagnostic performance in MASLD varies across the world. The most accurate NITs were Agile-3+ and Agile-4, with minimal variability. Histologic fibrosis stage and NITs were independently associated with mortality in MASLD.

Does measuring the components of the Fibrosis-4 index (FIB-4) separately on different days affect its diagnostic and prognostic performance in patients with metabolic dysfunction-associated steatotic liver disease (MASLD)?

Sherlot Juan Song[1,2], Vincent Wai-Sun Wong[1,2], Jennifer Kramer[3,4], Jimmy Lai[1,2], Grace Lai-Hung Wong[1,2], Fasiha Kanwal[3,4], Terry Cheuk-Fung Yip[1,2]. Email: 1155169298@link.cuhk.edu.hk

Background and aims: Current guidelines recommend FIB-4 as an initial assessment of fibrosis in patients with MASLD. However, in routine practice, the components of FIB-4 might be measured on different dates. The same issue might also affect big data research calculating FIB-4 with existing laboratory values. This study aims to determine the impact of the varying time intervals between the component laboratory tests used to calculate FIB-4 on the diagnostic and prognostic performance of FIB-4.
Method: We examined a cross-sectional liver biopsy cohort and a longitudinal territory-wide cohort from Hong Kong. In the cross-sectional liver biopsy cohort, the baseline date was the date of liver biopsy. In the territory-wide Clinical Data Analysis and Reporting System (CDARS) cohort, the baseline date was the date of MASLD diagnosis. Considering that alanine transaminase (ALT) and aspartate transaminase (AST) are commonly measured together in clinical practice, the performance of FIB-4 was examined using two approaches: i) ALT/AST measured at baseline with platelets (PLT) measured 1 or 2 years apart; or ii) PLT measured at baseline with ALT/AST measured 1 or 2 years apart. The area under the receiver operating characteristic curve (AUC) and 95% confidence intervals (95% CI) of FIB-4 to identify F3-4 fibrosis was calculated at the respective time intervals in the biopsy cohort. In the CDARS cohort, the C-index by Fine-Gray subdistribution hazard model was used to assess the discriminatory performance of FIB-4 in predicting liver-related events (LRE).

Results: 573 patients with biopsy-proven MASLD and 4524 patients in the CDARS cohort were included in the final analysis. In the biopsy cohort, the AUC of FIB-4 for F3-4 fibrosis was 0.764 (95% CI: 0.723-0.805) when all laboratory tests were taken at the time of liver biopsy, 0.760 (95% CI: 0.713–0.807) and 0.754 (95% CI: 0.703–0.804) when PLT was taken 1 and 2 years earlier, and 0.786 (95% CI: 0.689–0.883) and 0.796 (95% CI: 0.691–0.902) when ALT/AST were taken 1 and 2 years earlier, respectively. The sensitivity and specificity of FIB-4 were 56.5% and 97.3%, respectively and were similar regardless of the relative timing of PLT and ALT/AST tests. In the CDARS cohort, the reference C-index of FIB-4 in predicting LRE were 0.737 (95% CI: 0.692–0.783) when all tests were collected at baseline. The C-indices of FIB-4 were 0.763 (95% CI: 0.720–0.806) and 0.732 (95% CI: 0.689–0.783) when PLT was measured 1 or 2 years earlier, respectively. When ALT/AST were measured 1 or 2 years earlier, the C-indices of FIB-4 were 0.757 (95% CI: 0.711–0.804) and 0.725 (95% CI: 0.671–0.778), respectively.
Conclusion: The diagnostic and prognostic performance of FIB-4 remains stable when its components are measured at different time intervals. This suggests that FIB-4 can be used broadly in clinical practice, even when not all components are available simultaneously.

WED-366
Enhancing the non-invasive diagnosis of fibrosis in metabolic dysfunction-associated steatotic liver disease: the role of transient elastography and a two-stage machine learning diagnostic model

Zhengao Xu[1], Yong-Fen Zhu[1], Yilong Fu[2], Ruiqi Wang[2], Xiao Liang[1].
[1]*Department of General Surgery, Run Run Shaw Hospital Affiliated to Zhejiang University School of Medicine, Hangzhou, China;* [2]*School of Life Science, Zhejiang Chinese Medical University, Hangzhou, China*
Email: srrshlx@zju.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a rising chronic liver disease linked to lifestyle changes and obesity. Its progression leads to liver inflammation and fibrosis, increasing the risk of severe conditions like cirrhosis and hepatocellular carcinoma. Currently, early diagnosis of liver fibrosis relies on invasive liver biopsy. This study aims to develop a two-step diagnostic model that integrates demographic data, laboratory data, and transient elastography to improve liver fibrosis assessment in MASLD patients.
Method: We selected 361 patients with pathologically confirmed MASLD admitted to our hospital from July 2018 to July 2024. Collected data included gender, age, BMI, ALT, AST, GGT, albumin, platelet count, Chitinase 3-like 1 (CHI3L1), hypertension, diabetes and hyperlipidemia. Patients were categorized based on liver fibrosis degree (F≥2 and F<2). Various machine learning algorithms (decision trees, random forests, lasso, XGBoost, SVM, single hidden layer neural networks (SHLNNs), LightGBM) were employed to create a first-stage diagnostic model. Transient elastography was incorporated into the establishment of the second-stage model. The first-stage model with high sensitivity and the second-stage model with high specificity are regarded as the recommended diagnostic strategy. Diagnostic performance was evaluated using ROC, calibration, and decision curves, comparing results with established formulas like APRI, NFS, FIB-4, Agile3+, and Agile4.
Results: A total of 278 patients with complete data were included in the analysis, with 106 having liver fibrosis (F≥2) and 172 without (F<2). Among first-stage training set models, random forests (AUC 0.945; sens 0.934; spec 0.802), LightGBM (AUC 0.837; sens 0.651; spec 0.849), XGBoost (AUC 0.775; sens 0.774; spec 0.640), SVM (AUC 0.767; sens 0.830; spec 0.599), and Lasso (AUC 0.759; sens 0.868; spec 0.558) showed AUCs exceeding 0.75. In the second-stage training set model, random forests (AUC 0.957; sens 0.915; spec 0.855), LightGBM (AUC 0.963; sens 0.925; spec 0.963), XGBoost (AUC 0.874; sens 0.717; spec 0.878), SVM (AUC 0.781; sens 0.802; spec 0.645), Lasso (AUC 0.776; sens 0.811; spec 0.599), and SHLNNs (AUC 0.764; sens 0.640; spec 0.764) also exceeded 0.75. Established formulas had AUCs below 0.75. In the two-stage modeling, CHI3L1 and elastography each ranked high in importance.
Conclusion: The machine learning models outperformed existing diagnostic formulas for liver fibrosis in MASLD. The first-stage model highlighted the significance of CHI3L1. While transient elastography enhances the overall diagnostic efficacy of the machine learning models, it may compromise sensitivity in favor of improved specificity, making it unsuitable for large-scale liver screening in the initial stage. The optimal two-step diagnostic strategy identified in this study involves using the random forest model followed by the transient elastography enhanced LightGBM model.

WED-367-YI
Frequency and risk factors of fibrosis staging discrepancies between transient elastography and liver biopsy in patients with metabolic-associated steatotic liver disease: role of obesity and type 2 diabetes

Alba Jiménez-Masip[1], Laura Pagès[1], Diego Rojo[1], Clara Sabiote[1], Sergio Muñoz Martínez[1], Juan Bañares[1], Aina Martí Carretero[1], Juan Manuel Pericàs[1]. [1]*Liver Unit, Digestive Diseases Area, Vall d'Hebron University Hospital, Vall d'Hebron Institute for Research, Universitat Autònoma de Barcelona, Barcelona, Spain*
Email: 94jimenezalba@gmail.com

Background and aims: Discordance between transient elastography (TE) and liver biopsy (LB) in fibrosis staging among patients with metabolic-associated steatotic liver disease (MASLD) has been linked to metabolic factors, remarkably obesity and type 2 diabetes mellitus (T2D), but their independent roles remain unclear. This study evaluates the frequency and risk factors of discordance in fibrosis staging in a large cohort of patients with biopsy-confirmed MASLD.
Method: This cross-sectional observational study included patients with MASLD who underwent TE and a subsequent LB within 6 months, between 2013 and 2024. Concordance was defined as an identical fibrosis stage reported by both methods, with discordance assessed using Cohen's kappa. The primary outcome was the rate of discordance between TE and LB in determining fibrosis stage. Factors associated with discordance were analysed using univariate methods and multivariate logistic regression. Subgroup analyses were conducted for patients with ≥grade II obesity (BMI, body mass index, ≥35 kg/m²) and those with T2D.
Results: Among 415 patients, concordance between TE and LB was low (kappa = 0.220, p < 0.001), with an overall discordance rate of 58.1%. Reliable TE results were similar in concordant (74.5%) and discordant (75.9%) groups (p = 0.776). Higher rates were observed in the misclassification of advanced fibrosis (F3-F4 52.3% vs. 49.8% F0-F2). Univariate analysis identified age, obesity, liver stiffness, and platelet count as variables significantly associated with overall discordance. No association was found between discordance and transient elastography's technical validity. In multivariate analysis, liver stiffness (OR 0.93; 95%CI 0.91–0.97; p < 0.001), platelet count (OR 1.003; 95%CI 1.000–1.007; p = 0.049) and obesity (OR, 1.81; 95%CI 1.12–2.92; p = 0.015) were independently associated with discordance, while T2D was not (OR 0.94; 95%CI 0.59–1.51; p = 0.811). Discordance was subclassified into overestimation (38.6%) and underestimation (19.5%). Only BMI (OR 1.12; 95%CI1.07–1.16; p < 0.001) and bilirubin (OR 0.33; 95%CI 0.14–0.82; p = 0.016) remained significantly associated with overestimation. In the subgroup analysis, the discordance rate was higher among obese patients (63.1%) compared to diabetic patients (56.4%). BMI was linked to overestimation in both diabetic (OR 1.08; 95%CI 1.02–1.14; p = 0.011) and non-diabetic patients (OR 1.14; 95%CI 1.07–1.22; p < 0.001). Interestingly, higher HbA1c levels were inversely associated with overestimation in diabetic (OR 0.59; 95%CI 0.42–0.82; p = 0.002) and obese patients (OR 0.50; 95%CI 0.30–0.86; p = 0.011), but not in non-obese patients.
Conclusion: BMI ≥35 kg/m² was independently associated with higher discordance, driven by an increased rate of overestimation

regardless of T2D status. HbA1c levels were inversely associated with overestimation in both obese and diabetic patients.

Three proteins in advanced liver fibrosis: a minimalistic shallow-deep neural network approach on metabolic dysfunction–associated steatotic liver disease patients using open data

Eleni-Myrto Trifylli[1], Aleksandra Leszczynska[2], Anastasios Kriebardis[3], Nikolaos Papadopoulos[4], Melanie Deutsch[5], Athanasios Angelakis[6]. *[1]Laboratory of Reliability and Quality Control in Laboratory Hematology (HemQcR), Department of Biomedical Sciences, Section of Medical Laboratories, School of Health & Caring Sciences, University of West Attica, GI-Liver Unit, 2nd Dept of Internal Medicine National and Kapodistrian University of Athens, General Hospital of Athens "Hippocratio", First Department of Internal Medicine, 417 Army Share Fund Hospital, Athens, Greece; [2]Department of Pediatrics at UCSD, San Diego, United States; [3]Laboratory of Reliability and Quality Control in Laboratory Hematology (HemQcR), Department of Biomedical Sciences, Section of Medical Laboratories, School of Health & Caring Sciences, University of West Attica, Athens, Greece; [4]Second Department of Internal Medicine, 401 General Military Hospital, Athens, Greece; [5]GI-Liver Unit, 2nd Dept of Internal Medicine National and Kapodistrian University of Athens, General Hospital of Athens "Hippocratio", Athens, Greece; [6]Amsterdam University Medical Center, Amsterdam Public Health Research Institute, University of Amsterdam, Amsterdam, Netherlands*
Email: a.angelakis@amsterdamumc.nl

Background and aims: Steatotic liver disease affects 20–30% of the global population, representing a growing epidemic among metabolic dysfunction–associated steatotic liver disease (MASLD) patients. Non-invasive diagnosis of advanced liver fibrosis (ALF) (F3, F4) remains challenging due to the limitations of liver biopsy. This study aims to explore the feasibility of achieving robust diagnostic performance with a small dataset and a minimalistic biomarker set, leveraging shallow-deep neural networks (sDNN), inductive learning (IL), and explainable artificial intelligence (XAI).
Method: We used open data from 191 biopsy-validated MASLD patients, processed via SomaScan v.4.0 proteomics, which measured 4,730 proteins. Employing a non-linear feature selection (FS) methodology, integrating IL and feature engineering (FE), we identified three critical proteins. A 3-layres sDNN architecture (23, 23, 7) was trained using 10-fold cross-validation (10CV) for robustness and validated on a test set (train/test~90%/10%). Performance metrics included specificity (Spec), sensitivity (Sens), ROC-AUC, and F1-score.
Results: Three proteins—ADAMTSL2, MFAP4, and GDF2—emerged as the most informative biomarkers for ALF. ADAMTSL2 interacts with ECM proteins; MFAP4 is implicated in fibrogenesis; GDF2 regulates hepatic lipid homeostasis and angiogenesis. Using these proteins, the sDNN achieved exceptional performance: 10CV (Spec: 0.76 ± 0.21, Sens: 0.88 ± 0.14, ROC-AUC: 0.82 ± 0.13, F1: 0.79 ± 0.13) and Test (Spec: 0.91, Sens: 0.75, ROC-AUC: 0.83, F1: 0.80).
Conclusion: This study demonstrates that a minimalist approach using only three proteins and an optimized sDNN architecture can achieve remarkable diagnostic accuracy for ALF in MASLD patients, even with a limited dataset. These findings highlight the transformative potential of data science, XAI and sDNNs in biomedical research and warrant validation on larger cohorts.

WED-369

A shallow-deep neural network approach combining non-invasive tests to enhance advanced fibrosis detection in metabolic dysfunction–associated steatotic liver disease patients

Athanasios Angelakis[1]. *[1]Amsterdam University Medical Center, Amsterdam Public Health Research Institute, University of Amsterdam, Amsterdam, Netherlands*
Email: a.angelakis@amsterdamumc.nl

Background and aims: Advanced fibrosis detection in MASLD patients often relies on non-invasive tests (NITs), such as FIB-4, NFS, APRI, and AST/ALT. Despite their clinical utility, the sensitivity and specificity of individual NITs remain limited. We developed and validated a machine learning-enhanced NIT (MLE-NIT) framework using a deep neural network (DNN) to combine these scores and their underlying features. This study evaluates the performance of MLE-NIT on advanced fibrosis detection compared to standalone NITs in both internal validation and external cohorts.
Method: The training dataset consisted of 540 MASLD patients from a Chinese cohort, and the external validation set comprised 147 patients from a Malaysian cohort. Individual NIT cutoffs were determined for advanced fibrosis: FIB-4 (1.3), NFS (−1.455), APRI (0.64), and AST/ALT (0.87). A three-layer DNN architecture (5, 19, 17 nodes) was trained with a learning rate of 0.01 and 10 iterations. Performance metrics, including specificity, sensitivity, ROC-AUC, and F1-score, were calculated using 10-fold cross-validation (10CV) on the training set and on the external test set.
Results: The MLE-NIT approach significantly outperformed standalone NITs. For 10CV, MLE-NITs achieved an average ROC-AUC of 0.75, specificity of 0.76, and sensitivity of 0.74, compared to 0.70 (FIB-4), 0.70 (NFS), 0.64 (APRI), and 0.54 (AST/ALT) on ROC-AUC. On the external test set, MLE-NIT demonstrated superior generalization, achieving a ROC-AUC of 0.79, specificity of 0.84, and sensitivity of 0.74, whereas standalone NITs exhibited suboptimal results: (FIB-4, NFS, APRI, AST/ALT) = (0.75, 0.77, 0.71, 0.57) on ROC-AUC. These findings highlight the robustness and clinical utility of the MLE-NIT framework across diverse cohorts.
Conclusion: Our MLE-NIT framework provides a scientifically superior approach to advanced fibrosis detection in MASLD patients, leveraging the synergy of multiple NITs and their features. It demonstrates marked improvements in performance metrics over standalone tests in both internal and external validations. This approach underscores the potential of machine learning, and in particular DNNs, to transform fibrosis diagnostics, paving the way for broader implementation in clinical practice.

WED-370-YI

Comparative performance of controlled attenuation parameter and ultrasound-derived fat fraction in detecting hepatic steatosis in MASLD patients

Andrea Falcomata'[1], Francesco Ballesio[2], Paolo Gallo[1], Antonio De Vincentis[3], Francesca Terracciani[1], Valentina Flagiello[1], Giulia Di Pasquale[1], Federica Tavaglione[4], Simone Carotti[5], Daniele Peluso[2], Manuela Helmer-Citterich[2], Antonio Picardi[1], Umberto Vespasiani-Gentilucci[1]. *[1]Research unit of Clinical Medicine and Hepatology, Department of Medicine and Surgery, Università Campus Bio-Medico, Rome, Italy, Operative Unit of Clinical Medicine and Hepatology, Fondazione Policlinico Universitario Campus Bio-Medico, Rome, Italy; [2]Department of Biology, University of Rome, "Tor Vergata," Rome, Italy; [3]Research Unit of Internal Medicine, Department of Medicine and Surgery, Università Campus Bio-Medico, Rome, Italy, Operative Unit of Internal Medicine, Fondazione Policlinico Universitario Campus Bio-Medico, Rome, Italy; [4]Research unit of Clinical Medicine and Hepatology, Department of Medicine and Surgery, Università Campus Bio-Medico di Roma, University of California San Diego, La Jolla, United States; [5]Microscopic and Ultrastructural Anatomy Research Unit, Medicine and Surgery, Università Campus Bio-Medico, Rome, Italy*
Email: a.falcomata@unicampus.it

Background and aims: The amount of hepatic fat is the main determinant of Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD) progression to cirrhosis and hepatocellular carcinoma. For this reason, non-invasive tools capable of accurately determining hepatic fat content are essential. While Controlled

Attenuation Parameter (CAP) obtained using FibroScan® is widely used, Ultrasound-Derived Fat Fraction (UDFF) is emerging as a promising alternative. Here we aimed to evaluate correlation and degree of agreement in the diagnosis of steatosis at least 5% between CAP and UDFF in a large cohort of dysmetabolic subjects. We also assessed their performance against histological findings in a smaller subgroup undergoing liver biopsy.

Method: The All-Liver Interventional Global Network (ALIGN) screening study enrolled at the Fondazione Policlinico Universitario Campus Bio-Medico of Rome (ALIGN-CBM) 837 participants with a history of MASLD and/or diabetes and/or obesity. MASLD was diagnosed by CAP when >248 dB/m, and by UDFF when >5%. Correlation, and agreement between CAP and UDFF for the diagnosis of MASLD were evaluated, along with factors linked to discordance. In a subgroup undergoing liver biopsy (46 patients), CAP and UDFF accuracies for diagnosing MASLD and significant steatosis were compared to the histological gold standard (steatosis of at least 5% and 33%, respectively).

Results: After excluding individuals with other causes of chronic liver disease, missing CAP and UDFF data, or unreliable measurements, 707 cases were analyzed. There was a strong correlation between CAP and UDFF ($r = 0.71$, $p < 0.0001$). For the diagnosis of MASLD, CAP and UDFF were concordant in 583 cases (82%), and discordant in 124 cases (18%). Indeed, MASLD was diagnosed only by UDFF in 73 cases (11%), and only by CAP in 51 cases (7%). HOMA index, glycated hemoglobin, hypertension, ultrasound-measured visceral adipose tissue, and waist circumference were negatively associated with discordance in each of the 2 direction (all $p < 0.05$). In the biopsy subgroup, all cases displayed at least 5% steatosis. At the prespecified cut-offs, UDFF showed 100% sensitivity vs. 93.5% for CAP ($p = 0.3$). The AUC for significant steatosis were 0.815 for CAP and 0.825 for UDFF (Z score = −0.11, $p = 0.91$).

Conclusion: UDFF and CAP are effective non-invasive tools for detecting hepatic steatosis, with comparable diagnostic performance. Metabolic factors are negatively associated with discordance between the two methods, suggesting that, when one of the two tests is negative, the boundary between false positives and false negatives is more borderline. In this context, at the proposed cut-offs, UDFF appears slightly but non-significantly more sensitive, while extending the series with negative cases will allow comparison in terms of specificity. The performance of the two tools for detecting significant steatosis is comparable.

WED-371

ALT is an effective screening tool for advanced MASLD in children with obesity and overweight

Anne-Sophie Stroes[1], Laura Draijer[2], Malika Chegary[3], Felix Kreier[3], Erim van Os[4], Joery Goede[5], Venje Boonstra[6], Ilse Westerbeek[7], Saskia Bouma[8], Meeike Kusters[3], Roosje Roelants[9], Ulrich Beuers[1], A.G. (Onno) Holleboom[1], Marc Benninga[1], Bart Koot[1]. *[1]Amsterdam UMC, Amsterdam, Netherlands; [2]Amsterdam UMC, amsterdam, Netherlands; [3]Onze Lieve Vrouwen Gasthuis, Amsterdam, Netherlands; [4]Rode Kruis Ziekenhuis, Amsterdam, Netherlands; [5]Spaarne Gasthuis, Haarlem, Netherlands; [6]BovenIJ Ziekenhuis, Amsterdam, Netherlands; [7]Amstelland Ziekenhuis, Amsterdam, Netherlands; [8]De Kinderartsenpraktijk, Amsterdam, Netherlands; [9]Flevoziekenhuis, Almere, Netherlands*
Email: a.r.stroes@amsterdamumc.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has a high prevalence among children with obesity. However, screening remains controversial as neither the optimal method nor risks and benefits of screening have not been established. This study aims to evaluate the effectiveness of an Alanine Aminotransferase (ALT)-based screening algorithm for advanced MASLD in children with obesity or overweight.

Method: Children aged 8–18 years with (i) obesity or (ii) overweight and ≥1 additional risk factor seen at obesity outpatient clinics for co-morbidity screening were included. Participants were screened for MASLD using ALT and analysed in four groups based on ALT levels. Vibration-controlled transient elastography (VCTE) was performed to determine probable significant fibrosis (VCTE ≥7.4 kPa). Patients features associated with VCTE ≥7.4 kPa were assessed using logistic regression analysis. The diagnostic accuracy of ALT was compared to other non-invasive tests.

Results: Among 322 children (64% male, median age 13 years, mean BMI z-score 3.5), the prevalence of VCTE ≥7.4 kPa increased significantly with ALT elevation: 1.9% for normal ALT, 16.4% for mild ALT elevation (≥ULN: ♀ 22 IU/L, ♂ 26 IU/L), 21.3% for moderate ALT elevation (≥2 ULN: ♀ 44 IU/L, ♂ 52 IU/L), and 38.9% for strong ALT elevation (≥80 IU/L) ($p < 0.001$). Other non-invasive tests did not perform superiorly in this cohort. VCTE ≥7.4 kPa was positively associated with ALT ≥80 IU/L (OR 2.91, 95%CI: 1.25–6.74), age (OR 1.50, 95%CI 1.27–1.76), male gender (OR 2.37, 95%CI 1.04–5.40), BMI z-score (OR 3.01, 95%CI 1.62–5.61), and HOMA (OR 1.10, 95%CI 1.00–1.13).

Conclusion: This study shows that ALT is an effective primary screening tool for advanced MASLD in children with (i) obesity or (ii) overweight and additional risk factors.

WED-372

Epigenetic biomarkers and methylome-wide association study (MWAS) for non-invasive diagnosis of at-risk MASH from plasma cell-free DNA

Manal F. Abdelmalek[1], Anna Mae Diehl[2], Georgia Karachaliou[2], Brent A. Neuschwander-Tetri[3], Soheil Damangir[4], Hamed Amini[4], Leila Bazargan[4], Rohit Loomba[5]. *[1]Mayo Clinic, Rochester, United States; [2]Duke University, Durham, United States; [3]Saint Louis University, Saint Louis, United States; [4]Hepta Bio, Inc., Foster City, United States; [5]University of California San Diego, San Diego, United States*
Email: soheil@hepta.bio

Background and aims: The emergence of the first treatment for MASH underscores the pressing need for a single, non-invasive rule-in blood test (NIT) capable of identifying treatment candidates at scale. This study aims to assess the diagnostic accuracy of a proprietary AI algorithm applied to whole-methylome sequencing of cell-free DNA (cfDNA) in identifying at-risk MASH among patients with biopsy-proven MASLD.

Method: Cell-free DNA extraction was methylation library preparation was performed on plasma samples obtained from the Duke University Biobank. Deep methylome sequencing was performed using Illumina instruments. This approach allows for interrogation of methylation patterns across hundreds of millions of cfDNA molecules per sample. The dataset was randomly split into training and validation sets with a 2-to-1 ratio. A novel transformer-based neural network, designed to understand the contextual and interactive relationships between cfDNA fragments, was trained to detect at-risk MASH (NAS ≥4 and F2+). Diagnostic performance was calculated and compared to FIB4 and other NITs in literature. Additionally, a methylome-wide association study (MWAS) was conducted to identify relevant genes and pathways.

Results: The study cohort consisted of 217 patients with biopsy-confirmed MASLD and 59 control subjects without histologic MASLD. Among the MASLD participants, fibrosis staging was as follows: F0: 59, F1: 53, F2: 31, F3: 47, F4: 27, with 123 having NAS ≥4. In the validation set, the whole-genome methylation signature panel achieved an AUC of 0.86 [0.77–0.94] and a positive likelihood ratio (PLR) of 10.09 [8.74–13.4], both clinically and statistically significant. This performance significantly exceeded that of FIB4, which demonstrated an AUC of 0.69 [0.58–0.79] and a PLR of 3.25 [2.71–4.06]. Compared to state-of-the-art NITs reported in the literature, the methylation panel demonstrated superior diagnostic performance. Further analysis revealed methylome-wide differences in genes regulating pathways known to drive MASH progression. These findings not only bolster the biological plausibility of the model but

could also offer insights into the underlying mechanisms of the disease.
Conclusion: Whole methylome sequencing coupled with state-of-the-art AI represents a highly accurate and biologically grounded method for the non-invasive diagnosis of at-risk MASH. By delivering a superior PLR, this approach holds significant promise as a reliable single-test solution for identifying individuals with at-risk MASH and guiding treatment decisions.

WED-373
Agreement between hepatic histology and non-invasive methods and their ability to detect MASLD/MASH among morbidly obese patients undergoing bariatric surgery: an egyptian cross-sectional study
Rabab Omar[1], Ahmed Cordie[2,3], Eissa Abdelaal[1], Mohamed Fahmy[4], Dina Helmy[5], Sherif Musa[1], Heba Omar[1], Ahmed Kamel[6], Mawada Hesham[7], Gamal Esmat[1]. *[1]Cairo University Hospitals, Endemic hepatogastroenterology and infectious diseases department, Cairo, Egypt; [2]Cairo University Hospitals, Endemic hepatogastroenterology and infectious diseases department, Cairo University Hospitals HIV Clinic, Cairo, Egypt; [3]The Global NASH/MASH Council, Washington, DC, United States, Washington, United States; [4]Cairo University Hospitals, General and Laparoscopic surgery, Cairo, Egypt; [5]Department of pathology, Faculty of medicine, Cairo University, Cairo, Egypt; [6]Clinical Pharmacy Department, Faculty of Pharmacy, Cairo University, Cairo, Egypt; [7]Newgiza University, Cairo, Egypt*
Email: ahmedcordie@gmail.com

Background and aims: Obesity is a major risk factor for metabolic-associated steatotic liver disease (MASLD) and steatohepatitis (MASH), influencing their progression. This study evaluates the prevalence of MASLD/MASH in morbidly obese patients undergoing bariatric surgery and assesses the predictive accuracy of non-invasive diagnostic methods compared to liver biopsy.
Method: This cross-sectional study was conducted at Cairo University Hospital, Egypt, from March 2023 to September 2024. Morbidly obese patients (BMI ≥40) attending the bariatric clinic were recruited consecutively. Preoperative assessments included clinical and laboratory investigations, as well as non-invasive methods: Controlled Attenuation Parameter (CAP) and transient elastography (TE), alongside fibrosis scores (AST to Platelet Ratio Index [APRI], Fibrosis-4 [FIB-4], NAFLD Fibrosis Score [NFS], and FibroScan-AST [FAST]). Intraoperative liver biopsies were assessed using the NAFLD Activity Score (NAS), with cut-off values of ≥5 and ≤3 to rule in and rule out the diagnosis of MASH, respectively. The degree of macrovascular hepatic steatosis (HS) and hepatic fibrosis by Metavir score were also reported. Statistical analyses included the kappa statistic for agreement, area under the receiver operating curve (AUROC) for diagnostic accuracy, and sensitivity and specificity calculations for proposed cut-off points.
Results: Among 58 patients (89.6% females; mean age 37.98 ± 7.80 years; mean BMI 44.77 ± 4.14 kg/m²), diabetes mellitus and hypertension were reported in 13.79% and 22.41%, respectively. Definite MASH was diagnosed in 34.48%, and HS >33% was observed in 37.9%. Significant fibrosis (SF) ≥F2 was present in 27.59%. CAP demonstrated modest agreement with biopsy for HS ($\kappa = 0.262$, $p < 0.001$), with high concordance for S3 (88.9%) but more overlap for S1 and S2. CAP ≥285 provided better performance in detecting HS > S2 steatosis (AUROC = 0.92; sensitivity 86%; specificity 84%). TE, FIB-4, NFS, and APRI showed poor discrimination for SF ≥F2 (AUROC = 0.52 to 0.58). Fib-4, TE, and APRI exhibit high specificity (95.2–97.6%) but very low sensitivity (0–12.5%). NFS shows better sensitivity (71.4%) but lower specificity (40.5%). The agreement between non-invasive markers and biopsy classifications, measured by Kappa, was minimal (0–0.1). FAST score showed moderate rule-out ability for MASH with SF (AUROC = 0.60, sensitivity 31%, specificity 89%).
Conclusion: Although CAP measurements showed modest agreement with liver biopsy for diagnosing HS in a cohort of morbidly obese Egyptian patients, higher CAP cutoffs are suggested to improve its diagnostic accuracy. TE, FIB-4, NFS, APRI, and FAST scores had limited diagnostic accuracy for differentiating fibrosis stages, indicating further validation and the potential need for integrating hepatic histology assessment in bariatric surgery.

WED-374
Utilizing AI digital pathology for quantitative measurement, grading and differentiation of lobular and portal inflammation in MASH: preliminary analysis in liver histology
Kutbuddin Akbary[1], Yayun Ren[1], Carolin Lackner[2], Daniela Allende[3], Feng Liu[4], David E Kleiner[5], Dean Tai[1]. *[1]HistoIndex Pte Ltd, Singapore, Singapore; [2]Medical University of Graz, Graz, Austria; [3]Cleveland Clinic, Cleveland, Ohio, United States; [4]Peking University Hepatology Institute, Beijing, China; [5]Center for Cancer Research, NCI, Maryland, United States*
Email: akbary.kutbuddin@histoindex.com

Background and aims: Accurate histopathological assessment is pivotal for measuring treatment response in metabolic dysfunction-associated steatohepatitis (MASH). Accurately quantifying lobular and portal inflammation, important in disease progression, is challenging using light microscopy. AI-digital pathology automates and quantifies histological features, enabling standardized, reproducible evaluations. While qFibrosis, qSteatosis, and qBallooning algorithms are validated, qInflammation algorithm (qI) was developed last due to its greater complexity in development and validation.
Method: 269 MASH liver biopsy samples (from Peking University People's Hospital) were scanned by Leica Aperio system and randomly divided into training (n = 180) and validation (n = 89) cohorts. Inflammatory foci (as defined in Brunt et al. Am J Gastroenterol. 1999;94(9):2467–74) were identified by H&E-stained image analysis by qI. Images acquired by separate Hematoxylin & eosin imaging channels were processed to segment nuclei, detect inflammatory cells, and identify foci. Portal tracts were localized by convolutional neural networks, distinguishing portal from lobular inflammation by overlaying inflammation foci. Morphometric features like density, perimeter, and eccentricity informed qI-lobular and qI-portal indices, were built via multiple linear regressions on training cohort and validated on validation cohort. Statistical analysis by Spearman correlation (r-value), inter-rater concordance (weighted Kappa values). Concordance between pathologist and qI was by sensitivity (percentage of pathologist-identified inflammation also identified by qI), Positive predictive value (PPV; percentage of qI-identified inflammation also identified by pathologist).
Results: Histological portal inflammation grades were I0 (14%), I1 (48%), I2 (36%), I3 (2%), while lobular inflammation grades were I0 (2%), I1 (44%), I2 (47%), I3 (7%). qI-based identification had 58% PPV, 83% sensitivity for lobular foci, and 72% PPV, 89% sensitivity for portal inflammation detection. qI-lobular index had $r = 0.556$ ($p < 0.001$), whereas qI-portal index had $r = 0.606$ ($p < 0.001$). Inter-rater Kappa values of qI algorithm with pathologist grading for lobular and portal inflammation were 0.32 and 0.38 respectively, comparable to pathologist based inter-rater Kappa values in literature of 0.33–0.6 for lobular and 0.45 for portal inflammation respectively.
Conclusion: qI provides a promising tool for identifying and quantifying inflammation types in MASH, though further validation is needed on additional cohorts. Improved evaluation of portal and lobular inflammation can enhance screening and stratification in MASH trials and for optimized therapeutic strategies. The development of qI algorithm completes development of the panel of qFIBS algorithm to comprehensively assess and quantify MASH histology.

WED-375

Relevant incidental histologic diagnoses in MASLD patients enrolled in the NASH CRN

Daniela Allende[1], Patricia Belt[2], Laura Wilson[2], Cynthia Behling[3], Ryan Gill[4], Cynthia Guy[5], Danielle Carpenter[6], Oscar Cummings[7], Bryce Hatfield[8], Matthew Yeh[9], David E Kleiner[10]. *[1]Cleveland Clinic, Cleveland, United States; [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, United States; [3]University of California San Diego, San Diego, United States; [4]University of California San Francisco, San Francisco, United States; [5]Duke University, Durham, United States; [6]Saint Louis University, Saint Louis, United States; [7]Indiana University, Indianapolis, United States; [8]Virginia Commonwealth University Health System, Richmond, United States; [9]University of Washington, Seattle, United States; [10]National Cancer Institute, Bethesda, United States*
Email: allendd@ccf.org

Background and aims: Selection of patients with metabolic dysfunction associated steatotic liver disease (MASLD) for clinical trials and for FDA approved therapies requires strict inclusion criteria. The impact of coexistent chronic liver diseases is underrecognized. The aim of the study is to describe incidental histologic diagnoses observed in the NASH CRN cohort and their clinical correlations.
Methods: A total of 3,149 adult biopsies collected from 1988 to 2024 and reviewed in a consensus fashion by expert liver pathologists from the NASH CRN were included. Inclusion criteria for all studies required clinically suspected MASLD and exclusion of other liver diseases. Incidentally found histologic patterns of injury were assessed if present and classified into 5 patterns: cholestatic (bile duct proliferation/injury, cholestasis), hepatitic (chronic and/or acute), vascular, granulomatous and miscellaneous (cytoplasmic changes, inclusions, iron, suspicion of alcohol related injury, hepatocellular necrosis, hepatocellular atypia). A control population of patients with MASLD and no incidental histologic diagnosis was included for comparison (n = 2,727).
Results: There were 422 biopsies with incidental histologic findings: 124 cholestatic, 23 hepatitic, 25 vascular, 55 granulomatous, and 195 miscellaneous. There were no clinically meaningful differences in age, gender, race, BMI, or autoantibody detection (ANA, ASMA, AMA) when comparing study groups to controls. AST was higher in the hepatitic group than controls (67 U/L vs 50 U/L, $p = 0.02$). Alkaline phosphatase (ALK) and bilirubin (BIL) were higher in the cholestatic and vascular groups compared to controls (ALK 103 U/L and 113 U/L, respectively, versus 85 U/L in controls, $p < 0.001$; BIL 0.81 U/L and 0.87 U/L respectively versus 0.68 U/L in controls, $p \leq 0.02$). Most study groups, except granulomatous pattern, had lower NAS associated with lesser degree of steatosis in comparison to controls ($p < 0.001$). All study groups, except vascular injury, demonstrated higher percentages of cases with stage 3 and 4 fibrosis in comparison to controls ($p < 0.001$).
Conclusion: Incidentally found histologic diagnoses in patients with MASLD enrolled in our study was not uncommon despite strict inclusion criteria, representing 13% of cases. The most common patterns of injury are cholestatic and granulomatous injury; hepatitic and vascular injury are less frequent. Importantly, more advanced fibrosis (stage 3–4) was associated with the identification of these patterns in comparison to our control MASLD cases. The study highlights the importance of biopsy assessment in identifying other causes of liver disease, unsuspected by clinical screening, in a population at risk for MASLD.

WED-376

Fibroblast activity assessed by PRO-C3 is prognostic for fibrosis progression in MASH patients treated with insulin sensitizer MSDC-0602 K during a phase IIb clinical trial

Alejandro Mayorca Guiliani[1], Peder Frederiksen[1], Morten Karsdal[1], Jerry Colca[2], Diana Julie Leeming[3]. *[1]Nordic Bioscience A/S, Herlev, Denmark; [2]Cirius Therapeutics, Michigan, United States; [3]Nordic Bioscience A/S, Newcastle Upon Tyne, Denmark*
Email: amg@nordicbio.com

Background and aims: Liver fibrosis is a dynamic process driven by hepatic stellate and other mesenchymal cells forming ECM and disrupting normal organ architecture, while releasing ECM fragments into the bloodstream. These fragments are surrogates of ECM formation that can be leveraged as fibrosis biomarkers. Here, we measured the N-terminal of procollagen type 3 (PRO-C3) during EMMINENCE (ClinicalTrials.gov NCT02784444), a phase IIb clinical trial testing MSDC-0602 K, an insulin sensitizer, in MASH patients. While liver biopsies reveal the cumulative result of fibrosis, ECM biomarkers evaluate disease activity and can be used to prognosticate and monitor drug effectiveness. Here, we show that PRO-C3 discriminated between patients with regressing or progressing fibrosis and detected patients who would respond to treatment. MSDC-0602 K decreased collagen type III synthesis significantly.
Method: 392 MASH patients were randomized to placebo (PL), 62.5 mg, 125 mg or a 250 mg daily dose of MSDC-0602 K for 12 months. 334 completed the study. The primary efficacy endpoint was defined as an improvement of ≥2 points in NAS score, with ≥1 decrease in either ballooning or inflammation and no increase in fibrosis stage. Blood samples were collected at baseline, 6 months, and 12 months to assess PRO-C3.
Results: Treated patients who reached primary endpoint had lower baseline PRO-C3 ($p = 0.026$). PRO-C3 levels discriminated between patients showing regressing, stable or progressing fibrosis according to biopsy scoring ($p = 0.0076$). Patients with baseline F0/F1 fibrosis scores, but high PRO-C3, were likely to progress ($p = <0.0001$), while patients with F3/F4 and low PRO-C3 likely regressed ($p = <0.001$). The 125 mg and 250 mg doses of MSDC-0602 K reduced PRO-C3 at 6 months ($p = 0.0103$ and $p = 0.026$ respectively) and 12 months ($p = 0.0274$ and $p = 0.0311$) compared to placebo.
Conclusion: Lower fibroblast activity (PRO-C3) at baseline was associated with achieving primary endpoint as well as fibrosis regression, while higher baseline PRO-C3 was associated with fibrosis progression. MSDC-0602 K significantly reduced PRO-C3, suggesting an anti-fibrotic effect. PRO-C3 can identify MASH patients who are likely to respond to treatment and prognosticate their evolution.

WED-381

Identifying risk factors for "major liver-related outcomes" in patients with metabolic dysfunction-associated steatotic liver disease

Anastasia Raptis[1], Niharika Jakhar[1], Tobias Seibel[2], Jan Clusmann[3,4], Paul-Henry Koop[1], Ali Canbay[5], Kai Markus Schneider, Carolin V. Schneider. *[1]Department of Medicine III, University Hospital RWTH Aachen, Aachen, Germany; [2]UKAachen, Department of Gastroenterology, Aachen, Germany; [3]Department of Medicine III, University Hospital RWTH Aachen, Aachen, Germany; [4]Else Kröner Fresenius Center for Digital Health, Technical University Dresden, Dresden, Germany; [5]University Hospital of the Ruhr-University Bochum, Bochum, Germany*
Email: anastasia.raptis@gmx.de

Background and aims: Metabolic Dysfunction-Associated Liver Disease (MASLD) affects approximately 30% of the general population. It is characterized by fat accumulation in the liver and cardiometabolic risk factors. Understanding which subgroups of MASLD patients are at risk of major adverse liver outcomes (MALO) is crucial for developing personalized preventive strategies and treatments.
Method: 9,692 participants of the UK biobank cohort with available abdominal MRI and a proton density fat fraction (PDFF) of at least 5% were analyzed regarding their biochemical, genetic and lifestyle risk factors for MALO (n = 26). Proteomics analyses were available for 1237 participants in the cohort. To reduce the imbalance, propensity score matching was implemented in a 1:10 ratio, corrected for sex, age and BMI.

Results: The strongest predictors for MALO were elevated alkaline phosphatase (OR = 5.54 [2.35, 12.2]), elevated aspartate aminotransferase (OR = 2.05 [0.87, 4.49]) and gamma-glutamyl transferase (OR = 4.11 [1.89, 9.39], all p < 0.05). Insulin-like growth factor 1 was significantly lower in the participants with MALO (15.7 nmol/L [12.0, 20.7] vs. 20.6 nmol/L [16.3, 23.9], p = 0.008,). Arterial hypertension and type 2 diabetes were more common in the MALO group (OR = 4.88 [2.19, 11.9], p = 0.003, OR = 4.29 [1.81, 9.55], p = 0.047). History of risky alcohol consumption increased chances of MALO (OR = 13.1 [3.8, 34.9], p < 0.001). Transmembrane 6 superfamily member 2 (TM6SF2) polymorphism rs58542926 was associated with MALO (OR = 6.9 [1.07, 44.38], p = 0.042), while patatin-like phospholipase domain containing 3 (PNPLA3) I148M was not. Our proteomics analysis demonstrates a link between inflammation and cardiovascular disease and MALO risk.
Conclusion: We show that biomarkers might be a valuable contribution to the clinically challenging process of identifying patients at risk of MALO. Furthermore, lifestyle interventions are likely useful even in late disease stages, as common metabolic comorbidities heavily impact the disease course. Previous alcohol consumption affects MALO occurrence, even after years of abstinence. Genetic testing for common polymorphisms connected to liver disease could be evaluated in MASLD patients. These risk factors might identify a group of MASLD patients that could benefit from more detailed and frequent surveillance

WED-382-YI
Thrombospondin-2, a direct serum marker of fibrogenesis, to assess treatment response in MASLD in a 6-month lifestyle intervention program

Angelo Armandi[1], Rambabu Surabattula[2], Chiara Rosso[1], Gian Paolo Caviglia[1], Marta Guariglia[1], Eleonora Dileo[1], Simona Bo[3], Sudha Myneni[2], Detlef Schuppan[2,4], Elisabetta Bugianesi[1]. *[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy; [2]University Medical Center, Institute of Translational Immunology and Research Center for Immunotherapy, Johannes Gutenberg-University, Mainz, Germany; [3]Section of Dietetic and Clinical Nutrition, Department of Medical Sciences, University of Turin, Turin, Italy; [4]Beth Israel Deaconess Medical Center, Division of Gastroenterology, Harvard Medical School, Boston, United States*
Email: angelo.armandi@unito.it

Background and aims: Lifestyle intervention aiming at weight loss (WL) is the cornerstone of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) management. However, the non-invasive assessment of treatment response is not yet established. A novel fibrogenesis marker Thrombospondin-2 (TSP2) showed high accuracy to detect advanced fibrosis in cross-sectional multicentric cohorts of biopsied MASLD. Here, TSP2 was tested to assess antifibrotic treatment response in an intensive lifestyle intervention program.
Method: A 6-month lifestyle intervention program in 94 patients including guideline-based recommendations for a healthy diet and physical activity aiming at WL. Inclusion criteria: MASLD according to guidelines, Body Mass Index (BMI) between 25 and 35 kg/m^2, age<65 years. Exclusion criteria: HbA1c > 9.5%, insulin-dependent type 2 diabetes (T2D) or use of glucagon-like peptide 1 receptor agonists. Endpoints were 7% WL and improvement in HOMA index. Clinical and biochemical parameters were assessed at baseline and end of treatment. Serum T2 was measured through in-house optimized and standardized ELISA assay (Mainz), and compared to FIB-4 and liver stiffness measurement by vibration-controlled transient elastography (VCTE).
Results: Median age was 50.5 [IQR 43.0–61.0] years (71.3% male). Median BMI was 30.8 [28.8–34.2] kg/m^2 (17% with T2D). Overall, 17.0% of patients achieved 7–10% WL, and 11.7% achieved >10% WL. Median baseline TSP2 values were 58.3 [IQR 44.2–73.9] ng/ml and were similarly distributed between those who achieved <7% WL, 7–10% WL and >10% WL (p = 0.177). Median FIB-4 and VCTE values were 0.91 [0.71–1.29] and 5.2 [4.5–6.1] kPa, similarly distributed in the 3 groups. TSP2 levels significantly decreased after 6 months in patients achieving >10% WL: from median 53.8 ng/ml to 44.6 ng/ml (p = 0.009), which was higher than changes observed in <7% WL and 7–10% WL (inter-arm p = 0.034). Delta TSP2 values showed a stepwise increase across the 3 groups: from median 0.0 [−10.3 to 7.5] ng/ml in <7% WL to median −5.2 [−13.1–0.74]ng/ml in 7–10% WL to median −9.7 [−24.0 to −3.3] ng/ml in >10% WL (p = 0.029). In patients with baseline HOMA>2.7 (n = 29), delta TSP2 values were higher in those achieving HOMA normalization (−10.3 ng/ml, p = 0.023). FIB-4 and VCTE did not show clinically significant trends with regard to both endpoints. Delta TSP2 values were independently associated with at least 7% WL (aOR 0.96 [95%CI 0.92–0.99], p = 0.02) adjusted by age, sex, T2D and BMI. In patients achieving at least 7% WL, delta TSP2 were similarly distributed across ages (< or ≥50 years) (p = 0.757), sex (p = 0.683), BMI (< or ≥30 kg/m^2) (0.558) and across PNPLA3 genotypes (CC, CG, GG) (p = 0.973 l).
Conclusion: TSP2 levels fell significantly in MASLD patients in correlation to WL achieved through lifestyle intervention, and may be a useful tool to assess attenuation of hepatic fibrogenesis.

WED-383
Change in cT1 following interventions in metabolic dysfunction-associated steatotic liver disease: a systematic review and meta-analysis

Anneli Andersson[1], Rohit Loomba[2], Cayden Beyer[1], Sofia Mouchti[1], Raj Vuppalanchi[3], Mukesh Harisinghani[4], Saima Ajaz[5], Amreen Dinani[6], Amitava Banerjee[7], Mark Muthiah[8], Andrea Dennis[1], Michele Pansini[9,10]. *[1]Perspectum Ltd, Oxford, United Kingdom; [2]MASLD Research Center, University of California at San Diego, La Jolla, CA, United States; [3]Division of Gastroenterology and Hepatology, Indiana University School of Medicine, Indianapolis, IN, United States; [4]Massachusetts General Hospital, Boston, MA, United States; [5]Institute of liver studies, Kings College Hospital, London, United Kingdom; [6]Division of Gastroenterology and Hepatology, Duke University Health System, Durham, NC, United States; [7]Institute of Health Informatics, University College London, Department of Cardiology, University College London Hospitals NHS Foundation Trust, Department of Cardiology, Barts Health NHS Trust, London, United Kingdom; [8]Division of Gastroenterology and Hepatology, National University Health System, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore; [9]Clinica Di Radiologia EOC, Istituto Di Imaging Della Svizzera Italiana (IIMSI), Lugano, Switzerland; [10]Department of Radiology, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom*
Email: anneli.andersson@perspectum.com

Background and aims: Liver corrected T1 (cT1), measured with multiparametric magnetic resonance imaging (MRI), offers an alternative to liver biopsy to monitor treatment response and liver disease activity. However, a systematic evaluation of change in cT1 following a treatment intervention in adults with metabolic dysfunction-associated steatotic liver disease (MASLD) has not yet been performed.
Method: We searched the Cochrane Library, PubMed Central, and MEDLINE from 2014 to September 2024 for studies that examined cT1 responses following intervention in adults with MASLD. Two authors independently screened records, assessed risk of bias and extracted data. Meta-analyses were performed to explore the mean change in cT1 between baseline and end of study and the cT1 response rate (≥80 ms reduction).
Results: A total of 16 studies comprising 1134 individuals with MASLD were analysed (13 randomized controlled trials (n = 1077 individuals) and three prospective diet, lifestyle and bariatric surgery studies (n = 57)). Across all interventions, mean change in cT1 was −57 ms [95% CI: −62, −52] over a median 17 weeks (IQR: 12–24) treatment course. By treatment type, fibroblast growth factor (FGF) analogues (aldafermin; pegozafermin), glucagon-like peptide (GLP)-

1 receptor agonists (pemvidutide; tirzepatide) and farnesoid X receptor (FXR) agonists (vonafexor; ocaliva; TERN-101), cT1 had a mean change of −79 ms [95% CI: −90, −68], −8 ms [95% CI: −77, −58] and −62 ms [95% CI: −74, −49], respectively. In contrast, the placebo arms showed a mean change in cT1 of 0 ms [95% CI: −8, 8]. The proportion of responders on cT1 was 29% (95% CI: 25, 34) and 8% (95% CI: 3, 14) in the treatment and placebo group, respectively.
Conclusion: Evidence to-date supports a significant treatment-induced reduction in cT1 as compared to minimal changes in the placebo group. Our findings could inform current and future study designs for investigational therapies for liver disease and support monitoring of treatment response in individuals with MASLD in clinical trials and clinical practice.

WED-384
Non-invasive identification of MASLD patients eligible for resmetirom treatment – data from a multicenter biopsy-proven MASLD cohort
Katharina John[1], Martin Franck[1], Monika Rau[2], Andreas Geier[2], Jan-Peter Sowa[3], Jörn M. Schattenberg[4,5], Münevver Demir[6,7], Heiner Wedemeyer[1], Klaus Schulze-Osthoff[8], Heike Bantel[1].

Email: john.katharina@mh-hannover.de

Background and aims: The liver-directed thyroid hormone receptor (THR)-β agonist resmetirom has shown promising results in resolving metabolic dysfunction-associated steatohepatitis (MASH) and reversing fibrosis. Based on phase-3 trial data, the Food and Drug Administration (FDA) granted the conditional approval of resmetirom for treatment of MASH with moderate to advanced (F2/F3) fibrosis. An expert panel recently recommended vibration-controlled transient elastography (VCTE) with values between 10 and 19.9 kPa to identify patients with F2/F3 fibrosis who can benefit from resmetirom treatment, provided the absence of cirrhosis features (Noureddin M et al., Clin Gastroenterol Hepatol 2024).
Method: In a real-world multicenter study, we followed the recently provided guidance and evaluated the utility of VCTE as a recommended non-invasive tool for identifying patients with resmetirom indication. VCTE was performed in 291 primary biopsy-proven MASLD patients, who were not pre-selected for pharmacotherapy trials.
Results: We show that VCTE values <10 kPa were mainly associated with no or low fibrosis, while VCTE values ≥20 kPa primarily indicated advanced fibrosis or cirrhosis. Among MASLD patients with VCTE values of 10–19.9 kPa, a substantial subset did not meet the label criteria for resmetirom treatment, despite lacking features of cirrhosis such as thrombocytopenia/portal hypertension. Narrowing the range to 10–15 kPa reduced the off-label classification of the MASLD patients for resmetirom treatment but remained suboptimal.
Conclusion: The recommended VCTE cut-offs effectively excluded most MASLD patients with F0/F1 fibrosis from resmetirom treatment. However, in patients with VCTE values of 10–19.9 kPa and no features of cirrhosis, additional diagnostic tools, including liver biopsy or other non-invasive assessments, may be needed to minimize misclassification and optimize the identification of eligible patients.

WED-385
Prevalence and risk factors of steatotic liver disease in primary care in Slovakia
Beata Shiratori[1], Marek Rac[1], Tomas Koller[2], Maria Szantova[3], Sylvia Drazilova[4], Daniel Jan Havaj[5], Lubomir Skladany[5]. *[1]FN Nitra, Department of Internal Medicine, Nitra, Slovakia; [2]5th Department of Internal Medicine, Comenius University in Bratislava, Bratislava, Slovakia; [3]3rd Department of Medicine, Medical Faculty of Comenius University, Bratislava, Slovakia; [4]Pavol Jozef Šafárik University in Košice Faculty of Medicine, 2nd Department of Internal Medicine, Košice, Slovakia; [5]F.D. Roosevelt Teaching Hospital with Policlinic Banska Bystrica, Banska Bystrica, Slovakia*
Email: beatashiratori1@gmail.com

Background and aims: In recent years, steatotic liver disease has attained epidemic proportions. Screening, prevention and education of individuals with potential diseases in their initial forms, early detection and treatment is an important task of primary care.
The goal of the work was to investigate the prevalence and risk factors of steatotic liver disease in Slovakia. We aimed to raise awareness of liver health in primary care practitioners and patients and to emphasize the importance of performing non-invasive tests to assess the degree of liver steatosis and fibrosis.
Method: We retrospectively analysed the occurrence of steatotic liver disease in patients whose data were entered to free accessible online questionnaire www.hepkalkulacka.sk during their visit at primary care practitioner. We evaluated gender, age, BMI, occurrence of hyperglycemia or diabetes, hypertension, alcohol consumption, and lipid profile in 774 patients. We also retrospectively analysed the occurrence of steatotic liver disease in Slovakia regions based on BMI, FLI, APRI, NSF and FIB-4 indices.
Results: The participation of primary care practitioners in the project was 17%. We found differences in BMI and indices of steatosis and liver fibrosis among Slovakia regions, with alarming results exceeding the world average. Fasting hyperglycemia and/or diabetes were associated with the risk of developing hepatic steatosis, higher BMI and FLI values, but not with liver fibrosis predictors NFS, APRI and FIB-4. The risk of steatosis and liver fibrosis were higher in people consuming more alcohol.
Conclusion: We conclude that effective primary care screening of steatotic liver disease based on predictive indices is essential strategy to reduce advanced forms of steatotic liver disease and complications. We expect that this work will promote proper education, management and treatment of the affected patients.

WED-386
Alpha-1 antitrypsin Pi*MZ variant and risk of disease progression in MASLD and MASH
Bradley Jermy[1], Jack Brownrigg[2], Pavel Strnad[3], Rohit Loomba[4].
[1]BioMarin UK, London, United Kingdom; [2]BioMarin UK Ltd., London, United Kingdom; [3]Medical Clinic III, Gastroenterology, Metabolic Diseases and Intensive Care, University Hospital RWTH Aachen, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN RARE LIVER), Aachen, Germany; [4]Division of Gastroenterology, MASLD Research Center, University of California at San Diego, San Diego, United States
Email: jack.brownrigg@bmrn.com

Background and aims: Most investigational treatments for metabolic dysfunction-associated steatohepatitis (MASH) have shown modest anti-fibrotic effects. This is likely due to multifactorial etiology including genetics that impede a one-size-fits-all strategy. Among the genetic factors, the Pi*Z mutation in *SERPINA1* leads to proteotoxic liver injury, with homozygosity conferring a strong susceptibility to cirrhosis. The aim of this study was to investigate whether carriage of a *SERPINA1* Z mutation is associated with disease progression in MASH.
Method: A population of metabolic dysfunction-associated steatotic liver disease (MASLD) patients of European ancestry were identified

in UK BioBank using ICD-10 codes (N = 7339). To avoid misclassification bias, participants with alternative aetiologies of chronic liver disease diagnosed before or concurrently with MASLD were excluded (n = 1020), leaving 6319 participants for analysis. We used logistic and Cox models to estimate risk ratios for advanced liver disease as the primary outcome (composite of incident cirrhosis, hepatic decompensation and liver-related death or transplant) associated with the MZ genotype. The strength of association was compared with metabolic risk factors (obesity, dyslipidemia, hypertension and type 2 diabetes) and established genetic risk factors (PNPLA3, HSD17B13).
Results: During 38,422 person-years of follow-up, 499 of 6319 individuals experienced a primary outcome of advanced liver disease. The prevalence of the MZ genotype was 3.9% among individuals who did not experience the primary outcome and 7.6% among those who did. Event rates for the primary outcome among MM and MZ individuals with MASLD/ MASH were 12.8 and 22.1 per 1000 person-years, respectively. After adjustment for established metabolic and genetic risk factors, a significant association was observed for the primary outcome with the MZ genotype (adjusted OR 1.98, 95% CI 1.36–2.87). Genetic variants in PNPLA3 (I148M), type 2 diabetes, and presence of ≥2 metabolic risk factors all increased risk, whereas a common variant in HSD17B13 (rs9992651) was protective. The MZ genotype (unadjusted OR 1.90, 1.33–2.73) was a risk equivalent to ≥2 metabolic risk factors (uOR 1.75, 1.45–2.10) and PNPLA3 (uOR 1.32, 1.15–1.51).
Conclusion: Carriage of the Pi*Z mutation significantly affects the risk of future clinical outcomes among individuals with MASLD/ MASH. The MZ genotype confers a risk equivalent to established risk factors in MASLD/ MASH, underscoring the importance of screening and further work to understand the mechanisms behind this association.

WED-387
Improved reader alignment in metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis with the use of a study reading plan

Dylan Windell[1], Tom Davis[1], Paul Aljabar[1], Kenneth Fleming[2], Eve Fryer[3], Tim Kendall[4], Robert D. Goldin[5], Sarah Larkin[1], Phil Wakefield[1], Caitlin Langford[1]. *[1]Perspectum Ltd, Oxford, United Kingdom; [2]Green Templeton College, University of Oxford, Oxford, United Kingdom; [3]Department of Cellular Pathology, John Radcliffe Hospital, Oxford, United Kingdom; [4]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [5]Section for Pathology, Imperial College London, London, United Kingdom*
Email: dylan.windell@perspectum.com

Background and aims: Clinical trials use multiple expert pathologist readers in two formats; 1) to produce consensus scorings or 2) in a 2 +1 adjudicated format, where one pathologist acts as a tie-breaker in case of disagreement. While liver pathology is the gold-standard in Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD)/ Metabolic Dysfunction-associated Steatohepatitis (MASH) diagnosis, the levels of agreement between pathologists can be low, particularly with inflammation and ballooning scores. Our aim was to measure whether a study reading plan, which was curated over multiple alignment meetings with expert pathologists, increased agreement. The reading plan used the RAND/UCLA scoring criteria for MASLD/ MASH which included: NASH CRN fibrosis staging, NAS Steatosis grading, NAS expanded ballooned hepatocyte grading, Goodman portal inflammation, Goodman Mallory-Denk bodies grade and an alternate lobular inflammation grade. To determine fibrosis quality in advanced cases, the Beijing Classification of Regressive, Indeterminate and Progressive (P-I-R) fibrosis was scored.
Method: A prior scoring round which consisted of three pathologists scoring 35 slides using the NASH CRN scoring system was included as a baseline (R0). The initial round of scores (R1) involved four expert pathologists scoring 60 MASLD/MASH liver biopsies from 2 clinical cohorts using the RAND/UCLA and P-I-R scoring systems. This was performed 'blind' with no reading plan or alignment meetings between the pathologists. The second round (R2) was performed on the same slides and with the same pathologists after 4 alignment meetings and a finalized reading plan. In between each round there was a wash-out period of >4 weeks. Cohen's Kappa between each pathologist was calculated for all rounds.
Results: There was a moderate agreement with the RAND/UCLA scoring baseline and improved scores with the reading plan. The final Kappa scores for the metrics scored from each round (R0-R1-R2) showed a general increase in consensus, notable with lobular inflammation (0.17 kappa increase) and P-I-R scores (0.27 kappa increase): NAS Steatosis; 0.56-0.65-0.58, Expanded hepatocyte ballooning; 0.47–0.55–0.65, alternate lobular inflammatory score; 0.30–0.35–0.52, Goodman portal inflammation; 0.48–0.58–0.50, NASH CRN Fibrosis stage; 0.33–0.50–0.57. Not scored with original NAS criteria were Goodman Mallory Denk bodies grade; which showed a 0.05 kappa increase from 0.43–0.48 between R1–R2 and P-I-R fibrosis quality which increased by a substantial 0.27 kappa from 0.53–0.80 between R1–R2.
Conclusion: Our findings show that a reading plan improved inter-rater reliability across most metrics, particularly those with low baseline agreement. The introduction of a more detailed and granular scoring system early in a clinical trial setting will not only align pathologists with study-specific scoring criteria but assist in reducing inter-rater disagreement, which can heavily impact the outcome of phase 2b/3 trials.

WED-388
Artificial intelligence measurement of portal tracts enables quantification of portal, lobular and interface inflammation in metabolic dysfunction-associated steatotic liver disease, metabolic dysfunction-associated steatohepatitis and autoimmune hepatitis

Dylan Windell[1], Alastair Magness[1], Paul Aljabar[1], Kenneth Fleming[2], Eve Fryer[3], Tim Kendall[4], Robert D. Goldin[5], Phil Wakefield[1], Caitlin Langford[1]. *[1]Perspectum Ltd, Oxford, United Kingdom; [2]Green Templeton College, University of Oxford, Oxford, United Kingdom; [3]Department of Cellular Pathology, John Radcliffe Hospital, Oxford, United Kingdom; [4]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [5]Section for Pathology, Imperial College London, London, United Kingdom*
Email: dylan.windell@perspectum.com

Background and aims: A fundamental aspect of any pathological assessment of liver biopsies is the identification of Portal Tracts (PTs) as it allows assessment of biopsy adequacy (>6 PTs are required) and as differentiation of liver diseases often depending on recognising the differing anatomical distribution of abnormalities (e.g. portal, interface and lobular inflammation). We have developed a PT detection model showing good correlation with expert pathologists, which allows for the segmentation of individual PTs and accurate quantification and differentiation between lobular inflammation, portal inflammation, and interface hepatitis.
Method: Our AI model segmented core features of liver tissue (foreground, bile duct, hepatic artery, portal vein, and connective tissue) and performs geospatial processing to identify PTs and lobular regions based on the portal triad elements present in a region of connective tissue. PT segmentations were then paired with segmentations of inflammatory cells to measure portal and lobular inflammation. Concentric radial zones of ~100 microns thickness around PTs were identified to generate metrics across interface and periportal regions. The model was applied to Haematoxylin and Eosin stained Whole Slide Images (WSIs) from 3 Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD)/Metabolic Dysfunction-associated Steatohepatitis (MASH) datasets [N = 606] and 1 pediatric Autoimmune Hepatitis (AIH) study [N = 70]. Inflammation was measured as the percentage of inflammatory cells in proportion to total tissue area (Inflammatory Burden - IB) and the inflammatory

cell number (ICN). Comparisons were evaluated using Mann-Whitney and Kruskal-Wallis tests and correlations with inflammatory scores using Spearman's rho.
Results: Our system was able to accurately delineate and identify interface, portal and lobular regions across WSIs. Overall, when comparing across lobular and portal inflammation scores, the IB and ICN were significantly higher in AIH patients than MASLD/MASH patients, especially in zone 1 regions (closest to the PT) consistent with interface hepatitis (Median: 343 in AIH vs 109 in MASLD; $p < 0.001$). AIH also displayed significant ($p < 0.001$) ICN increases in portal (Median: 4332 vs 1579) and lobular regions (Median: 1707 vs 460) compared to MASLD/MASH. In addition, IB correlated with expert pathologist scorings for lobular ($r = 0.42$) and portal inflammation ($r = 0.64$). Patients matched for portal inflammation and fibrosis histology scores indicated significantly higher IB ($p < 0.001$) in AIH (5.29%) vs MASLD/MASH (1.53%).
Conclusion: PT characterisation is fundamental for establishing histological scoring and sample adequacy of liver biopsies. Our AI model for PT identification generates detailed segmented overlays to assist in pathological review and clinical trial pathology, as well as revealing a higher degree of granularity in the level of inflammation across WSIs.

WED-389
Cost-effectiveness of hepatic fibrosis screening in suspected MASLD cases in primary care settings
Hyo Young Lee[1], Eileen Yoon[2], Jihyun An[2], Ha Il Kim[2], Joo Hyun Sohn[3], Chul-min Lee[3], Mimi Kim[3], Bo-Kyeong Kang[3], Eun Chul Jang[4], Huiyul Park[5], Hye-Lin Kim[6], Sang Bong Ahn[7], Joo Hyun Oh[7], Hyunwoo Oh[8], Dae Won Jun[1]. *[1]Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [2]Hanyang University College of Medicine, seoul, Korea, Rep. of South; [3]Hanyang University College of Medicine, seoul, Korea, Rep. of South; [4]Soonchunhyang University College of Medicine, Seoul, Korea, Rep. of South; [5]Myoungji Hospital, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [6]Sahmyook University, Seoul, Korea, Rep. of South; [7]Nowon Eulji Medical Center, Eulji University, seoul, Korea, Rep. of South; [8]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South*
Email: catchhyong@gmail.com

Background and aims: In clinical practice, only a limited number of patients with metabolic dysfunction-associated steatotic liver disease (MASLD) undergo ultrasonographic examinations. Therefore, practice guidelines recommend screening for hepatic fibrosis even in suspected MASLD cases. This study aimed to analyze the cost-effectiveness of screening for hepatic fibrosis in suspected MASLD cases using serological noninvasive tests (NITs).
Method: Individuals with suspected MASLD were defined as those meeting criteria based on serological NITs, such as a fatty liver index (FLI) or a hepatic steatosis index (HSI). A combined decision tree and Markov model approach was employed from a healthcare perspective to estimate life-years, quality-adjusted life-years (QALYs), costs, and the incremental cost-effectiveness ratio (ICER) between the screening and no-screening groups in the United States.
Results: Advanced hepatic fibrosis prevalence in individuals with suspected MASLD using the FLI was significantly higher at 10.6% than at 1.3% in those without MASLD ($P < 0.001$). Regarding HSI, the prevalence was 8.6% versus 2.2% in non-MASLD cases ($P < 0.001$). Screening (base case) for suspected MASLD defined by FLI had an ICER of $69,192 per QALY and by HSI, $74,729 per QALY, both of which were considered cost-effective based on the implicit ICER threshold of $100,000/QALY in the United States. However, screening for other subgroups without evidence of MASLD was not deemed cost-effective. When applying medical costs and fibrosis distribution data from Korea, similar results were also observed.
Conclusion: Implementing a two-step screening algorithm for advanced hepatic fibrosis in patients with suspected MASLD based on HSI or FLI calculation is cost-effective in primary care settings.

WED-391
LiverPRO to diagnose and monitor liver fibrosis in patients with MASLD and obesity
Charlotte Wernberg[1], Peter Andersen[2], Katrine Lindvig, Lea Ladegaard Grønkjær[1], Camilla Dalby Hansen[2], Johanne Kragh Hansen[2,3], Nikolaj Torp, Andreas Sand[4], Søren Overgaard[4], Mads Israelsen[3,5], Aleksander Krag, Maja Thiele, Mette Lauridsen[1]. *[1]University of Southern Denmark, Department of Gastroenterology and Hepatology, Institution of Regional Health research, Liver research group, Esbjerg, Denmark; [2]Odense University Hospital, Department of Gastroenterology and Hepatology, Center for Liver Research, Odense, Denmark; [3]University of Southern Denmark, Institute of Clinical Research, Odense, Denmark; [4]Evido Health, Copenhagen, Denmark; [5]Odense University Hospital, Department of Gastroenterology and Hepatology, Odense, Denmark*
Email: katrine.prier.lindvig@rsyd.dk

Background and aims: Obesity is linked to liver fibrosis and progression in metabolic dysfunction-associated steatotic liver disease (MASLD). While weight loss improves metabolic health and reduces inflammation, monitoring fibrosis progression in individuals with obesity remains difficult due to the limited availability of reliable non-invasive biomarkers. This study aimed to validate LiverPRO in patients with obesity, evaluating its diagnostic performance for liver fibrosis and its ability to track changes in fibrosis and weight over time.
Method: This analysis used data from a case-control study of matched patients with obesity, either undergoing bariatric surgery or receiving standard of care, based on clinical decision-making and patient preferences. Patients were followed for 2.5 years, with liver biopsies performed prior to the bariatric surgery, and at the end of study. This analysis evaluated LiverPRO's diagnostic accuracy in detecting liver fibrosis and its ability to monitor changes in fibrosis and weight over time. We used Spearman's correlation coefficient due to the ordinal and non-parametric nature of Kleiner fibrosis score.
Results: The study included 266 participants with a mean age of 45 years (IQR 36–54), of whom 71% (n = 189) were female. The mean BMI was 43 kg/m² at baseline, and 38 kg/m² at the study's conclusion (follow-up in 103 patients). At inclusion, 29% of participants had fibrosis stage F2, 7% had F3 fibrosis, and 1% had cirrhosis. LiverPRO's diagnostic accuracy (ROC AUC) for advanced fibrosis (≥F3) was 0.78 (95% CI: 0.67–0.87), with a sensitivity of 0.74 (95% CI: 0.52–0.92) using a rule out cut off of 5%, and a specificity of 0.88 (95% CI: 0.84–0.92) using a rule in cut off of 15%. During follow up a total of 15 patients improved in fibrosis, 62 were stable, and 26 showed progression in fibrosis stage. No patients changed more than one fibrosis stage. LiverPRO scores correlated significantly with fibrosis progression (Spearman's $\rho > 0.33$, $p < 0.01$) and varied across fibrosis trajectory categories (improving, stable, or progression; Kruskal-Wallis $H = 11.38$, $p < 0.01$). Dunn's post-hoc test further demonstrated LiverPRO's ability to detect fibrosis progression, with significant differences between progression and both improvement ($p < 0.01$) and stable categories ($p < 0.03$). Participants were further categorized by weight change: improvement (≤−10 kg), stable and progression (≥+10 kg). While LiverPRO scores correlated modestly with weight changes (Spearman's $\rho = 0.245$, $p = 0.01$) and differed across weight-change groups (Kruskal-Wallis $H = 6.84$, $p = 0.03$), pairwise comparisons between groups (e.g., decreasers vs. increasers, $p = 0.112$) were not statistically significant.
Conclusion: LiverPRO shows robust diagnostic accuracy for advanced fibrosis in individuals with obesity and potential for monitoring fibrosis progression and weight-related changes over time.

Email: christian.a.sebesta@meduniwien.ac.at

Background and aims: Spleen stiffness (SSM) and liver stiffness measurements (LSM) are widely recognized as non-invasive markers of portal hypertension (PH), both showing a strong correlation with the hepatic venous pressure gradient (HVPG). In contrast to HVPG and LSM, SSM may offer an advantage in identifying presinusoidal contributions to PH. This study explored the SSM-to-LSM ratio and its relationship with HVPG, as well as other PH surrogates — including spleen size, platelet count (PLT), and von Willebrand factor (VWF)— across diverse liver disease etiologies.
Method: A total of 314 patients with compensated liver disease were prospectively enrolled for the study. All participants underwent HVPG measurement concurrent with LSM and SSM using SuperSonic-Imagine technology. Demographic, clinical, and laboratory data were recorded.
Results: Patients with alcohol-related liver disease (ALD; n = 162) exhibited higher median LSM (45.9 kPa) and HVPG (16.0 mmHg) compared to those with metabolic dysfunction-associated steatotic liver disease (MASLD; n = 28; LSM: 19.4 kPa; HVPG: 10.0 mmHg). However, SSM values were comparable between the two groups (median: 58.6 kPa vs. 52.0 kPa; p = 0.213). This resulted in a higher SSM/LSM ratio in MASLD (2.42) than in ALD (1.30), with the highest ratio observed in patients with porto-sinusoidal vascular liver disorder (3.45). VWF levels and spleen size were significantly higher in MASLD compared to ALD patients, even after adjusting for HVPG. Notably, stratification of patients across all etiologies by SSM/LSM ratio tertiles revealed no significant correlations with these PH surrogates.
Conclusion: Our study highlights distinct SSM/LSM ratio patterns across different liver disease etiologies. After controlling for liver disease severity, MASLD patients exhibited higher SSM/LSM ratios and more pronounced PH surrogates compared to ALD patients. These findings support the hypothesis of a presinusoidal component contributing to PH in MASLD.

WED-397

Nuclear magnetic resonance metabolomics for non-invasive MASLD phenotyping

Vlad Ratziu[1], Anja Svenson[2], Jan-Peter Sowa[3], Eric Schiffer[2], John Venz[2], Eric Schiffer[2], Christian Karger[2], Tiziana Errera[2], Ali Canbay[3], Bárbara Luna[4], Luis Téllez[4], Jesus Donate[4], Sonia Camano[4], Andreas Geier[5]. *[1]Inserm, Paris, France; [2]Numares AG, Regensburg, Germany; [3]Ruhr-Universität Bochrum, Bochrum, Germany; [4]Biobanco Hospital Universitario Ramón y Cajal, Madrid, Spain; [5]Universitätsklinikum Würzburg, Würzburg, Germany*
Email: andrew.robertson@numares.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) represents a significant health challenge and is both likely underdiagnosed yet rising in incidence globally. Early diagnosis and treatment are paramount to prevent illness progression and late-stage conditions, such as cirrhosis. However, current diagnostic approaches often lack adequate accuracy required for effective disease staging, and biopsies are invasive and costly. Given the central role of the liver in metabolic processes, we hypothesized that circulating metabolites could serve as biomarkers to differentiate clinically relevant MASLD disease stages. Specifically, we aimed to identify metabolomic constellations capable of identifying NAFLD Activity Score ≥4 (NAS 0–3 vs. NAS 4–8) and excluding advanced fibrosis (Fibrosis Stage F0-2 vs. F3-4) on a nuclear magnetic-resonance (NMR) platform.
Method: Using NMR spectroscopy in a retrospective multicenter European study, we analyzed blood samples from 281 biopsy-confirmed MASLD patients spanning various disease stages. NMR biomarker discovery was performed in all serum samples passing quality control. Biostatistical modelling was then performed in conjunction with clinical data and protein biomarkers in samples where available. Regularized logistic regression, as well partial least squares regression, was applied in nested cross-validation to build and evaluate prediction models. The prediction performances of these models were numerically compared to established tools, including FIB-4 and VCTE (Fibroscan LSM).
Results: Of 281 patients, 152 (54%) had a NAS ≥4, 98 (35%) had at-risk NASH and 54 (16%) had advanced fibrosis. In samples with available clinical data, the NMR metabolomics-based model for NAS stratification (NAS 0–3 vs. NAS 4–8) reached an AUC of 0.75, exceeding both FIB-4 (AUC 0.46) and Fibroscan (AUC 0.46). For fibrosis staging (F0-2 vs. F3-4), the NMR model achieved an AUC of 0.78, outperforming FIB-4 (AUC 0.66) and matching Fibroscan (AUC 0.76).
Conclusion: This study provides evidence that metabolomic constellation profiling measured on the NMR platform can offer a precise, non-invasive approach to staging MASLD. Beyond its diagnostic utility, metabolomics may shed light on patient-specific disease mechanisms, paving the way for personalized interventions and care. Ongoing efforts include expanding the dataset to enhance the robustness of the data and utility of this approach.

WED-398

Bone fragility and fracture risk assessment in metabolic disfunction-associated steatotic liver disease

Clelia Asero[1], Cecilia Oliveri[2], Maria Stella Franzè[3], Adele Di Giovanni[4], Roberto Filomia[5], Gaia Caccamo[5], Concetta Pitrone[5], Carlo Saitta[6], Carmela Morace[7], Nunziata Morabito[2], Giorgio Basile[2], Antonino Catalano[2], Irene Cacciola[8]. *[1]Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Messina, Italy; [2]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Unit and school of geriatrics, University Hospital of Messina, Messina (Italy), Messina, Italy; [3]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Messina, Italy; [4]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Unit and school of geriatrics, University Hospital of Messina, Messina (Italy), Messina, Italy; [5]Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Messina, Italy; [6]Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Messina, Italy; [7]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Lipid Clinic and Cardiometabolic Disease Center, University Hospital of Messina, Messina (Italy), Messina, Italy; [8]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Messina, Italy*
Email: clelia.asero@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and Type 2 diabetes (T2D) share several risk

factors for bone fragility despite the precise mechanism implied in fracture development is not defined. This study aims to evaluate fracture bone risk in patients with MASLD and T2D using the trabecular bone score (TBS), an index of bone microarchitecture quality.

Method: One-hundred-eight patients with MASLD and T2D (median age 62 years, 54% male, 26 cirrhotic, 47% with BMI > 30 kg/m^2) who consecutively attended the Hepatology Unit of the University Hospital of Messina from February 1st,2024, to October 31st,2024, were enrolled. Exclusion criteria were the presence of decompensated cirrhosis, thyroid/parathyroid diseases, chronic kidney disease, heart failure, active malignant neoplasia, and bone metabolism therapies used for >3 months. All patients underwent liver stiffness measurements (LSM)/Controlled Attenuation Parameter (CAP) evaluation by fibroscan and dual-energy X-ray absorptiometry (DEXA) with TBS assessment.

Results: Overall, study population presented median LSM and CAP values of 7.5 kPa (5.8–13.9) and 298 dB/m (255–324) respectively. Sixty-three patients (58.9%) had a pathological TBS (cut-off <1.350), and 55 (52%) presented sub-clinical vertebral fractures at DEXA. Patients with pathological TBS showed higher BMI values ($p < 0.0001$), LSM > 8 kPa ($p = 0.038$), higher CAP levels ($p = 0.007$), and LDL-c ($p = 0.035$) compared to patients without. TBS values were inversely correlated with CAP and visceral adiposity index ($p = 0.006$; $p = 0.003$, respectively) and directly with L1-L4 and femur BMD ($p < 0.0001$, $p = 0.002$). Patients with vertebral fractures showed higher BMI levels ($p = 0.001$), LSM ($p = 0.027$) and CAP ($p = 0.010$) values, and pathological TBS ($p < 0.001$). At logistic univariate and multivariate regression analysis, independent variables associated with the presence of a pathological TBS score were BMI > 30 kg/m^2 ($p < 0.001$), CAP > 298 dB/m ($p = 0.020$), and higher values of total FRAX score ($p = 0.027$).

Conclusion: Evaluation of TBS in MASLD and T2D patients could be useful for assessing bone fragility and enabling an early fracture diagnosis.

WED-399

Metabolic associated steatotic liver disease- related significant and advanced fibrosis' prevalence in Brazil and the associated accuracy of FIB-4 and vibration-controlled elastography - a national register

Email: crisvillelanog@gmail.com

Background and aims: Latin America (LATAM) has the highest prevalence of metabolically associated steatotic live disease (MASLD) globally. Recent data regarding the prevalence of significant and advanced MASLD-related fibrosis in Brazil, the largest country in LATAM, is unknown. We aimed to evaluate the prevalence of both significant (SF, F ≥2) and advanced (AF, F≥F3) fibrosis according to liver biopsy (LB) according to its different geographic regions, as well as the accuracy of FIB-4 and liver elastography by VCTE (Fibroscan, Echosens, Fr) for the diagnosis of SF and AF respectively.

Method: This was a sectional study in nine Brazilian hepatology university centers (Southeast, n = 5; Northeast, n = 1; South, n = 3). Demographics, clinic, liver stiffness measurement by VCTE (Fibroscan®, Echosens, Fr), and liver histology were registered, and PNPLA3 genotypes were registered if available.

Results: 2905 patients were included (53% women, 64% white, 51 ± 14 yrs). Regarding metabolic profile, 44% had T2DM for 8 (3–14) years, 60% had systemic arterial hypertension, and 58% had dyslipidemia. ALT and AST were abnormal in 36.2% and 18.1% respectively. According to LB (n = 2122), 75% were F0-F1, 12% F2, 9% F3 and 4% F4. Most patients with LB were in the South region (n = 1520, 72%) ($p < 0.001$). However, most data from VCTE are related to Southeast Brazil (n = 1084, 85%). The median liver stiffness measure (LSM) was 8.8 (6.1–15.8) kPa. LSM<8 kPa, between 8 and 12 kPa and ≥12 kPa was observed in 44%, 25% and 31% of patients. Most from the Southeast presented a LSM ≥ 12 kPa ($p = 0.01$). Overall, FIB-4 was under 1.3 in 81% of patients. The PNPLA genotype distribution (n = 707) was 41%,45% and 14% for CC, CG and GG respectively. For F3, the AUROC for FIB-4 and LSM were 0.75 (95% CI: 0.70–0.80; $p < 0.01$) and 0.72 (95% CI: 0.68–0.77; $p < 0.01$) respectively and for F2, 0.67 (95% CI: 0.62–0.72; $p < 0.01$) for FIB-4 and 0.64 (95% CI: 0.60–0.69; $p < 0.01$) for VCTE.

Conclusion: Although there is an underrepresentation of the North, West-Central and Northeast Brazilian regions, most MASLD patients with advanced fibrosis determined by LB or VCTE are from the Southeast. VCTE is available mostly in the Southeast region, which impacts the fibrosis stratification of MASLD in other regions due to the lack of equipment, justifying the higher proportion of LB in the South. The accuracy of FIB-4 and liver elastography by Fibroscan® is good for diagnosing stage 3 fibrosis, but neither NIT is a good tool for diagnosing F2 fibrosis. PNPLA distribution is similar to other countries, with a higher CC and CG genotype prevalence.

WED-400

Good diagnostic performance of Hepatoscope™ in diabetology clinics for the screening of MASLD patients with high risk of advanced liver fibrosis

Cyrielle Caussy[1], Bruno Vergès[2], Fabien Subtil[3], Abichou-Klich Amna[4], Valerie Hervieu[5], Laurent Milot[6], Bérénice Ségrestin[7], Bin Sylvie[8], Rouland Alexia[9], Dominique Delaunay[10], Hadjadj Samy[11], Bertrand Cariou[11], Primot Claire[11], Jean-Michel Petit[12], Philippe Moulin[13], Sybil Charrière[13], Emmanuel Disse[10]. *[1]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Laboratoire CarMen, Université Lyon 1, Institut d'hépatologie de Lyon, Pierre-Bénite, France; [2]Department of Endocrinology, Diabetes and Metabolic Disorders, Dijon University, Dijon, France; [3]Hospices Civils de Lyon, Service de Biostatistique, Université Claude Bernard Lyon 1, Lyon, France; [4]Hospices Civils de Lyon, Service de Biostatistique, Lyon, France; [5]Hospices Civils de Lyon, Biopathology of Tumours, GH Est (GHE) Hospital, Lyon, France; [6]Hospices Civils de Lyon, Service de Radiologie, Hôpital Edouard Herriot, Lyon, France; [7]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Lyon, France; [8]Hospices Civils de Lyon, Pôle de Santé Publique, Service Recherche et Epidémiologie Cliniques, Lyon, France; [9]Department of Endocrinology, Diabetes and Metabolic Disorders, Dijon University Hospital, Dijon, France; [10]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Pierre-Bénite, France; [11]Nantes Université, CHU Nantes, CNRS, INSERM, l'institut du thorax, Nantes, France; [12]Department of Endocrinology, Diabetes and Metabolic Disorders, Dijon University Hospital, Dijon, France; [13]Hospices Civils de Lyon, Fédération d'Endocrinologie, Diabète et Nutrition, Hôpital Cardiovasculaire, Bron, France*
Email: cyrielle.caussy@chu-lyon.fr

Background and aims: The screening for metabolic dysfunction-associated steatotic liver disease (MASLD) related advanced fibrosis (AF) is recommended in patients with type 2 diabetes (T2D) and obesity with metabolic comorbidities. We aimed at evaluating the diagnostic performance of a new ultrasound imaging point-of-care device: Hepatoscope™ for the detection of patients with high-risk of AF in diabetology.
Method: This is an ancillary study from of a prospective multicenter study (NCT04435054) including participants with T2D and/or obesity and MASLD age 40–80 years, BMI <40 kg/m^2 enrolled in 4 diabetes clinics in France between Dec 2022 and Sep 2024. Any other etiology of liver disease was systematically excluded. All participants underwent the same day: liver stiffness measurement using vibration-controlled transient elastography (VCTE) by FibroScan®, 2D-transient elastography (2DTE) using a prototype version (2DTE-V1) of Hepatoscope™. Post-acquisition reprocessing of the 2DTE data using the CE-certified version (2DTE-V2) of Hepatoscope™ was performed in a subgroup of n = 206 participants. High risk of AF was determined using a hierarchical composite criterion using either a liver biopsy ≥F3 if available, or magnetic resonance elastography (MRE) ≥3.62 kPa, or VCTE ≥12 kPa. The Spearman's correlation coefficients between VCTE and 2DTE-V1 or 2DTE-V2 were assessed in participants with valid VCTE (interquartile range/median ratio ≤0.30). The area under the ROC curve (AUROC) and 95% confidence interval (CI) were assessed for the detection of AF. An exploratory subgroup analysis was performed in n = 48 participants with magnetic resonance imaging proton density fat fraction (MRI-PDFF) and backscattering coefficient (BSC) by Hepatoscope™ for the quantification of hepatic fat content.
Results: 308 participants were included in the study: 57.5% male, 83.4% with T2D, 70.5% with obesity and with mean age: 60.1 ± 9.6 years, BMI: 32.6 ± 4.7 kg/m^2 and median [Q1–Q3] 2DTE-V1 of 5.7 [4.5–7.5] kPa, VCTE of 6.1 [4.9–7.9] kPa. The proportion of patients with AF was 10.7% (n = 33). VCTE and 2DTE-V1 were significantly correlated r^2: 0.38 [0.28–0.47], p < 0.001. The AUROC (95% CI) for the detection of high risk of advanced fibrosis was 0.81 (0.72–0.90). The correlation between VCTE and 2DTE-V2 was improved r^2: 0.61 [0.48–0.71] and 2DTE-V2 had an AUROC of 0.84 (0.73–0.95) for the detection of AF. Finally, exploratory analyses showed excellent correlation between BSC and MRI-PDFF: r^2: 0.80 [0.67–0.88], p < 0.001.
Conclusion: This proof-of-concept study indicates that Hepatoscope™ 2DTE has a good diagnostic performance for the identification of patients with high-risk of AF among patients with T2D and/or obesity screened in diabetology. Further studies in larger cohort using the 2DTE-V2 by Hepatoscope™ are needed to determine the optimal cut-offs.

WED-401-YI

Correlation between transient elastography, clinical scores and liver histology in patients with metabolic dysfunction-associated steatotic liver disease

Diederick van Doorn[1], Sebastiaan de Jager[1], Marten Lantinga[1], Joost PH Drenth[1], Joanne Verheij[1], R. Bart Takkenberg[1]. *[1]Amsterdam UMC, Amsterdam, Netherlands*
Email: d.j.vandoorn@amsterdamumc.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a rising cause of chronic liver disease. Liver stiffness measurement (LSM) is widely used as non-invasive tool to assess and quantify liver fibrosis in MASLD, but the diagnostic accuracy is uncertain. The aim of this study was to assess the correlation between LSM and liver histology in MASLD.
Method: We conducted a single center retrospective cohort study in patients with biopsy confirmed MASLD who underwent LSM within 6 months before biopsy, between 2015 and 2022. The primary endpoint was the correlation between LSM and histological grade of fibrosis. Secondary endpoints were correlation between Controlled Attenuation Parameter (CAP) values and histological grade of steatosis, diagnostic accuracy of steatosis by CAP compared to ultrasound, correlation of non-invasive scores and histological grades of fibrosis, and lastly to validate LSM cut-off values.
Results: We included 139 patients [53% male, median age 51] with a median BMI of 31 kg/m^2. Forty-six patients had diabetes mellitus (33%). Histological distribution of fibrosis stages was as follows: F0: 5%, F1: 15%, F2: 56%, F3: 14%, and F4: 9%. The median LSM (IQR) per histological fibrosis stage was 8.9 (20.4), 7.8 (4.5), 8.8 (5.4), 12.8 (4.8), and 37.4 (43.1) kPa, respectively. Our findings indicate a moderate positive correlation between LSM and histological fibrosis grade (r = 0.42, p < 0.001). When comparing individual groups of fibrosis, no significant difference in LSM was found between low degrees of fibrosis (F0–F2). However, a difference was found in comparison with F3 and upwards (p < 0.001). Moreover, when clustering fibrosis grades into low levels of fibrosis (F0–F2) and severe fibrosis (F3–F4), a difference was found between these two groups (p < 0.001). LSM ≥12 kPa demonstrated an excellent sensitivity (0.75) and specificity (0.80) in detecting severe fibrosis (≥F3), with an area under the receiver operating characteristics (AUROC) curve of 0.80. Clinical scores performed sub optimally in detecting and staging fibrosis, with exception of the APRI and NAFLD score. We found a weak positive correlation between CAP values and histological steatosis grades (r = 0.21, p = 0.21), with no significant differences between each grade of steatosis. Ultrasound and Fibroscan performed similarly in detecting the presence of steatosis.
Conclusion: LSM cannot discriminate between low levels of fibrosis but can accurately identify severe fibrosis/cirrhosis in MASLD patients using a threshold of LSM ≥12 kPa. LSM in combination with non-invasive scores may be suitable to confirm severe fibrosis or aid in the decision making for the need of liver biopsy. Fibroscan does not

accurately assess different grades of steatosis but can detect the presence of steatosis with the same accuracy as ultrasound.

WED-402

Clinical validation of MRI-PDFF super-response in identifying MASH resolution: data from a prospective cohort and validation in an RCT

Rohit Loomba[1], Egbert Madamba[1], Ricki Bettencourt[1], Harris Siddiqi[1], Cynthia Behling[1], Daniel Huang[2]. [1]*University of California San Diego, SanDiego, United States;* [2]*National University of Singapore, Singapore, Singapore*
Email: daniel_huang@nus.edu.sg

Background and aims: MRI-proton-density-fat fraction (MRI-PDFF) response (defined as ≥30% relative decline in MRI-PDFF) can help to detect metabolic dysfunction-associated steatohepatitis (MASH) resolution. The association of MRI-PDFF super-response (defined as ≥50% decline or greater in MRI-PDFF) on the likelihood of MASH resolution has not been systematically assessed and quantified. We examined the association between an MRI-PDFF super-response and MASH resolution in 2 prospective cohorts.
Method: This study included a cohort of 95 well-characterized adult participants (67% female) with biopsy-confirmed MASH who underwent contemporaneous laboratory testing, MRI-PDFF, and liver biopsy at two time points. The *primary outcome* was MASH resolution with no worsening of fibrosis. The findings were validated in a distinct cohort of 163 participants (64% female) with MASH from a clinical trial.
Results: The median (IQR) age and body mass index (BMI) were 55 (45–62) years and 32.0 (30–37) kg/m^2, respectively, in the primary cohort. The histologic response rate was significantly higher in combined MRI-PDFF super-responders versus non-super-responders (57% versus 12%, $p < 0.001$). After multivariable adjustment for age, sex, BMI, race/ethnicity, and type 2 diabetes, MEI-PDFF response (adjusted OR 4.94, 95% CI 1.53–15.94, $p = 0.007$) and MRI-PDFF super-response (adjusted OR 9.08, 95% CI 2.39–35.53, $p = 0.002$) remained statistically significant predictors of histologic response. We determined similar findings in a distinct cohort, with MRI-PDFF response (OR 5.47, 95% CI 1,81–16.60, $p = 0.003$) and MRI-PDFF super-response (OR 7.42, 95% CI 2.82–19.50, $p < 0.001$) associated with MASH resolution.
Conclusion: MRI-PDFF super-response predicts a greater likelihood of histologic response than MRI-PDFF response. These data have important implications for clinical trial design in MASH and assessing dose response and selection for Phase 3.

Email: denis.ouzan@wanadoo.fr

Background and aims: The STEATOLIB cohort was established to prospectively monitor patients with steatosis in hepatology private practice over a decade. This study focuses on liver fibrosis evaluation in this patient population.
Method: From February 2021 to June 2023, 18 centers enrolled 1,169 adult patients with morphological and/or histological steatosis and abnormal liver tests (ASAT, ALAT, GGT, and/or PAL) into the STEATOLIB cohort.
Results: Among the 1,169 patients included, 56% were men, with a mean age of 56 years (SD: 13). Comorbidities included diabetes (37%), hypertension (45%), and dyslipidemia (36%). Weekly alcohol consumption was: no consumption (56%), 1–10 units (33%), and >10 units per week (11%). The mean BMI was 31 ± 5.8 kg/m². Fibrosis was assessed using the FIB-4 score in 936 patients: 69% had a low fibrosis risk (FIB-4 <1.3/<2, age-dependent), 23% had an intermediate risk (FIB-4: 1.3/2–2.67), and 8% had a high risk (FIB-4 >2.67). Liver stiffness measurement (LSM) was available in 87% of patients: Fibroscan (n = 407) showed a mean stiffness of 8.3 kPa (SD 6.1), with 66% <8 kPa, 19% between 8 and 12 kPa, and 15% > 12 kPa. Shear Wave Elastography (n = 429) yielded similar results (mean: 8.0 kPa (SD 5.2)). The LiverRisk Score (LRS) was calculated in 654 patients: 41% had minimal risk (LRS <6), 51% had low risk (LRS <10), 7% had medium risk (LRS 10–15), and 1% had high risk (LRS >15). Confirmed fibrosis (LSM ≥8 kPa) was significantly associated with diabetes, FIB-4 > 1.3/>2, and LRS > 6. Liver biopsy, performed in 90 patients (8%), revealed advanced fibrosis (F2–F4) in 55 patients, significantly correlated with age, diabetes, and LSM. Using the EASL-recommended 2-step approach: Low fibrosis risk by FIB-4 was confirmed by LSM (<8 kPa) in 79% and by LRS (<10) in 96% of cases. Intermediate FIB-4 risk was confirmed by LSM (≥8 kPa) in 55% of cases and by high-risk LRS (≥10) in 16%. High FIB-4 risk was confirmed by LSM (≥8 kPa) in 77% of cases and by medium or high-risk LRS (≥10) in 30%. LRS <6 was observed in: 52%, 20%, and 4% of patients with low, intermediate, and high FIB-4 risks, respectively ($p < 0.001$), in 47% of patients with LSM <10 kPa vs. 4% with LSM ≥10 kPa ($p < 0.001$).
Conclusion: Hepatic fibrosis was confirmed in one-third of patients consulting for MASLD in hepatology private practice. The EASL 2-step approach is effective in identifying liver fibrosis. In resource-limited settings, second-line fibrosis testing can be restricted to patients with intermediate FIB-4 scores. While FIB-4 and LRS show strong concordance in low-risk zones, their agreement is more limited in the intermediate or high-risk zones of the FIB-4.

WED-404

Fibroblast activity (PRO-C3) and liver stiffness correlate with spatial distribution of collagens in MASLD and ALD: insights from digital pathology

Email: djl@nordicbio.com

Background and aims: In patients with metabolic dysfunction associated steatotic liver disease (MASLD) and alcohol-related liver disease (ALD) Kleiner fibrosis stage provides limited information on

the spatial distribution of collagen in the liver. Digital pathology provides a more advanced assessment of collagen localization; however, there is limited knowledge linking non-invasive tests to the spatial distribution of collagen.
Method: Liver biopsies and serum samples from 121 patients with MASLD and 33 patients with ALD were evaluated. Second harmonic imaging (SHG) was used to quantitate hepatic fibrosis by qFibrosis (qFib). qFib is a composite index combining collagen strings (#StrNumber), length of collagen strings (StrLength) in the central vein (CV), portal tract (PT) and zone 2. NordicPRO-C3, a blood-based type III collagen formation marker of fibroblast activity was measured and correlated to the SHG.
Results: The median age (Q1-Q3) of the MASLD or ALD cohort were 54[43–60]/64[59.5–68.5) years, 53%/84% male and a mean BMI of 32/30, respectively. Pathology assessed fibrosis distribution was as follows: F0-4 = 3/0%, 28/0%, 35/3%, 24/36% and 11/61% for MASLD/ALD. The median (Q1, Q3) at baseline for qFibrosis value for MASLD/ALD was 1.70 (1.4–2.4)/3.4 (2.4–5.0); PRO-C3 (11.5 (9.4–16.2)/22.6 (19.2–28.3) ng/mL; Transient Elastography (TE) for MASLD/ALD was 8.2 (5.6–12.7/21.1 (14.4–32.0). The Spearman correlation between PRO-C3 and qFib was similar in MASLD: ($r = 0.56$, $p > 0.0001$) and in ALD ($r = 0.55$, $p = 0.001$). The ADAPT score (PRO-C3, diabetes, platelets, age) was highly correlated to qFib in MASLD ($r = 0.72$, $p > 0.0001$) and less in ALD ($r = 0.43$, $p = 0.018$). TE was correlated to qFib in MASLD ($r = 0.58$, $p > 0.0001$) and in ALD (0.46, $p = 0.010$). The absolute amount of collagen across all regions (%SHG) correlated to PRO-C3 in MASLD ($r = 0.33$, $p = 0.0002$), and in ALD ($r = 0.54$, $p = 0.002$); ADAPT in MASLD ($r = 0.39$, $p = p > 0.0001$) and ALD ($r = 0.39$, 0.032) as well as TE in MASLD ($r = 0.38$, $p < 0.001$) and ALD ($r = 0.51$, $p < 0.004$). No correlation between qFib or %SHG were seen for AST or ALT in MASLD and ALT in ALD, except for AST versus qFib ($r = 0.41$, $p = 0.028$) and AST versus %SHG ($r = 0.42$, $p = 0.024$) in ALD only. Finally, the spatial distribution of collagen correlated with PRO-C3, ADAPT, TE for portal tract (StrAreaPT, StrArea; StrLengthPT) however not to AST or ALT.
Conclusion: We observed correlations between spatial distribution of collagens and systemically assessed active fibrogenesis and liver stiffness in both MASLD and ALD. While similarities and differences were observed, potentially influenced by etiology and sample size, these findings underscore the connection between biopsy-based digital pathology assessments and non-invasive tests for liver fibrosis.

WED-405
PRO-C4, a biomarker of perisinusoidal fibrosis, is related to cardiometabolic risk factors, steatosis, and liver stiffness

Ida Lønsmann Sorribes[1], Diana Julie Leeming[1], Morten Karsdal[1], Aleksander Krag, Maja Thiele. [1]*Nordic Bioscience, Herlev, Denmark*
Email: Ilc@nordicbio.com

Background and aims: Early intervention in patients with steatotic liver disease (SLD) is crucial to mitigating the risk of adverse outcomes. A histological characteristic of early liver damage is the formation of perisinusoidal fibrosis with thickening of the hepatocyte basement membrane. Type IV collagen is a key component of the basement membrane of the extracellular matrix and can be assessed serologically by the biomarker PRO-C4. Thus, PRO-C4 could potentially reflect early features of liver damage in patients with early-stage SLD.
Method: NordicPRO-C4 was measured in serum samples from a large Danish screening cohort of healthy individuals with known risk factors of SLD (n = 4736). NordicPRO-C4 was quantified using a chemiluminescence immunoassay on a high sensitivity IDS-i10 automated platform and compared between risk groups and to liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) by vibration-controlled transient elastography (VCTE) within well-defined risk groups.
Results: PRO-C4 was elevated in patients with metabolic-associated risk factors for liver disease, compared to patients with alcohol-related risk factors only or no known risk factors ($p < 0.0001$). PRO-C4 increased with presence of metabolic syndrome (MetS) and was elevated for all subcomponents of metabolic dysfunction ($p < 0.0001$). Furthermore, PRO-C4 increased with increasing steatosis estimated by CAP in all subgroups ($\rho = 0.315$, $p < 0.0001$) and was higher in patients with LSM by VCTE ≥8 kPa in all risk groups, however not in patients with no known risk factors.
Conclusion: Elevated PRO-C4 is associated with presence of cardiometabolic risk factors and LSM≥8 kPa. PRO-C4 potentially reflects perisinusoidal fibrosis from early liver damage and repair due to its relation to increasing degree of steatosis. Interestingly, PRO-C4 was also related to elevated liver stiffness in a population at risk of SLD.

Email: mromerogomez@us.es

Background and aims: The arrival of novel therapies for MASLD requires strategies to improve priorization. FICE-4C diagnostic algorithm has shown utility for fibrosis screening (*manuscript in preparation*), but its prognostic value remains unknown. Aims of this project are to: 1) Integrate FICE4C in a nomogram to facilitate its implementation at screening sites 2) Assess in a non-cirrhotic population its diagnostic accuracy for fibrosis together with its prognostic capacity to identify patients at higher risk of progressing to cirrhosis and its complications (ascites, hepatic encephalopathy, oesophageal varices bleeding and HCC).
Method: FICE-4C nomogram was created from data of two independent cohorts [N = 345 (4 Spanish hospitals)]. Variables were dichotomized and combined in two scores: Nomogram Intermediate risk (FICE4C-NIR), which requires FICE4 and any of the risk factors that compose the score, and Nomogram High Risk (FICE4-NHR) which requires at least two. Risk scores were estimated exclusively in non-cirrhotic patients and compared against VCTE, using EASL (≥8 kPa & 12 KPa) or Baveno cutoffs [10 & 15 kPa w/wo platelets $\leq 150 \times 10^9$/L)]. Diagnostic accuracy was assessed in each cohort separately (N = 179 & N = 127) and in the overall cohort. Prognostic analyses were restricted to patients in which follow-up data was available [(N = 125) (mean FU = 37 mo) (event rate = 9.3%] using Cox regression with and without adjusting for co-variates. All measurements come from baseline visit, which was performed within 3 months of the histological diagnosis.
Results: FICE4C-NIR showed a diagnostic accuracy comparable to the FICE4C original algorithm (FICE4C) and equal or even slightly better than VCTE for the detection of significant fibrosis [F2+ FICE4-NIR (AUC 0.70[0.65–0.75]) *vs* FICE4C (AUC 0.73[0.68–0.78]) *vs* VCTE at 8 kPa (AUC 0.62[0.58–0.67]), 10 kPa (AUC 0.67[0.62–0.73]), 12 kPa (AUC 0.67[0.62–0.73]) and advanced fibrosis [F3+ FICE4-NIR (AUC 0.71[0.66–0.76]) vs FICE4C (AUC 0.78[0.73–0.83]) vs VCTE at 8 kPa (AUC 0.66[0.62–0.69]), 10 kPa (AUC 0.73[0.69–0.78]), 12 kPa (AUC 0.73[0.67–0.79]) and 15 kPa (AUC 0.69[0.63–0.75])]. Both of them showed a strong prognostic association to liver outcomes [FICE4-NIR (HR 30.29 [7.03–129.9] p-value 4.12 E-06 & FICE4-NHR (HR 52.26 [10.64–256.8] p-value1.11 E-06)], paralleling the predictive capacity of VCTE [8 Kpa (HR 7.25 [0.93–56.16] p-value 0.058) 10 Kpa (HR 14.41 [1.86–111.6] p-value 0.011 12 Kpa (HR 26.88 [3.46–208.5] p-value 1.64 E-04) 15 Kpa (HR 12.39 [3.33–46.09] p-value 1.74 E-05) and 15 Kpa with low platelets (HR 22.49 [4.89–103.5] p-value 6.37E-05)] and histological fibrosis [F2-F3 (HR 7.96 [2.12–29.91] p-value 0.00214) F3 (HR 16.28 [4.77–55.54] p-value 8.37 E-06).
Conclusion: The FICE-4C nomogram, which is assessed via ELISA and uses routine care data, shows promise for identifying non-cirrhotic MASLD patients at high risk for severe outcomes.

WED-407
Are doppler alterations of the liver prognostic markers for MASLD Severity? How do doppler results correlate with transient elastography and anthropometric data?

Teodor-Marcel Puiu[1], Simona Ioanitescu[2], Mircea Istrate[2], Simu Razvan-Ioan[3], Andreea Simu[3], Laura Iliescu[3]. *[1]Fundeni Clinical Institute, Bucharest Romania, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]Fundeni Clinical Institute, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [3]Fundeni Clinical Institute, Bucharest Romania, Carol Davila University of Medicine and Pharmacy, Bucharest Romania, Bucharest, Romania*
Email: dr.teopuiu@gmail.com

Background and aims: MASLD (Metabolic Associated Steatotic Liver Disease) has emerged as a significant global health concern, requiring the validation of reliable prognostic markers. There is a lack of conclusive evidence regarding the correlation between clinical algorithms, ultrasound (US), and transient elastography (TE), with the latter being limited in accuracy, especially in patients with higher body mass index (BMI), waist circumference (WC), or increased parietal wall thickness, leading to significant failure rates in assessing liver stiffness. This study aimed to explore correlations between anthropometric data, Doppler US parameters of hepatic artery (HA), portal vein (PV), right hepatic vein (RHV) waveform patterns, and the degree of steatosis estimated by US elastography (US-E) and TE (Fibroscan®).
Method: A cohort of 142 patients, with a mean age of 52.3 ± 9.5 years, was classified based on the degree of steatosis using controlled attenuation parameter (CAP) values as a reference. We analyzed variations in the HA resistive index (HARI), PV pulsatility index (VPI), and RHV flow patterns, and examined their relationship to steatosis and anthropometric data (BMI, WC and preperitoneal fat (G).
Results: Significant differences were observed when comparing HARI and VPI between patients with significant steatosis (S2 and S3) and those with non-significant steatosis (S0 and S1): for HARI 0.683 versus 0.542, p = 0.04), for VPI 0.16 versus 0.28 (p = 0.03). Notably, anthropometric data, triphasic RHV flow pattern, and Doppler flow characteristics differed significantly between the two groups. HARI showed a stronger negative correlation, followed by VPI, with the severity of steatosis. Furthermore, a negative correlation between G and all US Doppler parameters was noted, suggesting the need to analyze US and TE data separately for lean versus overweight patients with MASLD.
Conclusion: The severity of steatosis in MASLD correlates significantly with HARI and VPI, demonstrating potential for diagnosing significant steatosis. The alterations in vascular compliance observed in Doppler US provide valuable insights into disease severity and hepatic parenchymal changes.

WED-408
Can we use coronary-CT scan for screening of metabolic-associated steatotic liver disease?

Teodor-Marcel Puiu[1], Mircea Istrate[1], Simu Razvan-Ioan[1], Andreea Simu[1], Adriana Rusie[1], Laura Iliescu[1]. *[1]Department of Internal Medicine, Fundeni Clinical Institute, Bucharest, Romania, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, Bucharest, Romania*
Email: dr.teopuiu@gmail.com

Background and aims: Metabolic-associated steatotic liver disease (MASLD) comprises a spectrum of pathologies frequently encountered in the general population, with rising incidence. There are common risk factors for MASLD and coronary artery disease (CAD) suggesting that these 2 pathologies require common management. Coronary-CT scan has become a routine evaluation for CAD in at risk populations. The aim of this study is to determine whether we can use information derived from coronary CT to diagnose liver steatosis, thus involving radiologists and cardiologists in MASLD screening and early diagnosis and management.
Method: We evaluated 138 patients with metabolic syndrome referred for coronary CT scan. On the native CT acquisitions, we measured liver and spleen density (LD, SD), as well as the thickness of epicardial adipose tissue (EAT). Patients were then referred for liver disease evaluation by Fibroscan (controlled attenuation parameter CAP). On CT, liver steatosis was defined as LD <40 HU or difference between SD and LD > 10 HU. We also determined liver function tests and body mass index (BMI). Patients with other causes of liver disease were excluded from the study.
Results: Mean age in the study group was 57.32 ± 22.72 years with 51.1% male and 48.5% female. Coronary CT scan revealed 107 patients with liver steatosis (77%). CAP analysis revealed 6 S0 patients (5.9%),

18 S1 patients (16.8%), 54 S2 patients (50.4%) and 29 S3 patients (27%) in the group with CT suspicion of steatosis and 23 S0 patients (74.1%), 5 S1 patients (15.1%) and 3 S2 patients (9.6%). We found a significant correlation between CAP and LD values (p = 0.01) as well as difference between SD and LD (p = 0.02). Increased EAT correlated to the presence of steatosis (S1 to S3) in patients with BMI > 30 kg/m^2 (p < 0.01) but not in patients with BMI <30 kg/m^2 (P = 0.08).
Conclusion: Coronary CT scan for CAD detection can be a useful tool for screening of liver steatosis, given the common pathological background between the two pathologies. Including data regarding LD and SD in the scan report may indicate a need for a hepatology consult in patients with suspicion of CAD and may lead to an early diagnosis of MASLD.

WED-413

Does hyperferritinemia predict ferroptosis in metabolic dysfunction associated steatotic liver disease? A real-world experience

Ritu Singh[1], Sonu Dhillon[1]. [1]*University of Illinois College of Medicine, Peoria, United States*
Email: drhrituraj83@gmail.com

Background and aims: Ferroptosis (iron-dependent oxidative damage resulting in programmed cell death) has been linked to metabolic diseases including hepatic steatosis. Ferroptosis leads to increased intracellular iron and serum ferritin has been investigated as a marker of liver fibrosis in metabolic dysfunction associated steatotic liver disease (MASLD). However, there is limited evidence to support use of serum ferritin as a surrogate marker of disease progression in MASLD. Herein, we aim to evaluate the role serum ferritin in predicting major clinical outcomes in patients with MASLD.
Method: We performed a retrospective cohort study utilizing a large research network (TriNetX) comprising data of over 110 million patients. Study period was January 2016 to December 2020. Patients 18 years with steatotic liver disease and at least one of the cardiometabolic factors were identified. Patients with other etiologies of chronic liver disease were excluded. Patients were followed for up to five years. Hyperferritinemia was defined as serum ferritin ³300 ng/ml. Control group was MASLD patients with serum ferritin <200 ng/ml. Primary outcomes were development of decompensated cirrhosis, hepatocellular carcinoma (HCC) and all-cause mortality in patients with MASLD with hyperferritinemia compared with the control group. Propensity score (1:1) matching was performed to control confounding variables. Kaplan-Meier survival analysis was performed to calculate the hazard ratio.
Results: We identified 3,185 patients with hyperferritinemia and 8,729 controls. Patients in the hyperferritinemia cohort were older (55.6 vs. 53.3), Black (8.35% vs. 6.68%) or Asian (5.79% vs. 3.37%) men (48.86% vs. 30.68%). Obesity (53.07% vs 40.34%) and diabetes mellitus (50.80% vs. 47.52%) were more common in the control group while cardiac comorbidities – ischemic heart disease (24.28% vs. 21.14%) and heart failure (15.26% vs. 11.19%) were more common in the hyperferritinemia group. In age-, gender- and comorbidity-matched cohorts, there was greater rate of decompensated cirrhosis (21.84% vs. 17.85%, hazard ratio [HR] 1.31, 95% confidence interval [CI] 1.18–1.47) and worse overall survival (71.16% vs. 83.09%, HR 2.03, 95% CI 1.81–2.29) in patients with hyperferritinemia compared with the control group, after a median follow up was 48.67 months. There was no difference in the incidence of HCC (1.94% vs. 1.92%, HR 0.83, 95% CI 0.69–0.99) between the two groups.
Conclusion: Hyperferritinemia is common in MASLD and serum ferritin above 300 ng/ml is associated with increased risk of decompensated cirrhosis and all-cause mortality. Our findings support the use of hyperferritinemia as a marker of worse clinical outcomes in MASLD.

Email: f.terracciani@unicampus.it

Background and aims: Fibrotic MASH, the inflammatory form of MASLD with significant activity and fibrosis (necroinflammatory activity -NAS score- ≥4 and fibrosis ≥2), is the most treatment-requiring progressive form of MASH. For this reason, much research is focusing on identifying non-invasive tools capable of diagnosing this condition. In the last years, multisensory analysis techniques are emerging as diagnostic/prognostic tools potentially useful in various disorders, including liver diseases. We aim to evaluate multisensorial electronic-technologies (e-nose and e-tongue) as novel noninvasive tools for the identification of fibrotic MASH.
Method: Consecutive patients with MASLD attending the Hepatology Unit of "Fondazione Policlinico Universitario Campus Biomedico" were enrolled. MASLD was diagnosed by the presence of cardiometabolic criteria and either histological or ultrasonographic steatosis. Fibrotic MASH was defined non-invasively as Fibroscan-AST (FAST) score ≥0.67 or fibrotic NASH index (FNI) ≥0.33 and, histologically, as NAS score ≥4 and fibrosis stage ≥2. All patients underwent breath sampling, analyzed by BIONOTE e-nose, and urine and saliva sampling, analyzed by BIONOTE e-tongue. The ability of e-nose/e-tongue to identify fibrotic-MASH was evaluated using Partial Least Squares Discriminant Analysis (PLS-DA) and described by confusion matrices.
Results: A total of 75 patients were enrolled (median age 58 years, male 64%, mean BMI 32.6 kg/m^2). FAST score and FNI were available for 67 and 49 patients, respectively, and 37 patients received liver biopsy. Fibrotic MASH was diagnosed by FAST score and FNI in 12/67 and 11/49 patients, respectively, and by histological criteria in 18 of the 37 patients undergoing liver biopsy. Breath, urine, and saliva samples were suitable for analysis in 57, 71 and 68 patients, respectively. Breath, saliva and urine accuracies were 75%, 70%, and 79% for predicting fibrotic MASH by FAST score, and 70%, 72%, and 71% by FNI score. While combining different sample analyses did not improve prediction by FAST, integrating urine, saliva, and breath enhanced fibrotic MASH prediction by FNI to 79%. In the histological subgroup, e-nose showed total accuracy (100%), correctly classifying 18/18 patients, while e-tongue saliva and urine had accuracies of 82% and 69%, respectively. Combining saliva and urine improved accuracy to 88%. Overall, e-technologies outperformed FAST (accuracy 64%) and, except for urine e-tongue alone, FNI (accuracy 75%), in predicting fibrotic MASH diagnosed by histology.
Conclusion: E-technologies exhibit good accuracy in identifying fibrotic MASH, outperforming FAST and FNI, two widely used noninvasive reference scores. These results, derived from a limited sample, suggest the potential of these tools for risk stratification in patients with MASLD/MASH, but require further validation in larger cohorts.

WED-415-YI

The association between non-invasive tests of liver fibrosis and early diastolic dysfunction in patients with metabolic dysfunction-associated steatotic liver disease

Fabrizio Amato[1], Angelo Armandi[1], Alessandro Andreis[2,3], Matteo Bellettini[2,3], Francesco Lorusso[3], Kamela Gjini[1], Martina Marano[1], Lorenza Vaira[1], Chiara Rosso[1], Gian Paolo Caviglia[1], Marta Guariglia[1], Eleonora Dileo[1], Davide Castagno[3], Gianluca Alunni[2,3], Gaetano De Ferrari[3], Elisabetta Bugianesi[1].
[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy, Turin, Italy; [2]Advanced Cardiovascular Echocardiographic Unit, Cardiovascular and Thoracic Department, Città della Salute e della Scienza di Torino University Hospital, Turin, Italy; [3]Division of Cardiology, Department of Medical Sciences, Città della Salute e della Scienza University Hospital, Turin, Italy
Email: fabrizio.amato@unito.it

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) may contribute to cardiac impairment, especially through diastolic dysfunction and heart failure with preserved ejection fraction. Non-invasive tests (NITs) for liver fibrosis are useful tools for risk stratification, though their utility in identifying patients with early or established diastolic dysfunction remains uncertain. In this study we aimed to assess the association between liver NITs (FIB-4 and liver stiffness measurement [LSM]) and echocardiographic markers of diastolic dysfunction.
Method: We prospectively enrolled 150 patients with MASLD and without cardiovascular disease history who referred to the hepatologic center of the "AOU Città della Salute e della Scienza di Torino" University Hospital. All patients underwent clinical and biochemical evaluation, vibration-controlled transient elastography for LSM, and screening echocardiography with speckle tracking analysis. Significant fibrosis was defined by FIB-4 > 1.3 or LSM ≥7 kPa. Diastolic dysfunction was defined by mitral E/E' ratio >9, while early diastolic dysfunction was defined by left atrial strain reservoir (LARS) (<22%) and left atrial stiffness index (LASi) ≥25 kPa. Pericardial fat thickness was also assessed.
Results: Increased FIB-4 was observed in 23.3% of patients (median age 62 [58.2–65.0]) with higher prevalence of type 2 diabetes (T2DM) (20%), arterial hypertension (74.3%) and dyslipidemia (62.9%). Overall prevalence of obesity was 43.9%. Compared to patients with low FIB-4, those with FIB-4 >1.3 had increased E/E' ratio, LASI and pericardial fat (respectively median 8.0 [6.0–9.2], p = 0.007; 0.34 kPa [0.20–0.42], p < 0.0001; 12.5 mm [8.5–17.2], p < 0.0001), and had reduced LARS (26.5% [19.0–33.0], p < 0.0001). In a multivariable stepwise regression analysis using 3 models (progressive adjustments for T2DM, obesity, sex, arterial hypertension, dyslipidemia and age > 50) FIB-4 >1.3 was independently associated with diastolic dysfunction (aOR 3.41 [1.08–10.74]) and with early diastolic dysfunction (aOR for reduced LARS 10.03 [2.01–49.8]; aOR for reduced LASi 4.24 [1.16–15.5]), while LSM ≥7 kPa was independently associated with LARS (aOR for reduced LASi 3.63 [1.01–13.0]). Finally, FIB-4 displayed Area Under the Curve (AUC) of 0.838 for the prediction of reduced LARS.
Conclusion: In patients with MASLD and without cardiac disease, NITS for liver fibrosis may be a useful tool to identify a high-risk group with early cardiac dysfunction. This would support tailored echocardiographic surveillance strategies to improve early detection and management. This study was funded by the Italian Ministry for Education, University and Research (MIUR) under the programme 'Dipartimenti di Eccellenza 2018–2022' Project code D15D18000410001.

Background and aims: Transient elastography (TE) is the preferred non-invasive method for assessing liver fibrosis and steatosis, especially in metabolic dysfunction-associated steatotic liver disease screening. Although TE is generally considered straightforward to learn, the accuracy and reproducibility depend on operator skill, requiring a structured training protocol to minimize technical variability. As part of the GENESIS (Genomics and Environmental Non-invasive Evaluation for Saudi Intrahepatic Steatosis) project, we aimed to develop and validate a competency-based TE training protocol for new operators to ensure reliable results.
Method: A team of hepatologists and gastroenterologists developed a standardized TE training protocol using FibroScan. Seven healthcare workers with no prior TE experience were pre-assigned as research coordinators for the GENESIS project and trained under certified supervision using hands-on experience with immediate feedback for each case. Each trainee performed 100 supervised and 10 unsupervised TE measurements. Supervisors, blinded to the unsupervised results, conducted TE on the same patients in the same setting for comparison. We recorded the controlled attenuation parameter (CAP), liver stiffness measurements (LSM), and the interquartile range (IQR) for both trainee and supervisor measurements. Reliable LSM data required an IQR-to-median ratio threshold of <30%. We assessed inter-operator reliability using intraclass correlation coefficients (ICCs), with a threshold of > 0.80 to indicate a strong agreement.
Results: Trainees (57.1% female), with a median age of 35 years (range: 26 to 38), and five years of clinical experience (range: 1 to 13). Their backgrounds included nursing (57.1%), pharmacy (14.3%), genomic medicine (14.3%), and radiology (14.3%). The trainees were supervised by six certified supervisors, five of whom were female (83.3%). Their backgrounds included three pharmacists (50.0%), one hepatologist/gastroenterologist (16.7%), one ultrasound technologist (16.7%), and one biochemist (16.7%). The median training duration was 20 days (range: 14 to 20), with a median of 6 hours daily (range: 4 to 8). Each trainee was supervised by a median of 2 supervisors

(range: 1 to 3). Six of seven trainees met the ICCs competency threshold on the first attempt; however, one trainee required a second attempt. For the first attempt, the median ICC for CAP was 0.95 (IQR: 0.92–0.99), and for fibrosis scores was 0.99 (IQR: 0.95–0.99), indicating high inter-operator reliability across the cohort. Median IQR-to-median ratio across all trainees was 13.0% (range: 8.5% to 17.5%), and for supervisors, it was 14.0% (range: 8.0% to 17.5%).
Conclusion: A rigorous training across an average of 20 days with 100 supervised measurements ensures that new operators achieve expert-level proficiency in TE. This protocol enhances diagnostic reliability and establishes a benchmark for training in diverse clinical and research settings.

Multiparametric ultrasound-based algorithm SteatoScore 2.0 versus monoparametric controlled attenuation parameter in clinical practice: a comparison study in a monocentric MASLD cohort

Giovanni Petralli[1], Antonio Salvati[2], Simone Cappelli[3], Lidia Surace, Gabriele Ricco[2], Laura De Rosa[4], Francesco Faita[4], Ferruccio Bonino[5], Maurizia Brunetto[2,3]. *[1]Department of Surgical, Medical, Molecular and Critical Area Pathology, University of Pisa, Pisa, Italy; [2]Hepatology Unit, University Hospital Pisa, Pisa, Italy; [3]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy; [4]Institute of Clinical Physiology, NationalResearch Council, Pisa, Italy; [5]Institute of Biostructure and Bioimaging, National Research Council, Naples, Italy*
Email: g.petralli94@gmail.com

Background and aims: A quantitative, accurate and non-invasive measurement of liver fat content (LFC) is an unmet need of clinical practice for Steatotic Liver Disease (SLD) evaluation. The most widespread non-invasive test in clinical practice is controlled attenuation parameter (CAP) by FibroScan ®. Multiparamatric Steatoscore 2.0 (StSc) was shown recently to provide LFC measures highly comparable to MRI-PDFF. Aim of the study was to analyze the StSc-CAP agreement in patients with metabolic dysfunction-associated SLD (MASLD) spectrum and their correlation with clinical/biochemical parameters.
Method: 450 patients consecutively evaluated from January 2019 to October 2024 for SLD at the Hepatology Unit of Pisa University Hospital were enrolled at MASLD diagnosis. Clinical, anthropometric, biochemical and instrumental data were collected. LFC was simultaneously measured with CAP and StSc and liver fibro-inflammatory one with FibroScan® liver stiffness measurement (LSM).
Results: Overall CAP and StSc were significantly correlated ($r = 0.485$, $p < 0.001$), but the agreement was poor and varied by LSM categories (<8 kPa: $r = 0.485$, $p < 0.001$; 8–12 kPa: $r = 0.462$, $p = 0.001$; 12–20 kPa: $r = 0.494$ $p = 0.005$, >20 kPa $r = -0.326$ $p = 0.330$) and BMI classes (normal weight: $r = 0.501$ $p < 0.001$, overweight: $r = 0.546$ $p < 0.001$, obese: $r = 0.385$ $p = 0.001$). StSc correlated inversely with age ($r = -0.111$ $p = 0.025$) and directly with overweight ($r = 0.133$ $p = 0.047$), while CAP did not. In non-advanced MASLD cohort (LSM < 12 kPa) we found a difference in correlation of StSc and CAP with AST (StSc $r = 0.290$ $p < 0.001$ vs CAP $r = 0.167$ $p < 0.001$, p for comparison = 0.010) and ALT (StSc $r = 0.358$ $p < 0.001$ vs CAP $r = 0.191$ $p = 0.001$, p for comparison = 0.0005).
Conclusion: In a MASLD cohort LFC measures by StSc and CAP were correlated but their agreement varied consistently along the spectrum of liver disease stage stratified non-invasively by LSM. Multiparametric StSc outperformed mono-parametric CAP and it significantly correlates with body weight. In earlier forms of MASLD StSc correlated better than CAP with liver enzymes in patients with progressive steato-hepatitis.

Background and aims: The availability of new drugs for the treatment of patients with metabolic dysfunction-associated steatotic liver disease (MASLD) underlines the need of early predictors of response to such therapies. This study evaluated the impact of 1-year changes in liver stiffness measurement by Vibration-Controlled Transient Elastography (LSM by VCTE), controlled attenuation parameters (CAP), and serum alanine aminotransferase (ALT) on liver outcomes in patients with MASLD-related liver disease.
Method: A large multicentre cohort of MASLD patients with LSM≥8 kPa and prospective follow-up was enrolled. Liver-related events (LRE), including hepatocellular carcinoma (HCC) and liver decompensation (LD), were evaluated during follow-up. LSM, CAP, and ALT were assessed at baseline and at 1-year follow-up. Cumulative incidence functions and cause-specific Cox regression analyses were performed to correlate 1-year reduction in LSM, CAP, and ALT with the risk of developing LRE, LD and HCC.
Results: In 2443 patients with MASLD and LSM≥8 kPa, a 1-year reduction in ALT of 17 IU/L (HR 0.62; 95% CI 0.41–0.95; p = 0.02) and a 20% reduction in LSM (HR 0.44; 95% CI 0.29–0.67; p < 0.001) were both independently associated with a lower risk of LRE. Similarly, in 1412 patients with MASLD and LSM≥10 kPa, a 1-year reduction in ALT of 17 IU/L (HR 0.62; 95% CI 0.39–0.98; p = 0.04) and a 20% reduction in LSM (HR 0.42; 95% CI 0.27–0.66; p < 0.001) were independently associated with a decreased risk of LRE. Comparable results were observed when considering LD separately, but not for HCC. One-year changes in CAP did not predict liver outcomes. When combining 1-year reduction in ALT of 17 IU/L and a 1-year 20% reduction in LSM, the 5-year probabilities of LRE ranged from 2.1% in the best profile to 5% in the worst profile in patients with LSM≥8 kPa, and from 3.3% to 8.1% in those with LSM≥10 kPa.
Conclusion: One-year reductions in ALT of 17 IU/L and in LSM by 20%, not changes in CAP, reduce long-term liver outcomes in patients with MASLD, providing a new perspective on monitoring therapy effectiveness.

WED-419

The urine steroid metabolome combined with machine learning performs similarly to established non-invasive markers to risk stratify for the presence of advanced MASLD fibrosis

Email: hamish.miller@nhs.net

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects around 30% of people worldwide (Younossi, Z.M., et al. 2023). The strongest predictor of clinical outcome in patients with MASLD is liver fibrosis stage (Dulai, P.S., et al. 2017, Ekstedt, M., et al. 2015, Sanyal, A.J., et al. 2021). Due to limitations with the liver biopsy, there is a need to develop reliable non-invasive tests to identify patients with advanced fibrosis. There are currently no validated non-invasive urine tests to stage MASLD; The TrUSt-NAFLD study aimed to prospectively validate the use of urine steroid metabolite analysis coupled with machine learning to diagnose and stage MASLD (Miller, H., et al. 2024)
Method: Between May 2021 and November 2023, 461 patients were recruited to the TrUSt-NAFLD study with ethical approval. 151 healthy control patients were recruited from the Oxford Biobank and 310 patients with biopsy-proven MASLD were recruited from 8 centres across the United Kingdom. Urine samples were analysed using liquid chromatography tandem mass spectrometry (LC-MS/MS) for 19 steroid metabolites. A machine learning based classifier, Generalised Matrix Learning Vector Quantisation (GMLVQ), was used to classify patients into early (F0-2) or advanced (F3-4) fibrosis.
Results: The TrUSt-NAFLD cohort is a representative cohort of patients with MASLD who underwent a clinically indicated liver biopsy to determine MASLD stage and a matched healthy control cohort. The advanced fibrosis (F3-4) cohort were significantly older

than those with early fibrosis (F0-2) (59 *vs.* 48 years, $p < 0.01$) but there were no significant differences in sex or BMI between the groups. There was a significantly higher rate of diabetes in the advanced fibrosis group when compared with participants with early fibrosis (69.1 *vs.* 38.8%, $p < 0.01$) and consistent with this, glycated haemoglobin was also higher (49.0 *vs.* 41.5 mmol/L; $p < 0.01$). The urine steroid metabolite analysis coupled with GMLVQ performed similarly to other established non-invasive biomarkers (AUROC = 0.67), including Fib-4 (0.72), NFS (0.69) and VCTE (0.69) at distinguishing early from advanced fibrosis. It was also able to distinguish healthy controls from patients with MASLD (AUROC = 0.79).

Conclusion: The urine steroid metabolome provides a non-invasive method of assessing liver phenotype based on non-classical liver markers. None of the non-invasive tests performed well at distinguishing early from advanced fibrosis, emphasizing the need to refine these tests, including this analysis, to limit the use of the liver biopsy. Further work needs to be undertaken to better understand how the urine steroid metabolome changes over time in relation to liver phenotype.

WED-420

Prescreening with a novel machine learning model (LiverPRO) may improve trial enrollment efficiency in metabolic dysfunction-associated steatohepatitis (MASH): a retrospective analysis of the SYNERGY-NASH trial

Mark Hartman[1], Yu Chen[1], Katrine Prier Lindvig[2,3], Yuanyuan Tang[1], Abhi Malatpure[1], Maja Thiele, Aleksander Krag. *[1]Eli Lilly and Company, Indianapolis, United States; [2]Evido Health, Copenhagen, Denmark; [3]Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark*
Email: hartman_mark_l@lilly.com

Background and aims: MASH is a progressive liver disease linked to increased liver-related morbidity and mortality. Patient recruitment for MASH clinical trials often requires liver biopsies, leading to screen failure rates exceeding 70%. LiverPRO is a machine learning model that predicts the risk of significant (≥F2) or advanced (≥F3) liver fibrosis based on age and 3 to 9 standard laboratory test results: AST, ALP, GGT, INR, albumin, bilirubin, platelets, sodium, and cholesterol. We evaluated the use of LiverPRO to improve enrollment efficiency of patients with biopsy-proven MASH and ≥F2 or ≥F3 fibrosis.

Method: We evaluated the performance of LiverPRO on screening data from SYNERGY-NASH, a completed phase 2 trial of tirzepatide in patients with biopsy-confirmed MASH and stage 2 or 3 fibrosis, which reported an overall screen failure rate of 87%. The trial used AST and Fibroscan-based criteria to select participants for "per-protocol" biopsies; LiverPRO's diagnostic performance was assessed on participants in this group (historical biopsies were excluded). We validated a strategy for deploying LiverPRO as a prescreening tool prior to applying the Fibroscan-AST (FAST) score.

Results: Of the 1583 screened patients, 1148 had results for ≥5 LiverPro input variables, allowing prediction (94%, 99% and 99.8% had 10, ≥9 and ≥8 variables, respectively); of these 462 had "per-protocol" biopsies. Using a standardized LiverPRO rule-in cutoff of 0.20 for detecting ≥F2 fibrosis across all sites, LiverPRO demonstrated a sensitivity of 89%, a specificity of 33%, and a positive predictive value (PPV) of 57%. When applying site-specific rule-in cutoffs for ≥F2 (0.20 for gastroenterology/hepatology sites and 0.65 for other sites), LiverPRO achieved a sensitivity of 54%, a specificity of 64% and a PPV of 60%. For detecting ≥F3 fibrosis with a rule-in cutoff of 0.15, LiverPRO showed a sensitivity of 25%, a specificity of 93% and a PPV of 58%. Based on these results, LiverPRO is predicted to improve the success rate for identifying patients with ≥F2 fibrosis from 50% to 60% (a 20% relative improvement) and for ≥F3 fibrosis from 29% to 58% (a 100% relative improvement) compared to the patient selection strategies used in SYNERGY-NASH. To evaluate a potential future screening strategy combining LiverPRO and the FAST score, we analyzed data from 952 participants with results from both tests. Using LiverPRO as a prescreening tool could reduce the number of patients screened for trial eligibility by 65% for the ≥F2 and by 89% for the ≥F3 population. This approach could also decrease the number of liver biopsies by 45% and 79% and improve enrollment by 96% and 307% for targeted ≥F2 and ≥F3 populations, respectively.

Conclusion: These data suggest that LiverPRO could significantly enhance the enrollment efficiency of MASH clinical trials with fewer liver biopsies, reduced costs and lower patient burden.

Email: hhuneau@emory.edu

Background and aims: Noninvasive tests (NITs) for identifying pediatric metabolic dysfunction-associated steatohepatitis (MASH) remain a critical need. The NASH Clinical Research Network (CRN) provides an extensive dataset of children and adolescents with biopsy-confirmed MASLD and MASH, including detailed clinical phenotyping and metabolomics data. This study aimed to identify and validate a robust screening panel for pediatric MASH using clinical and metabolomic biomarkers from a cross-sectional sample of youth enrolled in one of three NASH CRN studies (TONIC, DB1, and DB2), along with healthy controls.

Method: Untargeted metabolomics analysis was performed on fasting serum samples using liquid chromatography-mass spectrometry (LC-MS). Clinical assessments included anthropometrics, blood lipids, liver enzymes, and measures of glucose and insulin metabolism. MASLD/MASH status was determined by liver biopsy for NASH CRN participants and MRI for controls. A machine learning pipeline was developed to train a classification model. Clinical features were selected using the Kolmogorov-Smirnov test ($p < 0.05$), and the metabolomics feature set was initially reduced to the 52 metabolites that were assigned non-zero coefficients during LASSO regression. Feature importance was ranked using CatBoost, a gradient-boosted decision tree algorithm. The top 10 annotated metabolites, based on feature importance, were included in the final CatBoost model. The

model underwent hyperparameter tuning, and data were split into training, validation, and test sets to ensure robust classification.
Results: The cohort included 587 children aged 5–18 years, 70% male, with a mean BMI z-score of 2.35 ± 0.84, and 72% identifying as Hispanic. Among the participants, 391 were diagnosed with MASH (21% Zone 3 pattern, 41% Zone 1 pattern, and 38% definite MASH), while 196 were non-MASH. The model incorporated eight clinical variables: AST, ALT, GGT, platelets, HOMA-IR, BMI z-score, TG:HDL ratio, and alkaline phosphatase. Metabolite features prioritized by the model included amino acid derivatives (cysteine-glutathione disulfide, argininosuccinic acid, glutamic acid), the microbial byproduct indole, the polyamine diacetylspermine, and lipid-associated metabolites (oleic acid, methyl decanoate, LysoPC(16:1), PC(40:5), and PE(38:9)). The final model achieved an AUROC of 0.88, with 92% sensitivity and 71% specificity.
Conclusion: The screening panel integrating clinical and metabolomics features demonstrates high potential to differentiate between pediatric MASH and non-MASH, surpassing previous diagnostic tools with an AUROC of 0.88. Capitalizing on the depth provided by metabolomics analysis, this model offers a comprehensive approach to characterizing pediatric MASH. Future directions include validating the model's predictive performance in a longitudinal cohort.

WED-422

The diagnostic ability for hepatic steatosis by attenuation imaging using MRI-PDFF as reference standard; a prospective multicenter study in Japan

Email: hiroko-i@hyo-med.ac.jp

Background and aims: Attenuation imaging have been wide-spread as the non-invasive methods using ultrasound for diagnosing hepatic steatosis. We aimed to estimate the diagnostic ability of Attenuation Imaging(ATI) for diagnosing the degree of hepatic steatosis by magnetic resonance imaging(MRI)-based proton density fat fraction (PDFF) as reference standard.
Method: We performed the prospective, multicenter and large cohort study of 1059 patients with chronic liver disease who underwent ATI and MRI-PDFF from September 2021 to March 2023. Steatosis grade was defined as grade 0 (S0) with MRI-PDFF <5.2%, grade 1 (S1) with 5.2% ≤ MRI-PDFF <11.3%, grade 2 (S2) with 11.3% ≤ MRI-PDFF <17.1%, or grade 3 (S3) with MRI-PDFF ≥17.1%. ATI values were measured five times and defined as the median of five measurement values with IQR/Median≤0.3 and R^2 value ≥0.7. In patients with 10 valid CAP measurements, IQR/median >30% was defined as unreliable. Patients with SCD ≤25 mm were evaluated using the M probe and patients with SCD > 25 mm were evaluated using the XL probe.
Results: Median age was 61 years old and there were 109 (10.3%) patients with HBV, 100 (9.4%) with HCV, 5 (0.5%) with HBV and HCV, and 845 (79.8%) with nonBnonC including 573 (54.1%) with MASLD. The correlation coefficient (CC) for ATI and log MRI-PDFF was strong correlation(r = 0.78). The ATI values according to the degree of hepatic steatosis using MRI-PDFF as reference standard were significantly increased with the progression of hepatic steatosis grade (P < 0.001). Area under the receiver operating curve(AUROC) and cutoff values of ATI for detecting ≥S1, ≥S2 and S3 steatosis using MRI-PDFF as reference standard were 0.91(95%CI; 0.89–0.92) and 0.65(dB/cm/MHz), 0.93(95%CI; 0.91–0.94) and 0.69(dB/cm/MHz), 0.91(95%CI; 0.89–0.93) and 0.72(dB/cm/MHz), respectively. For the 562 out of 1059 patients, Controlled Attenuation Parameter(CAP) were also measured. The correlation coefficient (CC) for ATI and log MRI-PDFF was significantly higher than that for CAP and log MRI-PDFF (P < 0.001). CC for CAP and log MRI-PDFF in the BMI ≥30 kg/m^2 groups were significantly lower than those in the BMI<30 kg/m^2 groups, respectively, but CC for ATI and log MRI-PDFF were not. ATI and CAP according to hepatic steatosis grade increased significantly with increasing hepatic steatosis grade. The AUROCs for ATI in detecting ≥S1, ≥S2 and S3 steatosis were significantly higher than that for CAP (P = 0.004, <0.001 and <0.001).
Conclusion: ATI is a useful non-invasive method for diagnosing hepatic steatosis.

WED-423

Risk factors for hepatic steatosis- a study of deceased liver donors

Jaimie Chang[1], Yanyu Zhang[1], Dr. Edie Chan[1]. *[1]Rush University Medical Center, Chicago, United States*
Email: jaimie_chang@rush.edu

Background and aims: Higher degrees of hepatic steatosis in liver donors are associated with higher rates of primary nonfunction and poorer liver transplant recipient outcomes. Therefore, assessing steatosis is an important factor to consider when selecting a liver donor. While there are some imaging techniques and basic calculators to non-invasively evaluate steatosis, liver biopsy with histologic analysis remains the gold standard. In this study we utilized a large, national donor database to identify risk factors for biopsy proven hepatic steatosis.
Method: Using the Scientific Registry of Transplant Recipients (SRTR) database, all deceased liver donors in the United States between 1987–2024 older than 18 years with recorded macrovesicular steatosis that was determined from a liver biopsy assessed by a pathologist were included in the study. Risk factors for hepatic steatosis were evaluated using univariate and multivariate logistic regression with least squares means and Tukey-Kramer adjustment for multiple comparisons. A binary outcome of less than or greater than 30% steatosis was used in statistical analyses. P < 0.05 was considered significant.
Results: 63,885 deceased liver donors met criteria to be included in the study, of which 53,433 (83.6%) had less than 30% and 10,452 (16.4%) had greater than or equal to 30% biopsy proven macrovesicular steatosis. After adjusting for covariates, the following variables were identified as independent risk factors for having greater than 30% steatosis on liver biopsy: female sex (OR = 1.21, p < 0.05), Hispanic ethnicity (OR = 1.28, p < 0.05), higher body mass index (BMI) (OR = 1.06, p < 0.0001) higher total bilirubin (OR = 1.13, p < 0.01), higher hemoglobin A1c (OR = 1.10, p < 0.01). Donors without a history of heavy alcohol use were at a decreased odds of having > 30% steatosis compared to those that did (OR = 0.59, p < 0.001).
Conclusion: Our outcomes demonstrate that sex, ethnicity, BMI, total bilirubin, Hgb A1c, and heavy alcohol use are independent risk factors for having greater than 30% macrovesicular steatosis on liver biopsy.

These results may inform transplant surgeons of steatosis when selecting liver donors when a biopsy is not able to be done.

WED-424

Fibroscan-based screening to determine the prevalence and severity of steatotic liver disease in type 1 diabetes – an australian quantentary centre experience

Janakan Selvarajah[1], Omar Salehi[1], Christine Lu[1], Faris Gondal[1], Bennett Anderson[1], Maddison Terlato[1], Ashok Raj[1]. [1]*The Royal Melbourne Hospital, Parkville, Australia*
Email: janakanlrh@gmail.com

Background and aims: Type 2 Diabetes (T2D) is one of the strongest risk factors for the development of Metabolic-dysfunction Associated Steatotic Liver Disease (MASLD), but the association with Type 1 DM (T1D) is less clear. Patients with T1D are at increased risk of hepatic steatosis due to traditional metabolic risk factors and also T1D-specific factors. There are limited epidemiological data for the prevalence of steatosis in T1DM, and no recommendations in EASL or AASLD guidelines on appropriate screening for MASLD. Here we prospectively screened patients with T1D for steatosis and fibrosis by in comparison to a population of T2D. Secondary aims were to determine clinical factors associated with MASLD and significant fibrosis, and the sensitivity of non-invasive blood markers for screening for significant fibrosis.
Method: ProspectiveFibroscan® assessment of consecutive patients attending outpatient T1D & T2D diabetes clinics was undertaken over a 9 month period in 2024. Steatosis was defined as CAP > 250 db/m^2 for M probe, CAP > 263 db/m^2 for XL probe.MASLD was defined by the AASLD 2023 consensus criteria. Significant fibrosis was defined as LSM ≥8.0 kPa. Clinical records were assessed for severity of diabetes, complications, and presentations related to major adverse cardiac events (MACE). FIB-4score ≥1.3 and NAFLD-fibrosis score ≥ - 1.455 were considered at risk for advanced fibrosis.
Results: Fifty four patients with T1D and 57 with T2D were assessed. For T1D, prevalence of steatosis and significant fibrosis were 48% and 17% respectively. Of those with steatosis, all met the definition for MASLD, independent ofHbA1c. Significant fibrosis was associated with higher BMI (37 vs 28 kg/m^2, p = 0.001), ALT (34 vs 21 U/L, p = 0.002), and recurrent unexplained hypoglycaemia (67% vs 4%, p = 0.028) but male sex (33% vs 44%), median duration of diabetes (31 yrs vs 24 yrs), HbA1c (8.0% vs 8.2%), MACE outcomes, microvascular and macovascular complications were not significantly different. Application of non-invasive tests in T1D cohort showed FIB-4 score had a sensitivity of 22% and specificity of 80% while NAFLD-fibrosis scores had a sensitivity of 67% and specificity of 38% to detect advanced fibrosis. In comparison in T2D, the prevalence of steatosis and significant fibrosis were 84% and 42%. Significant fibrosis was also associated with BMI (34 vs 28 kg/m^2, p = 0.002), ALT (42 vs 27, p = 0.033) and recurrent unexplained hypoglycaemia (50% vs 18%, p = 0.020). FIB-4 score had a sensitivity of 73% and specificity of 67%, and NAFLD-fibrosis scores had a sensitivity of 95% and specificity of 67% to detect advanced fibrosis.
Conclusion: Fibroscan-based screening in a quaternary diabetes clinic population showed a high prevalence of both steatosis and significant fibrosis for T1D but not to the same level as T2D. Significant fibrosis is associated with high BMI, ALT and also unexplained recurrent hypoglycaemia in both T1D and T2D. Non-invasive tests performed poorly to screen for advanced fibrosis in people with T1D and T2D.

WED-425

Validation of proposed non-invasive criteria for resmetirom treatment in metabolic-associated liver disease in clinical practice

Email: javi.ampuero@gmail.com

Background and aims: Resmetirom is the first FDA-approved drug for the targeted treatment of metabolic-associated liver disease (MASLD) in F2–F3 patients with steatohepatitis (MASH), initially excluding those with mild fibrosis or cirrhosis. Non-invasive criteria have been proposed for initiating treatment; however, these have not yet been validated in clinical practice. We aimed to evaluate the validity of proposed criteria for initiating resmetirom treatment in fibrotic MASH in clinical practice.
Method: Cross-sectional study of 1281 patients from the Hepamet registry with liver biopsy, comorbidity assessment, analytical profile, transient elastography (TE), and CAP. Fibrotic MASH was considered as fibrosis stage 2 and 3 with presence of MASH. A comprehensive review of international guidelines and expert consensus up to November 1, 2024, focusing on therapeutic indications for resmetirom and criteria for referral to specialists: a) Noureddin criteria for treatment: CAP > 280 dB/m, ALT > 20 UI/L in men and 17 UI/L in woman, TE > 10 kPa and TE<20 kPa, platelets > 140; b) AASLD Practice Guidance for treatment: TE 8–15 kPa; c) EASL guidelines for referring patients: FIB-4 > 2.67 or FIB-4 1.30–2.67 and TE > 8 kPa; d) AASLD guidelines for referring patients: FIB-4 > 2.67 or FIB-4 1.30–2.67 and TE > 12 kPa.
Results: MASH was identified in 44% (567/1281) of the population, while the distribution of fibrosis stages was as follows: F0 in 26% (331/1281), F1 in 26% (330/1281), F2 in 18% (227/1281), F3 in 20% (259/1281), and F4 in 10% (134/1281). Considering the primary endpoint, 22% (281/1281) of patients exhibited fibrotic MASH (F2 and F3 with MASH). However, only 31% (using AASLD therapeutic criteria) to 67% (using EASL referral criteria) of these patients met the treatment eligibility criteria under any strategy. Treatment-focused criteria included a higher proportion of patients at early fibrosis stages (approximately 45%), whereas referral-focused criteria included more patients with cirrhosis (around 25%). Consequently, false positive and false negative rates ranged from 26% to 45% and 32% to 59%, respectively. Sensitivity and specificity were: a) Noureddin criteria: 41% and 74%; b) AASLD treatment criteria: 53% and 55%; c) EASL referring criteria: 68% and 60%; d) AASLD referring criteria: 46% and 73%. All strategies demonstrated AUROCs below 0.65, with the EASL referral guidelines achieving the best performance (AUROC

0.63). Additionally, EASL-based referral criteria yielded the most favorable outcomes, identifying 32% (175/552) of patients compared to 13% (84/647) (p = 0.0001). These results were further corroborated by Cohen's kappa statistics and decision curve analysis.
Conclusion: The diagnostic performance and reliability of the proposed non-invasive criteria for initiating resmetirom treatment and for reffering patients to specialized units were suboptimal. More than half of the indicated patients (fibrotic MASH) would not receive treatment under these criteria.

WED-429

The utility of noninvasive tests - LIVERFASt, FIB4 and vibration-controlled transient elastography (VCTE, Fibroscan) - in the initiation and monitoring of the therapy with TNR-beta agonist (resmetirom) in MASH patients

Jeevin Sandhu[1], Shaheen Mehrara[2], Mona Munteanu[3], Mangesh Pagadala[4], Ashwini Mehta[1], John Lee[3], Parvez Mantry[2].
[1]Methodist Dallas Medical Center, Division of Hepatology, Internal Medicine, Dallas, TX, United States; [2]Methodist Dallas Medical Center, Division of Hepatology, Dallas, United States; [3]Fibronostics, Indian Harbour, FL, United States; [4]Methodist Dallas Medical Center, Division of Hepatology, Dallas, TX, United States
Email: mona.munteanu@fibronostics.com

Background and aims: Resmetirom therapy (RT) was recently approved by the FDA for non-cirrhotic MASH with fibrosis. The impact of RT on noninvasive tests (NIT) has not been assessed in real-life patients (pts). LIVERFASt (LFAST) is a new blood-based NIT that assesses liver fibrosis, activity, and steatosis, potentially useful in monitoring pts under RT. The aim was to assess retrospectively the dynamic of NITs in initiating/monitoring of pts ongoing RT [fibrosis, activity and steatosis progression rate (PR) and mean change from baseline].
Method: Pts with baseline and repeated either NITs [LFAST, vibration-controlled transient elastography (VCTE) and FIB4] during RT have been included. LFAST is a blood-based test that generates scores (0.00–1.00) proportional to the severity of fibrosis, activity, and steatosis. Statistics assessed PR between baseline (t0) and repeated (t1) NITs using repeated measurements ANOVA, descriptive and sensitivity (for GLP-1 analog treated pts) analysis.
Results: 24 eligible patients have been enrolled without RT discontinuation (42% 100 mg-dose), 46% male, 54% T2D, mean (se) age 59 (2), BMI 33 (1), ALT 48 (6), AST 36 (5), platelets 237 (11), FIB4 1.46 (0.13). Using LFAST and VCTE, baseline prevalence of F2F3 were 54% and 55%. Median (range) delays (months) t0-t1 were 6.4 (4.3;7.9) for LFAST and 5.1 (2;7.4) for FIB4. 52% patients t0-FIB4 ≥1.3 and 15 patients already had t1-FIB4, without significant change for FIB4, ALT or AST (1.62 vs 1.68), despite platelets count improvement (241 vs 226*109, p = 0.04). 6 patients that had concomitant GLP-1 analogs (FIB4 1.54 vs 1.57, p = ns). Only two patients had repeated VCTE/CAP (kPa/dB/m) with changes in LSM of 0.4/87 and in CAP of 1/10. Up to date 6 patients had achieved t1-LFAST: median fibrosis (0.39 vs 0.39), steatosis (0.62 vs 0.53), activity (0.30 vs 0.34). The median (range) PR t0-to-t1 per month were: for FIB4 –0.028 (–0.28;1.00) and for LFAST fibrosis 0.006 (–0.02;0.05), steatosis –0.009 (–0.09;0.01) and activity 0.002 (–0.07;0.03). The mean (se) decreases in total cholesterol [–18 (11) mg/dl] had no significant impact in Apolipoprotein A1 [–4.2 (8.0) mg/dl] and LFAST score [0.02 (0.02)].
Conclusion: Initiation of RT based on non-invasive assessment of patients using LFAST, FIB4 (fibrosis only) and VCTE is efficient and allows further non-invasive monitoring. A rapid trend in steatosis improvement was observed.

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) with fibrosis is a highly prevalent condition among people with type 2 diabetes (T2D). T2D is a major risk factor for more severe stages of liver disease (e.g., cirrhosis and hepatocellular carcinoma) resulting in a high economic burden globally. We aimed to identify cost-effective management approaches to detect, prevent and treat MASH with liver fibrosis in people with T2D.
Method: A generalized cost-effectiveness analysis was conducted from a health system perspective in 12 countries representing all six WHO regions: Brazil, Chile, Germany, Italy, Japan, Saudi Arabia, South Africa, Spain, Sweden, Tanzania, Thailand and United States of America (USA). Using an 80% coverage level for each approach, 14 approaches, including the standard of care (SoC) defined as the absence of any systematic intervention, were considered: (1) Fibrosis-4 (FIB-4) screening; (2A) FIB-4 + vibration-controlled transient elastography (VCTE); (2B) FIB-4 + enhanced liver fibrosis test (ELF);

(3A) FIB-4, VCTE, hepatologist, intensive lifestyle intervention (ILI); (3B) FIB-4, ELF, hepatologist, ILI; (4A) FIB-4, VCTE, hepatologist, resmetirom; (4B) FIB-4, ELF, hepatologist, resmetirom; (5A) FIB-4, VCTE, hepatologist, resmetirom, ILI; (5B) FIB-4, ELF, hepatologist, resmetirom, ILI; (6A) FIB-4, VCTE, hepatologist, semaglutide; (6B) FIB-4, ELF, hepatologist, semaglutide; (7A) FIB-4, VCTE, hepatologist, semaglutide, ILI; (7B) FIB-4, ELF, hepatologist, semaglutide, ILI. A cohort state-transition model simulated liver fibrosis progression/regression and the 14 approaches' impact over the cohort's lifetime among 10 health states (from no fibrosis to death). Outcomes of interest were the average cost-effectiveness ratios (ACERs) and incremental cost-effective ratios. The comparator was the null scenario. The lower the ACER, the more cost-effective the approach, for a given threshold.

Results: The SoC, had the lowest ACERs in 8 of the 12 countries (not in Chile, Germany, Saudi Arabia, and USA). Treatment with ILI, after screening through ELF or VCTE, was found to be cost-effective in all countries. ILI and treatment with semaglutide were cost-effective in 11 out of 12 countries (not Tanzania) and ILI with resmetirom was found to be cost-effective in 7 out of 12 countries (not Brazil, Chile, South Africa, Tanzania, and Thailand). One GDP per capita was used as threshold for each country.

Conclusion: Screening approaches that are followed by both lifestyle and pharmacological treatments aimed at tackling liver fibrosis in patients with T2D and liver fibrosis with MASH were found to be cost-effective based on the reported and estimated costs in the majority of the countries studied. These "best buys," evaluated in relation to the willingness to pay threshold of each country, can inform health policy decision-making.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of the general population and is the most rapidly rising cause of hepatocellular carcinoma (HCC). Current guidelines recommend HCC surveillance in patients with cirrhosis when the annual HCC incidence exceeds 1% without specifying the role of noninvasive tests in patient selection. Thus, we aimed to define noninvasive test thresholds to select patients with MASLD for HCC surveillance.

Method: This cohort study included patients with MASLD who had received vibration-controlled transient elastography (VCTE) examination at 16 centres across the US, Europe, and Asia, of which data were collected prospectively at 14 centres. Adult patients aged 18 years or older with hepatic steatosis diagnosed by histologic methods (steatosis in ≥5% of hepatocytes) or imaging studies (ultrasonography, computed tomography or magnetic resonance imaging, or controlled attenuation parameter ≥248 dB/m by VCTE) and available fibrosis-4 index (FIB-4) and VCTE results were included. The primary outcome was incident HCC, with non-liver-related death treated as a competing event.

Results: A total of 12,950 patients had FIB-4 and liver stiffness measurement (LSM) (mean [SD] age 51.7 [13.9] years; 5,316 [41.1%] male). At a median follow-up of 47.7 (IQR, 23.3–72.3) months, 109 (0.8%) patients developed HCC. FIB-4 was below the low cutoff (<1.3 for patients aged <65 years, and <2.0 for patients aged ≥65 years), between the low cutoff and <2.67, 2.67–<3.25, and ≥3.25 in 66.3%, 23.9%, 3.4%, and 6.4% of patients, and the corresponding annual HCC incidence was 0.07%, 0.17%, 0.77%, and 1.18%, respectively. As a standalone test, the annual HCC incidence exceeded 0.2% when LSM was ≥10 kPa and 1% when LSM was ≥20 kPa. If LSM was performed as a second step only among patients with FIB-4 above the low cutoff, the annual HCC incidence exceeded 0.2% when LSM was ≥10 kPa and 1% when LSM was ≥15 kPa. The performance of the noninvasive tests was consistent across subgroups based on age and the presence of diabetes.

Conclusion: HCC surveillance should be offered to MASLD patients with FIB-4 ≥3.25 or LSM ≥20 kPa. When a two-step approach is adopted, LSM ≥15 kPa in patients with increased FIB-4 predicts a high risk of HCC.

WED-433-YI

Translating genetic information into clinical practice: Improved decision-making in advanced fibrosis assessment

Dong Yun Kim[1], Hyun-Soo Zhang[1], Jae Seung Lee[1], Hye Won Lee[1], Mi Na Kim[1], Beom Kyung Kim[1], Seung Up Kim[1], Do Young Kim[1], Sang Hoon Ahn[1], Hyun Woong Lee[1], Heon Yung Gee[1], Jung Il Lee[1], Jun Yong Park[1]. [1]*Yonsei University College of Medicine, Seoul, Korea, Rep. of South*
Email: drpjy@yuhs.ac

Background and aims: Genetic information is not yet used for the clinical diagnosis of advanced fibrosis in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Here we investigated whether incorporating genetic information regarding *PNPLA3* and *TM6SF2* into existing non-invasive fibrosis scoring systems could enhance the predictive accuracy, particularly in terms of reducing indeterminate diagnostic zones.
Method: Data were collected from a cohort of 573 patients with biopsy-proven MASLD. All participants underwent liver stiffness measurement (LSM), serum marker analysis, and genotyping for *PNPLA3* (rs738409), *TM6SF2* (rs58542926), and other relevant SNPs. We evaluated the benefit of adding genetic information to existing non-invasive tests (NIT)—including the Agile 3+, Fibrosis-4 (FIB-4) index, and NAFLD fibrosis score (NFS). Decision curve analysis (DCA) was performed to determine the net benefit of adding genetic information, and we analyzed the impact on reducing indeterminate zones.
Results: Integration of *PNPLA3* and *TM6SF2* genotypes improved the predictive accuracy of existing models, particularly by reducing the indeterminate diagnostic zones Additionally, integrating genotype data into existing NIT significantly improved their performance, as demonstrated by higher net benefits compared to models without genetic information. The net benefit at a 30% threshold increased from 18.7 to 19.0 per 100 patients with genotypes for Agile 3+, increased from 12.7 to 13.7 for the NFS, and increased from 9.2 to 12.1 for FIB-4.
Conclusion: Incorporating genetic data into NIT for MASLD enhanced their predictive accuracy. Addition of genetic data particularly reduced indeterminate zones, thereby offering a more reliable tool for identifying patients at risk for advanced fibrosis. This approach may improve clinical decision-making and outcomes.

WED-434

Use of noninvasive tests (NITs) to diagnose and follow non-alcoholic steatohepatitis (NASH) with liver fibrosis patients treated with resmetirom

Jörn M. Schattenberg[1], Naim Alkhouri[2], Rebecca Taub[3], Dominic Labriola[3], Arun J. Sanyal[4], Vlad Ratziu[5], Mazen Noureddin[6]. [1]*Metabolic Liver Research Program, I. Department of Medicine, University Medical Center of Johannes Gutenburg University Mainz, Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany;* [2]*Arizona Liver Health, Phoenix, United States;* [3]*Madrigal Pharmaceuticals, West Conshohocken, United States;* [4]*Virginia Commonwealth University, Richmond, United States;* [5]*Sorbonne Université, ICAN Institute for Cardiometabolism and Nutrition, Assistance Publique–Hôpitaux de Paris (APHP), INSERM, UMRS 1138, Centre de Recherche des Cordeliers, Paris, FRANCE, Paris, France;* [6]*Houston Methodist Hospital, Houston, United States*
Email: joern.schattenberg@uks.eu

Background and aims: MAESTRO-NASH (NCT03900429) is an ongoing 54-month, randomized, double-blind, placebo-controlled Phase 3 trial evaluating the efficacy of resmetirom in patients with biopsy-confirmed NASH and fibrosis. 966 patients with biopsy-confirmed NASH were randomized 1:1:1 to resmetirom 80 mg, resmetirom 100 mg, or placebo once daily. Dual primary endpoints at Week 52 were achieved with both resmetirom 80 mg and 100 mg: NASH resolution with no worsening of fibrosis (NR) or ≥1-stage improvement in fibrosis with no worsening of NAS (FI). Both Week 52 liver biopsy endpoints, NR and FI, were achieved. Resmetirom was recently approved for the treatment of adult patients with noncirrhotic NASH and liver fibrosis consistent with F2 to F3 stages. Expert guidances recommend treatment with resmetirom based on staging fibrosis using FibroScan VCTE. EASL recommends stratifying patients using FIB-4. Most guidelines recommend using VCTE cutoffs lower than 10≤15 kPa for treatment.
Method: We assessed results from baseline noninvasive tests (FIB-4, VCTE) against biopsy results in MAESTRO-NASH to measure how well they diagnosed noncirrhotic patients with NASH (consistent with F2–F3 stages at baseline). We assessed the utility of a lower VCTE cutoff (8.5 to <10 kPa) in capture of F2 and F3 patients who otherwise would be missed. Also evaluated was the addition of MRE/MRI-PDFF or ELF to FibroScan VCTE to assess diagnostic utility.
Results: FIB-4 poorly predicted patients in the non-cirrhotic fibrosis stages: F2 (60% patients fell into low-risk) and F3 (40% fell into low-risk). Including a lower cutoff of VCTE (8.5 to <10 kPa) captured F1B (34% 8.5≤10 kPa) and many F2 (25% 8.5≤10 kPa) and F3 patients (19% 8.5≤10 kPa). The addition of MRE/MRI-PDFF to FibroScan VCTE increased diagnostic accuracy for F2/F3 to 68% and F4 to 81%. The addition of the ELF to the FibroScan VCTE suggested that a low ELF result paired with high VCTE may warrant a VCTE repeat.
Conclusion: Identification of patients with NASH F2 to F3 was achieved with FibroScan and VCTE. F1B are F2 equivalent (F1B is moderate fibrosis on biopsy). Patients with fibrosis stage F4 were effectively ruled out. In addition to FibroScan VCTE, practitioners may consider expanded noninvasive criteria (ELF, MRE) to help refine fibrosis staging.

Development of a novel model using machine learning algorithms to predict absence of metabolic associated steatotic liver disease in healthy and patient trial volunteers. A population screening tool

Charlene Cheong[1], Jorg Taubel[2], Ulrike Lorch[3], Tom York[4], Dilshat Djumanov[5], James Rickard[6]. [1]*Imperial College London, King's College London, London, United Kingdom;* [2]*Richmond Research Institute, Richmond Pharmacology Ltd, King's College London, London, United Kingdom;* [3]*Richmond Pharmacology Ltd, London, United Kingdom;* [4]*Imperial College London, London, United Kingdom;* [5]*Richmond Pharmacology Ltd, King's College London, London, United Kingdom;* [6]*Richmond Research Institute, King's College London, London, United Kingdom*
Email: jrickard@richmondresearchinstitute.org

Background and aims: Metabolic associated steatotic liver disease (MASLD) affects approximately one in four of the global adult population, and ranges in severity from benign fatty liver infiltration, to hepatitis, cirrhosis, hepatocellular carcinoma, and death. MASLD has important implications for clinical trial volunteers as an occult co-morbid condition – there is evidence that MASLD modulates drug metabolism, with studies suggesting that Grade 3–4 liver reactions are four times more common in healthy volunteers with probable MASLD than without. Halting promising potential new drug therapies in clinical development due to false positive liver safety signals. Additionally, the tool could be used to screen the population for those not exhibiting symptoms.
Method: An observational cross-sectional study of 1507 clinical trial volunteers was completed, collecting bioimpedance vector analysis (visceral fat%, total body fat% and skeletal muscle %), anthropometric measurement and laboratory bloods. A FibroScan is performed as a pragmatic gold standard 'outcome' for MASLD using >248 dB/m or >7.6 kPa as a positive. The data was divided into a training set of (75%) used to build the model, (25%) used to validate its predictive accuracy. Lasso Logistic Regression, Elastic Net Logistic Regression, Random Forest and XGBoost were then compared for model with highest performance. SHAP analysis was used to identify feature importance and remodelling with reduced features to simplify clinical data needed for the model was performed.

Results: All models achieved an AUROC 0.91 or better. Random Forest produced the highest performing model using all 18 features achieving AUROC 0.92, Accuracy 0.866, F1 score 0.705 and NPV 0.932. A reduced feature model developed with 7 features (Waist circumference, WHR, BMI, ALT, ALP, weight, age) achieving AUROC 0.91, Accuracy 0.879, F1 Score 0.714 and NPV 0.923.
Conclusion: The model developed produces a highly accuracy tool which using waist circumference, height, weight, ALT, ALP and Age – readily available in clinical settings. Allowing research teams to identify prospectively confirm enrolled volunteers with pre-clinical MASLD. This is a group where the effective detection of concomitant, occult fatty liver disease is possible and has significant implications for adverse drug reactions in first-in-human studies. Feasibility in the health screening setting is now starting for earlier identification and intervention.

Identifying risk factors linked to metabolic-associated steatotic hepatitis in people living with HIV in Newark, New Jersey
Jihad Slim[1], Paul Bellafiore[1], Bereket Tewoldemedhin[1], Barbara Tempalski[2], Corey Rosmarin-DeStefano[2], Kevin Leyden[2], Ronald Poblete[2]. *[1]St Michaels Medical Center, NYMC, Newark, United States; [2]North Jersey Community Research Initiative (NJCRI), Newark, United States*
Email: jsmdsmmc@gmail.com

Background and aims: People living with HIV (PLWH) have a high incidence of comorbid conditions increasing their risk for metabolic-associated steatotic hepatitis (MASH). Limited data exists on risk factors that contribute to the highest risk for MASH, particularly among PLWH. In this study, we analyze several possible demographic and metabolic risk factors to better understand their contribution to MASH risk in this population.
Method: A cross-sectional study was conducted at two HIV clinics in Newark, NJ, USA between July 2024 and October 2024. Liver elastography was used to measure the controlled attenuation parameter (CAP) in PLWH attending these clinics. Eligible participants were over 18 years old, fasting for at least two hours prior to testing, and had an HIV viral load <200 c/ml. Individuals with chronic hepatitis B or C or excessive alcohol consumption (AUDIT score >5) were excluded. Participants were categorized into two groups based on CAP values: Group 1 (CAP consistent with S0-S1) and Group 2 (CAP consistent with S2-S3). Epidemiologic data, anthropometric measurements, comorbid conditions, and current medications were collected, and visceral adiposity index (VAI) was calculated. Risk factors for MASH were analysed using bivariate and multivariate methods.
Results: A total of 222 patients underwent liver elastography, with 143 patients categorized into Group 1 and 79 into Group 2. Descriptive results indicate a higher proportion of males in both groups, with Group 1 having 69.2% and Group 2 at 59.5%. Blacks are the majority race (60.1% in Group 1, 53.2% in Group 2). Hispanic and non-Hispanic representation is consistent across groups (32.2%–32.9% and 67.1%–67.8%, respectively). Older participants (>50 years) are more prevalent in Group 2 (82.3%) compared to Group 1 (63.4%). No statistically significant differences were found between the groups in gender, race, ethnicity, use of tenofovir alafenamide, second-generation integrase inhibitors, diabetes mellitus, or concurrent statin use ($p \geq 0.05$). Significant differences were identified in age ($p = 0.0086$), BMI ($p = 0.0001$), waist-hip ratio ($p = 0.0012$), and visceral adiposity index (VAI) ($p = 0.0004$). High cholesterol (total cholesterol >200 mg/dL) showed a weak association with MASH ($p = 0.04$). Additionally, results indicated Black PLWH had a 36% prevalence of excessive fat accumulation in the liver.
Conclusion: The strongest predictors of MASH were VAI, waist-hip ratio, BMI, and age. Refining MASH screening recommendations for PLWH involves prioritizing high-risk individuals based on specific metabolic indicators, integrating non-invasive tools into routine HIV care, and addressing health disparities through resource allocation and tailored guidelines. These efforts can improve early detection, intervention, and overall outcomes for this vulnerable population.

WED-437
suPAR levels independently discriminate patients with at-risk MASLD
Julian Pohl[1], Alexander Otto[1], Sven Lamatsch[1], Cornelius Engelmann[1], Kai Kappert[2], Frank Tacke[1], Münevver Demir[1]. *[1]Department of Hepatology and Gastroenterology, Campus Virchow Klinikum (CVK) and Campus Charité Mitte (CCM), Charité-Universitätsmedizin Berlin, Augustenburger Platz 1, 13353 Berlin, Germany, Berlin, Germany; [2]Charité - Universitätsmedizin Berlin, corporate member of Freie Universität Berlin and Humboldt-Universität zu Berlin, Institute of Diagnostic Laboratory Medicine, Clinical Chemistry and Pathobiochemistry, Augustenburger Platz 1, 13353 Berlin, Germany, Berlin, Germany*
Email: julian.pohl@charite.de

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading global cause of liver fibrosis. Early identification of patients at risk for significant fibrosis, which can progress to cirrhosis and other liver-related complications, relies heavily on non-invasive tests. The soluble urokinase plasminogen activator receptor (suPAR), an inflammatory biomarker linked to adverse outcome in various chronic conditions, has shown promise in liver disease and may offer added value in identifying MASLD at risk. This study aimed to assess the predictive value of suPAR for significant fibrosis in patients with MASLD and to compare its performance with other well-established non-invasive fibrosis scores, including FIB-4, APRI, NFS, and FAST. Finally, we explored whether suPAR adds predictive value or enhances current at-risk prediction models.
Method: From 2020 to 2021, we prospectively enrolled 259 patients with MASLD at the Department of Gastroenterology and Hepatology, Charité, Berlin, Germany. Each patient's epidemiological, medical, and laboratory data were systematically collected. At enrollment, all patients underwent a vibration-controlled transient elastography (by FibroScan®), routine laboratory work-up, as well as measurement of suPAR levels. Using non-invasive fibrosis assessments (FibroScan®, ultrasound, and various scoring models), we stratified patients into two groups based on their risk for at least significant fibrosis (≥8.0 kPa or sonographic signs of significant fibrosis). We then compared suPAR levels between the low- and high-risk groups and analyzed each scoring system's AUROC for fibrosis detection.
Results: In total, 66.41% (n = 172) patients were grouped in the low-risk group and 33.59% (n = 87) in the high-risk group. suPAR showed a good predictive value for significant fibrosis, still, its AUROC (0.813) was significantly inferior to the FAST and FIB-4 scores (0.865; $p = 0.012$ and 0.874; $p = 0.036$, respectively). suPAR performed non-inferior to the APRI and NFS scores. In both univariate and multivariate regression analyses, suPAR demonstrated the highest discriminatory power (OR: 1.787; $p < 0.001$ and OR: 1.263; $p = 0.013$) among all single laboratory and epidemiological parameters assessed for identifying higher stages of fibrosis (at-risk MASLD).
Conclusion: suPAR shows a good predictive power in the detection of significant stages of fibrosis compared to other, well-established scores, only FIB-4 and FAST performed better in our cohort. Still, its high discriminatory power on at-risk MASLD warrants the ability for suPAR in enhancing prognostic scores on fibrosis detection in the future.

WED-438

Systematic review of care pathways for metabolic dysfunction-associated steatotic liver disease (MASLD)

Email: k.m.vaneekhout@amsterdamumc.nl

Background and aims: The rising prevalence of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) demands diagnostic approaches to identify advanced liver fibrosis while simultaneously reducing unnecessary referrals of mild cases. Guidelines advocate clinical care pathways using a combination of non-invasive tests (NITs). However, the optimal sequence for efficient detection of advanced fibrosis across healthcare levels has not been unequivocally established. The aim of this paper is to provide a systematic review of studies on clinical care pathways for detecting and risk stratifying advanced fibrotic MASLD.

Method: A systematic literature search identified studies describing care pathways screening for advanced fibrotic MASLD. Articles were included if they described a care pathway at least consisting of: a well-defined group of patients, a well-defined structured plan of care, and a pathway applicable to several aspects of care (and not merely diagnosis). The search strategy was applied in the databases MEDLINE, Embase, Cochrane Library, and Scopus and finalized on October 4th, 2024. Study selection was conducted by two independent reviewers.

Results: Nine studies met the criteria: 4 one-tier, 4 two-tier, and 1 three-tier pathway. Study size ranged from 162 to 3,669, encompassing a total of 11,566 participants. Pathway populations included patients with type 2 diabetes mellitus (T2DM) (4 studies), a broader range of cardiometabolic risk factors (1 study), confirmed MASLD (3 studies), or the general population (1 study). FIB-4 and VCTE were the most commonly used NITs, followed by NFS and APRI. Seven pathways ultimately stratified their patients into low- and high-risk groups for advanced fibrosis, two added an intermediate-risk category. The number needed to screen (NNS) for hepatology referral varied significantly: 2–19 in T2DM, 5–12 in confirmed MASLD, and 49 in the general population. NNS for advanced fibrosis detection ranged from 11 to 89 in T2DM and 12 to 33 in confirmed MASLD. All studies concluded that patient risk identification improved. However, the studies differed in their definition of advanced fibrosis. Attendance rate progressively declined at each subsequent pathway step.

Conclusion: Clinical care pathways with NITs can align patient flows and organize transmural care for MASLD. Implementation of care pathways for MASLD showed a considerable amount of heterogeneity in the current evidence. The NNS is acceptably low when T2DM is present, but the high NNS in the general population argues against screening in this context. Evidence for screening with NITs in large cohorts with cardiometabolic risk factors for fibrotic MASLD is lacking and is very much awaited.

The GRIPonMASH project is supported by the Innovative Health Initiative Joint Undertaking, its members and its contributing partners under grant agreement No 101132946.

WED-439

Comparison of FibroScan© and iLivTouch© for liver stiffness and steatosis assessment in patients with MASLD

Kamela Gjini[1], Gian Paolo Caviglia[1], Angelo Armandi[1], Chiara Rosso[1], Fabrizio Amato[1], Martina Marano[1], Lorenza Vaira[1], Eleonora Dileo[1], Marta Guariglia[1], Elisabetta Bugianesi[1]. *[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy*
Email: kamelagjini@gmail.com

Background and aims: Noninvasive assessment of liver stiffness and steatosis is critical for managing MASLD, given its rising prevalence and risk of progression to fibrosis and cirrhosis. Vibration-controlled transient elastography (VCTE) with FibroScan remains the clinical benchmark in clinical practice. Recently, the iLivTouch device emerged as an alternative. This study evaluates the concordance of FibroScan and iLivTouch in assessing liver stiffness and steatosis in Caucasian patients with MASLD.

Method: This study included 56 adult patients with MASLD, recruited consecutively. Clinical, biochemical and anthropometric data were recorded. Liver stiffness and hepatic steatosis were assessed using FibroScan (Echosens, France) and iLivTouch (Wuxi Hisky Medical Technologies Co., Ltd., China) on the same day. FibroScan measurements included liver stiffness in kPa (F0 – F1: ≤7 kPa, F1 – F2: 7.1–8.6 kPa, F2 – F3: 8.7–9.5 kPa, F3: 9.6–10.2 kPa, F4: >10.3 kPa) and steatosis using CAP (dB/m). iLivTouch measurements included liver stiffness (kPa) categorized into fibrosis stages based on the device-specific cut-offs for MASLD (F0 – F1: ≤8 kPa, F1 – F2: 9–11 kPa, F2 – F3: 12–14 kPa, F3: 15–17 kPa, F4: >17 kPa) and ultrasound attenuation parameter (UAP) for steatosis severity (absent: <244 dB/m, mild: 244–269 dB/m, moderate: 269–296 dB/m, severe: >296 dB/m). The diagnostic agreement between the two devices was analyzed by Spearman correlation and inter-rater agreement (k).

Results: A total of 56 adult patients with MASLD were included in the study. Patients' median age was 60 (21–77) years; 32 (57.1%) patients were males. The median BMI was 29.7 (22.5–45.5) kg/m². Laboratory evaluations showed a median ALT level of 24.5 (9–140) U/L. The agreement between FibroScan and iLivTouch, evaluated using continuous variables, showed a moderate-to-good correlation (r_s = 0.726, 95% CI 0.574–0.830, $P < 0.001$) for liver stiffness values. Similarly, CAP (FibroScan) and UAP (iLivTouch) values for steatosis demonstrated acceptable correlation (r_s = 0.742, 95% CI 0.597–0.840, $p < 0.001$).

When evaluating agreement across fibrosis stages (F0–F1, F2, F3, F4) and steatosis grades (mild, moderate, severe), FibroScan and iLivTouch showed good agreement for both liver stiffness (k = 0.79, CI 0.64–0.95, $p < 0.001$) and CAP stages (k = 0.68, CI 0.50–0.85, $p < 0.001$). Patients were further grouped into two categories: F0 – 1 - 2 (mild to moderate fibrosis) and F3 - 4 (advanced fibrosis and cirrhosis), with agreement between devices for identifying these groups showing moderate-to-good concordance (k = 0.65, CI 0.37–0.93, $p < 0.001$).

Conclusion: iLivTouch showed a good agreement with FibroScan for liver stiffness and steatosis assessment in patients with MASLD. These preliminary results suggest that iLivTouch may be a viable alternative for non-invasive evaluation, with further studies needed to confirm its broader applicability.

Effect of liver damage on telomere length in people with diabetic kidney disease

Viktoriia Yerokhovych[1], Yeva Ilkiv[1], Dmytro Krasnienkov[2], Olena Karpenko[1], Iuliia Komissarenko[1], Nazarii Kobyliak[1].
[1]*Bogomolets National Medical University, Kyiv, Ukraine;* [2]*Institute of Gerontology Academy of Medical Sciences of Ukraine, Kyiv, Ukraine*
Email: korinna.viktoriaer@gmail.com

Background and aims: Renal and hepatic changes in the pathogenesis and progression of diabetes mellitus are closely related and comorbid. Chronic kidney disease (CKD) more often manifests in type 2 diabetes (T2D) due to the influence of metabolic disorders, early microvascular damage, the activation of systemic inflammation, atherosclerotic changes, and genetics. The presence of concomitant metabolic dysfunction–associated steatotic liver disease (MASLD) worsens the course of CKD in individuals with T2D. The relative telomere length of leukocytes (RTL) is considered a prognostic marker associated with life expectancy and the frequency of complications of diabetes, including liver and renal changes. This study aimed to compare RTL in people with hepatorenal syndrome and CKD without liver damage on a background of T2D.
Method: A total of 47 people with T2D participated in the cross-sectional study. The inclusion criteria were as follows: age over 18 years, presence of T2D, and CKD. Persons were divided into 2 groups depending on the presence of MASLD: group I, with hepatorenal lesions (n = 25), and group II, with only renal lesions (n = 22). The diagnosis of MASLD was established according to the criteria of the EASL–EASD–EASO guidelines 2024 and CKD–KDIGO 2022. A standardized method of real-time quantitative monochrome multiplex polymerase chain reaction was used to determine the relative LTL. In addition, laboratory indicators of the GFR according to the EPI-CKD formula, ALT, AST, metabolic profile, and results of ultrasound examinations of the kidneys and liver were used to establish the diagnosis.
Results: The RTL in leukocytes from the group of people with combined liver and kidney pathology was significantly shorter than that in the group with only renal lesions in T2D patients (1.06 (0.97; 1.18) vs. 1.19 (1.14; 1, 36), p = 0.002), which confirms the negative effects of comorbidities on patient outcome and prognosis. An inverse correlation was found between RTL and ALT in group I (r = −0.535; p = 0.005). The RTL, with a cutoff value of 1.02, can be considered a prognostic biomarker of hepatorenal development (sensitivity of 56%, specificity of 90%). The AUROC for the model was 0.76, 95% CI 0.621–0.899 (p = 0.025).
Conclusion: The results demonstrated that hepatorenal syndrome in T2D is associated with the accelerated aging and shortening of leukocytes RTL, which could impact the course of T2D and the development of complications.

WED-445

A comparison of the prognostic value of 12 body composition markers for MASLD, at-risk MASH and Increased liver stiffness in a general population setting

Laurens A. van Kleef[1], Maurice Michel[2], Jesse Pustjens[1], Mesut Savas[3], Roel van de Laar[4], Edith Koehler[5], Elisabeth van Rossum[3], Harry L.A. Janssen[1], Jörn M. Schattenberg[2], Willem Pieter Brouwer[1].

Email: l.vankleef@erasmusmc.nl

Background and aims: Excess visceral fat is the cornerstone of metabolic dysfunction steatotic liver disease (MASLD), development of metabolic dysfunction associated steatohepatitis (MASH) and fibrosis. Although body mass index (BMI) is used primarily, it might not be the body composition marker that has most prognostic value for impaired liver health. Here we compare 12 different body composition parameters and how they relate to MASLD, MASH and fibrosis.
Method: We used data from the NHANES 2017–2020 cycle, a United States population-based cohort with data on controlled attenuation parameter (CAP) and liver stiffness measurements (LSM). We selected patients with complete data on weight, height, waist circumference (WC) and hip circumference (HC). MASLD was defined as CAP ≥275 dB/m with metabolic dysfunction, MASH as FibroScan AST (FAST) score ≥0.35 and fibrosis as LSM ≥8 kPa. The prognostic value by area under curve (AUC)-analysis of a body shape index (ABSI), body adiposity index (BAI), BMI, body roundness index (BRI), fat mass (FM), HC, WC, waist to hip ratio (WHR), waist to height ratio (WHtR), waist adjusted BMI (wBMI), Weight adjusted waist index (WWI) and weight was determined for MASLD, MASH and fibrosis. Statistically significant differences were assessed by DeLong test. Non-linearity was assessed via restricted cubic splines adjusted for age, sex, ethnicity, smoking and alcohol consumption.
Results: The cohort comprised 6867 participants (age 48[32–62], 49% male) among them 41.3% had MASLD, 5.8% MASH and 8.7% fibrosis. WC obtained the highest AUC levels in the overall population for steatosis, MASH and fibrosis (AUC 0.81, 0.74 and 0.76, respectively); WHtR and BRI in male (AUC 0.83, 0.76 and 0.73, respectively) and female (AUC 0.79, 0.73 and 0.81, respectively). WC was not significantly inferior compared to WHtR or BRI in the sex-stratified analysis for all investigated outcomes. The best AUC for fibrosis was higher in females compared to males (0.81 vs 0.73). Restricted cubic spline analysis indicated non-linear associations for MASLD and fibrosis, but not for MASH. MASLD risk increased across the entire spectrum, but the increase attenuated slightly after WC >110 cm, whereas the risk of fibrosis remained stable until WC 100 cm, and started to rapidly increase thereafter.
Conclusion: Waist circumference was the body composition parameter with the highest prognostic value for MASLD, at-risk MASH, and increased LSM in a general population setting. Waist-circumference based body composition markers such as BRI or WHtR did not have significantly additional predictive value compared to waist circumference. Waist circumference should be considered as the preferred body composition parameter in individuals at risk of MASLD, MASH or fibrosis. Importantly, the risk of MASLD and MASH increases across the entire spectrum, whereas fibrosis risk only increases after waist circumference >100 cm.

Email: laura.derosa.95@gmail.com

Background and aims: Liver steatosis can be easily qualitative/semi-quantitative diagnosed by routine abdominal ultrasound (US) examination by mean of indirect US parameters associated with liver fat accumulation or the automated monoparametric measurement of US beams attenuation rate index. The unmet need remains a reliable quantitative US measure of liver fat content. We proposed a multiparametric method, Steatoscore2.0 (StSc) that was shown to estimate LFC from B-mode images with high correlation and agreement with the gold standard magnetic resonance LFC-based measurement (DOI: 10.1111/liv.16078). The aim of this study was to evaluate the feasibility and reproducibility of StSc using retrospectively registered abdominal US images routinely obtained for screening/diagnostic aims in a general population.
Method: We included 471 consecutive subjects (sbj) from a general population cohort (ProgeNIA including inhabitants from 4 towns in east-central Sardinia whose genetics and epidemiology of aging-related traits and diseases were prospectively studied) with available routine US abdominal images acquired during 2013–2015. In a feasibility study we investigated the percentage of sbj whose retrospectively acquired US abdominal images allowed the StSc assessment. We analyzed inter-operator reproducibility evaluating StSc assessed by two different operators [Pearson's correlation (R), Intraclass Correlation Coefficient (ICC) and Bland-Altman Analysis (BAA) with 95% limits of agreement]. Then we performed a correlation analysis between StSc and sbj characteristics: age, sex, BMI, waist circumference (WC), AST, ALT, GGT, triglycerides and Fatty liver index (FLI).
Results: The feasibility study reported a success of StSc computation equal to 92.1% (N = 434 of 471; F:M 235:199; median [IQR]: BMI 25.2 [23.0, 28.4] kg/m^2, WC 88 [81, 96] cm, StSc 2.8 [2.3 7.3] %, FLI 13.1 [5.6 32.0]). The inter-operator reproducibility analysis (N = 75 sbj) showed an R = 0.88 and ICC of 0.94; BAA revealed a non-significant bias of 0.38 and [-4.4 5.5] of 95% limits of agreements. Correlation analysis showed moderate correlations between StSc and both BMI and FLI (R of 0.42 and 0.44 for BMI, FLI, respectively, both with $p < 0.001$).
Conclusion: This pilot study demonstrated that StSc is a robust and reliable LFC quantification tool showing a very satisfactory feasibility even on retrospectively registered liver US images with very high inter-operator agreement. These results qualify StSc as a valuable first level investigation method for LFC quantification, identifying subjects from general populations that would benefit from LFC monitoring.

WED-447
The ultrasound multiparametric method Steatoscore2.0 measures liver steatosis with high inter- and intra- operator reproducibility

Laura De Rosa[1,2], Giovanni Petralli[3], Simone Cappelli[4], Antonio Salvati[5], Ferruccio Bonino[6], Maurizia Brunetto[4,5,6], Francesco Faita[7]. [1]*Institute of Clinical Physiology, National Research Council, Pisa, Pisa, Italy;* [2]*Department of Information Engineering and Computer Science, University of Trento, Trento, Italy;* [3]*Department of Surgical Medical, Molecular and Critical Area Pathology, University of Pisa, Pisa, Italy;* [4]*Department of Clinical and Experimental Medicine, Pisa University, Pisa, Italy;* [5]*Hepatology Unit, Pisa University Hospital, Pisa, Italy;* [6]*Institute of Biostructure and Bioimaging, National Research Council, Naples, Italy;* [7]*Institute of Clinical Physiology, National Research Council, Pisa, Italy*
Email: laura.derosa.95@gmail.com

Background and aims: Abdominal Ultrasound (US) is currently used to diagnose and monitor steatotic liver disease (SLD). However, there is an unmet need for quantitative US-based methods with high sensitivity and reproducibility. We recently proposed a multiparametric method, Steatoscore 2.0 (StSc), for estimating liver fat content (LFC) from B-mode images and validated against the gold standard LFC quantification by magnetic resonance. The aim of this study was to evaluate the reproducibility of StSc, through an inter- and intra-operator variability analysis.
Method: We studied 94 patients (pts) consecutively enrolled from September 2023 to October 2024 at the Hepatology Unit of the University Hospital of Pisa, Italy. US liver B-mode images were acquired according to a standardized acquisition protocol by using Esaote MyLab X8 and GE Healthcare LogiQ E9, both equipped with a convex probe (1.8–5 MHz). Three operators were involved in the study, OP1 (expert with >10 years' experience in abdominal echography), OP2 (5 years' experience), OP3 (on training). Thirty-seven pts underwent repeated B-mode acquisitions from OP1 and OP2, 44 were acquired by OP1 and OP3 and 34 by OP2 and OP3. In addition, a subset of 54 pts underwent double B-mode scans by OP3 (a/b). Finally, 14 pts were analyzed by all three operators with double acquisitions by OP3a/b. All B-mode images were processed by one specialist (>5 years' experience) and used to study the intra-/inter-operator reproducibility of the StSc measures assessed by Pearson' correlation coefficient (R), Intraclass Correlation Coefficient (ICC) and Bland-Altman analysis (BAA) with 95% limits of agreements (LoA).
Results: On the whole cohort (F:M 45:49; qualitative FLC classification S0:S1:S2:S3 26:10:33:25; mean ± standard deviation: BMI 30.4 ± 6.2 kg/m^2, age 57.2 ± 12.5 years old), inter-/intra- operator variability showed the following results:
OP1 vs OP2 on 37 pts: R = 0.94, ICC = 0.97, BAA: bias of 0.79 (p = n.s.) and LoA [−4.3 5.9];
OP1 vs OP3 on 44 pts: R = 0.93, ICC = 0.92, BAA: bias of – 0.38 (p = n.s.) and LoA [−11 9.9];
OP3a vs OP3b on 54 pts: R = 0.95, ICC = 0.97, BAA: bias of +0.70 (p = n.s.) and LoA [−5.2 6.6];
OP2 vs OP3 on 34 pts: R = 0.89, ICC = 0.94, BAA: bias of +0.70 (p = n.s.) and LoA [−6.9 7.3];
OP1 vs OP2 vs OP3 on 14 pts: ICC = 0.97, BA (OP1 vs mean(OP2, OP3)) with bias of 0.89 (p = n.s.) and LoA [−4.2 6.0].

Conclusion: StSc showed a very good performance with very high inter-/intra operator agreement (>0.89/0.95 for inter-/intra-, respectively) and high reproducibility independent from the experience of the operators in liver US. These results qualify StSc as an appropriate, reliable and cheap tool to monitor non- invasively the outcome of LFC in SLD patients in clinical practice.

WED-448
Steatotic liver disease in patients with irritable bowel syndrome- a new category? Evidence based on response to therapy

Laura Iliescu[1], Mircea Istrate[1], Simu Razvan-Ioan[1], Teodor-Marcel Puiu[1], Letitia Toma[1]. [1]*Deparment of Internal Medicine, Fundeni Clinical Institute, Bucharest, Romania, "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania, Bucharest, Romania*
Email: laura_ate@yahoo.com

Background and aims: Gut microbiome and permeability, as well as bile acid metabolism are altered in the setting of irritable bowel syndrome (IBS). Recent advances have found a possible link between liver steatosis and gut microbiome, thus opening the possibility of common therapeutic strategies in steatotic liver disease (SLD) and IBS. The aim of this study is to determine the prevalence of SLD in IBS patients and whether SLD can be improved by a standard treatment for IBS.
Method: From January 2023 to January 2024 241 patients with a recent diagnosis of IBS according to the ROMA IV criteria were screened for SLD by non- invasive methods: Fibroscan® determination of fibrosis and steatosis (liver stiffness and controlled attenuation parameter CAP) and Fibromax® determination of fibrosis (FibroTest) and steatosis (SteatoTest). We also determined serum levels of liver function tests. Patients were classified according to IBS category (with constipation, with diarrhea, with mixed bowel habits or unclassified). Patients received treatment with trimebutine maleate 300 mg daily and a probiotic containing Saccharomyces cerevisiae for three months and were re-evaluated.
Results: Mean age in the study group was 31.24 ± 10.92 years old, 65.1% female. IBS classification revealed 138 patients with

constipation (57.2%), 78 patients with diarrhea (32.3%) and 28 patients with mixt or indeterminate IBS (11.6%). Initial distribution according to degree of fibrosis, estimated by Fibroscan and Fibrotest revealed: 84 vs 83 F0 patients, 157 vs 144 F1 patients. No F2 values were obtained regarding liver stiffness, but Fibrotest categorized 14 patients as F2. CAP versus Steatotest revealed: 64 vs 82 S0 patients, 106 vs 132 S1 patients and 71 vs 52 S2 patients. At three months follow-up we found significantly lower values of AST and GGT in all categories, without significant changes in ALT values. Also, mean levels of liver stiffness and CAP significantly decreased in all categories: in F0: 3.4 KPa vs 2.9 KPa, in F1: 5.5 KPa vs 4.3 KPa, in S0: 198 dB/m vs 173 dB/m, in S1: 252 dB/m vs 237 dB/m, in S2: 272 dB/m vs 257 dB/m, with more patients classified as lower degrees of fibrosis and steatosis. Fibrotest reveled fewer F1 patients (54 vs 144) and fewer S2 patients (13 vs 54).

Conclusion: Rapid changes in degrees of steatosis and fibrosis under IBS treatment suggest common pathological pathways between IBS and SLD and potential reversal in the early stages.

WED-449

Exploring the evolution of circulating protein biomarkers in liver transplantation setting for MASH, ALD, and MetALD

Laura Martínez-Arenas[1], Mireia Gromaz[2], Fernando Diaz Fontela[3], Isabel Conde[4], Patrice Marques[5], Ariadna Bono[2], Julio Llorente[2], Ângela Carvalho-Gomes[6], Marina Berenguer[7]. *[1]IIS La Fe Health Research Institute, Universitat Politècnica de València, CIBEREHD, Valencia, Spain; [2]IIS La Fe Health Research Institute, Valencia, Spain; [3]Hospital General Universitario Gregorio Marañón, Madrid, Spain; [4]Hospital Universitario y Politécnico La Fe, IIS La Fe Health Research Institute, CIBEREHD, Valencia, Spain; [5]IIS La Fe Health Research Institute, CIBEREHD, Valencia, Spain; [6]CIBEREHD, IIS La Fe Health Research Institute, Valencia, Spain; [7]Hospital Universitario y Politécnico La Fe, IIS La Fe, Universidad de Valencia, CIBEREHD, Valencia, Spain*
Email: laura_munera15@hotmail.com

Background and aims: There is a significant lack of data on the utility of peripheral biomarkers (e.g. cytokines, chemokines, adipokines, and inflammatory or tissue remodeling mediators) in the non-invasive assessment of metabolic dysfunction-associated steatotic liver disease (MASLD) in the post-liver transplantation (LT) setting. This study aimed to explore whether circulating levels of selected plasma proteins could associate with graft fibrosis after liver transplantation (LT) for metabolic dysfunction-associated steatohepatitis (MASH), alcohol-associated liver disease (ALD), and metabolic dysfunction- and alcohol-associated steatotic liver disease (MetALD).

Method: This prospective cohort study included 61 adults transplanted for cirrhosis due to MASH (n = 20), ALD (n = 20), or MetALD (n = 21) between January 2019 and February 2023 in two LT centers in Spain. Plasma levels of IL-1alpha, IL-1beta, IL-6, IL-8, IL-10, IL-12p70, IL-18, MCP-1, TNFalpha, adiponectin, resistin, tPAI-1, sIL-1RI, sIL-2Ralpha, CHI3L1, CK-18 M30, CK-18 M65, IGF-1, leptin, M2BPGi and TIMP-1 were measured before LT and at 6, 12, 24 and 36 months after LT by Luminex multiplex assay or enzyme-linked immunosorbent assay (ELISA), as appropriate. The 6-month post-LT measurement was assumed as the baseline timepoint after LT without significant/advanced fibrosis. FibroScan was carried out at least 1 year after LT, and liver stiffness measurement (LSM) values <8 kPa were used to rule out significant/advanced graft fibrosis.

Results: In the pre-LT setting, all patients, regardless of the etiology, had similar levels of the biomarkers tested ($p > 0.05$), except for resistin (lower levels in ALD group vs. MASH or MetALD groups, $p < 0.001$) and tPAI-1 (higher levels in MASH group vs. ALD or MetALD groups, $p < 0.022$). When comparing pre-LT vs. 6-month post-LT timepoints, all biomarkers "normalized" after LT ($p < 0.05$), except for IL-1alpha, IL-1beta, resistin, sIL-1RI, and TNFalpha. When categorizing by etiology, only IL-6, IL-8, tPAI-1, CHI3L1, CK-18 M30, M2BPGi and TIMP-1 "normalized" in the 3 groups ($p < 0.05$). Regarding the FibroScan outcomes (median time from LT = 26.6 months/IQR: 15.5–36.5), 14 patients (23%) had LSM values >8 kPa (30% were MASH patients, n = 6; 20% were ALD patients, n = 4; and 19% were MetALD patients, n = 4; $p = 0.657$). Patients with significant/advanced fibrosis (LSM values >8 kPa*) had significantly higher levels of CK-18 M30 ($p = 0.047$) and CK-18 M65 (0.049) at the last elastographic evaluation. In addition, this former group also presented increased levels of CK-18 M30 ($p = 0.011$) and CK-18 M65 ($p = 0.013$) at 6, 12, 24 and 36 months after LT.

Conclusion: The evolution of the circulating biomarker profile among transplanted MASH, ALD or MetALD patients may serve as a potential non-invasive tool to assess/predict graft fibrosis. Nevertheless, the causal associations between specific protein biomarkers and MASLD remain elusive.

WED-450-YI

The use of controlled attenuation parameter for the assessment of treatment response in patients with metabolic dysfunction-associated steatotic liver disease undergoing a lifestyle intervention program

Lorenza Vaira[1], Angelo Armandi[1], Chiara Rosso[1], Gian Paolo Caviglia[1], Martina Marano[1], Fabrizio Amato[1], Kamela Gjini[1], Marta Guariglia[1], Eleonora Dileo[1], Ilaria Goitre[2], Davide Giuseppe Ribaldone[1], Simona Bo[2], Elisabetta Bugianesi[1]. *[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy, Torino, Italy; [2]Section of Dietetic and Clinical Nutrition, Department of Medical Sciences, University of Turin, Turin, Italy, Torino, Italy*
Email: lorenza.vaira@unito.it

Background and aims: The identification of non-invasive biomarkers to monitor treatment response is crucial for the effective management of metabolic dysfunction-associated steatotic liver disease (MASLD). This study investigated the utility of the controlled attenuation parameter (CAP), measured by vibration-controlled transient elastography (VCTE), and the role of PNPLA3 gene variants in assessing weight loss outcomes in MASLD patients undergoing a 6-month dietary intervention.

Method: A total of 94 patients with MASLD were enrolled and randomized into three dietary intervention groups: mediterranean diet (MD), low-carb diet (LCD), and control diet (CD). Inclusion criteria were a BMI of 26–35 kg/m², CAP ≥248 dB/m, and liver stiffness measurement (LSM) <12.5 kPa. Exclusion criteria were decompensated type 2 diabetes (HbA1c >9.5%), insulin-dependent diabetes, therapy with GLP-1 receptor agonists, alcohol consumption >30 g/day for men or >20 g/day for women, liver diseases of other etiologies, or the use of steatogenic medications. The primary endpoint was achieving ≥7% weight loss at the end of the 6-month intervention. Clinical, biochemical, and VCTE assessments were performed at baseline and after 6 months.

Results: The median age of participants was 50.5 years [IQR 43.0–61.0], and 71.3% were male. Type 2 diabetes was present in 17% of the cohort, while the PNPLA3 GG genotype was observed in 19.1% of patients. After 6 months, 28.7% of participants achieved ≥7% weight loss, with the LCD group showing the highest success rate (36.2%). In patients achieving weight loss, CAP decreased significantly (from a median of 294 to 246 dB/m, $p < 0.0001$), compared to changes observed in those who did not achieve weight loss (inter-group $p = 0.001$). Delta CAP values were significantly higher in the LCD group compared to other groups ($p = 0.040$). A progressive increase in the delta CAP was observed across incremental weight loss categories (<5%, 5–10%, >10%) ($p = 0.026$). Among patients achieving ≥7% weight loss, higher delta CAP values were noted in patients with the CC/CG genotype of PNPLA3 ($p = 0.0004$), as compared to GG carriers ($p = 0.79$). Additionally, the reduction in CAP (delta CAP) associated with weight loss was more pronounced in females than in males, even though the present inter-group statement seems not to be

statistically relevant (p = 0.15). These findings highlight potential sex-related differences in treatment response.
Conclusion: The present study demonstrates that in MASLD patients, achieving ≥7% weight loss through dietary intervention is associated with significant reductions in CAP, indicating decreased hepatic steatosis. PNPLA3 genotyping may offer additional insights for stratifying patients and personalizing therapeutic approaches. Further research is needed to explore the role of genetic and sex-related factors in optimizing treatment outcomes.

WED-451
Comparison of the pathophysiology of "metabolic" and "genetic" MASLD: a multiOmics cohort study
Mario Masarone[1], Benedetta Maria Motta[1], Pietro Torre[1], Martina Lombardi[2], Tommaso Sarcina[1], Roberta Coppola[1], Mariano Festa[1], Jacopo Troisi[1,2], Marcello Persico[1]. *[1]Internal Medicine and Hepatology Division, Department of Medicine, Surgery and Odontostomatology "Scuola Medica Salernitana", University of Salerno, Baronissi (Salerno), Italy; [2]Theoreo srl, Montecorvino Pugliano (Salerno), Italy*
Email: mario.masarone@gmail.com

Background and aims: MASLD pathogenesis can be explained by a metabolic component and a genetic component. In fact, several single nucleotide polymorphisms(SNPs) have been correlated with high risk of fibrosis/inflammation in MASLD and even a "genetic risk score"(GRS) has been validated. Recently, it has been hypothesized that "metabolic MASLD"(MM-without any genetic mutation) may have a different pathophysiology in respect to "genetic MASLD"(GM). Aims: To investigate, in a large cohort of MASLD, if and how the metabolomic profiles of GM are different from MM and in respect to healthy controls.
Method: 270 MASLD patients from a tertiary center of Southern Italy and 102 controls were evaluated by clinical, laboratory, genetic and untargeted metabolomics analysis. Inclusion criteria: US evidence of steatosis in absence of any other liver disease. Patients were classified by fibrosis risk in three groups:(A)low-risk,(B)high risk of fibrosis and (C)cirrhosis, by clinical/laboratory parameters, liver stiffness and/or liver biopsy as by European guidelines. All the subjects were genotyped for PNPLA3, MBOAT7, GCKR, and TM6SF2 SNPs by TaqMan 5′-nuclease assays. Patients were defined as GM if they had any of the analyzed SNPs at-risk mutations, and MM if they did not, also categorizing them into high and low genetic risk groups on the basis of a weighted GRS. Untargeted metabolomics analysis was performed through Gas Chromatography-Mass Spectrometry.
Results: Patients with GM were the majority(216/270:80%). However, GM and MM patients did not differ for clinical parameters other than BMI(higher in MM, p:0.029) GGT(higher in GM, p:0.019) and Ferritin (higher in GM, p:0.033). The prevalence of at-risk SNP mutations was not different in patients vs controls, except for PNPLA3(higher in patients p:0.033). On the contrary, untargeted metabolomics demonstrated progressive separation between fibrosis risk classes, with key metabolites including lactic acid, urea, pyroglutamic acid, hydroxydecanoic acid, 2-hydroxyisocaproic acid, and acetoacetic acid. Pathway analysis highlighted alterations in starch, sucrose, galactose, and amino sugar metabolism. In a separate model focused on genetic risk, significant separation was observed between High- and Low-Risk groups. Metabolites in this analysis included palmitic, mandelic, pyroglutamic, lactic, and ribonic acids. Altered pathways involved phenylalanine, tyrosine, and tryptophan biosynthesis, as well as valine, leucine, and isoleucine metabolism.
Conclusion: Clinical/laboratory evaluation was not able to discriminate between "genetic" and "metabolic" MASLD. On the contrary, a marked separation emerged between high- and low- fibrosis and genetic-risk groups, indicating potential for early diagnostics and stratified patient management. This approach may offer promising avenues for personalized therapeutic strategies, ultimately supporting more effective and individualized care at the dawn of pharmacological treatment of MASLD.

WED-452
Development of novel supervised machine learning models to predict the population at risk of metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis in a spanish mediterranean population
Marta Cedenilla[1], Javier Díaz[2], Inma Saurí[2], Gonzalo Fernandez[3], Antón Gómez[3], Carlos Martos[3], Carlos Hurtado[3], David Marti[4], Desamparados Escudero[4], Jorge Navarro[5], Josep Redón[5]. *[1]Value & Implementation, Global Medical & Scientific Affairs, MSD Spain, Madrid, Spain, Madrid, Spain; [2]Instituto de Investigación Sanitaria INCLIVA, Hospital Clínico Universitario, Valencia, Spain, Valencia, Spain; [3]Value & Implementation Global Medical and Scientific Affairs, MSD Spain, Madrid, Spain, Madrid, Spain; [4]Instituto de Investigación Sanitaria INCLIVA, Hospital Clínico Universitario, Valencia, Spain, Gastroenterology and Hepatology, Hospital Clínico Universitario, Valencia, Spain, Madrid, Spain; [5]Instituto de Investigación Sanitaria INCLIVA, Hospital Clínico Universitario, Valencia, Spain, Madrid, Spain*
Email: marta.cedenilla@merck.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is among the most prevalent primary liver disease worldwide, but since it is a generally asymptomatic disease its prevalence is not well described. In this real-world, longitudinal retrospective study on a Spanish Mediterranean Electronic Health Records (EHR) database we aimed to predict the probability of potential risk of MASLD and Metabolic dysfunction-associated steatohepatitis (MASH) in the general population and in people with type 2 diabetes mellitus (T2DM) or obesity by using a novel Machine Learning (ML) approach.
Method: Supervised ML Models (SMLM) were developed from an EHR of 2267 subjects in which MASLD and MASH were identified by Vibration-Controlled Transient Elastography Controlled Attenuation Parameter (VCTE-CAP), Liver Stifness Measurement (LSM) and FibroScan-AST (FAST) score as well as available data on comorbidities and laboratory tests. SMLM (*Random forest and XGBoost*) developed to predict the potential risk of MASLD or MASH were trained with a k-fold cross-validation method and tested using classification metrics (*sensitivity, specificity, AUROC, Kappa*). Algorithms were calibrated for high sensitivity and applied in a general population of 3,6 million adult subjects and in individuals with T2DM or obesity from 2012 to 2019. The selected variables for prediction included comorbidities and analytical variables.
Results: The best-performing models for MASLD and MASH consisted of 12 and 7 variables respectively and exhibited high performance as measured by area under the curve (0.76 for MASLD, 0.84 for MASH). The proportion of individuals who could be at risk predicted by SMLM was up to 46% for MASLD and 11% for MASH in the general population. Furthermore, according to the SMLM, up to 99% of people with T2DM or obesity (2 times higher vs general EHR) could be at risk of developing MASLD if left untreated. In contrast, the prevalence of MASLD and MASH by ICD codes in the overall EHR were 2.2% and <1% with MASH being ~4 and 3 times higher in people with T2DM and obesity respectively vs general population. Moreover, from 2012 to 2019 the ICD-based prevalence and SMLM-based risk of MASLD increased from 0.8% (ICD)/31.9% (SMLM) to 2.2% (ICD)/46.1% (SMLM).
Conclusion: According to our SMLM, individuals potentially at risk of MASLD and MASH in the population could be up to 46% and 11% with 2 times higher prevalence in the T2DM or obese population. These results indicate a potentially large risk of developing MASLD/MASH within the population despite currently low diagnosis rate of the disease. Use of predictive clinical risk factors could be useful as a complementary approach to identify patients at risk of MASLD/MASH in clinical setting. This could aid in early and more comprehensive

disease management and avoid long-term outcomes associated with MASLD/MASH. Study sponsored and funded by MSD Spain

Referral algorithm from primary care based on the risk calculation for significant fibrosis

Marta Hernández Conde[1], Elba Llop Herrera[1], Ana Pérez[1], Marta López-Gómez[1], Javier Abad Guerra[1], Jesús Rivera[1], José Luis Calleja Panero[1]. [1]*Hospital Universitario Puerta de Hierro Majadahonda, Madrid, Spain*
Email: marta.hernandez.conde@gmail.com

Background and aims: Non-invasive methods (NIMs) for diagnosing liver fibrosis in Primary Care (PC) aim to stratify risk and facilitate decision-making. However, these NIMs have a high number of false positives (FP), which increases costs and resource consumption. Our objective was to develop a referral algorithm to reduce FPs and optimize the indication of transient elastography (Fibroscan®; TE) in patients with suspected significant fibrosis (F2-4).
Method: This was a cross-sectional cohort study in which the FIB4 score was calculated for all patients aged 18–64 years from Area 6 of Madrid who underwent routine blood tests with glycated hemoglobin in PC. Patients with FIB-4 >1.3 were referred to the hospital for TE. For patients with indeterminate FIB4 results (1.3–2.67), second-line NIMs—Enhanced Liver Fibrosis (ELF) and Fatty Liver Index (FLI)—were performed.
Results: A total of 1,927 patients were evaluated. Of these, 412 patients (21.4%) had FIB4 >1.3. The baseline characteristics are: 71.2% were male, 28.2% had type 2 diabetes (T2D), and mean BMI was 29 kg/m² (41% overweight and 37.4% obese). 90.8% of referred patients had indeterminate FIB4. Within this subgroup, 45.2% had pathological ELF (≥9.8), and 54.1% had pathological FLI (≥60). We calculated the AUROC for ELF and FLI: ELF: 0.75 (sensitivity: 85.3%, specificity: 64.9%) and FLI: 0.74 (sensitivity: 93.4%, specificity: 56.4%). Based on these data, we developed a formula using ELF and FLI to establish the probability of F2-4 in TE for those with indeterminate FIB4. This formula was incorporated into an online risk calculator: https://investigacionpuertadehierro.com/calculadora-riesgo-de-fibrosis-significativa/. An arbitrary cutoff point was set, considering acceptable sensitivity and specificity. Patients with a probability >10% were referred for TE, while those with a probability <10% were not. By applying this approach, the number of transient elastographies performed was reduced by 51.2%, with the model achieving a sensitivity of 84.9%, a specificity of 57.7%, and a negative predictive value (NPV) of 95.5%.
Conclusion: The proposed referral algorithm, based on serological NIMs, allows for the selection of patients with a higher likelihood of F2-4 and reduces unnecessary referrals for TE. However, further studies are needed to optimize the cutoff point to maximize the efficiency of patient selection.

Email: marta.wojciechowska@ndm.ox.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) may remain benign or progress to cirrhosis. Fibrosis, the primary prognostic marker, is graded on an ordinal scale but has significant interobserver variability. We hypothesized that continuous, deep-learning-derived histological measures could improve predictions of MASLD progression. Additionally, we integrated molecular and morphological features by combining histological metrics with RNA-seq data.
Method: This prospective cohort study included patients with suspected MASLD with fibrosis who underwent liver biopsy. Baseline and annual evaluations were performed. Bulk RNA-sequencing of FFPE tissue was conducted using the RNeasy FFPE Kit and Illumina NovaSeq platform. Digitized slides were analysed using a bespoke deep-learning U-net model for collagen segmentation. The output of the segmentation model was used for quantification of collagen proportionate area (CPA), and secondly for the development of a novel deep-learning algorithm for subtyping collagen deposition patterns. The results of the quantitative image analysis were used alongside pathologist fibrosis staging to perform differential gene expression experiments. We performed liver stiffness measurements (LSM) at baseline and during annual follow-up visits. We defined a clinically relevant increase in LSM as ≥5 kPa and ≥20% increase from the baseline value. Liver-related events (LRE) included varices on endoscopy, variceal bleeding, ascites, jaundice, hepatic encephalopathy, hepatorenal syndrome, HCC, or cirrhosis-related death.
Results: We analysed 187 MASLD patients (F0: 35, F1: 53, F2: 50, F3: 24, F4: 25) followed for a median of 4.85 years. LSM progression occurred in 14.0% by year 2 (19/136) and 14.3% by year 3 (16/112). LREs developed in 8.0% (15 patients), including 7 cirrhosis-related deaths. Higher CPA and collagen clusters C4 and C5 were associated with increased odds of LSM progression (C5: year 2 OR 1.71, p = 0.008, AUC 0.76; year 3 OR 1.75, p = 0.01, AUC 0.80) and LREs (OR 2.28, p = 0.0008, AUC 0.86). DGE analyses identified the most enriched KEGG pathways (150) for C5, outperforming all other metrics.
Conclusion: CPA and collagen clusters C4 and C5 are significant predictors of MASLD progression. These deep-learning-derived histological parameters demonstrate considerable potential for improving risk stratification in MASLD patients. DGE revealed CPA and clustering as superior metrics for identifying fibrosis-related metabolic pathways. Validation studies are needed to confirm these findings.

WED-455

Sampling variability of liver fibrosis assessed by digital pathology in pre-cirrhotic patients with MASH

Adi Lightstone[1], Li Chen[1], Mathieu Petitjean[1], Vlad Ratziu[2]. [1]*PharmaNest Inc, Princeton, United States;* [2]*Hospital Pitié-Salpêtrière, Paris, France*
Email: adi.lightstone@pharmanest.com

Background and aims: Liver biopsy remains the gold standard for assessing fibrosis in patients with MASH. As highly sensitive, reproducible, and continuous digital pathology biomarkers are increasingly utilized for evaluating liver biopsies, the impact of heterogeneity in the distribution of histological features and the associated sampling variability of biopsies emerges as a critical analytical consideration.
Method: Large (10mm × 10 mm) liver wedge biopsies from 12 patients histologically diagnosed with MASH (and fibrosis stages of F0, n = 0, F2, n = 3, F3, n = 5, F4, n = 3) undergoing bariatric surgery were stained with Picro-Sirius Red (PSR) and imaged at 40X. Virtual biopsies[1] were created by selecting 4–5 Regions of Interest (ROIs) of 1.5 × 10 mm from each wedge biopsy image, simulating a half-length 16G needle adequate[2] biopsy ("adequate biopsy"). These were further divided into short (5 mm long) and thin (800micron wide, sub-adequate biopsies). FibroNest™ analysis of the virtual biopsies, extracted 335 quantitative fibrosis traits. Key traits were used to generate a Phenotypic Fibrosis Composite Score (Ph-FCS) of severity

as described[2]. The coefficient of variation CoV (standard deviation/mean, %) of the Ph-FCS was calculated and averaged for both adequate and sub-adequate biopsies.
Results: The average CoV of the Ph-FCS (<CoV>) was 6.51% ± 0.71 (n = 58, CI = 68%, range 2.29% – 11.46%) for adequate virtual biopsies. Values were slightly higher for thin (resp. short) sub adequate biopsies with <CoV> = 7.25% ± 0.63 (n = 116, CI = 68%, range 5.22% – 12.68%) and <CoV> = 8.82% ± 0.96 (n = 116, CI = 68%, range 5.25% – 15.03%). The combination of both effects of size can be interpolated to <CoV>~9.56% ± 1.88 (n = 116, CI = 68%). There is not statistically significant relationship between severity stages and COV% (F0 <CoV> = 8.6%, F2 7.0%, F3 6.3%, F4 5.6%, for adequate virtual biopsies). Extreme values of the CoV are attributed to fragments of non-contributory peri-vascular fibrosis being partially interpreted by the AI algorithms as phenotypes of severity.
Conclusion: The sampling variability of the Ph-FCS Digital Pathology biomarker in pre-cirrhotic MASH patients is 6–10% regardless of severity, outperforming other histological and computational methods. This superior performance stems from its phenotypic analytical approach and the exceptional signal-to-noise ratio (~110:1) of the FibroNest method. These findings underscore the robustness of the FibroNest™ biomarker in accurately quantifying fibrosis severity, even with minor biopsy dimension variations, reinforcing its reliability for clinical study use and interpretation.

Intra-abdominal fat thickness measured by ultrasound correlates with CAP (Controlled Attenuation Parameter) measured by FibroScan® in a cohort of patients followed for MASLD/MASH at an urban liver centre: Impact of utilization in clinical practice

Magdy Elkhashab[1], Mehrdad Modarresi[1], Bernie Charlton[2], Veera Bharatwal[2], Gabriel Tarzi[1], Kimia Behzad Moghadam[1], Daniel Botros[1], Jia Xu Xu[1], Elizaveta Shpilevaia[1], Anish Jammu[1], Aleena Ghafoor[1], Mohsina Chaklader[1], Claire Lee[1], Marzena Magnes[1]. *[1]Toronto Liver Centre, TORONTO, Canada; [2]LIGHTHOUSE MEDICAL IMAGING, TORONTO, Canada*
Email: modmeh2@yahoo.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction-associated steatohepatitis (MASH) are very common liver diseases in clinical practice with significant global health implications and estimated prevalence over 30% worldwide. Despite its widespread use, abdominal ultrasound, the primary screening tool for diagnosis of liver steatosis, has suboptimal sensitivity and specificity for reliable diagnosis of steatotic liver disease.
Abdominal ultrasound is the initial screening test for diagnosis of steatotic liver disease in clinical practice - non-invasive and accessible. Having said that, its diagnostic accuracy is limited, particularly in cases of mild steatosis and obesity. We sought to explore weather enhancing the diagnostic accuracy of ultrasound through additional measurement of intra abdominal fat could improve liver steatosis detection without or very minimal additional costs.
Method: The measurement of intra-abdominal fat thickness was performed using a 3.5 to 3.75 MHz probe, either linear or curved array, positioned midline, 1–5 cm superior to the umbilicus or midway between the xiphoid process and the umbilicus in the transverse plane. The image was captured with the rectus abdominis muscle and aorta in view, and the measurement was taken from the anterior wall of the aorta to the posterior surface of the rectus abdominis muscle.
Results: This retrospective analysis involved 456 patients diagnosed with MASH or MASLD, including 237 females and 219 males. BMI of the patients ranged from 17.3 to 49.5 kg/m², with ages between 20 and 90 years (an average 59.5 years). Intra-abdominal fat thickness measurements varied from 1.1 to 13.4 cm and CAP scores from 142 to 400 dB/m.
Utilizing a regression statistical analysis model revealed a significant correlation between Controlled Attenuation Parameter (CAP) scores and intra-abdominal fat thickness. Both CAP and BMI were significant predictors of intra-abdominal fat thickness. We defined high risk as intra-abdominal fat thickness >9 cm for males and >8 cm for females. Although the predictive model showed some limitations due to the smaller dataset, utilizing the binary high vs. low-risk models consistently indicated CAP and BMI as significant predictors.
Conclusion: Incorporating intra-abdominal fat thickness measurement into routine abdominal ultrasound procedures can enhance the accuracy of liver steatosis assessment. Future prospective studies are planned to further explore the utility of intra-abdominal fat thickness measurement and its correlation with CAP and various components of metabolic syndrome.

WED-461

Potential issues with practical implementation of EASL-EASD-EASO clinical practice guidelines on management of metabolic-associated steatotic liver disease in a Swedish healthcare setting

Merle Roeren[1], Emilie Toresson Grip[1,2], Helena Skröder[1], Ying Shang[1], Hannes Hagström[1,3]. *[1]Karolinska Institute, Stockholm, Sweden; [2]Quantify Research, Stockholm, Sweden; [3]Karolinska University Hospital, Stockholm, Sweden*
Email: merle.roeren@ki.se

Background and aims: Metabolic-associated steatotic liver disease (MASLD) is particularly common among patients with Type 2 Diabetes (T2D), with an estimated prevalence of 65%. Its silent progression often leads to under-detection of patients at risk of fibrosis, delaying referrals to hepatology specialists. The 2024 clinical practice guidelines by EASL-EASD-EASO recommend screening individuals at a high risk for having MASLD for advanced fibrosis but their feasibility in primary care is uncertain. We aimed to estimate numbers within each proposed screening pathway and evaluate the applicability of these guidelines in a Swedish healthcare setting.
Method: We estimated the numbers for each pathway using data on FIB-4 risk categories and vibration-controlled transient elastography (VCTE) measurements (≥8.0 kPa) in individuals with T2D. Data were used from the Health Outcomes and Risk Assessment in Chronic Liver Disease (HERALD) dataset, which includes most individuals with T2D in Stockholm County between 2010 and 2020 who have FIB-4 scores available from primary and secondary care. Among the 23,070 individuals identified, 69% had a FIB-4 score of <1.3, 21% had scores between 1.3 and 2.67, and 10% had scores >2.67. Additionally, a recent cross-sectional study of 1,005 T2D patients undergoing VCTE reported a 16% prevalence of VCTE ≥8 kPa. Descriptive statistics were used to assess the healthcare landscape in Stockholm County.
Results: Applying these cutoffs to 140,000 individuals with T2D (estimated prevalence of 5.8% in Stockholm County) resulted in the following estimated distribution: around 96,600 individuals classified as low risk (FIB-4 : <1.3), 29,400 individuals at intermediate risk needing VCTE or another second test (FIB- 4: 1.3–2.67), and 14,000 individuals who would be directly referred to hepatologists (FIB-4 : >2.67). Assuming that at least 16% of patients at intermediate risk have a VCTE ≥8.0 kPa, an additional 4,704 individuals would be referred to hepatology. Thus, approximately 31% (43,400) of individuals with T2D are expected to need at least one VCTE for liver assessment, and around 13% (18,200) would require a referral to hepatology.
Conclusion: Our findings highlight the challenges of applying current EASL-EASD-EASO guidelines for liver assessment, especially with limited elastography resources and specialist care. The reduced sensitivity of FIB-4 and VCTE in T2D patients further emphasizes the

need for better tools and targeted algorithms to identify those at risk of advanced fibrosis.

WED-462

Determinants of liver stiffness improvements and worsening in metabolic dysfunction associated steatotic liver disease: insights from two cohorts

Mirko Zoncapè[1,2], Antonio Liguori[1,3], Serena Pelusi[4], Cristiana Bianco[4], Davide Roccarina[1,5], Laura Iogna Prat[1], Anna Mantovani[1,6], Jennifer-Louise Clancy[1], Atul Goyale[1], Luca Valenti[4], Emmanuel Tsochatzis[1]. *[1]University College London (UCL) Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom; [2]Liver Unit, Department of Internal Medicine, University and Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy; [3]Department of Translational Medicine and Surgery, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Università Cattolica del Sacro Cuore, Roma, Italy; [4]Department of Pathophysiology and Transplantation, Università degli Studi di Milano, and Translational Medicine, Department of Transfusion Medicine and Hematology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milano, Italy; [5]Department of Experimental and Clinical Medicine, University of Florence, Florence, Italy; [6]Division of General Medicine C, Department of Internal Medicine, University and Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy*
Email: mirko.zonky@yahoo.it

Background and aims: Liver stiffness measurement (LSM) is key for monitoring disease progression in patients with Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD). Identifying predictors of LSM change could enhance prognosis and guide management. This study assessed metabolic and clinical factors that impact LSM changes over time in two large cohorts of MASLD patients.

Method: We included MASLD patients with ≥2 outpatient visits from 2014 to 2022. Follow-up LSM was >6 months from baseline. LSM worsening was defined as >30% increase if baseline LSM was ≥5 kPa, or as follow-up LSM >6 kPa if baseline was <5 kPa. LSM improvement was defined as >30% LSM decrease (if baseline >6 kPa). Alternate analyses used a >40% change cut-off. Significant weight and HbA1c changes were defined as >5% and >10%, respectively. We calculated the difference between actual and "expected" FIB-4 at follow-up (based on the patient's age at the follow-up visit, but using the blood tests performed at the first visit), and we defined "expected" Fibroscan improvement or worsening based on changes in weight, HbA1c, ALT, and FIB-4, where at least one variable showed a corresponding improvement or worsening while the others remained stable.

Results: Among 400 enrolled (mean age 54, 70% male), median follow-up was 20 months. LSM improved by >30% in 13.5% of patients and worsened >30% in 11.3%; using a >40% cut-off, 6.5% showed improvement and 6.0% showed worsening. Only about one-third of patients with LSM > 30% or >40% changes showed corresponding shifts in FIB-4. In multivariate logistic regression analysis, LSM worsening >30% was independently associated with increased HbA1c (OR 1.03), longer follow-up (OR 1.07) and total cholesterol change (OR 0.97, indicating a lower likelihood of LSM worsening), while LSM improvement > 30% correlated with weight reduction (OR 0.89). Similarly, in multivariate logistic regression analysis, LSM worsening >40% was independently associated with an increase in HbA1c (OR 1.04), while LSM improvement >40% was independently associated with weight reduction (OR 0.89). "Expected" Fibroscan improvement was linked with actual Fibroscan reduction (p = 0.002), showing high negative predictive values (NPV: 92–96%), but expected worsening did not predict actual LSM increase (NPV: 72–89%).

Conclusion: About 20% of MASLD patients experienced significant LSM changes over 20 months. Weight reduction improved LSM, while increased HbA1c predicted worsening LSM, supporting a focus on metabolic management. The variables contributing to "expected" Fibroscan changes may aid in guiding diagnostic pathways but require a comprehensive, multidisciplinary model of care.

WED-463

Three-tier testing pathways are required in metabolic dysfunction-associated steatotic liver disease for improved detection of advanced fibrosis

Mirko Zoncapè[1,2], Laura Iogna Prat[1], Antonio Liguori[1,3], Atul Goyale[1], Emmanuel Tsochatzis[1]. *[1]University College London (UCL) Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom; [2]Liver Unit, Department of Internal Medicine, University and Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy; [3]Department of Translational Medicine and Surgery, Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Università Cattolica del Sacro Cuore, Rome, Italy*
Email: mirko.zonky@yahoo.it

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the leading cause of secondary care referrals for chronic liver disease in Western countries. Two-step hierarchical algorithms with FIB-4 followed by transient elastography (TE) or the Enhanced Liver Fibrosis (ELF) test are recommended in various guidelines to rationalize referrals from primary to secondary care. We aimed to evaluate the utility of an algorithm with TE as the thirds step after a FIB-4 and an ELF. We assessed the concordance between ELF scores and FibroScan measurements, and their diagnostic accuracy compared to liver biopsy in a consecutive cohort of patients referred with increased ELF scores.

Method: We included consecutive patients referred between June 2014 and September 2024 due to MASLD and an ELF score ≥9.5, following local referral pathways. All included patients underwent TE using FibroScan to assess liver stiffness measurement (LSM) upon referral, and met MASLD diagnostic criteria. Patients with other liver diseases were excluded. Demographic, clinical, and laboratory data were collected. Concordance between ELF scores, FibroScan results, and liver biopsy findings was assessed.

Results: A total of 777 patients were included: 47% male, mean age 62 ± 10 years, mean BMI 32 ± 7 kg/m². 38% had diabetes, 65% dyslipidaemia, and 60% hypertension. Median LSM was 6.1 (4.6–8.7) kPa. LSM was ≥8 kPa in 231 (30%) patients and ≥10 kPa in 143 (18%). Therefore, the concordance of LSM and ELF for advanced fibrosis (cut-off 10 kPa) was 18%, while there was a significant discordance (LSM <6 kPa) in 368 (47%) of the cases. Liver biopsy data were available for 109 patients (14% of the total population studied) and 54 (50%) had advanced fibrosis (≥F3). 41 (37.6%) patients with a high ELF score had no or minimal fibrosis (F0-F1) on liver biopsy. 22 and 14 of these patients had LSM above 8 kPa and 10 kPa, respectively. Among patients with biopsy-proven advanced fibrosis, only 2 had LSM<8 kPa. Increasing the ELF cut-off to 10.5 would reduce the number of false positive results without an increase in false negatives, assuming a TE threshold of 8 Kpa: among 53 patients with ELF ≥10.5 and available biopsy, only 1 with advanced fibrosis had an LSM<8 kPa.

Conclusion: Hierarchical two-step algorithms in unselected cohorts of patients with MASLD with relatively low prevalence of advanced fibrosis require an additional second-line non-invasive test to improve diagnostic accuracy. Using TE after a high ELF score improves the detection of advanced fibrosis.

WED-464-YI

Gaps in screening and management of metabolic dysfunction-associated steatotic liver disease: a retrospective audit of patients at cardiometabolic risk in a secondary care setting

Monica Cucco[1], Renata De Maria[2], Chiara Pavanello[2], Lucia Cesarini[1], Giuliana Mombelli[3], Antonia Alberti[4], Federico Bertuzzi[5], Luca Saverio Belli[1], Laura Calabresi[2]. *[1]Hepatology and Gastroenterology Unit, ASST GOM Niguarda, Milan, Italy; [2]Centro E. Grossi Paoletti, Department of Pharmacological and Biomolecular Sciences, Università degli Studi di Milano, Milan, Italy; [3]Dyslipidemia Center, ASST GOM*

Niguarda, Milan, Italy; [4]Cardiology 5, De Gasperis Cardio Center, ASST GOM Niguarda, Milan, Italy; [5]Diabetes Unit, ASST GOM Niguarda, Milan, Italy
Email: monicacucco@alice.it

Background and aims: Significant gaps exist between cross-specialty guidelines and the management of cardiometabolic patients at high risk for metabolic dysfunction-associated steatotic liver disease (MASLD), particularly those referred to secondary specialist settings. A siloed approach and poor communication in secondary care substantially hamper effective MASLD management and prospective actions to decrease disease burden. This study aims to identify and address these practice gaps.
Method: OPTIMA-NASH is a retrospective, longitudinal practice improvement initiative, based on a clinical audit. The study population includes patients seen in Niguarda outpatient clinics over 24 months. Eligible patients had at least one cardiometabolic risk factor (CMR, e.g., prediabetes, type 2 diabetes, overweight or obesity, dyslipidemia, arterial hypertension), or atherosclerotic cardiovascular disease (ASCVD). Data collection focused on calculating MASLD risk scores, including FIB-4 and NAFLD-Fibrosis Score (NFS), and assessing the use of transient elastography (TE).
Results: A total of 854 patients were reviewed, with a mean age of 65.8 ± 15 years and 485 (56.8%) were male. CMR prevalence was: 41.3% diabetes, 27.5% obesity (mean BMI 27.9 ± 4.9 kg/m^2), 29.6% dyslipidemia, 59.3% arterial hypertension. Additionally, 15.6% had ischemic heart disease, 25.1% atrial fibrillation, 2.8% heart failure, 4.8% a history of TIA/stroke, and 10.2% an eGFR <60 ml/min/1.73 m². Overall, 692 (81.0%) patients had 2 or more risk factors, reflecting a very high CMR. Data to calculate the FIB-4 score were available for 311 records. Mean FIB-4 score was 1.7 ± 1.67; 159 patients (51%) had a FIB-4 score >1.3, indicating a need for transient elastography (TE) measurements using Fibroscan. For the NAFLD-Fibrosis score (NFS), data were available in 162 records, mean NFS was −1.224 ± 1.733; 85 (52%) had an NFS ≥1.455. TE was documented for 153 patients, mean TE 8 ± 6.9 kPa. Both FIB-4 and NFS demonstrated moderate accuracy for predicting fibrosis stages ≥F3: AUROCs were 0.768 (95% CI 0.617–0.919) for FIB-4 and 0.739 (95%CI 0.568–0.909) for NFS, respectively, consistent with literature on MASLD. Controlled attenuation parameter (CAP) measurements were available for only 80 patients; mean CAP was 306.5 dB/m ± 49.9; 62 patients (77.5%) had a CAP > 275 dB/m.
Conclusion: In this secondary care setting, a minority of patients with cardiometabolic risk factors were screened for MASLD, highlighting critical areas for improvement in practice. This gap underscores the need for improved protocols and enhanced communication between specialties to facilitate timely screenings and interventions. By addressing these pitfalls, we can better manage MASLD and reduce its associated burden in at-risk populations.

WED-465
Association of hepatic steatosis biomarkers with hepatic steatosis prevalence and risk of developing MASLD fibrosis in patients with type 2 diabetes mellitus in eastern Croatia: a pilot study

Farah Khaznader[1,2], Ana Jurić[1], Omar Khaznader[1], Kristina Bojanić[1], Robert Smolic[1], Kristina Kralik[2], Marija Hefer[1], Ana Petrovic[1], Martina Smolic[1]. *[1]University of Osijek, Faculty of Dental Medicine and Health, Osijek, Croatia; [2]University of Osijek, Faculty of Medicine Osijek, Osijek, Croatia*
Email: msmolic@fdmz.hr

Background and aims: Despite its high prevalence and severe clinical consequences in patients with type 2 diabetes mellitus (T2DM), metabolic dysfunction-associated steatotic liver disease (MASLD) is often overlooked in clinical practise. Therefore, the aim of this study was to investigate the prevalence of steatosis and fibrosis in T2DM patients in Eastern Croatia and its association with hepatic steatosis biomarkers and the risk of MASLD fibrosis.
Method: In this pilot study, 52 T2DM patients (29 men and 23 women) aged between 31 and 87 years were included. Liver fibrosis was assessed using 2D shear wave elastography (2D SWE) to measure liver stiffness and liver steatosis was assessed using the ultrasound-guided attenuation parameter (UGAP) method. Blood was drawn for an enzyme-linked immunosorbent assay (ELISA) to determine liver steatosis biomarkers: peroxisome proliferator-activated receptor (PPAR) alpha, PPAR gamma, sterol regulatory element-binding protein (SREBP) 1 and microsomal triglyceride transfer protein (MTTP). In addition, the complete blood count, liver transaminases, coagulogram, proteins, albumins, lipidogram, blood glucose and HbA1c levels were measured. The MASLD fibrosis score was calculated to assess the risk of developing MASLD fibrosis.
Results: 73% of patients had stage F1 fibrosis, while 15% were classified with advanced F4 fibrosis, with a maximum value of 40.28 kPa in one patient. Regarding steatosis, S0 and advanced stage S3 (with a maximum value of 0.83 dB/cm/MHz) were evenly represented (13%) and the other intermediate stages were also almost evenly distributed. The Spearman correlation coefficient showed that there was a significant correlation between fibrosis and steatosis (Rho = 0.311, p = 0.04). However, no significant correlation was observed between 2D SWE and UGAP steatosis with the biomarkers of hepatic steatosis (p > 0.05). Higher plasma glucose (Rho = 0.583 p < 0.001), HbA1c (Rho = 0.370, p = 0.02), triglycerides (Rho = 0.338, p = 0.04), alkaline phosphatase (Rho = 0.352, p = 0.03), gamma-glutamyltransferase (Rho = 0.336, p = 0.04), alanine transaminase (Rho = 0.634, p < 0.001) and lower protein levels (Rho = -0.443, p = 0.01) were significantly associated with increased UGAP steatosis. The Kruskal-Wallis test showed that higher 2DSWE levels were present in patients at high risk of MASLD fibrosis (p = 0.009) and higher PPAR alpha levels were present in patients at intermediate risk of MASLD fibrosis (p = 0.04) compared to patients at low risk of MASLD fibrosis.
Conclusion: Although only a relatively small group of patients were included in our study, liver steatosis and fibrosis were frequently observed, and in a few patients fibrosis and steatosis were extremely high. This strongly emphasizes the urgent need to adopt liver SWE and UGAP, supported by the MASLD fibrosis score, into routine clinical practice to reduce the risk of fibrosis progression, which is a significant health threat worldwide.

WED-466-YI
Serum biomolecules improve liver enzyme-based prediction scores of significant liver fibrosis and fibrotic metabolic dysfunction-associated steatohepatitis

Nateneal Beyene[1], Lotte Schoenmakers[2], Wilhelmus J Kwanten[2], Eveline Dirinck[3], An Verrijken[3], Jolien Derdeyn[2], Toon Steinhauser[2], Thomas Vanwolleghem[2], Ann Driessen[4], Christophe De Block[3], Sven Francque[2], Luisa Vonghia[2]. *[1]Laboratory of Experimental Medicine and Pediatrics, University of Antwerp, Antwerp, Belgium; [2]Department of Gastroenterology and Hepatology, Antwerp University Hospital, Antwerp, Belgium; [3]Department of Endocrinology, Diabetology and Metabolic Diseases, Antwerp University Hospital, Antwerp, Belgium; [4]Department of Pathology, Antwerp University Hospital, Antwerp, Belgium*
Email: natenealtamerat.beyene@uantwerpen.be

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) with significant fibrosis (i.e. MASH with fibrosis ≥F2) have a higher risk of developing advanced liver disease. The gold standard for identifying MASH and fibrosis remains biopsy based histological evaluation, an invasive and costly procedure. Hence, blood biomarkers-based prediction scores may provide an improved option. Thus, the study aims to establish a serum-based non-invasive score model to predict significant liver fibrosis and fibrotic MASH.
Method: Two comparable cohorts, a derivative and validation, comprising respectively 120 and 118 patients underwent liver biopsy for a suspicion of MASLD at the Gastro-enterology and

Hepatology Department of the Antwerp University Hospital. The NAFLD activity score system was used to determine the histological MASLD features. Beside standard serum biochemistry, serum biomolecules of metabolic, inflammatory, and vascular proteins were measured. Independent predictors of F ≥2 identified by multivariate logistic regression, and the predicted probabilities were used to generate prediction models. The area under the receiver operating characteristic curves (AUROC) of the models and FIB-4 index were compared using the DeLong test. And $p < 0.05$ was considered statistically significant.

Results: The derivation cohort included patients with fibrosis F ≥2 (40%), MASH (40%), and fibrotic MASH (28.3%), while the validation cohort comprised fibrosis F ≥2 (44%), MASH (45.8%), and fibrotic MASH (33.9%). A novel model, Model-2S3 created by unweighted integration of three serum biomolecules and two enzymes. In the derivation cohort, Model-2S3 predicted fibrosis F ≥2 with an AUC of 0.96 (95% CI: 0.93–0.99), maintaining 94% sensitivity and 91% specificity. For fibrotic MASH, Model-2S3 achieved an AUC of 0.90 (95% CI: 0.83–0.95), with 85% sensitivity and 86% specificity. Model-2S3 significantly outperformed FIB4 in predicting fibrosis F≥2 (AUC: 0.83, 95% CI: 0.76–0.90, $P = 0.002$) or fibrotic MASH (AUC: 0.71, 95% CI: 0.61–0.80, $P = 0.001$). Alternatively, Model-E integrating ALT, AST and GGT performed acceptable but also worse than Model-2S3 for prediction of fibrosis F ≥ 2 (AUC: 0.89, 95% CI: 0.83–0.95, $P = 0.008$) and fibrotic MASH (AUC: 0.78, 95% CI: 0.70–0.87, $P = 0.01$). In the validation cohort, Model-2S3 maintained high accuracy, predicting fibrosis F ≥2 with an AUC of 0.95 (95% CI: 0.92–0.99), 84% sensitivity, and 98% specificity. For fibrotic MASH, it achieved an AUC of 0.89 (95% CI: 0.83–0.96), with 85% sensitivity and 87% specificity. In this cohort Model-2S3 also significantly outperformed FIB4 and Model-E in predicting fibrosis F ≥2 and fibrotic MASH.

Conclusion: A composite score of serum biomolecules and enzymes yields high accuracy to predict significant fibrosis or fibrotic MASH. This new model outperformed scores based on routinely available parameters and might be considered as a promising non-invasive tool.

WED-467

Low sensitivity of the 2024 EASL screening criteria for identifying MASLD fibrosis in the NHANES cohort

Clemence Canivet[1], Ongaro Marie[1], Laurent Spahr[1], Nicolas Goossens[1].
[1]*Geneva University Hospital, Geneva, Switzerland*
Email: nicolas.goossens@hcuge.ch

Background and aims: The 2024 European Association for the Study of the Liver (EASL) guidelines propose a sequential screening approach using metabolic risk criteria, FIB-4, and transient elastography (TE) to identify patients with metabolic dysfunction-associated steatotic liver disease (MASLD) who require hepatology referral. This study evaluates the diagnostic performance of these recommendations in the NHANES cohort.

Method: Adult participants with complete TE data from NHANES 2017–2020 were included. MASLD was defined as hepatic steatosis (CAP ≥248 dB/m) with at least one cardiometabolic risk factor (CMRF). The EASL screening strategy was applied sequentially: (1) metabolic risk criteria (obesity with ≥1 CMRF, type 2 diabetes [T2D], or raised liver enzymes), (2) age-adjusted FIB-4 thresholds (≥1.3 for age <65 years or ≥2.0 for age ≥65 years), and (3) hepatology referral criteria (FIB-4 > 2.67 or TE ≥8 kPa). Diagnostic performance was assessed for MASLD with fibrosis (TE ≥8 kPa), with subgroup analyses by age and T2D.

Results: Of 7,768 included participants, MASLD and MASLD with fibrosis were present in 45% and 6%, respectively. Applying the EASL criteria sequentially, 45% of the total population met metabolic risk criteria, 7.5% had elevated FIB-4, and 3% qualified for hepatology referral. The overall sensitivity and specificity of the sequential pathway for identifying MASLD with fibrosis were 21% and 98%, respectively. Sensitivity declined from 86% to 29% when age-adjusted FIB-4 thresholds were applied, while specificity improved from 56% to 93%. Subgroup analyses revealed particularly low sensitivity in younger individuals (<50 years, 6%) and those without T2D (16%), whereas specificity exceeded 90% across all subgroups. Sensitivity analyses using higher fibrosis thresholds (MASLD with TE ≥12 kPa) confirmed similarly poor sensitivity (29%).

Conclusion: The 2024 EASL screening criteria exhibit high specificity but poor sensitivity for detecting MASLD with fibrosis, particularly in younger or non-diabetic individuals. The low sensitivity is primarily attributed to FIB-4's poor performance within the sequential algorithm. These findings underscore the need for better-performing non-invasive tests to optimize referral for specialist care.

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) clinical trials rely on liver biopsies; thus, the predictive potential of non-invasive tests (NITs) has not been widely investigated. We evaluated the predictive potential of changes in NITs for biopsy outcomes in a phase 2 trial in people with biopsy-confirmed MASH and F1 – F3 liver fibrosis who were treated with survodutide, a novel glucagon receptor/glucagon-like peptide-1 receptor dual agonist.

Method: 295 patients were randomised to once-weekly subcutaneous injections of placebo or survodutide 2.4, 4.8, or 6.0 mg (NCT04771273). This post-hoc analysis involved patients with F2/F3 fibrosis and paired biopsies and NITs (n = 138). We assessed whether % change from baseline after 48 weeks in FibroScan®-aspartate aminotransferase (FAST) score, Agile 3+ (FibroScan-based score), alanine transaminase (ALT), body weight, magnetic resonance imaging proton density fat fraction (MRI-PDFF), controlled attenuation parameter (CAP; FibroScan), vibration-controlled transient elastography (FibroScan), propeptide of type III collagen (PRO-C3), and absolute change in enhanced liver fibrosis (ELF™) score, had predictive potential for 2 biopsy based outcomes: resolution of MASH with no worsening of fibrosis, and improvement of fibrosis with no worsening of MASH. Variables were dichotomized based on cut-off points that were established using the Youden Index. Potential predictors were chosen using the least absolute shrinkage and

selection operator (LASSO) method and threefold cross-validation (CV), adjusted for changes in body weight. The importance of predictors was determined on the absolute value of the regression coefficients of the dichotomized biomarkers. The model's performance was assessed using area under the curve (AUC), with a 95% confidence interval (CI) and a p-value derived from the one-sided Mann-Whitney test.
Results: Only participants receiving survodutide were included in the analysis to avoid a potential confounding effect from the active treatment. Changes in MRI-PDFF (relative importance to the prediction: 100%), ELF (61.9%), and FAST score (50.4%) were predictive of resolution of MASH with no worsening of fibrosis (full dataset: AUC 0.854, 95% CI: 0.78 to 0.93, $p < 0.0001$; AUC based on CV: 0.84). Changes in ELF (100%), ALT (87.2%), PRO-C3 (76.3%), MRI-PDFF (75.6%), FAST Score (72.3%), Agile 3+ (50.5%), and CAP (13.6%) were predictive of improvement of fibrosis with no worsening of MASH (full dataset: AUC 0.811, 95% CI: 0.73 to 0.90, $p < 0.0001$; AUC based on CV: 0.76).
Conclusion: We found evidence for predictive potential of changes in NITs such as MRI-PDFF, ELF, or FAST Score for biopsy outcomes, however predictive models incorporating multiple top NIT candidates are under investigation to enhance model accuracy and refinement.

WED-469
Novel point-of-care, rapid breath test to identify subjects with metabolic-dysfunction associated steatotic liver disease with advanced fibrosis - a pilot study
Osnat Sella Tavor[1], Orit Marom Albeck[1], Ilay Marom[1], Omer Meroz[1], Gilad Feinberg[1], Rifaat Safadi[2]. *[1]NaNose Medical Ltd, Netanya, Israel; [2]Hadassah University Hospital, Liver Institute, Jerusalem, Israel*
Email: osnatst@nanosemed.com

Background and aims: There is a clear need for cost-effective, easy-to-use Point of Care (PoC) screening technologies for diagnosing metabolic-dysfunction associated steatotic liver disease (MASLD) and steatohepatitis (MASH), particularly those identifying advanced fibrosis, a key predictor of liver-related mortality. Volatile organic compounds (VOCs) biomarkers in exhaled breath, which reflect altered hepatic metabolism, are promising but current VOC analysis technologies are labor-intensive. NaNose Medical Ltd. is developing a unique nanotechnology-based sensing device, DiaNose, which uses semi-selective chemiresistor sensor array and machine learning to detect "breath fingerprints" without complex VOC concentrations analysis. Sensors' signals data from clinical studies is used to train models to classify disease stages.
Method: The sensor array consists of functionalized metal nanoparticle films over electrodes, detecting VOCs through electric response. DiaNose includes a single-use breath collection unit, a replaceable sensor, and a measurement system. In clinical studies, it collects data from MASLD patients with different fibrosis stages, verified through biopsy or FibroScan tests.
Results: Data from 30 MASLD patients (13 with no/early fibrosis, 17 with advanced fibrosis) were used to develop a classification model. Cross-validation produced accuracies of 85.5% sensitivity, 79% specificity, and 82.3% overall accuracy. Data collection is ongoing to enhance stability and generalization.
Conclusion: Preliminary results indicate DiaNose's potential for non-invasive PoC screening, accurately distinguishing MASLD with early versus advanced fibrosis. This tool could facilitate patient referral, optimize primary care management, and support trial stratification to advance treatment development.

AI improves non-invasive diagnosis and screening of advanced MASLD
Paul Cales[1], Adele Delamarre, Charlotte Costentin[2], Gilles Hunault[1], Adrien Lannes[3], Frédéric Oberti[3], Isabelle Fouchard[3], Jerome Boursier[1]. *[1]Angers University, Angers, France; [2]University Hospital, Grenoble, France; [3]University Hospital, Angers, France*
Email: paul.cales@univ-angers.fr

Background and aims: The FIB-4 blood test and liver stiffness measurement (LSM) are popular, especially in the screening of advanced liver fibrosis in subjects at risk of MASLD (AASLD and EASL algorithms). Recently, AI has been shown to give a performance of new non-invasive tests (NITs), including usual liver blood markers, like that of proprietary NITs in MASLD (JHep 2025). We assessed whether AI could also improve the performance of FIB-4 and LSM.
Method: We included 1038 patients with MASLD who were split into derivation ($n = 624$) and validation ($n = 414$) sets. The primary endpoint was advanced fibrosis (Kleiner F3+4). The AI used new multi-targeted supervised learning. The new AI versions of FIB-4 and LSM included the same biomarkers adjusted for clinical variables that have been shown to influence NIT accuracy: age, BMI, diabetes for FIB-4 plus IQR for LSM (Fibroscan). Performance was measured by AUROC and the correct classification rate (accuracy). NIT thresholds were set in the derivation set by the Youden index for binary diagnosis and by sensitivity and specificity at 90% for ternary diagnosis. The accuracy of the indeterminate zone was set at 0%.
Results: The results are those of the validation set. 1/ FIB-4. The AUROC for advanced fibrosis increased from 0.757 in its original version to 0.814 ($p = 0.002$) in its AI version called FIB-4A. The binary accuracy increased from 68.8% to 75.6%, respectively ($p = 0.002$). The ternary accuracy increased from 41.1% to 51.0% ($p < 0.001$). The indeterminate rate decreased from 49.0% to 38.6% ($p < 0.001$). 2/ LSM. The LSM AUROC increased from 0.852 in its original version to 0.881 ($p = 0.006$) in its AI version called LSM-A. The binary accuracy increased from 75.6% to 79.2% ($p = 0.024$). The ternary accuracy increased from 59.7% to 65.0% ($p = 0.013$). LSM-A improved LSM reliability by increasing accuracy from 52.6% to 71.1% ($p = 0.039$) in poorly reliable LSM. Aging and diabetes decreased LSM accuracy ($p < 0.001$) but not LSM-A accuracy ($p = 0.755$). 3/ FIB-4A and LSM-A. Their scores directly reflected Kleiner's F-score from 0 to 4 with intra-class correlation coefficient at 0.717 and 0.808, respectively. The accuracy of the AASLD algorithm increased from 66.4% with original NITs to 72.5% ($p = 0.006$) by including FIB-4A and LSM-A. AI significantly decreased the indeterminate rate from 16.4% to 11.6% ($p = 0.019$) and the LSM recourse from 49.0% to 38.6% ($p < 0.001$). This significantly reduces the need for a 2nd fee-paying NIT and for a specialist in all the recommended screening algorithms, including the EASL algorithm. Finally, a new FIABLE algorithm, based on different segmentations of new AI-NITs, significantly improved AASLD algorithm performance.
Conclusion: AI remarkably increases the performance of FIB-4 and LSM. This leads to a significant improvement in LSM reliability, negative influence of age and diabetes, and diagnosis or screening by sequential algorithms of advanced MASLD.

WED-471
Noninvasive fibrosis indices are less effective in predicting significant fibrosis in younger adults with metabolic dysfunction-associated steatotic liver disease
Jaejun Lee[1], Chang In Han[2], Hyun Yang[1], Si Hyun Bae[1]. *[1]The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]Armed Forces Goyang Hospital, Seoul, Korea, Rep. of South*
Email: pwln0516@gmail.com

Background and aims: Although numerous noninvasive indices have been developed to assess significant fibrosis, none have been specifically validated in young adults with metabolic dysfunction-

associated steatotic liver disease (MASLD). This study aims to evaluate the performance of these indices in a younger population.
Method: Retrospective data from patients under the age of 35 who visited the 'Liver Health Clinic' at Armed Forces Goyang Hospital between June 2022 and January 2024 were collected consecutively. Significant fibrosis was defined as a liver stiffness measurement (LSM) ≥7.0 kPa. Patients with alanine aminotransferase (ALT) levels exceeding 80 IU/L were excluded to mitigate the risk of overestimating LSM. MASLD was defined as the presence of hepatic steatosis accompanied by at least one cardiometabolic risk factor.
Results: Among the 972 MASLD patients, 45 had significant fibrosis according to LSM. The mean age of study participants was 23.7 and males were predominant (97.3%). Five noninvasive indices, including FIB-4 index, APRI, FIB-8 index, NAFLD Fibrosis Score (NFS), and BARD score were assessed for their predictive performance. The FIB-4 index demonstrated an area under the curve (AUC) of 0.528, while APRI showed an AUC of 0.659. The FIB-8 index, NFS, and BARD score yielded AUCs of 0.735, 0.603, and 0.469, respectively. Correlation analyses between these indices and LSM revealed coefficients of −0.001 (p = 0.352) for FIB-4, 0.0165 (p < 0.001) for APRI, 0.0380 (p < 0.001) for FIB-8, and 0.0014 (p = 0.125) for NFS. Sensitivity analyses using an LSM cutoff of 8.0 kPa for significant fibrosis showed slightly improved AUCs, with values of 0.591 for FIB-4, 0.666 for APRI, 0.759 for FIB-8, 0.649 for NFS, and 0.531 for BARD.591 for FIB-4, 0.666 for APRI, 0.759 for FIB-8, 0.649 for NFS, and 0.531 for BARD.
Conclusion: Noninvasive fibrosis indices demonstrated inadequate performance in predicting significant fibrosis among young adults with MASLD. These findings underscore the need for developing novel noninvasive indices designed to detect significant fibrosis in this younger population.

WED-472
Vibration-controlled transient elastography scores to predict liver fibrosis in biopsy-proven metabolic dysfunction-associated steatotic liver disease patients with diabetes: a prospective, multicenter study

Bingtian Dong[1], Yuping Chen[2], Chuan Liu[2], Huapeng Lin[3], Airong Hu[4], Xiao Liang[5], Yiling Li[6], Wei Gou[7], Ming-Hua Zheng[8], Xiaolong Qi[2]. *[1]the First Affiliated Hospital of Anhui Medical University, Zhongda Hospital, Southeast University, Hefei, China; [2]Zhongda Hospital, Southeast University, Nanjing, China; [3]Center for Digestive Diseases Research and Clinical Translation of Shanghai Jiao Tong University, Shanghai, China; [4]Ningbo No. 2 Hospital, Ningbo, China; [5]Sir Run-Run Shaw Hospital, Zhejiang University School of Medicine, Hangzhou, China; [6]The First Hospital of China Medical University, Shenyang, China; [7]Qingdao Sixth People's Hospital, Qingdao, China; [8]the First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China*
Email: dongbingtian@foxmail.com

Background and aims: Agile 3+ and Agile 4 scores, based on vibration-controlled transient elastography (VCTE), provide non-invasive tools for identifying advanced fibrosis (AF, F≥3) and cirrhosis (F = 4) in metabolic dysfunction-associated steatotic liver disease (MASLD). This study aimed to evaluate the diagnostic performance of Agile scores in biopsy-proven MASLD patients with type 2 diabetes mellitus (T2DM), a high-risk subgroup.
Method: This prospective multicenter study included 321 MASLD patients with T2DM from five Chinese hospitals between October 2017 and June 2024. The median age was 49.0 years, and 169 patients (52.6%) were male. MASLD was diagnosed based on presence of steatosis, cardiometabolic risk factors, and non-harmful alcohol intake. Liver fibrosis staging was performed histologically, and Agile scores were calculated. Diagnostic performance was assessed using receiver operating characteristic (ROC) curve analysis and compared with liver stiffness measurement (LSM), fibrosis-4 index (FIB-4), aspartate aminotransferase (AST) to platelet ratio index (APRI), FibroScan-AST score (FAST), and NAFLD fibrosis score (NFS). Sensitivity, specificity, and predictive values of their well-defined dual cut-offs value were tested.
Results: Median Agile 3+ was 0.430 (interquartile range [IQR] 0.199–0.721), and median Agile 4 was 0.045 (IQR 0.014–0.152), while the median LSM was 8.1 (IQR 6.0–12.1) kPa. AF and cirrhosis prevalence were 21.5% (69/321) and 7.2% (23/321), respectively. Agile 3+ achieved an area under the ROC (AUROC) of 0.794 (95% confidence interval [CI] 0.728–0.861) for AF, significantly outperforming APRI (p = 0.036), FAST (p = 0.017), and NFS (p = 0.007). Agile 4 demonstrated an AUROC of 0.876 (95% CI 0.778–0.973) for cirrhosis, significantly higher than APRI (p = 0.005) and FAST (p < 0.001). Agile 4 and Agile 3 + outperformed FIB-4 and LSM in terms of AUROC, percentage of patients with indeterminate results and positive predictive value to rule-in cirrhosis or AF. The percentages of patients in the grey zone were 18.7% and 13.4% for Agile 3+ and Agile 4, respectively. Agile scores yielded fewer indeterminate results and higher rule-in and rule-out rates compared to other non-invasive tests.
Conclusion: Agile scores demonstrated excellent diagnostic accuracy for AF and cirrhosis in MASLD patients with T2DM, providing a reliable and non-invasive alternative for fibrosis assessment in this high-risk population.

WED-475
Plasma FSTL-1 accurately assesses MASH-associated liver fibrosis stage

Jianhua Rao[1], Yongquan Chi[1], Wenzhu Li[1], Junda Li[1], Haipeng Jiang[1], Xiaoguo Li[2], Wei Xu[1], Shanke Sun[1], Xiaolong Qi[2]. *[1]The First Affiliated Hospital with Nanjing Medical University, Nanjing, China; [2]Center of Portal Hypertension, Department of Radiology, Zhongda Hospital, Medical School, Southeast University, Nanjing, China, Nanjing, China*
Email: raojh@njmu.edu.cn

Background and aims: Emerging drugs for MASH target at liver fibrosis, especially alleviating F2/F3 liver fibrosis. Reliable non-invasive biomarkers for assessing MASH-associated fibrosis are crucial for clinical assessment and drug development. This study aimed at evaluating the accuracy of plasma Follistatin-like protein 1 (FSTL-1) in assessing MASH-associated fibrosis stages.
Method: Clinical data, plasma and liver biopsy tissues from 115 patients were collected including healthy controls (n = 37) and MASH (n = 78) from 2023 March to 2024 May. The plasma FSTL-1 levels were measured along with the steatosis levels and fibrosis stages based on liver biopsy tissues.
Results: Plasma FSTL-1 levels were significantly higher in MASH patients (0.47, IQR 0.30–0.60) than controls (0.32, IQR 0.16–0.43), showing a 1.5-fold increase. FSTL-1 levels positively correlated with steatosis and fibrosis stages. Among the MASH cohort, 36 patients (46%) had F2 and more, 22 (28%) had F3 and more. Plasma FSTL-1 distinguished fibrosis stages with high accuracy, achieving area under the receiver operating characteristic curve (AUROC) of 0.82 (95% confidence interval [CI], 0.72–0.91) for F ≥2 and 0.93 (95% CI, 0.84–1.00) for F ≥3, indicating that plasma FSTL-1 can accurately assess the MASH-associated liver fibrosis and distinguish participants from F2 and F3 highlighting its relevance in evaluating drug efficacy and facilitating drug discovery for MASH-associated fibrosis.
Conclusion: Plasma FSTL-1 can accurately assess the MASH-associated liver fibrosis and distinguishing liver fibrosis stages in MASH patients, offering a potential drug discovery for MASH-associated fibrosis.

WED-476-YI

Misclassification in non-invasive tests for liver fibrosis is expected: an example predicting liver stiffness in an international cohort

Email: rickard.strandberg@ki.se

Background and aims: Vibration-controlled transient elastography (VCTE) is a common tool for diagnosing liver fibrosis and steatosis. In locations where VCTE is not readily available, alternative blood-based scores such as the recently published LiverRisk score might be useful. However, even good alternatives are expected to give deviating results, since they are based on variables with limited predictive power. In this study we illustrate this by predicting VCTE liver stiffness using some of the most common non-invasive biomarkers—both by validating the LiverRisk score, and by developing a new score specifically for this study.
Method: We used an international multicenter cohort of patients with MASLD examined using VCTE. We used ordinal regression on the continuous outcome of VCTE liver stiffness. We predicted this outcome using flexible modelling with age, sex, center, and the most common liver-related blood-based biomarkers (aspartate aminotransferase, alanine aminotransferase, gamma-glutamyl transferase, platelet count, cholesterol, glucose, albumin, and bilirubin). This modelling approach includes the LiverRisk score as a special case. The discrimination and calibration of LiverRisk and this new model were assessed using the c-index for predicting liver stiffness >8 kPa and a calibration curve. Overall goodness-of-fit was then assessed using R^2 and the mean absolute prediction error (MAPE).
Results: We used 15,196 patients with MASLD without prior diagnosis of decompensated cirrhosis or hepatocellular carcinoma to train the model. The median (interquartile range) liver stiffness was 6.0 kPa (4.7–8.3). The new score showed good discrimination (c-index = 84%) and good calibration according to the calibration curve. Nonetheless, the proportion of explained variation was low (R^2 = 0.38) and the mean absolute prediction error was high (MAPE = 2.66 kPa). The sensitivity and specificity for classifying patients with and without VCTE liver stiffness >8 kPa were 53% and 89%, respectively. The positive and negative prediction values were 63% and 84%. The LiverRisk score understandably performed worse than the new score, mostly due to being developed in a different population (c-index = 74%, R^2 = 0.14).
Conclusion: When using risk scores for referral to specialist care, many patients are expected to be completely healthy, even in a seemingly good score. This is because the variables used in the scores contain limited information about the outcome of interest.

WED-477

Validating non-invasive tests for diagnostic prediction of fibrosis in patients with biopsy-proven MASLD: CORE, LiverRisk, and FIB-4

Rickard Strandberg[1], Ying Shang[1], Mattias Ekstedt[2], Johan Vessby[3], Hannes Hagström[1,4]. *[1]Karolinska Institutet, Stockholm, Sweden; [2]Linköping University, Linköping, Sweden; [3]Uppsala University Hospital, Uppsala, Sweden; [4]Karolinska University Hospital, Stockholm, Sweden*
Email: rickard.strandberg@ki.se

Background and aims: Several non-invasive blood-based tests have been proposed for finding advanced fibrosis in patients with known or suspected MASLD. However, also patients with earlier stages of fibrosis (F2) may require and be eligible for approved treatments. Here, we validated the novel risk scores CORE and LiverRisk, compared with the current first-line test FIB-4 for predicting the stage of liver fibrosis according to biopsy in patients with biopsy-proven MASLD.
Method: We used data from patients diagnosed with MASLD at three Swedish university hospitals between 1974–2021 with available biopsy results. We used ordinal regression to map values of each risk score to probabilities of having each fibrosis stage. We used the c-index, the Brier score, and decision curve analysis to compare each score's ability to select patients with fibrosis stage F2 or higher, and F3 or higher.
Results: Among the 964 included patients, 367 (38%) had fibrosis stage F2 or higher, and 155 (16%) had stage F3 or higher. Overall, the scores were better at predicting patients with stage F3+ (c-index & Brier score for CORE: 0.78 & 0.116, LiverRisk: 0.74 & 0.121, FIB-4: 0.81 & 0.107) than patients with stage F2+ (c-index & Brier score for CORE: 0.68 & 0.213, LiverRisk: 0.64 & 0.222, FIB-4: 0.70 & 0.203). The decision curve analysis consistently showed the highest net benefit between true positives and false positives for FIB-4, followed by CORE and then LiverRisk.
Conclusion: In patients with known MASLD and available liver biopsy, FIB-4 was the preferred non-invasive test for predicting advanced fibrosis. All models performed worse to detect fibrosis stage 2 or more, suggesting the need for improved models to define earlier stages of fibrosis. The clinical utility of all scores for referral to subsequent testing with vibration-controlled transient elastography or hepatology referral depends on a so far undetermined risk tolerance for correct versus incorrect referral.

WED-478

Novel multiparametric MRI imaging predicts histologic response in resmetirom versus placebo in the multicentre, international, Maestro NASH phase 3 trial

Andrea Dennis[1], Hang Zhang[2], Anneli Andersson[1], Dominic Labriola[2], Rebecca Taub[2], Rohit Loomba[3]. *[1]Perspectum, Oxford, United Kingdom; [2]Madrigal Pharmaceuticals, Conshohocken, PA, United States; [3]MASLD Research Center, University of California at San Diego, La Jolla, United States*
Email: andrea.dennis@perspectum.com

Background and aims: Resmetirom was approved by FDA in March 2024 and is indicated for the treatment of adults with noncirrhotic nonalcoholic steatohepatitis (NASH) with moderate to advanced liver fibrosis (consistent with stages F2 to F3). MAESTRO-NASH (NCT03900429) is an ongoing 54-month, randomized, double-blind, placebo-controlled Phase 3 trial evaluating the efficacy of resmetirom in patients with biopsy confirmed non-alcoholic steatohepatitis (NASH) and fibrosis. Dual primary endpoints at Week 52 were achieved with both resmetirom 80 mg and 100 mg: NASH resolution with no worsening of fibrosis or ≥1-stage reduction in fibrosis with no worsening of NAS. All participants also received non-invasive tests, with change in MRI-PDFF a key secondary endpoint. For a subset of patients MRI-derived cT1, a marker of fibro-inflammation, was collected. A reduction in cT1 of −80 ms has been identified as the optimal threshold associated with histological

response. We explored the cT1 responses observed in the Maestro-NASH trial.
Method: Adults with ≥3 metabolic risk factors, liver stiffness ≥8.5 kPa, hepatic fat ≥8%, biopsy-confirmed NASH with F1B-F3 fibrosis, and NAS ≥4 were eligible to participate in MAESTRO-NASH. cT1 was acquired using LiverMultiScan. Average changes in cT1 with increasing dose, and with histological response was assessed and summary descriptive statistics reported. cT1 responders were considered those who had an ≥80 ms reduction in cT1.
Results: 156 patients had cT1 and histology data (mean age: 57 years old, 56% female, mean BMI: 37 kg/m^2). cT1 and PDFF were positively correlated (Spearman's rho ranging between 0.68–0.83) and cT1 increased with increasing fibrosis stage. After 16-weeks of Resmetirom treatment, the mean reduction in cT1 was −48 ms (SD: 101 ms) in the 80 mg group (N = 37) and −78 ms (SD: 88 ms) in the 100 mg group (n = 46). There was minimal change in the in the placebo group (−8 ms, (SD: 56 ms), N = 51). This dose-dependent pattern in cT1 change was maintained at 52 weeks. Additionally, 25% and 36% met the cT1 response criteria in the 80 mg and 100 mg arms, respectively. cT1 reduction was larger in histological responders than non-responders for NASH Resolution in the 100 mg arm (mean change −125 ms versus −46 ms; cT1 responders 53% versus 19%) and for fibrosis Improvement in both 80 mg (mean change −84 ms versus −11 ms) and 100 mg arms (mean change −124 ms versus −74 ms; cT1 responders 70% versus 24%).
Conclusion: A positive association with fibrosis stage and with MRI-PDFF was observed for cT1 in this subset analysis. cT1 demonstrated a dose dependent reduction with Resmetirom treatment, with the greatest reductions in the 100 mg group, and a negligible placebo response. A reduction in cT1 of >80 ms was associated with high likelihood of histological response. These data suggest cT1 may be a suitable test for monitoring response in patients being treated with Resmetirom.

WED-479
Assessment of the metabolic dysfunction-associated steatohepatitis resolution index and component biomarkers in prediction of histology response to denifanstat in the FASCINATE-2 trial

Rohit Loomba[1], Wen-Wei Tsai[2], Laura Hover[3], Shipra Gupta[2], Katharine Grimmer[2], Julie Dubourg[2], Eduardo Martins[2], George Kemble[4], Marie O' Farrell[2]. *[1]University of California San Diego School of Medicine, San Diego, United States; [2]Sagimet Biosciences, san mateo, United States; [3]Monoceros Biosystems LLC, San Diego, United States; [4]Sagimet Biosciences, San Mateo, United States*
Email: marie.ofarrell@sagimet.com

Background and aims: Denifanstat, a fatty acid synthase inhibitor in clinical development for metabolic dysfunction-associated steatohepatitis (MASH), met statistical significance in histology endpoints in Ph2b FASCINATE-2. Liver biopsy is the currently accepted endpoint in MASH trials for accelerated regulatory approval. However, because of biopsy's invasive nature and variability, there is an important unmet clinical need to identify and test non-invasive biomarkers to more efficiently diagnose, monitor and predict treatment response in clinical trials and in the real-world setting. The MASH Resolution Index (MR-I) has recently been defined by Loomba et al., as a non-invasive biomarker score including liver fat, ALT and AST that predicts MASH resolution (MR) by histology. This analysis aimed to test the performance of MRI-I in predicting MR by denifanstat by retrospective analysis of FASCINATE-2.
Method: 168 patients with biopsy-confirmed F2/F3 MASH were randomized 2:1 to once daily oral denifanstat 50 mg or placebo for 52 wk. Pre- and wk52 liver biopsy slides were read by an expert central pathologist using NASH-CRN criteria. Liver fat by MRI-PDFF was measured pre, wk26 and wk52. ALT and AST also at wk4 and wk13. MR-I was calculated at wk26 and wk52 for each patient, defined as 0.520–0.003 × baseline ALT (U/L) −0.024 × (latest ALT [U/L]- baseline ALT (U/L)) −0.048 × baseline MRI-PDFF −2.571 × ((latest MRI-PDFF - baseline MRI-PDFF)/baseline MRI-PDFF) −0.039 × baseline AST (U/L). Logistic regression (LR) models were used for analysis versus MR.
Results: Wk52 MR-I showed strong performance and predicted week 52 MR with an AUC of 0.72 ($p < 0.05$ LR), 83% negative predictive power (NPV), and 81% specificity. The week 26 MR-I predicted wk52 MR with an AUC of 0.73, 86% NPV, 56% PPV, 78% specificity, 66% sensitivity, $p > 0.05$ (LR). Testing individual biomarkers showed liver fat change at week 26 had strong diagnostic performance (AUC 0.73, $p > 0.05$), notably high NPV of 91% and 83% sensitivity. ALT change as a continuous variable had AUC of 0.60 and 0.68 at wk4 and wk13, with up to 94% specificity for prediction of wk52 MR, $p < 0.05$ (LR). Taken together, these results indicate that MR-I and its components have potential application to enrich for responders to denifanstat.
Conclusion: This retrospective analysis of the FASCINATE-2 Phase 2b trial demonstrated that MR-I can predict MR. In this analysis, MR-I showed potential to predict non-responders. Further analysis and additional non-invasive markers are being pursued specifically at earlier timepoints, to provide non-invasive approaches to predict response to treatment in future MASH clinical studies.

WED-480
Denifanstat-mediated reduction of plasma glycine- and taurine-conjugated bile acids correlates with histological improvements in denifanstat-treated metabolic dysfunction-associated steatohepatitis patients in phase 2b FASCINATE-2 study

Rohit Loomba[1], Wen-Wei Tsai[2], Cristina Alonso[3], Alejandro Montilla[3], Katharine Grimmer[2], Julie Dubourg[2], Eduardo Martins[2], George Kemble[2], Marie O' Farrell[2], Mary E. Rinella[4], Arun J. Sanyal[5]. *[1]Division of Gastroenterology, UC San Diego School of Medicine, La Jolla, CA, United States; [2]Sagimet Biosciences, San Mateo, CA, United States; [3]OWL Metabolomics, Derio, Bizkaia, Spain; [4]Division of Gastroenterology & Hepatology, University of Chicago Pritzker School of Medicine, Chicago, IL, United States; [5]Stravitz–Sanyal Institute for Liver Disease and Metabolic Health, Virginia Commonwealth University School of Medicine, Richmond, VA, United States*
Email: wen-wei.tsai@sagimet.com

Background and aims: Increased *de novo* lipogenesis (DNL) drives the development of metabolic dysfunction-associated steatohepatitis (MASH). Fatty acid synthase (FASN) is the rate-limiting enzyme in the DNL pathway. In the Phase 2b FASCINATE-2 study, 56% of MASH patients with F2/F3 fibrosis treated with denifanstat, a selective FASN inhibitor, achieved either fibrosis improvement ³ 1 stage or MASH resolution. To identify potential biomarkers that predict histological responses, plasma lipidomic/metabolomic analyses were performed. Glycine- and taurine-conjugated bile acids play a crucial role in emulsifying and solubilizing dietary fats in the small intestine. In addition to their digestive functions, these conjugated bile acids act as endocrine hormones, mediating gut-liver crosstalk. Elevated serum bile acid levels have been associated with metabolic disorders, such as MASH and type 2 diabetes. This study evaluated the correlation between bile acid changes and histological improvements in MASH patients treated with denifanstat.
Method: MASH patients with biopsy confirmed F2/F3 fibrosis and NAFLD Activity Score ≥4 were enrolled in FASCINATE-2 for 52 weeks treatment. Comprehensive lipidomic and metabolomic analyses were conducted at several visits in the study (OWL Metabolomics).
Results: In the lipidomic/metabolomic analyses, ten abundant plasma bile acids were measured in MASH patients, and glycine- and taurine-conjugated bile acid pools (G- and T-BAs) showed significant reductions following 52 weeks of denifanstat treatment (-27% and −45% vs. placebo +5% and +7%, respectively, $p < 0.001$). Notably, five specific G/T-BAs demonstrated significant reductions in patients with histological responses (³ 1-stage fibrosis improvement or MASH resolution) compared to non-responders or placebo patients. Furthermore, significant reductions in these five G/T-BAs were evident by week 26 in denifanstat-treated patients who

achieved histological improvements by week 52. Among these G/T-BAs, glycodeoxycholic acid and taurodeoxycholic acid exhibited rapid and significant decreases as early as weeks 4 and 13 in histological responders treated with denifanstat, with no significant decreases shown in non-responders or placebo patients.
Conclusion: Identifying reliable biomarkers for response prediction is crucial for advancing precision medicine. In MASH patients treated with denifanstat, glycine- and taurine-conjugated bile acids were significantly reduced at 26 weeks in histological responders for both fibrosis regression and MASH resolution, suggesting that this could potentially be leveraged as a response biomarker in patients treated with denifanstat.

WED-481
Advanced metabolic-dysfunction associated steatotic liver disease fibrosis: low number-needed-to screen in multiple lines of care
Stan Driessen[1], Koen van Son[2,3], Gerlinde Haverkamp[4], Maaike J. Denters[4], Sara-Joan Pinto[2], Nordin Hanssen[2], Manuel Castro Cabezas[5,6], R. Bart Takkenberg[1], Henk Schers[7,8], Max Nieuwdorp[2], Joost PH Drenth[9], Maarten Tushuizen[10], A.G. (Onno) Holleboom[1]. *[1]Amsterdam UMC, Vascular medicine, Amsterdam, Netherlands; [2]Amsterdam UMC, Vascular medicine, amsterdam, Netherlands; [3]Radboudumc, Gastroenterology and hepatology, nijmegen, Netherlands; [4]Zaans MC, Zaandam, Netherlands; [5]Julius Clinical, Utrecht, Netherlands; [6]Franciscus Gasthuis, Rotterdam, Netherlands; [7]Radboudumc, Nijmegen, Netherlands; [8]Primary care healthcare centre Thermion, Lent, Netherlands; [9]Amsterdam UMC, Vascular medicine, Amterdam, Netherlands; [10]Leiden University Medical Center, Leiden, Netherlands*
Email: s.driessen2@amsterdamumc.nl

Background and aims: Non-invasive liver tests (NITs) can detect advanced fibrotic MASLD and reduce unnecessary referrals. Yet data comparing numbers-needed-to-screen (NNS) in multiple lines of care are scarce. Therefore we introduced NLA2, the first Dutch MASLD care path, encompassing primary, secondary and tertiary clinics.
Method: Patients at cardiometabolic risk for MASLD were recruited from GPs, regional clinics and a UMC, whilst excluding other liver diseases. Simultaneous FIB4, MAF5, Enhanced Liver Fibrosis (ELF)-test and vibration-controlled transient elastography (VCTE/ FibroScan®) allowed testing of NIT combinations. FIB4 ≥3.25 and/or Liver Stiffness Measurement (LSM) ≥8.0 kPa indicated potential advanced fibrosis, prompting referral to hepatology. Referral patterns were compared to regular care between 2016 and 2024 using a predefined evaluation standard.
Results: 655 participants entered NLA2, 270 from primary, 156 from secondary and 229 from tertiary care. After excluding patients with MetALD or other liver diseases, 597 were analyzed. Median age was 60 years (51–68), 45.9% were women, 51.4% had obesity and 45.2% had T2DM. 73.9% of participants had CAP ≥ 248 dB/m, suggesting ≥ S1 steatosis. 15.5% had LSM ≥8.0 kPa, yielding a NNS of 6.7. NNS decreased across lines of care: 12.1, 5.1 and 5.2 for primary, secondary and tertiary care respectively, inversely related to cardiometabolic comorbidities (mean number 2.1, 2.3, 2.9). ELF was available for 535 participants. 20.0% had ELF ≥9.8, yielding NNS of 5.0. FIB4 stratifies 64% as low risk for advanced fibrosis and 36% as intermediate/high risk. MAF5 stratifies 40% as low risk for advanced fibrosis and 60% as high risk. In a 2-tiered algorithm in case of MAF5 ≥1, VCTE as second test would refer 6.4%; using ELF would refer 11.7%. In a 2-tiered algorithm in case of intermediate FIB4 (1.3–3.25), VCTE as second test would refer 13.1%; using ELF would refer 13.5%. Of 96 patients at risk for advanced fibrosis, 72 were referred to hepatology. 465 patients were referred to hepatology via regular care between 2016 and 2024. Compared to regular care, NLA2 improved correct referrals 4-fold (RR 4.03; 95% CI 2.53–6.41). Unnecessary referrals were reduced 2-fold (RR 0.44; 95% CI 0.27–0.69).
Conclusion: The first Dutch MASLD care path study shows incrementally lower NNS for potential advanced fibrosis detection across multiple lines of care and a significantly improved referral pattern for fibrotic MASLD. We found a marked difference in referral-rate between different NIT combinations.

WED-482
Leveraging natural language processing (CogStack) to analyse FibroScan data: a seven-year exploration (2016–2023) of socioeconomic disparities, ethnic variations, and fibrosis trends
Saima Ajaz[1], Mahd Siddiqi[2], Mohammad Al-Agil[1], Kosh Agarwal[1]. *[1]Kings College Hospital, London, United Kingdom; [2]Kings College London, London, United Kingdom*
Email: saima.ajaz@nhs.net

Background and aims: Non-invasive liver health assessments, such as FibroScan, are increasingly valuable for identifying fibrosis and liver damage across diverse populations. This study leverages CogStack, an advanced data retrieval and analysis platform, to evaluate FibroScan data. The primary aims were to analyse trends in the deprivation index and ethnic diversity among individuals undergoing FibroScan and correlate these variables with the severity of fibrosis.
Method: This retrospective study analysed FibroScan results from electronic health records (EHR) collected between 2016 and 2023 at King's College Hospital's liver outpatient clinic. Data processing was conducted using CogStack, which enabled efficient extraction of both structured and unstructured clinical information. Collected patient demographics included age, gender, ethnicity, and deprivation index scores. Liver stiffness measurements (LSM) and Controlled Attenuation Parameter (CAP) values were analysed to assess fibrosis and steatosis trends over time.
Results: A total of 24,908 FibroScan results were analysed through CogStack. The catchment areas for the patients included Lewisham (25.89%), Lambeth (27.21%), Southwark (29.70%), and Bromley (17.21%). The cohort had a slight male predominance, with 53.3% male and 46.7% female patients, and a mean age of 45 years. The majority of patients were White (42.85%), followed by Unknown (22.56%), Black (20.90%), Asian (8.30%), Other (5.51%), and Mixed (0.30%) ethnicities. The mean liver stiffness measurement (LSM) was 8.38, with 28% of patients showing high LSM values indicative of significant fibrosis. The mean CAP value was 313.68, suggesting a trend towards hepatic steatosis in a significant proportion of patients. For our data, we had 9302 patients index of multiple deprivation (IMD) data (37.35% of the total cohort), with 67.83% of patients being in the fifth decile or below. For these the mean LSM was 8.15, with an interquartile range (IQR) of 4.5 to 7.9.
Conclusion: This study underscores the utility of CogStack for extracting and analysing large-scale clinical data to identify disparities and trends in liver health. Findings highlight the need for targeted public health interventions addressing high-risk populations defined by socioeconomic and ethnic factors.

WED-483
Development of a deep learning-based model for predicting liver-related events in steatotic liver disease using specific health checkup data
Shun-ichi Wakabayashi[1], Takefumi Kimura[1], Nobuharu Tamaki[2]. *[1]Shinshu University School of Medicine, Matsumoto, Japan; [2]Musashino Red Cross Hospital, Musashino, Japan*
Email: shun_1@me.com

Background and aims: Steatotic liver disease (SLD) affects approximately 30% of the population, posing challenges in risk stratification. This study aimed to develop a predictive model for liver-related events (LREs) using Health Checkup data, which annually screens 7.6 million individuals in Japan.
Method: From the JMDC database, 1,449,032 SLD patients were identified after excluding those with chronic liver diseases or a history of LREs or cardiovascular events. Data were split into a training set (1,049,322 patients) and a test set (449,710 patients). Predictive

models, including DeepSurv, Random Survival Forest (RSF), and Cox proportional hazards (CoxPH), were developed and evaluated using Harrell's C-index. Risk stratification and SHAP (SHapley Additive exPlanations) analyses were performed with the best-performing model.
Results: The median follow-up was 4.5 years, with cumulative LRE rates of 0.03% at 3 years, 0.07% at 5 years, and 0.16% at 10 years. The DeepSurv model (C-index: 0.893) outperformed RSF (C-index: 0.879), CoxPH (C-index: 0.875), and conventional metrics like Fatty Liver Index (C-index: 0.339). Risk stratification revealed significantly higher LRE rates in the high-risk group (0.658%/10 years) compared to intermediate-risk (0.058%/10 years, $p < 0.0001$) and low-risk groups (0.009%/10 years, $p < 0.0001$). SHAP analysis identified age, AST, ALT, GTP, BMI, and smoking as key predictors.
Conclusion: The DeepSurv model demonstrated superior predictive performance and enabled effective risk stratification for LREs in SLD patients.

WED-484
The culprits behind methotrexate-proposed hepatotoxicity are modifiable risk factors

Sinan Sharba[1], Amin Mountagui[1], Johan Waern[1], Yahya Hamada[1], Marie-Louise Andersson[2], Eva Klingberg[2], Al-Dury Samer[1].
[1]*Department of Gastroenterology and Hepatology, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden;* [2]*Department of Rheumatology and Inflammation Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden*
Email: samer.al-dury@wlab.gu.se

Background and aims: Methotrexate (MTX), a cornerstone in managing rheumatoid arthritis (RA) and psoriatic arthritis (PsA), is often discontinued due to hepatotoxicity concerns. Emerging evidence suggests a multifactorial etiology involving modifiable risk factors such as metabolic syndrome. This study aimed to identify specific risk factors underlying MTX-related hepatotoxicity and examine the utility of non-invasive liver fibrosis scores to rule out patients at risk of liver fibrosis, thus minimizing unnecessary MTX discontinuation.
Method: This prospective study included 179 patients (108 women, 71 men; median age 61 years, range 53–67 years) with RA (n = 123) or PsA (n = 56), categorized by MTX treatment duration. Liver assessments were carried out using acoustic radiation force impulse (ARFI) and Fibroscan® (fibrosis measured in kilopascal (kPa) and steatosis grade measured by controlled attenuation parameter (CAP)). Participants underwent comprehensive blood tests, anthropometric measurements, and questionnaires. Non-invasive fibrosis scores (e.g., FIB-4, APRI) were calculated and compared to imaging results.
Results: There were no signs of liver fibrosis on Fibroscan® (median: 4.6 kPa, range 3.85–5.85) or ARFI (median: 2.8 kPa, range 2.2–3.6) despite many Fib-4 and APRI scores indicating the presence of fibrosis. On the other hand, several patients had varying degrees of liver steatosis on Fibroscan® (CAP median: 242.5 dB/m, range 213.5–278.0; Steatosis Grade: S2) which may explain this discrepancy. We found statistically significant correlations between steatosis and metabolic factors including higher body weight (CI:0.226–0.523, $p < 0.0001$), waist circumference (CI:0.174–0.483, $p < 0.0001$), triglycerides (CI:0.112–0.432, $p < 0.0014$), fasting glucose (CI:0.013–0.347, $p = 0.004$), and lower HDL-cholesterol (CI:-0.446 to – 0.129, $p = 0.0007$). Interestingly, higher Alcohol consumption, analysed using B-PEth showed no significant correlation with steatosis (CI:–0.019 to 0.314, $p = 0.08$). Neither MTX dose nor duration showed any significant correlation with steatosis or fibrosis grade (CI:–246–0.108, $p = 0.437$).
Conclusion: A majority of patients on MTX do not have liver fibrosis but rather varying degrees of steatosis, suggesting metabolic dysfunction-associated steatotic liver disease (MASLD) as a modifiable risk factor emphasizing the importance of addressing MTX-related hepatotoxicity. Steatosis in these patients can be detected using simple non-invasive tests such as the FIB-4 index reducing the need for specialized personnel or instrumentation.

WED-485
US markers and necroinflammation, steatosis, and fibrosis in metabolic dysfunction-associated steatotic liver disease: the iLEAD study

Email: sugimoto@tokyo-med.ac.jp

Background and aims: Attenuation coefficient (AC) and shear-wave speed (SWS) are established US markers for assessing patients with metabolic dysfunction-associated steatotic liver disease (MASLD), while shear-wave dispersion slope (DS) is not. The purpose of this study was to assess the relationship between the multiparametric US imaging markers DS, AC, and SWS and liver histopathologic necroinflammation in patients with MASLD.
Method: This international multicenter prospective study enrolled consecutive patients with biopsy-proven MASLD between June 2019 and March 2023. Before biopsy, all participants underwent multiparametric US, and measurements of DS, AC, and SWS were obtained. Multivariable linear regression analyses were performed to assess the association of clinical variables and imaging markers with pathologic findings. The diagnostic performance of imaging markers for determining inflammation grade, steatosis grade, and fibrosis stage was assessed using the area under the receiver operating characteristic curve (AUC).
Results: A total of 124 participants (mean age, 53 years ± 15 [SD]; 62 males) were evaluated. In multivariable regression, lobular inflammation was associated with DS (regression coefficient, 0.06; $P = 0.02$), alanine aminotransferase level (regression coefficient, 0.002; $P = 0.002$), and Hispanic or Latino ethnicity (regression coefficient, –0.68; $P = 0.047$), while steatosis was associated with AC (regression coefficient, 3.66; $P < 0.001$) and fibrosis was associated with SWS (regression coefficient, 2.02; $P < 0.001$) and body mass index (regression coefficient, 0.05; $P = 0.02$). DS achieved an AUC of 0.72 (95% CI: 0.63, 0.82) for identifying participants with inflammation grade A2 or higher (moderate to severe inflammation). AC showed excellent performance for identifying participants with grade S1 (mild) or higher steatosis (AUC, 0.92 [95% CI: 0.87, 0.97]), while SWS

showed excellent performance for identifying participants with fibrosis stage F2 or higher (clinically significant fibrosis) (AUC, 0.91 [95% CI: 0.86, 0.96]). Of the three US markers, SWS showed the highest AUC (0.81 [95% CI: 0.74, 0.89]) for the diagnosis of metabolic dysfunction-associated steatohepatitis.
Conclusion: Of the three US imaging markers (DS, AC, and SWS), DS was most associated with lobular inflammation grade at histologic examination and demonstrated fair diagnostic performance in distinguishing moderate to severe lobular inflammation.

WED-486
First construction and validation of new circulating markers (NITs) to assess the risk of early-fibrosis (eF) occurrence in outpatients with type-2 diabetes (T2D) and elevated transaminases
Thierry Poynard[1], Olivier Deckmyn[2], Valentina Peta[3], Raluca Pais[4], Judith Aron-Wisnewsky[4], Karine Clement[4], Jean-Michel Oppert[4], Laurent Castera[5], Vlad Ratziu[6]. *[1]Sorbonne University, BioPredictive, Paris, France; [2]Biopredictive, Paris, France; [3]BioPredictive, Paris, France; [4]INSERM, Paris, France; [5]QUIDNASH, APHP, Paris, France; [6]INSERM, PARIS, France*
Email: thierry@poynard.com

Background and aims: An unmet need in MASLD is a single NIT predicting together the time-dependent steatosis (S) and inflammatory activity (I) and the fibrosis stage (F) occurring later. Here, we constructed such SIF-FibroTest combining SteatoTest-2, NashTest-2 and FibroTest, separately previously validated in 402 consecutive T2D-outpatients with elevated transaminases (QuidNash-cohort). The histological comparator was based on a modified 5tier-CRN score, with F0-F1A-F1C being no-bridging-fibrosis, F1B early fibrosis (eF), significant fibrosis stages (sF) still being the standard CRN F2-to-F4. This higher granularity for the diagnosis of eF was already used in the phase-3 trial of the resmetirom treatment, which demonstrated a superiority to placebo in improving non-cirrhotic stages by at least one-stage with NASH-resolution.
Method: We characterized the profiles of F0-F1A-F1C patients compared to those with eF, including confounding factors (CFs). Among these 402 subjects, 32%were F0-F1A-F1C at biopsy, 31%eF, 17% F2, 28%F3 and 9%F4. Secondly, we constructed the SIF-FibroTest calibrated for the diagnosis at predicting eF at baseline and the F trajectories according to I, S, age, and BMI. SIF-FibroTest was compared head-to-head and intention-to-diagnose at baseline with SIF-VCTE one combining VCTE for eF, controlled-attenuation-parameter (CAP) for S, and AST for I. CFs were identified by logistic-regression odds-ratio (OR), F-trajectories used cumulative-hazard ratio (HR) function, and Cox-models for the occurrence of sF and AUROCs for performances.
Results: In the F0-profiles, prevalence of Nash-activity score (NAS)≥1 was already 91% and higher in eF versus F0 (OR = 2.7; 95% 1.7–4.1; p = 0.001). F0-profiles were similar (all p > 0.50) to those of eF: age median 57years, male-sex (39% vs 35%) and BMI (31 kg/m^2). Versus F0-profiles, SteatoTest-2 was elevated in eF (OR = 7.1; 1–4.3; p = 0.04), and sF (OR = 32;4.7–82; p = 0.003). Higher steatosis-grades estimated using biopsy or SteatoTest-2 were associated with earlier sF occurrence, and NashTest-2 later. Higher steatosis-grade (HR95% CI; 1.3;1.1–1.5;p = 0.0005) and higher BMI accelerated eF-occurrence (HR = 1.03; HR95% CI; 1.01–1.05; p = 0.001). SIF-FibroTest (0.77; 95% 0.73–0.82) and SIF-VCTE AUROCs (0.76; 0.71–0.80) had a non-significant difference (equivalence-p = 0.08).
Conclusion: If confirmed by independent studies, NITs calibrated for eF could replace liver biopsy for surveillance and approval of anti-fibrosis treatments in T2D outpatients with elevated transaminases.

WED-487
The blood-based SteatoTest-2 score identifies a previously invisible early steatosis phenotype
Thierry Poynard[1], Olivier Deckmyn[2], Raluca Pais[3], Valentina Peta[2], Judith Aron-Wisnewsky[3], Karine Clement[3], Dominique Thabut[4], Dominique Valla[5], Laurent Castera[5], Vlad Ratziu[3]. *[1]Sorbonne University, BioPredictive, Paris, France; [2]Biopredictive, Paris, France; [3]INSERM, Paris, France; [4]APHP, INSERM, Paris, France; [5]APHP, Paris, France*
Email: thierry@poynard.com

Background and aims: Steatosis is a major liver feature of the steatosis-associated liver disease (SLD) definition. There is a consensus on using hepatic proton density fat fraction (PDFF) as a reference for assessing the diagnosis performance of circulating liver steatosis non-invasive circulating biomarkers (NITs). However, Steatosis grade S1 had been defined arbitrarily as PDFF≥5% to 33%. As PDFF has a low 1.2–1.6% measurement error, we aimed to identify if an early-steatosis (ES) phenotype (S1A) defined as PDFF from 3.2–6.4% following Kim et al recommendations (APT 2023) could be identified in a general population with or without risk of MASLD and MetALD, as well as in outpatients with type-2 diabetes (T2D) with biopsy. Then, we constructed and validated a new NIT for an earlier identification of SLD. S1B was defined as PDFF from 6.4%-17.4%, S2 S3 remained with PDFF 17.4–22.1% and ≥22.1% respectively.
Method: For this purpose, we first post-hoc analyzed apparently healthy participants of the UK-biobank (n = 31,715) with repeated PDFF and used a proxy of the validated SteatoTest-2 (ST2proxy) to assess the prevalence of ES in UKB participants (n = 343,064) among MASLD and MetALD, according to the number of cardiometabolic risk-factors (CF 1–4/5) and alcohol intake (verylow-increased). Characteristics of subjects with S0, S1A and S1B as well as overall mortality were compared using, uni- and analyses (separate logistic regression by sex) and AUROCs to validate the specificity of the phenotypes S1A vs S0 and vs S1B subjects.
Results: In UKB, in 16,322 women the prevalence of S0/S1A/S1B were 45/33/22% and in15,403 men 22.5/42.5/35%). Between the 20 subsets stratified by MASLD, MetALD, CF and alcohol intake all the S1A prevalences ranged significantly. The range was 9–25% in women, and 17–31% in men. The multivariate analysis among in subjects without S2S3 found that only hypertension Hazard-Ratio was significantly associated with 10 years overall mortality in women (HR; 95% CI = 1.80;1.19–171;p = .04) and men (1.36;1.01–0.048; p = 0.048), and glucose (1.40;1.02–1.94; p = 0.04), triglycerides (1.40;1.03–1.90; p = 0.03) increases only in men. In 145 T2D with PDFF, the prevalence of S0/S1A/S1B were 0/12/88%. ST-2TD permitted to diagnose the stage S1A vs S2B with a significant AUROC = 0.77; 95% CI 0.60–0.87; p < 0.0001.
Conclusion: With the limitation of a European origin context of use, these results strongly suggest than subjects with early steatosis stage S1A have a phenotype at risk of MASLD.

WED-488
Weight loss-related changes in MRI-derived measures of body composition and liver health: a large-scale analysis from the UK biobank
Magdalena Nowak[1], Tim Pagliaro[2], Anneli Andersson[1], Iulia Popescu[1], Tushy Kailayanathan[1], Andrea Dennis[1], Helena Thomaides Brears[1]. *[1]Perspectum Ltd., Oxford, United Kingdom; [2]Perspectum, Boston, United States*
Email: magdalena.nowak@perspectum.com

Background and aims: Amid rising global obesity rates and recent advances in weight-loss therapies, measuring body composition and the resolution of ectopic fat relative to weight loss could refine treatment strategies to enhance liver, cardiometabolic, and skeletal muscle health. This study aimed to investigate weight loss-related changes in visceral and subcutaneous adipose tissue, skeletal muscle

volume, and the associated changes in liver fibro-inflammation and fat content using MRI, in a large-scale cohort from the UK Biobank.
Method: Participants (N = 3,919) from the UK Biobank with whole-body Dixon MRI scans from two visits, spaced 1–3 years apart (mean 2.6 years), were included. MRI data were processed automatically to derive volumetric visceral adipose tissue (VAT), subcutaneous adipose tissue (SAT), and skeletal muscle (SM) in the abdominal region. Liver fat content (liver steatosis from proton density fat fraction) and liver fibro-inflammation (cT1) were assessed using LiverMultiScan. Participants were categorized into two groups based on relative weight change between visits: ≥5% weight loss and <5% weight loss (causes of weight loss were not investigated). Within-group comparisons were conducted using the paired Wilcoxon signed-rank test, while between-group comparisons were assessed with the Wilcoxon rank-sum test.
Results: In the ≥5% weight loss group (N = 415, mean age 64 years, male 47%, BMI 27 kg/m^2, baseline VAT 3.9 litres (L), SAT 7L, SM 5.4L, LFC 3.6%, cT1 703 ms), significant reductions from baseline were observed: LFC −25%, VAT of −27%, SAT of −21%, and SM of −3.4% (all $p < 0.001$). Liver cT1 decreased by 1.2% (10 ms), which was not clinically significant. In the <5% weight loss group (N = 3,294, mean age 63 years, male 51%, BMI 26 kg/m^2, baseline VAT 3.2L, SAT 6L, SM 5.5L, LFC 3%, SM 5.5L, cT1 689 ms), no significant reductions were observed in any of the body composition or liver metrics. Between-group comparisons showed significant differences across all metrics ($p < 0.001$).
Conclusion: Individuals who lost ≥5% weight demonstrated substantial reductions between imaging visits in liver fat, VAT, SAT, and skeletal muscle volume, and compared to the <5% weight loss group. Reductions in liver fat were not accompanied by parallel improvements in metrics of liver fibro-inflammation. While a weight loss of ≥5% significantly improves MRI adiposity-related measures, targeted therapeutic strategies and patient stratification prior to intervention may be necessary to minimize muscle loss, and reduce liver steatosis and its sequela of fibro-inflammation.

WED-489

Similar prevalence of MASLD and liver fibrosis when screening high-risk patients identified in primary care versus outpatient clinics in secondary care

Vivian de Jong[1,2], Alina Saidi[3], Laura Konings[3], Sofia Carvalhana[4], A.G. (Onno) Holleboom[5], Christophe Moreno[6], Manuel Romero-Gómez[7], Helena Cortez-Pinto[4], Jörn M. Email: v.d.dejong-5@umcutrecht.nl

Background and aims: Suboptimal awareness and insufficient knowledge about MASLD and its progressive stages (MASH and advanced fibrosis) still lead to significant underdiagnosis. The 'Global Research Initiative for Patient Screening on MASH' (GRIPonMASH) Consortium aims to facilitate and investigate care path implementation at primary and secondary care level.
Method: In this prospective multicenter observational study, we aim to screen 10.000 individuals with cardiometabolic risk factors, but no prior liver disease diagnosis, in 10 European countries. High-risk is defined as having type 2 diabetes mellitus (T2DM), metabolic syndrome (MetS), obesity or arterial hypertension. Patients qualifying as high-risk are identified at both primary care centers and at outpatient clinics. In this preliminary analysis we report descriptives of the screened populations and results of vibration-controlled transient elastography (VCTE) measurements with FibroScan. MASLD was assumed if controlled attenuation parameter (CAP) ≥275, as all included patients have cardiometabolic risk factors.
Results: Thus far, 412 individuals from 5 countries (NL, BE, DE, ES, PT) have been included, of whom 56% were recruited at primary care centers and 44% in outpatient clinics (i.e. internal medicine, diabetology, endocrinology). The median age was 60 (IQR: 16) years in primary care versus 57 (17) years at the outpatient clinic, 42% vs. 52% was female, mean weight was 93 (± SD: 20) vs. 96 (± 20) kg and mean BMI 32 (± 6) vs. 33 (± 6) kg/m2 respectively. The majority of the population was Caucasian (75%). In primary care, the primary diagnosis for inclusion was arterial hypertension (33%), followed by T2DM (32%), obesity (30%) and MetS (5%). At the outpatient clinic, this was T2DM (41%), obesity (30%), arterial hypertension (28%) and MetS (2%). The level of liver steatosis measured by CAP was similar between patients recruited in primary care vs. the outpatient clinic: mean 285 (± 57) vs. 285 (± 53) dB/m. The prevalence of MASLD was 59% and 58%, respectively. Liver stiffness measurement (LSM) by VCTE was also similar: median 5.3 (IQR 2.9) vs. 5.3 (2.6) kPa. In primary care 83% had a low risk of fibrosis (<8.0 kPa), 13% were at risk for significant fibrosis (8.0–12.0 kPa) and 4% had advanced fibrosis (>12.0 kPa). Results in the outpatient clinic were again similar with 82%, 12% and 6% respectively. The most striking difference between the recruitment locations was the higher use of insulin at the outpatient clinic.
Conclusion: In this preliminary analysis in a first subset of the GRIPonMASH cohort, the prevalence of MASLD and advanced fibrosis was similar for high-risk patients screened after identification in primary care and at the outpatient clinic. The GRIPonMASH project is supported by the Innovative Health Initiative Joint Undertaking, its members and its contributing partners under grant agreement No 101132946.

WED-490

Ultrasound-derived visceral adipose tissue: an easily obtainable adiposity index strongly associated with metabolic dysfunction-associated steatotic liver disease and metabolic parameters

Valentina Flagiello[1], Paolo Gallo[1], Francesca Terracciani[1], Andrea Falcomata'[1], Antonio De Vincentis[2], Federica Tavaglione[1,3], Antonio Picardi[1], Umberto Vespasiani-Gentilucci[1]. *[1]Clinical Medicine and Hepatology Unit, Campus Bio-Medico University, Rome, Italy; [2]Internal Medicine Unit, Campus Bio-Medico University, Rome, Italy; [3]University of California San Diego, La Jolla, United States*
Email: v.flagiello@unicampus.it

Background and aims: Emerging evidence suggests that adiposity indices beyond body mass index (BMI) are better predictors of metabolic complications, including metabolic dysfunction-associated steatotic liver disease (MASLD). Among these indices, visceral adipose tissue (VAT) has garnered attention, but the clinical translation of available techniques (magnetic resonance imaging and computed tomography) remains constrained due to their intrinsic limitations. Ultrasound (US)-based VAT measurements offer a feasible alternative. However, only a few studies evaluating this approach have been reported. Here we aimed to evaluate the associations of US-measured VAT with metabolic parameters, liver enzymes and hepatic steatosis in comparison with those of BMI and waist circumference (WC).
Method: Patients enrolled at Fondazione Policlinico Universitario Campus Bio-Medico of Rome for the All-Liver Interventional Global

Network (ALIGN) screening study were included. Inclusion criteria were age 18–75 years, and history of hepatic steatosis and/or diabetes and/or obesity, without other causes of chronic liver disease. US-measured VAT was assessed as the distance between the inner surface of the anterior rectus muscle and the anterior aortic wall. Steatosis was defined by ultrasound derived fat fraction (UDFF). Correlations and linear regression analyses were performed to assess the relationship between VAT, metabolic parameters, liver enzymes, UDFF, and FibroScan-AST (FAST) score.

Results: 837 patients were included [mean age 56 years (SD 11.5), 60% male], with a median BMI of 31.1 kg/m² (IQR 27.8–34.4). Higher US-measured VAT tertiles were associated with an increased prevalence of diabetes ($p = 0.002$), hypertension ($p < 0.0001$), elevated triglycerides ($p < 0.0001$), and liver enzymes [AST ($p = 0.005$), ALT ($p = 0.001$)]. The correlations of US-measured VAT with metabolic and hepatic parameters were almost always stronger than those of BMI and WC: HbA1c ($p = 0.019$ vs BMI), triglycerides ($p < 0.0001$ vs BMI; $p = 0.0004$ vs WC), ALT ($p = 0.002$ vs BMI; $p = 0.026$ vs WC), UDFF ($p = 0.00005$ vs BMI; $p = 0.00091$ vs WC), and FibroScan-AST (FAST) score ($p = 0.035$ vs BMI). At multivariate linear regression, VAT (beta = 1.33, $p < 0.001$) was the only adiposity index associated with UDFF, along with triglycerides (beta = 0.01, $p = 0.008$) and hypertension (beta = 1.52, $p = 0.021$). Notably, for any given BMI, higher VAT tertiles were associated with a progressively greater mean UDFF percentage (T2 vs T1: + 33.07%; T3 vs T1: + 62.17%; T3 vs T2: + 22.26%).

Conclusion: US-measured VAT is an easily obtainable measure that strongly correlates with metabolic parameters and UDFF, outperforming BMI and WC. If validated in larger cohorts, the measurement of VAT can be proposed to complement liver ultrasound examination for baseline assessment and monitoring of patients with suspected/known MASLD.

WED-491

Longitudinal validation of the AGA, AASLD and EASL care pathways for metabolic dysfunction-associated steatotic liver disease (masld) in a prospective cohort of individuals with type 2 diabetes

Veeral Ajmera[1], Luis Antonio Diaz[1], Federica Tavaglione[1], Monica Tincopa[1], Egbert Madamba[1], Ricki Bettencourt[1], Lisa Richards[1], Rohit Loomba[1]. *[1]University of California, San Diego, La Jolla, United States*
Email: v1ajmera@ucsd.edu

Background and aims: Multiple international societies recommend a care pathway with sequential testing with FIB-4 and vibration-controlled transient elastography (VCTE) for populations at-risk for MASLD, including those with type 2 diabetes (T2DM). However, there are limited data on the longitudinal performance of these pathways in patients with systematic follow-up assessment. We aimed to validate longitudinal care pathway assessment in a prospectively recruited cohort with T2DM at risk for MASLD with 2-year follow up using magnetic resonance elastography (MRE), the most accurate non-invasive biomarker of fibrosis.

Method: This prospective study enrolled adults age ≥50 years with T2DM recruited from primary care and endocrinology clinics. Participants underwent a standardized clinical research visit with MRI-PDFF, MRE and VCTE and follow up assessment. Participants with alcohol intake exceeding AASLD guidance for MASLD were excluded. The outcomes were the diagnostic performance of the clinical pathway for MRE ≥ 3.3 kPa based on recently published recommendations supporting pharmacologic treatment at this threshold.

Results: 188 patients (40% men) with baseline and follow up visits separated by a mean (SD) of 2.1 (0.75) years were included. The mean (±SD) age and BMI were 64.3 (±7.7) years and 31.1 (±4.8) kg/m^2, respectively. At baseline 148 (79%) of individuals were classified as low risk; 92 with FIB-4 <1.3 and 56 with FIB-4 1.3–2.67 and VCTE <8 kPa. The false negative rate for detecting significant fibrosis warranting treatment in patients classified as low risk was 7.6% and 21% of the cohort would qualify for specialty referral. 90% of false negatives were related to FIB-4 <1.3. Among the 148 low-risk individuals on baseline assessment, 137 (93%) remained low risk and the false negative rate decreased to 3.4%. Follow up of the false negative participants at baseline demonstrated that only 20% remained misclassified, 40% had an increase in repeat FIB-4 with appropriate classification at follow up and 40% had liver stiffness decrease below the significant fibrosis threshold indicating improvement.

Conclusion: Longitudinal validation of multi-society guidance in a well-phenotyped, prospectively recruited cohort of adults with T2DM revealed that repeat assessment at 2-years enhanced performance to detect patients with significant fibrosis who may be eligible for treatment and require specialty care by reclassifying false negative FIB-4 assessments.

WED-492

Liver fibrosis is a strong predictor of all-cause mortality in patients with metabolic dysfunction-associated steatotic liver disease independent from metabolic syndrome

WeiWei Xu[1], Guyu Zeng[2], Peizhi Wang[3], Qinxue Li[4], Tianyu Li[5], Yue Tian[6], Bochuan Huang[7], Jinqing Yuan[5], Diederick Grobbee[8], Manuel Castro Cabezas[9]. *[1]Julius Center, University Medical Center Utrecht, Utrecht, Netherlands; [2]Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; [3]Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Center for Molecular Cardiology, University of Zurich, Zurich, Switzerland, Beijing, China; [4]Department of Cardiology, Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China, Beijing, China; [5]Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China, Beijing, China; [6]Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; [7]Peking Union Medical College Hospital, Peking Union Medical College, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; [8]Julius Center, University Medical Center Utrecht, Julius Clinical, Utrecht, Netherlands; [9]Julius Clinical, Franciscus Gasthuis & Vlietland, Erasmus MC Medical Center, Rotterdam, Netherlands*
Email: w.xu2@students.uu.nl

Background and aims: The impact of metabolic syndrome (MetS) on mortality in metabolic dysfunction-associated steatotic liver disease (MASLD) remains unclear. This study examines the association between MetS and mortality in MASLD patients and evaluates liver fibrosis as a potential predictor.

Method: A population-based cohort study was conducted using data from the United States National Health and Nutrition Examination Survey III, including 9,217 participants with complete datasets. Participants were classified into four groups — no steatotic liver disease (SLD), MASLD, metabolic dysfunction-associated alcohol-related liver disease (MetALD), and alcohol-related liver disease (ALD) — based on the criteria recently published in the EASL-EASD-EASO clinical guidelines for the management of MASLD. Participants were stratified into two groups based on the presence or absence of MetS using IDF criteria. In the MASLD group, liver fibrosis was assessed using the FIB-4 index: FIB-4 ≤1.3 indicated no fibrosis, 1.3–2.67 intermediate risk, and >2.67 advanced fibrosis. Cox regression analysis was performed, with results reported as percentages and hazard ratios (HR) with 95% confidence intervals (CI).

Results: Over a median follow-up period of 26.4 years, a total of 3,521 mortality events were recorded among all participants. Of the 9,217 participants, 5,615 had no SLD and 3,602 had SLD, with 3,323

classified as having MASLD. Among these 3,323 MASLD patients, 1,859 had MetS, while 1,464 did not. The proportions of patients with high FIB-4 scores were 1.8% in the MASLD(+)/MetS(+) group and 0.8% in the MASLD(+)/MetS(-) group. After adjusting for multiple variables, the risk of all-cause mortality was not significantly elevated in either the MASLD(+)/MetS(+) or MASLD(+)/MetS(-) groups compared to the healthy control group, with HR of 1.19 (95% CI: 0.98–1.45) and 0.97 (0.83–1.14), respectively. However, MASLD patients with advanced liver fibrosis demonstrated a significantly increased risk of all-cause mortality, independent from MetS status, with HRs of 1.51 (1.06–2.13) for the MASLD(+)/MetS(+) group and 1.89 (1.42–2.52) for the MASLD(+)/MetS(-) group. Additionally, MASLD patients with an intermediate fibrosis risk and MetS(+) had a higher risk of all-cause mortality (HR: 1.30, 1.13–1.50). In contrast, MASLD patients with intermediate fibrosis risk but without MetS, as well as those without liver fibrosis independent from MetS status, showed no increased all-cause mortality risk compared to healthy participants.

Conclusion: MASLD, independent from MetS status, was not associated with an increased risk of all-cause mortality in NHANES. In contrast, advanced liver fibrosis estimated by FIB-4, independently predicted all-cause mortality irrespective of MetS status. Identifying high-risk subjects with FIB-4 may help to select those eligible for the most intensive treatment.

Evaluating noninvasive tests for significant fibrosis in a population-based MASLD cohort: insights from NHANES 2017–2020

Winston Dunn[1], Terry Cheuk-Fung Yip[2], Leon Adams[3], Nipun Verma[4], Vincent Wai-Sun Wong[2], Laurent Castera[5], Manal F. Abdelmalek[6], Ashwani K. Singal[7], Nicholas Dunn[1], Vincent Chen[8], Grace Lai-Hung Wong[2], Syed-Mohammed Jafri[9], Juan Pablo Arab[10], Julie Dubourg[11], Ajay Kumar Duseja, Wamda Ahmed[1], Luis Antonio Diaz[12], Bihui Zhong[13], Naim Alkhouri[14]. *[1]University of Kansas Medical Center, Kansas City, United States, [2]The Chinese University of Hong Kong, Hong Kong, Hong Kong; [3]University of Western Australia, Crawley, Australia; [4]Postgraduate Institute of Medical Education and Research, Chandigarh, India; [5]Université Paris-Cité, Paris, France; [6]Mayo Clinic, Rochester, United States; [7]University of Louisville, Louisville, United States; [8]University of Michigan, Ann Arbor, United States; [9]Henry Ford Hospital, Detroit, United States; [10]Virginia Commonwealth University School of Medicine, Richmond, United States; [11]Summit Clinical Research, San Antonio, United States; [12]Pontificia Universidad Católica de Chile, Santiago, United States; [13]The First Affiliated Hospital, Sun Yat-sen University, Guangzhou, United States; [14]Arizona Liver Health, Chandler, United States*
Email: naim.alkhouri@gmail.com

Background and aims: Resmetirom is FDA-approved for metabolic dysfunction-associated steatotic liver disease (MASLD) with significant (F2) to advanced (F3) fibrosis. While current AASLD guidance recommended Vibration-Controlled Transient Elastography for treatment consideration, limited availability highlights the need for noninvasive tests (NITs) using common laboratory parameters. Most existing NITs were developed in tertiary referral centers and are not optimized for screening significant fibrosis in general populations. This study compares among ALADDIN-F2-Lab, FIB-4, NAFLD Fibrosis Score (NFS), SAFE, and Liver Risk Score for identifying significant fibrosis or higher in a population based cohort.

Method: The National Health and Nutrition Examination Survey (NHANES) 2017–2020 database was used. NHANES survey design weights, strata, and clusters ensured nationally representative estimates. Adults (≥18 years) with steatotic liver disease (CAP ≥248 dB/m) and at least one cardiometabolic risk factor were included. Alcohol intake was calculated from survey responses, and patients with alcohol intake ≥20 g/day for females, ≥30 g/day for males, viral hepatitis, or missing liver stiffness measurement (LSM) were excluded. Significant fibrosis was defined as LSM ≥8 kPa. NITs including ALADDIN-F2-Lab, FIB-4, NFS, SAFE Score, and Liver Risk Score were categorized into low, intermediate, and high-risk groups using published cutoffs.

Results: Among 4,022 participants with MASLD, 16.0% (SE 1.4%) had significant fibrosis (≥8 kPa). ALADDIN-F2-Lab, FIB-4, and Liver Risk Score classified the majority of participants as low risk, at 80.4%, 74.7%, and 96.1%, respectively, making them suitable for community-based screening. Among these, ALADDIN-F2-Lab demonstrated the highest sensitivity (36.5%), followed by FIB-4 (32.5%) and Liver Risk Score (10.2%). NFS displayed a comparable sensitivity (33.8%) but identified only 33.4% as low risk. SAFE Score achieved the highest sensitivity (85.5%) but classified only 30.8% of participants as low risk. For high-risk classification, ALADDIN-F2-Lab (83.7%), FIB-4 (76.1%), NFS (80.9%), and Liver Risk Score (94.2%) demonstrated excellent specificity. ALADDIN-F2-Lab achieved the highest PPV (69.6%) due to fewer patients being classified as high risk.

Conclusion: While ALADDIN-F2-Lab demonstrated the highest PPV among NITs for high-risk classification and SAFE achieved superior sensitivity, no NIT showed sufficient sensitivity (<50%) to reliably identify the majority of patients with significant fibrosis (LSM ≥8 kPa) in a general population cohort. This highlights the challenge of applying NITs derived from tertiary centers to broader, community-based settings. Reassessing existing cutoffs and optimizing NITs for use in general populations may improve their utility as first-line screening tools for significant fibrosis or higher. Until such adjustments are made, their adoption in clinical practice should be approached with caution.

WED-494

Development and validation of two NIS2+®-based models for the detection of MASH resolution and fibrosis improvement

Vlad Ratziu[1], Sven Francque[2], Yacine Hajji[3], Jeremy Magnanensi[3], Zouher Majd[3], Dean Hum[3], Bart Staels[4], Quentin M. Anstee[5,6], Arun J. [INSERT WED-494F01 HERE]NIS2+® is a blood-based biomarker developed for at-risk MASH (MAS =4; F = 2) detection. NIS2+® changes over time have previously shown significant association with histological improvement. We aimed to develop and validate predictive models for EP1 and EP2 based on demographic data and successive NIS2+® measurements.

Method: Pts included in the RESOLVE-IT phase 3 trial (NCT02704403) with MASH, MAS = 4 and F 1–3 at baseline and NIS2+® available at all 8 trial visits between baseline and end-of-study (EOS) were selected (N = 703). This cohort was randomly split in training (N = 280, 40%) and test (N = 423, 60%) sets. Seven demographic features at baseline and 56 features describing NIS2+® changes over time were used as potential predictors. For each endpoint, a logistic Lasso regression model was developed in the training set, proceeding to a selection of features; 23 features retained in the model for EP1 (M1) and 8 in the model for EP2 (M2). For each model, low (Lc) and high (Hc) cutoffs were derived in the training set to respectively reach a sensitivity (Sen) and specificity (Spe) of 80%, creating intermediate risk zones (IRZ: Lc ≤ NIS2+® < Hc). Performance of M1 and M2 were validated in the test set, and evaluated for decreasing number of NIS2+® measures

collected between baseline and EOS and shorter duration of follow-up.
Results: Mean follow-up was 19 months. Prevalences of EP1 and EP2 ranged 21%-23% in both training and test sets. M1 reached an AUC of 0.85 in training, 0.81 in test. At Lc (0.41), M1 reached a Sen of 80%, Spe of 67% and NPV of 93% in the test set, while at Hc (0.52), Spe was 79%, Sen 68% and PPV 46%. Importantly, only 12% of pts were classified in the IRZ. M2 achieved an AUC of 0.78 in training, 0.74 in test. At Lc (0.48), M2 showed a Sen of 72%, Spe of 61% and NPV of 88% in the test set, while at Hc (0.56), Spe was 78%, Sen 53% and PPV 41%; 18% of patients were in the IRZ. Similar diagnostic performance was observed when using ≥4 measures of NIS2+® between baseline and EOS with high concordance of classification (kappa >0.75). Decreased AUCs were observed when using only 3 NIS2+® measures vs 8 (M1: 0.78 vs 0.81, p = 0.07; M2: 0.71 vs 0.74, p = 0.02). AUCs increased with increasing duration of follow-up, reaching compelling performance after only 13 months of follow-up with 4 NIS2+® measures (M1: AUC = 0.75, M2: AUC = 0.73).
Conclusion: We developed and validated 2 NIS2+®-based models with high performance in ruling-in/out MASH resolution and F improvement, allowing a potential use for monitoring treatment response. While a ~1-year follow-up could potentially allow for early detection of histological improvement, a design with 4 measures over ~1.5 years using Hc is recommended.

WED-495
Liver stiffness measurement as a tool for identifying risk of hepatic-related hospitalizations: insights from a large real-world cohort
YaeL Milgrom[1], Callum Wood[2], Ian Rowe[3], Richard Parker[1]. *[1]Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom; [2]Leads Teaching Hospitals NHS Trust, Leeds, United Kingdom; [3]Leeds Teaching Hospital NHS Trust, Leeds, United Kingdom*
Email: yaelmilgrom@yahoo.com

Background and aims: Chronic liver disease affects a significant portion of the population, but only a minority will progress to a severe form that impacts morbidity and mortality. As a result, there is an ongoing need for non-invasive tools to risk stratify chronic liver patients. The long-term implications of elevated liver stiffness in routine care are not well described. This study retrospectively evaluated a large cohort of patients who underwent liver stiffness measurement (LSM) at a single tertiary liver referral centre and examined how liver stiffness correlated with liver-related hospitalizations.
Method: Patients undergoing transient elastography were identified from a prospective database. Basic demographic and clinical variables were collected and data regarding hospitalizations were extracted from the electronic health record.
Results: A total of 10,723 patients were included in the study. The cohort had a mean age of 51.7 years (SD 15.3, range 16–96), comprising 58.8% males and 41.2% females. The largest proportion of diagnoses was 'Other' (38.4%), followed by SLD (37.6%), viral (18.5%), cholestatic (2.9%), and AIH (2.6%). The mean deprivation index was 4.1 (SD 3.0, range 1–10), with higher scores indicating greater socioeconomic disadvantage. Participants were followed for a mean of 3.8 years (median: 4.2 years, IQR: 0.3–6.2 years). The majority of patients had LSM <8 kPa 6510 (60.7%), while 1603 (15%) had LSM > 15 kPa. Increasing liver stiffness was strongly associated with age and male sex. The probability of at least one hospital admission with liver disease as the primary cause increased with increasing liver stiffness: from 0.058 in those with LSM <8 kPa to 0.366 in those with LSM > 15 kPa (p < 0.001). While the probability of at least one admission with liver disease as the primary cause was highest in those with the highest LSM, 376 patients with LSM <8 kPa met this criterion, compared to 587 patients with LSM > 15 kPa.
Conclusion: Liver stiffness measurement serves as a valuable non-invasive tool for risk stratification in chronic liver disease in routine clinical practice. It is significantly correlated with liver-related hospitalizations though a substantial number of liver related hospitalisations still occur in those patients at the lowest risk. This study supports the use of LSM in clinical practice to better identify high-risk chronic liver patients and serves to highlight opportunities to link patients to care even following favourable risk stratification.

WED-496
Anthropometric measures and mortality risk in individuals with metabolic dysfunction-associated steatotic liver disease (MASLD): a population-based cohort study
Yee Hui Yeo[1], Yixuan Zhu[2], Jingli Gao[3], Shanghao Liu[4], Wenjing Ni[5], Fajuan Rui[5], Xue Bai[2], Nan Geng[2], Rui Jin[2], Elizabeth Speliotes[6], Chao Wu[2], Junping Shi[7], Xiaolong Qi[4], Vincent Chen[8], Philip Newsome[9], Jie Li[2]. *[1]Karsh Division of Gastroenterology and Hepatology, Department of Medicine, Cedars-Sinai Medical Center, Los Angeles 90048, California, USA, Los Angeles, United States; [2]Department of Infectious Diseases, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, Jiangsu, China, Nanjing, China; [3]Department of Intensive Care Unit, Kailuan General Hospital, Tangshan, China., Tangshan, China; [4]Center of Portal Hypertension, Department of Radiology, Zhongda Hospital, Medical School, Southeast University, Nanjing 210009, China, Nanjing, China; [5]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Traditional Chinese and Western Medicine, Nanjing University of Chinese Medicine Nanjing, Jiangsu, China, Nanjing, China; [6]Division of Gastroenterology and Hepatology, Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan, Michigan, United States; [7]The department of Hepatology, the Affiliated Hospital & Institute of Hepatology and Metabolic Disease, Hangzhou Normal University, Hangzhou, Zhejiang, China, Hangzhou, China; [8]Division of Gastroenterology and Hepatology, Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan, Michigan, United States; [9]Centre for Liver and Gastrointestinal Research, Institute of Immunology and Inflammation, and National Institute for Health Research (NIHR) Birmingham Biomedical Research Centre, The Medical School, University of Birmingham, Birmingham, B15 2TT, UK, Birmingham, United Kingdom*
Email: lijier@sina.com

Background and aims: As the primary anthropometric measure in metabolic dysfunction-associated steatotic liver disease (MASLD), waist circumference (WC) may more accurately reflect the visceral fat distribution and metabolic risks than body mass index (BMI). This study aimed to evaluate and compare the prognostic value of BMI, WC, and WC-related indices including waist-hip ratio (WHR), body shape index (BSI), and weight-adjusted-waist index (WWI) in individuals with MASLD.
Method: Four large-scale cohorts with well-characterized MASLD participants with comprehensive demographic, anthropometric, and clinical data were analyzed. The first cross-sectional cohort from the National Health and Nutrition Examination Survey (NHANES 2017–2020) assessed the association between anthropometric measures and liver stiffness/controlled attenuation parameter values. The second cohort, from NHANES III (1988–1994), followed 51,793 person-years and evaluated mortality risk across these measures using multivariate Cox proportional hazards regression and restrictive cubic spline. External validations were conducted using the Kailuan (317,501 person-years) and UK Biobank cohort (40,302 person-years).
Results: The Pearson correlation coefficient of WC with hepatic steatosis and fibrosis was better than that of BMI. WC and WC-related indices, but not BMI, indicated a significant mortality risk gradient among individuals with MASLD. The finding was consistently demonstrated across both sex and racial/ethnic subgroups. External validation further supported the application of WC-related indices. There was a dose-dependent distribution of the prevalence of MASLD and fibrosis across the quartiles of WC-related indices. Notably, low

BMI and high WC-related indices portended the highest mortality risk.
Conclusion: WC and WC-related indices are better parameters in prognosticating MASLD than BMI. The BMI-related 'obesity paradox' may be a misnomer resulting from the use of an incorrect metric. WC should be measured more routinely among individuals with MASLD.

WED-497
Steatotic liver disease as a mortality risk enhancer in the presence of metabolic syndrome
Guyu Zeng[1,2], Peizhi Wang[1], WeiWei Xu[3], Qinxue Li[1], Tianyu Li[1], Yue Tian[1], Bochuan Huang[4], Diederick Grobbee[3,5], Manuel Castro Cabezas[5,6,7], Jinqing Yuan[1]. Email: zengguyu0408@163.com

Background and aims: Steatotic liver disease (SLD) is an overarching term to encompass the various aetiologies of steatosis, including metabolic-dysfunction associated steatotic liver disease (MASLD), MASLD with increased alcohol intake (MetALD), and alcohol-associated liver disease (ALD). However, the impact of metabolic syndrome (MetS) on the association between SLD and mortality risk remains uncertain. This study aims to compare all-cause and cause-specific mortality across SLD subtypes in individuals with or without MetS.
Method: A population-based cohort study was conducted from the United States National Health and Nutrition Examination Surveys (NHANES III). A total of 9,217 participants with complete data were included. Participants were categorized into four groups: no SLD, MASLD, MetALD, and ALD based on the cardiometabolic factor, liver steatosis and alcohol consumption according to the 2024 EASL–EASD–EASO Clinical Practice Guidelines. These groups were further stratified into eight subgroups based on the presence or absence of MetS, defined according to the International Diabetes Federation criteria.
Results: Over a median follow-up of 26.4 years, 3,521 mortality events occurred, including 985 cardiac-related, 850 cancer-related, and 474 diabetes-related deaths. After full adjustment, SLD with MetS was significantly associated with an increased risk of all-cause mortality compared with healthy controls, particularly in the MetALD and ALD groups. In contrast, no significant association was found between SLD subtypes without MetS and all-cause mortality risk or cause-specific risks. When stratified by MetS presence, ALD, MetALD, and MASLD were all significantly associated with increased mortality risk compared to the no SLD group in the presence of MetS, which was primarily driven by increased cancer-related and diabetes-related mortality risk. However, this association was not observed in the population without MetS.
Conclusion: This study reveals that the significant association between SLD subtypes and mortality risk is mediated by MetS. To enhance risk stratification and to improve long-term health outcomes, it is crucial to distinguish between MASLD, MetALD, and other SLD types, and to control metabolic status while reducing alcohol consumption.

WED-498
Hepatic collagen percent by morphometry correlates with non-invasive tests in metabolic dysfunction associated steatotic liver disease
Brian Lam[1,2], Daisong Tan[2], Fanny Monge[2], James M Estep[2], Andrei Racila[3,4,5], Maria Stepanova[1,2,6], Zachary Goodman[2], Zobair Younossi[1,2,6]. Email: zobair.younossi@cldq.org

Background and aims: Hepatic % collagen can provide an accurate assessment of hepatic fibrosis. Although non-invasive tests (NITs) for fibrosis correlate with semi-quantitative pathologic staging of hepatic fibrosis, this has not been done for other NITs. Our aim was to associate % collagen with commonly used NITs in metabolic dysfunction associated steatotic liver disease (MASLD).
Method: Liver biopsy slides of MASLD patients were stained with Sirius red; % collagen and % morphometric hepatic fat quantification were evaluated using computer-assisted morphometry. The histologic stages of fibrosis (F0-F4) and grade of steatosis (S0-S3) were evaluated using semi-quantitative scoring. Serum samples collected at the time of biopsy were used to measure FIB-4, enhanced liver fibrosis (ELF), Hepatis Steatosis Index (HSI), Fatty Liver Index (FLI) and liver stiffness measurement (LSM) by transient elastography.
Results: There were 660 MASLD patients [age 46 ± 12 years, 28% male, 93% obese (BMI > 30), 36% type 2 diabetes, 52% hyperlipidemia, 59% hypertension, 43% MASH, 47% with PNPLA3 rs738409 CG or GG genotype (linked to higher risk), 60% histologic F0/F1, 19% F2, 13% F3, 7% F4; mean (SD) FIB-4 score 1.18 (1.64) with 75% having FIB-4 <1.30 (low-risk); mean (SD) ELF score 9.1 (1.3) with 72% having ELF <9.8 (low-risk)]. The mean (SD) % collagen was 3.74 (3.90) % and mean (SD) % fat was 11 (10) %. There was a strong association between % collagen with histologic stage of fibrosis (trend $p < 0.0001$). In particular, pooled together, patients with advanced fibrosis (F3-F4) had significantly higher % collagen than patients with mild or moderate fibrosis (F0-F2): 7.20 (5.87) % vs. 2.87 (2.58) % in F0-F2 ($p < 0.0001$). Among NITs, there were significant correlations of % collagen with FIB-4 ($r = +0.28$) and ELF ($r = +0.28$) scores as well as LSM ($r = +0.33$) (all $p < 0.0001$). Patients with elevated ELF (≥9.8) had higher % collagen than those with low-risk ELF: 5.79 (5.32) % vs. 3.70 (4.39) %, $p = 0.0001$. Similarly, patients with elevated FIB-4 (≥1.30) had higher % collagen than those with low-risk FIB-4: 6.18 (5.70) % vs. 3.03 (3.06) %, $p < 0.0001$. Also, patients with elevated LSM (≥10 kPa) had higher % collagen than those with low-risk LSM: 7.48 (5.56) % vs. 4.36 (3.66) %, $p = 0.0004$. Finally, patients with high-risk PNPLA3 rs738409 genotype (CG/GG) had higher % collagen than those with the CC genotype: 3.78 (3.50) % vs. 3.16 (3.10) %, $p = 0.0148$. The morphometric % fat correlated with histologic steatosis grade ($r = +0.52$) but less strongly with HSI ($r = +0.16$) ($p < 0.0001$).
Conclusion: In MASLD patients, morphometric assessment of histologic steatosis and fibrosis correlate with semi-quantitative assessment by histology as well as commonly used NITs to include FIB-4, ELF, and liver stiffness by transient elastography.

MASLD – Experimental and pathophysiology

Lipidomics crosstalk with hepatic stellate cells and macrophages in people with metabolic dysfunction-associated steatotic liver disease

Dan Wang[1], Tong Liu[1], Maria Castanho Martins[2], Krista Rombouts[2], Qi Zhong[1], Zoe Hall[1], Pinelopi Manousou[1], Julian L. Griffin[3], Mark R. Thursz[1]. [1]*Imperial College London, MDR department, London, United Kingdom;* [2]*University College London, Institute for Liver and Digestive Health, London, United Kingdom;* [3]*The University of Aberdeen, Rowett Institute, Aberdeen, United Kingdom*
Email: 695854750@qq.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a complex metabolic disorder characterized by excessive fat accumulation in the liver. This study aimed to elucidate lipids crosstalk with hepatic stellate cells (HSCs) and macrophages in MASLD progression.
Method: Untargeted lipidomics were employed to analyse lipid profiles in plasma, plasma nanoparticles (PNs) and liver tissue from MASLD patients and normal controls. In vitro, HepG2 cells were stimulated with the identified lipids with potential significance between the groups. Gene and protein expression were assessed by Western blot and RT-PCR. EVs isolated from lipid-stimulated HepG2 cells were co-cultured with primary human macrophages and cytokines' secretion was measured. PNs isolated from MASLD patients and controls were co-cultured with primary human HSCs, and aSMA expression was evaluated by RT-PCR.
Results: Lysophosphatidylcholine (LPC 16:0) was elevated in plasma but reduced in PNs and liver tissue in MASLD. PNs from MASLD patients showed reduced sphingomyelin (SM) and increased ceramide (Cer), with SM levels correlating with MASLD severity. Plasmalogens decreased in plasma, PNs, and liver tissue, whereas their precursor (1-O-alkyl-2-acylglycerol) was elevated in liver tissue. Cardiolipins were significantly depleted.
HepG2 cells treated with LPC 16:0, upregulated inositol-requiring enzyme 1(IRE1), sphingomyelinases (SMase1 and SMase2), choline/ethanolamine phosphotransferase 1(CEPT1) and ethanolamine phosphotransferase 1(EPT1), the key enzymes for plasmalogen synthesis. LPC 16:0-induced EVs from HepG2 were then used to stimulate primary human macrophages from healthy controls. IL-1b and IL-6 were significantly upregulated compared to controls ($P < 0.05$). Furthermore, PNs derived from MASLD patients activated primary human HSCs, isolated from controls, by upregulating aSMA, whereas PNs derived from healthy controls did not.
Conclusion: Circulating LPC 16:0 induced endoplasmic reticulum (ER) stress in vitro and triggered reactive oxygen species (ROS) accumulation, resulting in progressive plasmalogen depletion even though the synthesis were increased. The lipid synthesis was regulated by LPC 16:0 inducing EVs, - enriched in Cer but depleted of SM – released from hepatocytes to promote a pro-inflammatory response in macrophages and activate HSCs, contributing to a pro-fibrotic effect in MASLD.

Characterizing the response to high-dose gene therapy in non-human primates with a healthy or fibrotic liver at single nucleus resolution

Joanne Hsieh[1], Linda Chio[1], Jingshu Chen[1], Vinay Kartha[1], Heather Burkart[2], Susan Appt[2], Daniel Fuentes[1], Chris Carrico[1], Amber Lim[1], Smitha Shambhu[1], Dimitry Popov[1], Kylie Kavanagh[2], Chris Towne[1], Martin Borch Jensen[1]. [1]*Gordian Biotechnology, South San Francisco, United States;* [2]*Wake Forest University School of Medicine, Winston-Salem, United States*
Email: joanne@gordian.bio

Background and aims: Adeno-associated viral (AAV) vector-mediated gene therapies present a direct approach to treat liver disease, especially for rare genetic disorders. Candidate gene therapies are often tested in healthy non-human primate (NHP) models, however, due to the essentiality of the affected genes to hepatocyte metabolism, patients are more likely to have a liver that has experienced prolonged damage. Therefore, testing in NHPs with healthy livers may not fully recapitulate the patient response to a gene therapy. Here we investigate how a NHP with an inflamed and fibrotic liver would respond to an AAV gene therapy.
Method: African Green monkeys, one healthy and one fed a high fat, cholesterol and fructose diet for 82 weeks to induce metabolic dysfunction-associated steatohepatitis (MASH), were administered about 2×10^{13} vg/kg of a hepatocyte-targeted AAV gene therapy encoding a red fluorescent protein (RFP) alongside a 6-day immunosuppression protocol. Both NHPs were confirmed to be negative for AAV serotype-specific neutralizing antibodies prior to treatment. Single nucleus RNA-Sequencing (snRNA-Seq) was performed on liver biopsies at 2 weeks and 4 weeks after the AAV infusion.
Results: Differences between the healthy and MASH NHP were observed through histology and blood panels. The liver of the healthy NHP showed normal histology while the MASH NHP's liver histology showed steatosis, inflammation and extensive perisinusoidal fibrosis. Both the healthy and MASH NHP showed a transient increase in serum ALT that peaked at 7 days post-AAV infusion and returned to baseline levels within 14 days. ALT reached 342 U/L in the healthy NHP and 559 U/L in the MASH NHP. Bilirubin did not increase throughout the duration of the study. In both the healthy and MASH NHP, hepatocytes comprised the largest cell population in the liver, followed by endothelial cells. Two weeks following the AAV infusion, the most abundant cell type was a macrophage-like population in the MASH NHP. By 4 weeks, hepatocytes were once-again the most abundant cell type in the liver of the MASH NHP. The 2-week RFP-positive cells in the MASH NHP appeared primarily to be hepatocyte-macrophage doublets, suggesting active phagocytosis of transduced hepatocytes. In contrast, in the healthy NHP, the RFP-positive cells were primarily hepatocyte singlets.
Conclusion: In a NHP model, a healthy liver and a MASH liver showed dramatically different responses to AAV-mediated gene therapy. Steatohepatitis is associated with an exaggerated immune response. Caution should be exercised when extrapolating the findings of a hepatocyte-directed gene therapy in healthy NHPs to patients with liver disease.

Bispecific small interfering RNA targeting YAP1/WWTR1 as a novel therapeutic agent for metabolic dysfunction-associated steatohepatitis

Masayuki Sugimoto[1], Tatsuki Sato[1], Kaito Ueda[1], Yuki Yamada[1], Misa Yoshida[1], Sachiko Sakamoto[1], Masashi Kamiyama[1], Hiroyuki Tanaka[1], Kenjiro Minomi[1], Hiroshi Yamada[1]. [1]*Nitto Denko Corporation, Drug Delivery Research and Development Department, Osaka, Japan*
Email: masayuki.sugimoto@nitto.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is the leading cause of liver fibrosis worldwide, but the efficacy of approved drugs is limited. It is well known that YAP (Yes-associated protein, encoded by *YAP1*) and TAZ (transcriptional coactivator with PDZ-binding motif, encoded by *WWTR1*) contribute to fibrogenesis in the liver, but there are no approved therapeutic agents targeting YAP/TAZ directly. This study aimed to establish bispecific small interfering RNA (bsiRNA) targeting *YAP1*/*WWTR1* (bsiYW), in which one antisense oligonucleotide binds to specific regions of both genes, and to explore the therapeutic potential and mode of action of bsiYW for MASH.

Method: In vitro studies involved transfecting HepG2, a human liver cancer cell line, and AML12, a mouse normal liver cell line, with negative control siRNA (siNC), siRNA targeting *YAP1* (siY) or *WWTR1* (siW), and bsiYW, followed by gene expression analysis, psiCHECK and Oil Red O (ORO) staining. Each siRNA was chemically modified and encapsulated in lipid nanoparticles (LNP) or conjugated with N-acetylgalactosamine (GalNAc). Each formulation was administered bi-weekly for 8 weeks to mice fed a choline-deficient L-amino-acid-defined high-fat diet (CDAHFD) for 12 weeks. Gene and protein expressions, biochemistry, histology, and metabolome analyses were then performed.
Results: RNA-seq and psiCHECK revealed that bsiYW has no fatal off-target genes. bsiYW synergistically suppressed the transcriptions of YAP/TAZ-responsive genes, CCN family member 1, 2, and ankyrin repeat domain-containing protein 1 mRNA, and the ORO-positive area, compared to siY and siW in HepG2 and AML12. bsiYW/LNP suppressed the expression of *Yap1* and *Wwtr1* in both parenchymal cells (PCs) and non-PCs in the liver of mice. A single dose of bsiYW/LNP suppressed the expression of YAP and TAZ by more than 50% at both the gene and protein levels in the liver of CDAHFD-fed mice for at least 3 weeks. Repeated doses of bsiYW/LNP synergistically suppressed the levels of hepatic triglycerides (TG) compared to siY and siW in CDAHFD-fed mice. bsiYW/LNP also significantly suppressed the levels of hydroxyproline (HYP) and collagen 1 in the liver, as well as plasma alanine aminotransferase, in CDAHFD-fed mice in comparison with vehicle. Metabolome analysis showed that hepatic free fatty acids, especially polyunsaturated fatty acids, were significantly increased by bsiYW/LNP in comparison with vehicle, despite a significant reduction of TG. Hepatic TG and HYP were also decreased by bsiYW/GalNAc in CDAHFD-fed mice, whereas the expressions of *Yap1* and *Wwtr1* were decreased only in PCs in mice.
Conclusion: Dual silencing of *YAP1* and *WWTR1* synergistically suppressed the YAP/TAZ pathway in vitro and in vivo. bsiYW ameliorated hepatic steatosis and fibrosis in CDAHFD-fed mice depending on the hepatocytes-derived mechanisms, such as remodeling of lipid composition, at least in part. These findings suggest that bsiYW could be a novel therapeutic approach for MASH.

TOP-441

CD8+ T cells are pro-inflammatory, cytotoxic, and clonally expanded in the early stages of fibrosis due to metabolic dysfunction-associated steatohepatitis (MASH)

Raju Kumar[1], Wenhao Li[1], John Loy[2], Kalpana Devalia[2], Adam Goralcyzk[2], Humza Malik[2], Louisa James[3], Federica Marelli-Berg[4], Prakash Ramachandran[5], James Boot[3], Paul Stevens[3], Eva Wozniak[3], Chaz Mein[3], Robert D. Email: w.alazawi@qmul.ac.uk

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is characterized by hepatic accumulation of immune cells and can lead to fibrosis. We previously found increased number and activation of peripheral blood CD8$^+$ T cells in patients with MASH compared to steatosis and healthy controls. In cirrhosis, clonally expanded, phenotypically exhausted, CD8 T cells are found in the liver. However clonality and activation status of CD8 T cells in early stages of MASH fibrosis remain unclear and may give unique insights into pathogenesis. We characterised the phenotype and T cell receptor repertoire of CD8 T cells in blood, liver and adipose tissue sampled simultaneously from patients ranging from health to non-cirrhotic fibrosis.
Method: We performed antibody-augmented single cell RNA and T cell receptor sequencing on immune (CD45$^+$)-enriched cell populations sampled from liver, blood, subcutaneous, and visceral adipose tissue sampled during bariatric surgery in 18 individuals with F0 -F3 fibrosis (gallbladder surgery for healthy). Histological assessment of MASLD and fibrosis was conducted by a specialist pathologist according to the NASH CRN.
Results: Unsupervised clustering of 129,500 cells from all individuals and tissues revealed 29 distinct clusters. Cell-cell communication was higher in disease than health with greatest incoming signalling in clusters containing CD8 T cells. VDJ sequencing showed many CD8 T cells in these high-signalling clusters were clonally expanded (suggesting peptide-specific activation) at higher numbers in patients with greater fibrosis. The same clones were found in liver and adipose suggestive of migration between tissues. Pathway and leading-edge analysis in expanded clones showed expression of cytotoxic (eg granzyme and perforin) and inflammatory (TNFa/NFKB signalling) genes. We annotated potential epitopes of expanded clones based on CDR3 sequencing (excluding common viral targets) and identified known liver, diabetes, and obesity-related epitopes which may be relevant to MASH and some unannotated epitopes that require further characterisation.
Conclusion: Clonal expansion of CD8 T cells with cytotoxic and pro-inflammatory expression profiles occurs early in MASH-related fibrosis and may be a key pathogenic factor in progressive disease. This has important implications for understanding pathogenesis and may influence diagnosis, risk-stratification and even treatment of MASH and fibrosis.

Background and aims: The contribution of somatic mutation to end-stage metabolic-dysfunction associated steatotic liver disease (MASLD) has recently been discovered. Enlarging hepatocyte clones, sequestered by fibrosis, independently acquire recurrent somatic mutations in genes encoding regulators of lipid metabolism. The heterogeneity of MASLD has been reflected through inter-patient variability in the mutational landscape from a modest number of donors with cirrhosis to date. The temporal accrual of such mutations during, and their causative role in MASLD disease progression, remain unknown.
Method: Using whole-exome NanoSeq, a single DNA molecule sequencing protocol, DNA from archival fresh-frozen needle biopsies of 20 patients with MASLD fibrosis stages F0-F3 was sequenced to a cumulative duplex coverage of 3,164dx. Donors had median follow-up of 12 years post-biopsy; 10 donors experienced MASLD progression, 10 had stable liver disease. Genes under positive selection pressure were identified using *dNdScv*, a statistical model comparing ratios of non-synonymous somatic mutations to evolutionarily neutral synonymous mutations. Genes were considered to have significant excess of non-synonymous mutations after correction for multiple hypothesis testing with a q-value of <0.1.
Results: The pattern and density of somatic mutations varied extensively between individuals, even in this early disease stage,

though we observed minimal correlation of mutation burden to age or fibrosis stage with this limited cohort size. 9 genes were found to have a significant excess of non-synonymous somatic mutations, indicative of positive selection. These included lineage-defining, highly hepatocyte-specific genes such as Albumin (*ALB*) and transferrin (*TF*), with a pattern of short insertion and deletion ('indel') excess, hypothesised to relate to high gene expression. Recurrent variants in genes recognised as drivers in end-stage MASLD were found to be under positive selection, including *ACVR2A, TNRC6B* and *CIDEB*. A potentially novel driver gene was identified in a metabolic pathway responsible for conjugation of lipophilic compounds.

Conclusion: We provide evidence of positive selection of somatic variants across the MASLD disease spectrum. Recurrent somatic mutagenesis of genes implicated in lipid metabolism suggest hepatocytes develop adaptive pathways in attempt to escape their lipotoxic environment prior to development of advanced liver disease. Deep-targeted sequencing across a wider cohort spanning the disease spectrum will now be conducted, with long-term outcome data to allow clinical correlation.

Paneth cells regulate intestinal lymphangiogenesis and lipid metabolism in metabolic dysfunction-associated steatotic liver disease

Oriol Juanola[1], Nathalie Coutry[2], Marco Felber[3], Bahtiyar Yilmaz[4], Elisa Sorrenti[1], Giandomenica Iezzi[1], Fabienne Birrer[4], Tural Yarahmadov[4], Reiner Wiest[3], Deborah Stroka[4], Philippe Jay[2], Andrea De Gottardi[5], Sheida Moghadamrad[1]. *[1]Laboratories for Translational Research, Ente Ospedaliero Cantonale, Faculty of Biomedical Science, Università della Svizzera Italiana, Lugano, Switzerland; [2]Self-renewal and differentiation of epithelia, Institute of Functional Genomics, University of Montpellier, Montpellier, France; [3]Department for Biomedical Research, University of Bern, Bern, Switzerland; [4]Department of Visceral Surgery and Medicine, Inselspital, University of Bern, Bern, Switzerland; [5]Gastroenterologie & Hepatologie, Lucerne Kantonsspital, Luzern, Switzerland*
Email: sheida.moghadamrad@usi.ch

Background and aims: Paneth cells (PC) are involved in the regulation of intestinal microbiota, and their function in intestinal lymph- and angiogenesis has been recently described. Uptake of dietary lipids is largely dependent on intestinal lymphatic vessels, and impairments in their density or function may result in significant depletion of lipids in the liver. In this study, we assessed the effects of PC deficiency in a model of metabolic dysfunction associated steatotic liver disease (MASLD).

Method: We induced functional inactivation of PC in male and female mice ($Sox9^{lox/lox}VilCre^{ERT2}$) by intraperitoneal injection of 1 mg/day of tamoxifen for three consecutive days. One week later, all mice, PC-deficient, and control littermates were randomly subjected to a high sucrose/fructose - high fat (60% lard) (HFD) or standard (SD) diet for 16 weeks. Intraepithelial leakage of FITC-albumin was measured *in vivo* using laser-probe endomicroscopy. Several tissues were harvested for histological examination, molecular biology analyses, and imaging mass cytometry (IMC). Fecal samples were collected at both the start and end of the experiment to assess intestinal dysbiosis.

Results: All mice fed HFD gained weight compared to SD, but the weight gain in PC-deficient-HFD was significantly lower than in HFD-controls. Consistent with these findings, the severity of hepatic steatosis was significantly lower in PC-deficient-HFD compared to HFD-control mice. IMC of liver tissue revealed lower levels of collagen deposition and steatosis associated with fewer macrophages and neutrophils activation/infiltration in PC-deficient-HFD than in control-HFD mice. In vivo, microscopy showed a lower disruption of intestinal vascular barriers in PC-deficient-HFD than in HFD-control mice. The intestinal expression of distinct lymphangiogenic genes (VEGFC, VEGFR3, Prox1) was reduced in the PC-deficient HFD or SD. The alpha diversity of the fecal microbiota showed no significant differences based on gender or PC deficiency in the SD groups. Nevertheless, the beta diversity showed significant differences in PC-deficient fed SD after 16 weeks. Furthermore, we found significant alpha- and -beta diversity associated with decreased *Bacteroidota* and increased *Firmicutes* in HFD and PC-deficient mice.

Conclusion: PC deficiency attenuated the severity of steatosis and fibrosis in mice, suggesting their regulatory role on intestinal lymphatics contributing to the pathogenesis of MASLD. Thus, Paneth cells may represent a novel target for intervention in MASLD.

FRI-323

Redundant yet distinct role of Vacuole membrane protein 1 and transmembrane protein 41B in regulating hepatic lipoprotein secretion and autophagy in metabolic dysfunction-associated steatohepatitis

Allen Chen[1], Wen-Xing Ding[1], Hongmin Ni[1]. *[1]University of Kansas Medical Center, Kansas City, United States*
Email: hni@kumc.edu

Background and aims: Vacuole membrane protein 1 (VMP1) and transmembrane protein 41B (TMEM41B) are two endoplasmic reticulum (ER)-resident scramblases with important roles in autophagy and lipoprotein secretion. Hepatic loss of VMP1 or TMEM41B leads to defective autophagy and rapid development of metabolic dysfunction-associated steatohepatitis (MASH) in mice. Previous studies showed that overexpression of VMP1 or TMEM41B alleviates steatosis in MASH diet-fed or ob/ob mice. However, whether VMP1 and TMEM41B regulate lipoprotein secretion in MASH complementarily or independently is unknown.

Method: Liver-specific VMP1 knockout ($Vmp1^{LKO}$), TMEM41B KO ($Tmem41b^{LKO}$), VMP1 and TMEM41B double knockout ($Vmp1/Tmem41b^{DKO}$), TMEM41 KO/VMP1 knockin ($Tmem41b^{LKO}/Vmp1^{LKI}$), VMP1 KO/TMEM41B KI ($Vmp1^{LKO}/Tmem41b^{LKI}$) and ATG5 KO ($Atg5^{LKO}$) mice were generated. VLDL secretion, liver histology, biochemical assays, hepatic lipidomics, and autophagy were analyzed. VMP1 and TMEM41B protein levels were examined in human liver tissues from healthy and MASLD patients.

Results: $Vmp1^{LKO}$, $Tmem41b^{LKO}$, and $Vmp1/Tmem41b^{DKO}$ mice at one-month-old fed on a chow diet severely impaired VLDL secretion, resulting in massive microsteatosis, increased hepatic triglyceride, inflammation and fibrosis. Vmp1/Tmem41bDKO mice did not further impair VLDL secretion compared with single KO mice. Lipidomics analysis of liver tissues showed decreased phosphatidylcholine and phosphatidylethanolamine and increased neutral lipids. Cellular fractionation studies revealed that VMP1 and TMEM41B localized at the mitochondrial associate membrane (MAM). Electron microscopy analysis showed decreased mitochondria-ER contact in VMP1 and TMEM41B deficient hepatocytes. Hepatic loss of VMP1 or TMEM41B led to markedly increased levels of LC3-II and p62/SQSTM1, indicating impaired autophagic flux, unaffected by the double deletion of VMP1 and TMEM41B. Restoration of VMP1 in $Tmem41b^{LKO}$ mice partially corrected VLDL secretion but not autophagy. Restoration of TMEM41B in $Vmp1^{LKO}$ mice partially corrected VLDL secretion and autophagy. Intriguingly, $Atg5^{LKO}$ mice developed hepatomegaly without affecting VLDL secretion. Moreover, VMP1 and TMEM41B protein levels decreased in human liver samples with MASLD.

Conclusion: Loss of hepatic VMP1 or TMEM41B decreases MAM and phospholipids content and VLDL secretion resulting in the development of MASH independent of autophagy. VMP1 and TMEM41B may have redundant but distinct mechanisms regulating lipoprotein secretion and autophagy.

FRI-324

Fgl2-C3aR axis mediated NETs promote intravascular coagulation and liver fibrosis in MASLD progression

Xitang Li[1], Junjian Hu[1], Suping Hai[1], Qiang Gao[1], Wenhui Wu[1], Binghui Yu[1], Xiaojing Wang[1], Qin Ning[1]. [1]*Department and Institute of Infectious Disease, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Huazhong University of Science and Technology, Wuhan, China*
Email: qning@vip.sina.com

Background and aims: Procoagulant imbalance was observed in metabolic dysfunction-associated steatotic liver disease (MASLD) patients with liver fibrosis, but the role of coagulation in MASLD-associated fibrosis remains largely unclear. Neutrophil extracellular traps (NETs) served as an essential factor in immuno-thrombosis. Here, we aim to study the role of NETs-mediated complement and coagulation activation in MASLD progression and the underlying mechanism.
Method: NETs were depleted by intraperitoneal injection of DNase-1. Wild type (WT) and *fgl2*$^{-/-}$ C57BL/6 mice were treated either with 60% high fat diet (HFD) or methionine/choline-deficient (MCD) diet to induce MASLD-associated fibrosis. RNA-Seq of hepatic tissues or liver leukocytes were conducted in WT and *fgl2*$^{-/-}$ mice. Bone marrow neutrophils from WT and *fgl2*$^{-/-}$ mice were subjected to palmitic acid (PA) and LPS *in vitro*.
Results: Abundant neutrophil accumulation and NETs formation were observed in MASLD progression. NETs depletion improved liver fibrosis, inflammatory response and lipid accumulation both in HFD and MCD models. Meanwhile, decreased coagulation activation, including lower level of plasma thrombin-anti-thrombin complex (TAT) and hepatic fibrin deposition was observed following DNase-1 treatment. Highly expressed on hepatic neutrophils, fibrinogen-like protein 2 (FGL2) colocalized tightly with NETs area. Fgl2 knockout inhibits NETs formation and coagulation activation in MASLD progression. Combined with RNA-Seq analysis, *in vivo and in vitro* experiment identified that NETs formation was regulated by FGL2-C3aR axis. Treatment with C3aR antagonist alleviated NETs formation, coagulation activation and liver fibrosis *in vivo*.
Conclusion: NETs mediated coagulation dysregulation promotes MASLD progression. In depth, NETs formation was regulated by FGL2-C3aR axis.

FRI-325-YI

Sorafenib alleviates portal hypertension associated with metabolic dysfunction-associated liver disease by attenuating hepatic sinusoidal capillarization

Yingjie Ai[1,2], Sitao Ye[1], Ling Wu[1,2], Detlef Schuppan[2,3], Shiyao Chen[1]. [1]*Zhongshan Hospital, Fudan University, Shanghai, China;* [2]*Institute of Translational Immunology and Research Center for Immunotherapy, University Medical Center, Johannes Gutenberg University, Mainz, Germany;* [3]*Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, United States*
Email: 23111210016@m.fudan.edu.cn

Background and aims: Portal hypertension (PHT) commonly arises from cirrhosis, but non-cirrhotic portal hypertension (NCPH) associated with metabolic dysfunction, -associated steatotic liver disease (MASLD), presents unique challenges. Recent studies have shown that PHT can precede liver fibrosis and may act as a driving factor in the development of MASLD, as evidenced by both animal models and clinical cases where portal pressure was elevated in the absence of advanced fibrosis. Sorafenib (Sora) is the first-line therapy for advanced hepatocellular carcinoma and has shown some efficacy in treating liver fibrosis. This study aims to investigate the therapeutic potential of Sora to ameliorate MASLD-associated PHT, focusing on its impact on hepatic sinusoidal capillarization.
Method: A high fat diet (HFD, 60% calories from fat) was used to induce MASLD-associated PHT in C57BL/6J mice. Sora (10 mg/kg) vs vehicle alone was administered by gavage (200μl, q.d.) from week 10 to week 12 of HFD feeding to evaluate its effects on portal pressure. Histopathological assessments, electron microscopy (EM), RT-PCR and Western blot were performed to analyze sinusoidal capillarization and underlying mechanisms.
Results: Sora treatment significantly reduced portal pressure (5.42 ± 0.54 vs 4.55 ± 0.35 mmHg, p = 0.008, n = 6) and decreased the spleen-to-body weight ratio, an indirect indicator of portal pressure (0.0022 ± 0.00014 vs 0.0019 ± 0.0003, p = 0.029). H&E and Masson staining showed that Sora reduced luminal narrowing and occasional occlusion in portal vein branches, and decreased perivascular fibrosis compared to the control group. EM demonstrated that Sora counteracted the loss of sinusoidal fenestrae, upregulated liver sinusoidal endothelial cell markers (Lyve1, Stab1, Stab2, Msr) and downregulated normal venous endothelial markers (CD31, CD34, endomucin, apelin) indicating mitigation of sinusoidal capillarization.
Conclusion: Sorafenib demonstrates potential in alleviating MASLD-associated PHT by attenuating hepatic sinusoidal capillarization, offering a promising therapeutic approach for managing non-cirrhotic PHT in MASLD.

FRI-333

Exercise protects against semaglutide-induced muscle loss in obese Ldlr-/-.Leiden mice

José A. Inia[1], Eveline Gart[1], Jessica Snabel[1], J. Wouter Jukema[2], Hans M.G. Princen[1], Anita M. van den Hoek[3]. [1]*The Netherlands Organization for Applied Scientific Research (TNO), Leiden, Netherlands;* [2]*Leiden University Medical Center (LUMC), Leiden, Netherlands;* [3]*The Netherlands Organisation for Applied Scientific Research (TNO), Leiden, Netherlands*
Email: a.vandenhoek@tno.nl

Background and aims: Semaglutide, a glucagon-like peptide-1 receptor agonist, is an antidiabetic medication that has recently been approved for treatment of obesity as well. While the benefits of semaglutide for weight management are encouraging, concomitant muscle loss can be a potential drawback. Here, we evaluated the metabolic effects of semaglutide, exercise and the combination thereof in a translational model of obesity and the Metabolic Syndrome.
Method: Ldlr-/-.Leiden mice received a high fat diet (HFD) for 20 weeks to induce obesity, insulin resistance and hyperlipidemia. Mice were subsequently left untreated (control) or were treated for 14 weeks with semaglutide, exercise (running-wheel) or the combination thereof. Body weight, lean body mass (EchoMRI) and plasma parameters were evaluated during the study and liver, muscles, adipose tissue depots, hearts and brain were collected at end-point for future histological analysis and transcriptomics.
Results: Already after 2 weeks of treatment, semaglutide either alone (−21%), or in combination with exercise (−23%) significantly decreased body weight, while exercise monotreatment tended to slightly reduce body weight (with −3%, p = 0.056). Semaglutide monotreatment significantly reduced both fat mass (-43%) and lean body mass (−11%), while in combination with exercise fat mass was significantly decreased (−50%), but loss of lean body mass could be prevented. Semaglutide treatment either alone, or in combination with exercise significantly improved blood glucose, plasma insulin, cholesterol and triglyceride levels as well. All these changes remained until the end of the study. Tissue analyses are currently ongoing.
Conclusion: Using a translational model of obesity and the Metabolic Syndrome, we demonstrated that semaglutide has beneficial metabolic effects, but combination with exercise is required to prevent muscle loss.

FRI-334

Adaptative immune activation as a biomarker of Metabolic dysfunction- associated steatotic liver disease severity

Adriana Martínez-Cuazitl[1], Eira Cerda Reyes[2], Stefanny Cornejo-Hernández[2], Esquivel-Alarcón Esly[2], Mata-Miranda Monica Maribel[3], Vazquez-Zapien Gustavo Jesús[3], Juan Salvador García-Hernandez[2], Hernandez-Espinosa Reina[2], García-Araiza Mayra Gabriela[2]. *[1]SEDENA-HCM, CDMX, Mexico; [2]HCM-SEDENA, CDMX, Mexico; [3]SEDENA, CDMX, Mexico*
Email: adyta0@hotmail.com

Background and aims: Metabolic dysfunction- associated steatotic liver disease (MASLD) is a multifactorial disease in which several stresses factor, that contribute to the overall pathophysiology MASLD severity and is related to the immune system activated. The cascade of inflammatory events in MASLD has been marked as type 3 inflammatory response, characterized by fibrosis and production of cytokine IL-17A. The inflammatory trigger that initiates inflammation is MASLD includes tissue-resident-innate-like T cells, increasing gut permeability, Mucosal-associated invariant T (MAIT) cells respond to bacterial antigens contributing to liver fibrosis in IL-17A/TNF-α dependent manner. Increase intake of dietary components like toxic lipid species, danger-associated molecular patterns, and gut derived pathogens associated molecular patterns (PAMPS) activate recruited myeloid cells, leading to the secretion of effector cytokines (as TNF-α, IL-1β, TGFβ, and IL-6). Finally for liver inflammation, adaptative immune cells such as $CD4^+$, Th17 cells, $CD8^+T^-$ and B cells, on this phase there are an extensive hepatocyte cell death and deposition of extracellular matrix by activate hepatic stellate cells. The main objective of these study was evaluated immunological profile of MASLD severity.

Method: Patients with metabolic criteria were evaluated by hepatic elastography, and, saliva was collected to analyzed by Fourier-transformed infrared spectroscopy (FTIR, at 4000 and 400 cm^{-1}). Also, IMC, hematologic biochemic with differential count, biochemical (coagulopathy profile, glucose, urea, creatinine, uric acid, Bilirubin, ALT, AST, ALP, GGT, cholesterol, triglycerides, HDL, LDL, and HbAc1) were collected. The study of the immune response analysis through FTIR were at IgG (1560–1464), IgA (1285–1237), and IgM (1160–1028), IFN-γ (1061–1044), TNF-α (1243–1217), IL-6 (1436–1428). For statistical analysis SPSSv26 was employed, Shapiro -Wilk normality test were performed, analyzed by U-Mann-Whitney, or T-Student, and Spearman correlation were employed ($p < 0.05$, statistical significant).

Results: On this study we included 19 patients with MASLD, 3 was male and 16 was female, with media age 45 years ± 7.6 years. Eight patients was S2 and 11 patients was S3. The CAP, Lymphocytes and HbAc1 were significant increase on S3 in comparison with S2. There were not any other differences on any other parameters. Regarding to the immunological findings we found a significant increase on IgA, IgG, TNF-α, and IL-6. We found a correlation between levels of CAP and kPa, lymphocytes, IMC, TNF-α, IgA, the IMC was not significant correlation to TNF-α, IgA.

Conclusion: The changes on immunoglobulins related to adaptative immune and mucosal response (IgG and IgA), and correlation to overexpression with TNF-α, and IL-6, on saliva is related to the increase on lymphocytes regarding to the MASLD severity, and disease progression.

FRI-335

Therapeutic potential of a GHRH analog in experimental MASLD

Antonio Gil-Gómez[1,2], Ángela Rojas Álvarez-Ossorio[2,3], Vanessa García-Fernández[4], Rocío Munoz-Hernández[2,4,5], Tania Chica-Cid[4], Sara Morcuende[5], M America Davis-Lopez de Carrizosa[5], Beatriz Benítez-Temiño[5], Manuel Romero-Gómez[2,4,6]. *[1]Seliver Group. Email: agil-ibis@us.es

Background and aims: Tesamorelin, an analog of growth hormone-releasing hormone (GHRH), has shown promise in improving metabolic health by reducing visceral adiposity and enhancing lipid profiles in patients with HIV. Its potential in MASLD patients lies in its ability to target underlying metabolic dysregulation and alleviate liver steatosis, addressing key drivers of liver disease progression. The aim of this work was to evaluate the effects of this treatment in murine models of MASLD.

Method: To understand the effect of Tesamorelin (TheraTechnologies), we used two different animal models of MASLD: CDAC-HFD (n = 36) (45% fat, 0.1% methionine, no choline, 1% cholesterol) and HFHCC (42% fat, high sucrose, 1.25% cholesterol + glucose/fructose in the drinking water) (n = 40). For both experiments, animals were fed the MASLD-inducing diet or chow for 20 weeks, being treated with Tesamorelin (0.7 mg/Kg, IP, daily) or vehicle for the last 4 weeks. Phenotypic, histologic and biochemical data were collected for experiments.

Results: In CDAC-HFD fed animals, Tesamorelin was associated with a reduction in eWAT/body weight (1.3 ± 0.4 vs 0.8 ± 0.4%; $p < 0.05$) and liver/BW (10.1 ± 0.5 vs 9.1 ± 0.6; $p < 0.05$). Also, we observed a decrease in ALT (225 ± 81 vs 119 ± 78 U/L; $p < 0.01$) and AST (445 ± 152 vs 346 ± 102 U/L; $p = 0.1$) levels, and in the number of liver nodules per mouse (3.8 ± 3.8 vs 1.1 ± 1.0 U/L; $p < 0.05$) and collagen deposition. However, there were no significant differences in the NAFLD activity score. HFHCC-fed animals under Tesamorelin demonstrated a reduction in body weight gain (1.7 ± 2.4 vs −2.5 ± 2.4%; $p < 0.001$), and obesity measured by the Lee index (0.35 ± 0.01 vs 0.33 ± 0.01; $p < 0.05$). It was also associated with a decrease in circulating LDL (1.9 ± 0.5 vs 1.0 ± 0.4 mmol/L; $p < 0.001$) and HDL (6.3 ± 1.0 vs 4.4 ± 1.2 mmol/L; $p < 0.001$) particles, ALT (210 ± 120 vs 177 ± 81; p = ns), AST (585 ± 460 vs 411 ± 310 U/L; p = ns) and a 70% improvement in HOMA-IR. Histologically, there was evidence of reduced NAS and fibrosis.

Conclusion: Tesamorelin administration induced a reduction of adipose tissue with consequent weight loss. Also, it improved liver enzymes, lipid profile and insulin resistance. Further experiments are needed to better understand and isolate peripherical GH effects from IGF-1-mediated liver protection.

FRI-336-YI

Genetic variation in GPAM and protection against histologic severity in metabolic dysfunction-associated steatotic liver disease

Aaron Hakim[1], Tae-Hwi Linus Schwantes-An, Callie Zaborenko[2], Marco Abreu[2], Xiuqing Guo[3], Jie Yao[3], Jingyi Tan[3], Luca Lotta[4], Niek Verweij[4], Naga Chalasani. *[1]Beth Israel Deaconess Medical Center, Boston, United States; [2]Indiana University School of Medicine, Indianapolis, United States; [3]The Lundquist Institute, Torrance, United States; [4]Regeneron Genetics Center, Tarrytown, United States*
Email: ahakim@bidmc.harvard.edu

Background and aims: Recently, a novel genetic locus in the mitochondrial glycerol-3-phosphate acyltransferase (*GPAM*) has shown an association with liver biochemistries and steatosis by imaging. Since the causal variant in *GPAM* is unknown, we applied statistical fine mapping to identify lead SNPs in *GPAM* and subsequently tested their association with histologic disease severity in a large biopsy-confirmed metabolic dysfunction-associated steatotic liver disease (MASLD) cohort.

Method: We performed statistical fine mapping using FINEMAP and SuSiE at the *GPAM* locus for associations with liver biochemistries in UK Biobank (n = 361,194). We tested the association of the lead variants from the target loci with histologic severity in the NASH CRN cohort (n = 3,049). We used logistic regression to assess the relationship between the *GPAM* polymorphism and fibrosis stage as a continuous variable, advanced fibrosis (≥ F3), and NAS ≥ 4. We adjusted for age, sex, body mass index, type 2 diabetes, and the first 10 principal components of ancestry.
Results: Fine mapping identified 8 polymorphisms at the *GPAM* locus with posterior probability of association > 0.1, representing two independent genomic loci. Variants within each locus were in complete linkage disequilibrium and GWAS of ALT in the UK Biobank identified rs55875049 and rs10797429 as the lead SNPs from these two *GPAM* loci. In the UK Biobank, the minor allele frequency for rs55875049 and rs55875049 are 19% and 27%, respectively. In adults (n = 2,149), *GPAM* rs55875049 was protective against increased fibrosis stage (OR 0.82, 95% CI: 0.75–0.90, p = 5.08E-05), advanced fibrosis (OR 0.78, 95% CI: 0.65–0.94, p = 0.007), and NAS ≥ 4 (OR 0.78, 95% CI:0.66–0.92, p = 0.003); rs10787429 was also protective against NAS ≥ 4 (OR = 0.86, 95% CI: 0.74–1.00, p = 0.04), but not against fibrosis stage (OR = 0.94, 95% CI: 0.87–1.02, p = 0.16), or advanced fibrosis (OR = 1.0, 95% CI: 0.85–1.17, p = 0.97). The direction and strength of associations were similar after adjusting for *PNPLA3* genotype. In children (n = 900), *GPAM* rs55875049 was not associated with fibrosis stage, advanced fibrosis, or NAS ≥ 4 (p > 0.05 for all). GPAM rs10787429 was protective against fibrosis stage (OR 0.91, 95% CI: 0.82–1.02), p = 0.098) and advanced fibrosis (OR 0.73, 95% CI: 0.54–1.00, p = 0.04), but not NAS ≥ 4 (OR 1.28, 95% CI: 1.02–1.60, p = 0.03).
Conclusion: We identified rs55875049 and rs10797429 as the lead SNPs from two independent *GPAM* loci potentially associated with MASLD. *GPAM* rs55875049 showed strong protection against fibrosis and steatohepatitis in adults but not children with MASLD. *GPAM* rs10787429 showed protection against fibrosis in children but not in adults. These findings provide additional insight into the genetic basis of MASLD.

FRI-337

ETX-312, a GalOmic siRNA for the treatment of MASH, effectively improves the MASH phenotype of GAN DIO-MASH mice alone or in combination with emerging therapies

Gaye Saginc Giannoustas[1], Natalie Pursell[1], Alexandre Debacker[1], Damian Elle[1], Alan Whitmore[1]. [1]*e-therapeutics plc, London, United Kingdom*
Email: Gaye.Saginc@etherapeutics.co.uk

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a chronic liver disease with remaining high unmet need despite recent therapeutic advances. e-therapeutics used its HepNet computational platform to identify a novel, liver-expressed target gene implicated in MASH and designed a potent GalOmic siRNA to silence its expression in hepatocytes. ETX-312 previously demonstrated efficacy alone and in combination with a THR-beta agonist or GLP-1 receptor agonist in the Gubra-Amylin NASH diet-induced obese (GAN-DIO) mouse model. The aim of this study was to assess the liver histopathological effects of ETX-312, alone or in combination with additional emerging MASH treatments, in the GAN-DIO mouse model.
Method: Male C57BL/6 mice were fed the GAN diet high in fat, fructose, and cholesterol for 32 weeks prior to study start. A liver biopsy was collected 4 weeks prior to study start for confirmation of liver pathology and mice randomized based on quantitative liver fibrosis staining. ETX-312 was administered alone or in combination with a GLP-1/GIP receptor (GLP-1R/GIPR) agonist or an FGF-21 analogue for 16 weeks. Body weight was measured weekly and histopathological pre-to-post individual assessment of NAFLD activity score (NAS) was performed. Other terminal endpoints included quantitative liver histology and plasma biomarkers of MASH.
Results: ETX-312 treatment, alone and in combination with relevant clinical comparators, led to a marked improvement in NAS driven by a reduction in steatosis and inflammation. 95% of DIO-MASH mice treated with ETX-312 monotherapy had at least a 1-point improvement in NAS, with 60% achieving at least a 2-point improvement, surpassing both the GLP-1R/GIPR agonist and FGF-21 analogue comparators arms. Combination of ETX-312 with GLP-1R/GIPR agonist or FGF-21 analogue resulted in additive improvement in NAS compared to either therapy alone. In both ETX-312 combination groups, all DIO-MASH mice had at least a 2-point improvement in NAS, with up to 5-point improvement observed. DIO-MASH mice treated with ETX-312 demonstrated lower rates of fibrosis progression comparable to the effects observed in the FGF-21 analogue and GLP-1R/GIPR agonist groups. Beneficial effects of ETX-312 on fibrosis were further supported by a statistically significant reduction in collagen staining of liver biopsies and significant improvements of the plasma biomarkers TIMP1 and PIIINP.
Conclusion: High unmet need remains despite recent advances in treatments of MASH. These results highlight the potential of ETX-312 as an effective treatment for MASH as a monotherapy with a desirable quarterly subcutaneous dosing regimen; or as part of a combination regimen, to further improve the efficacy of emerging therapies. ETX-312 has been selected for clinical development and is being evaluated in IND-enabling studies, with an IND submission planned for 2025.

FRI-338

Genetic predisposition for hepatic fat accumulation impacts the uptake of fatty acids through fatty acid translocase in a human stem cell-based in vitro model

Alexandra Gatzios[1], Matthias Rombaut[1], Joery De Kock[1], Anouk Verhoeven[1], Dinja De Win[1], Anja Heymans[1], Vera Rogiers[1], Robim M. Rodrigues[1], Joost Boeckmans[1], Tamara Vanhaecke[1]. [1]*In Vitro Toxicology and Dermato-cosmetology (IVTD) research group, Vrije Universiteit Brussel, Brussels, Belgium*
Email: alexandra.gatzios@vub.be

Background and aims: Several single nucleotide polymorphisms relevant to metabolic dysfunction-associated steatohepatitis (MASH) - PNPLA3 rs738409 C > G, TM6SF2 rs58542926 C > T, GCKR rs1260326 C > T, and MBOAT7 rs641738 C > T - have been combined into a polygenic risk score for hepatic fat content (PRS-HFC). While earlier research by our group has validated the PRS-HFC in an *in vitro* model of hepatic cells differentiated from human skin-derived precursors (hSKP-HPC), the underlying mechanisms driving this genetic predisposition remain to be elucidated. We hypothesized that genetic predisposition for hepatic fat accumulation can influence the active uptake of fatty acids (FAs) and aimed to investigate this in the hSKP-HPC-based *in vitro* model.
Method: 92 hSKP cell lines were genotyped and classified according to their PRS-HFC (risk category ($RC)_{low}$, $RC_{intermediate}$, RC_{high}). Of both RC_{low} and RC_{high}, five cell lines were selected and differentiated to hSKP-HPCs. The cell cultures were exposed for 24 hours to a 'MASH' mix consisting of oleic acid, palmitic acid, fructose, lipopolysaccharide and tumor necrosis factor alpha, or vehicle-matched control medium. Both conditions also contained linoleic acid, which was present as a supplement in the differentiation medium. Intracellular lipids were stained with BODIPY™ 493/503 and quantified using flow cytometry. Active uptake of FAs was evaluated using the BODIPY™ FL C_{16} probe. Further, the expression of genes related to FA uptake was assessed.
Results: In the control condition, lipid accumulation was 4.6-fold higher for RC_{high} cultures compared to RC_{low} (p = 0.0051). In concordance with mRNA expression data, where a 3.8-fold higher expression of *cluster of differentiation 36* (CD36, fatty acid translocase) was found (p < 0.0001), active uptake of FAs was significantly

increased in the RC_{high} category compared to RC_{low} (1.6-fold, $p < 0.0001$). Gene expression of *solute carrier family 27 member 5*, encoding fatty acid transport protein 5, was unaltered between RCs. After exposure to the 'MASH' mix, the lipid load in the RC_{high} cultures was 3.5-fold higher than in the RC_{low} cultures ($p = 0.0004$). The mRNA expression of CD36 was markedly reduced in the RC_{high} cultures compared to their control condition (0.32-fold, $p < 0.0001$), and similarly modulated in the RC_{low} cultures (0.66-fold, $p = 0.0962$). On the functional level, this was reflected by a reduction in active FA uptake in RC_{high} (0.70-fold, $p < 0.0001$) and RC_{low} cultures (0.79-fold, $p = 0.039$). Nevertheless, CD36 expression and active uptake remained respectively 1.85-fold ($p = 0.0296$) and 1.45-fold ($p < 0.0001$) higher in RC_{high} than in RC_{low} cultures.

Conclusion: Increased FA uptake through fatty acid translocase might be one of the mechanisms through which genetic predisposition contributes to hepatic fat accumulation. In the current *in vitro* study, this effect was predominantly observed in the control condition, suggesting a possible role for differential FA transport during early stages of steatosis development.

FRI-339

Identifying health-to-disease transitional biomarkers in 3D human organotypic models of metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction-associated steatohepatitis (MASH)

Anabel Martinez Lyons[1], Callum Rafferty[1], Debbie Neill[1], Tim Kendall[2], Jonathan Fallowfield[2], Justyna Cholewa-Waclaw[3], Pierre Bagnaninchi[3], Leonard J. Nelson[1]. [1]*Institute for Bioengineering, School of Engineering, University of Edinburgh, Edinburgh, United Kingdom;* [2]*Centre for Inflammation Research, University of Edinburgh, Edinburgh, United Kingdom;* [3]*Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom*
Email: anabel.martinezlyons@ed.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects two billion adults worldwide and precedes the inflammatory condition metabolic dysfunction-associated steatohepatitis (MASH). Current diagnostic and therapeutic approaches are limited by a lack of cell-type specific biomarkers that distinguish transitional states between health, MASLD, and MASH. This study aimed to identify such biomarkers by using novel 3D human spheroid models of MASLD and MASH pathogenesis that recapitulated the cellular complexity within patient livers.

Method: We developed a human hepatic spheroid model composed of biliary epithelial cells (BECs) and hepatocytes (HepaRG116^{TM}), stellate, monocyte (Kupffer cell analogue), and endothelial cells (all from Biopredic International; BPI). 5000 cells/spheroid were seeded in William's E medium supplemented with general purpose serum (BPI). From day 3, spheroids were given maintenance and metabolism medium (MMM; BPI). From day 7, spheroids were treated with oleate (MASLD model) or a nutrient-excess and pro-inflammatory cocktail of lactate, pyruvate, octanoate and ammonia (LPON; MASH model). Controls were cultured in MMM. Media and cell lysates were collected at 0, 24, 48, and 72 h. HepaRG116^{TM} cells were used as a 2D comparator system. Pathogenic cell states were assessed by confocal microscopy with the Opera Phenix Plus Imaging System (Revvity) and validated with MASLD/MASH patient RNA-seq data (SteatoSITE.com). Image quantification was performed with Harmony (Revvity) or Fiji/ImageJ software. Lipid dynamics were assessed by holographic tomography (HT) (Nanolive) and CellPose/Cell Profiler software. Molecular profiling was achieved by SDS-PAGE/Western blotting, and cell health markers (ALT, AST, and L-lactate) were measured by enzyme-linked immunosorbent assays. Statistics were performed with GraphPad Prism 10 software.

Results: MASH spheroids showed extensive lipid accumulation, elevated ALT, AST, and L-lactate levels, and inflammatory activation of monocytes, resembling *in vivo* MASLD-MASH pathogenesis. Nanolive HT revealed lipid loading in MASH hepatocytes and BECs, and reduced BEC proliferation, compared to 2D MASLD and control models. Immunoblotting revealed increased epithelial (ZO-1 and E-Cadherin) and reduced mesenchymal (N-Cadherin, SNAIL1, alpha-SMA, and Vimentin) biomarkers in 2D MASH compared to both MASLD and control models. Confocal imaging of spheroids identified cell-type specific phenotypes for hepatocytes, monocytes, and stellate cells in 2D and spheroid MASH models over time. Patient RNA-seq data validated the cell type signatures identified in our MASLD and MASH models.

Conclusion: This study sought to tackle the need for reliable and specific molecular profiling for MASLD or MASH patients. Our human hepatic spheroid model provides a unique platform for studying real-time progression from health to MASLD and MASH at the cellular level and for putative biomarker discovery.

FRI-340-YI

Brain dysfunction is ameliorated by alpha 2A adrenergic receptor antagonism in experimental metabolic dysfunction-associated steatotic liver disease through vasodilatory and anti-inflammatory effects

Anne Catrine Daugaard Mikkelsen[1], Kristoffer Kjærgaard[1], Cecilie Bay-Richter[2], Betina Elfving[2], Olivia Greenham[3], Elizaveta Melnikova[4], Vladimir Matchkov[4], Karen Louise Thomsen[1,3], Rajeshwar Prosad Mookerjee[1,3]. Email: ancami@clin.au.dk

Background and aims: Brain dysfunction in terms of cognitive impairment and neurobiological changes is a recognised complication of metabolic dysfunction-associated steatotic liver disease (MASLD), and treatments for this condition are lacking. We have previously shown that antagonising the alpha 2A adrenergic receptor (ADRA2A) ameliorates liver inflammation, portal hypertension and disease progression in MASLD. This study aimed to investigate the potential of ADRA2A antagonism to treat brain dysfunction in MASLD and to explore the potential beneficial mechanisms.

Method: Two animal models of MASLD were evaluated in this study. Male C57BL/6NTac mice were fed a modified Amylin-liver non-alcoholic steatohepatitis (AMLN) diet or a standard diet (controls) for 36 weeks. Male Sprague Dawley rats were fed a high-fat, high-cholesterol (HFHC) diet or a standard diet (controls) for 16 weeks. Half of the MASLD animals in both protocols received the ADRA2a antagonist Yohimbine, in their drinking water for the final 10 weeks. Neurobehavioural tests were conducted in all animals. In the AMLN model, we also examined brain perfusion and conducted proteomic analyses of the cerebral cortex. In the HFHC model, we assessed inflammation in the liver, systemic circulation and brain.

Results: ADRA2a antagonism ameliorated impaired memory and depressive-like behaviour in both MASLD models, and also anxiety-like behaviour in the AMLN model. ADRA2a antagonism increased total cortex perfusion in the AMLN model and prevented an inhibition of pathways leading to vasodilation in the cerebral cortex, through Ca^{2+}-Calmodulin-NOS1 signalling. In the HFHC model, ADRA2a antagonism decreased systemic and liver inflammation and ameliorated signs of neuroinflammation by reducing levels of pro-inflammatory cytokines in the hypothalamus and cerebrospinal fluid.

Conclusion: Ten weeks of ADRA2a antagonism in two rodent MASLD models ameliorated cognitive dysfunction. This seemed to be through two mechanisms: 1) increased cerebral perfusion through facilitation of vasodilatory pathways and 2) decreased liver, systemic and brain inflammation.

FRI-341

miRNA isoforms are differentially expressed with increasing disease activity and fibrosis in metabolic dysfunction-associated steatotic liver disease

Christian Brion[1], Stephen Hoang[2], Guangliang Wang[1], Faridoddin Mirshahi[2], Jessie Ang[1], Matthew Long[1], Zheng Zhu[1], Bhanu Sakhamuri[1], Molly Srour[1], Mohammad Siddiqui[2,3], Amon Asgharpour[2,3], Neal Foster[1], David Salzman[1], Arun J. Sanyal[2,3]. *[1]Gatehouse Bio, Natick, MA, United States; [2]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, Virginia Commonwealth University School of Medicine, Richmond, VA, United States; [3]Division of Gastroenterology, Hepatology and Nutrition, Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, VA, United States*
Email: david.salzman@gatehousebio.com

Background and aims: microRNA isoforms (isomiRs) may contribute to the differential functions of miRNAs, thus providing a novel class of druggable targets. Their expression and relationship to disease severity in MASLD is unknown. We therefore aimed to assess: (1) the isomiR landscape in MASLD, (2) its relationship to histological features, and (3) its role in disease biology.
Method: Snap-frozen liver tissue at the time of liver biopsy was obtained (MASL = 19, MASH = 47, MASH-cirrhosis = 11, control without liver disease = 2). Small RNA (sRNA) was sequenced and characterized for post-transcriptional modification, resulting in sRNA isoforms. Two independent approaches were used to relate isomiRs to histological activity and fibrosis stage: differential expression analysis (DEA) selecting isomiRs with adjusted $p < 0.05$ and by machine-learning (ML) methods with 10x k-fold cross-validation. TargetScan was used to determine their gene targets and to identify potential regulatory networks. The results were validated in an independent cohort.
Results: 7 classes of sRNA were identified with miRNA (74.5%) and piRNA (11.3%) representing the majority; 66% of miRNA were isomiRs. mir122, mir143, mir21 and let7a and let7b were the most common miRNA with both templated and non-templated additions of nucleotides. 1824 and 7818 sRNAs were differentially expressed with high activity (NAS > 4) and advanced fibrosis (AF), (stage 3–4). miRNA had the largest upregulated (n = 621) and downregulated (n = 141) species with AF. The data were split in a training and validation set for ML (glmnet + SVM) identification of high NAS and AF yielding an AUROC of 0.75 and 0.79 respectively. These differentially expressed isoforms were mapped to differentially expressed genes linked to 33 pathways including insulin- and PPAR-signaling, cholesterol metabolism and fibrosis. Specific isoforms of mir122 and mir21 targeting specific pathways e.g. -GAGTGTG 5′ isomiR122 for cholesterol metabolism and -TAGCTTA 5′ isomiR21 for modulation of integrin-cell surface interactions and response of TGF-β were identified. Gene targets were further validated in an independent data set.
Conclusion: These data expand the druggable genome by identifying novel sRNAs correlated to MASLD severity that can modulate specific pathways linked to disease activity and fibrosis providing foundational data for a new array of potential RNA-therapeutics.

FRI-342

Exploring the repurposing of Telmisartan for the treatment of MASLD: characterization of its antisteatotic mechanism of action

Roger Bentanachs[1,2], Bianca Braster[3,4], Anastasia Emmanouilidou[3,4], Endrina Mujica[3,4], Amin Allalou[4,5], Patricia Ramírez-Carrasco[1,2], Núria Roglans[1,2,6], Juan Carlos Laguna[1,2,6], Marta Alegret[1,2,6], Marcel den Hoed[3,4]. *[1]School of pharmacy and Food Sciences, universitat de Barcelona, Barcelona, Spain; [2]IBUB, Barcelona, Spain; [3]Department of immunology, genetics and pathology, Uppsala university, Uppsala, Sweden; [4]SciLifeLab, Uppsala, Sweden; [5]Department of information technology, Uppsala university, Uppsala, Sweden; [6]CIBERObn, Barcelona, Spain*
Email: bentanachs@ub.edu

Background and aims: Metabolic dysfunction-associated steatotic liver (MASL), the initial stage of metabolic dysfunction-associated steatotic liver disease (MASLD), is directly involved in the progression to steatohepatitis. Moreover, individuals with MASL are already at increased risk of cardiovascular disease (CVD). Thus, the repurposing of Telmisartan, an angiotensin II type I receptor (AGTR1) antagonist approved to prevent cardiovascular events, as a treatment for MASL could represent a promising strategy to mitigate further clinical complications.
Method: Two-month-old female Sprague Dawley rats were randomized into three groups (n = 8 each): control diet and water; high-fat plus 10% drinking fructose (HFHFr); or HFHFr diet plus telmisartan 10 mg/kg/day in the final month.
Five days post-fertilization (dpf) zebrafish larvae with transgenically expressed fluorescent labels on hepatocytes (Tg[2.8fabp10a:GFP]) were randomly distributed into 4 groups until 10 dpf: standard-fed controls (ST), overfed plus 3% glucose (OF+GL), OF+GL plus Telmisartan at 0.4μM (Tel0.4μM) or OF+GL plus Telmisartan at 2μM (Tel2μM). Telmisartan was added from 8 to 10 dpf. For mutant zebrafish experiments, CRISPR/Cas9-induced mutated larvae and controls were distributed 50:50 to untreated or treated tanks at 5 dpf, with all tanks fed OF+GL. At 10 dpf we acquired whole-body and liver images of live larvae, and quantified lipids using a deep neural network. Fragment length analysis was used to ascertain the presence/absence of mutations.
Results: In the rodent model, Telmisartan reduced intrahepatic triglycerides (TG), % Oil Red O area (x0.34 and x0.22 vs. HFHFr, respectively), and perigonadal white adipose tissue weight (x 0.78) without affecting calorie intake or body weight. Hepatic lipid uptake, blood TG levels and β-oxidation markers were not modified by the drug treatment. In contrast, phosphoenolpyruvate carboxy kinase (PCK1) protein levels were restored (x2.07), and lipogenesis markers like ATP citrate lyase protein levels (x 0,64), fatty acid synthase (x 0,52) and stearoyl-CoA desaturase (x 0,59) mRNA levels were downregulated. Treatment with 2 μM Telmisartan reduced liver fat content (x 0.78) in a OF+GL challenged zebrafish larvae. The antisteatotic effect of Telmisartan was attenuated in larvae with CRISPR/Cas9-induced mutations in its targets (*agtr1* or *pck1*).
Conclusion: Telmisartan treatment attenuates steatosis in two dietary-induced MASLD models, potentially through the AGTR1 blockade and restoration of PCK1 levels. Our findings strongly encourage further clinical research to explore the repurposing of Telmisartan for the treatment of MASLD. Grants: PID2023-146140OB-I00, funded by MICIU/AEI/10.13039/501100011033 and FEDER-UE, and 2021SGR-00345. Swedish Heart-Lung Foundation (20230518), Swedish Research Council (2023-02556).

FRI-343

Anti-steatosis effect of telmisartan in a MASL-dietary rat model does not associates to changes in faecal bile acid metabolome

Roger Bentanachs[1,2], Patricia Ramírez-Carrasco[1,2], Marta Alegret[1,2,3], Juan Carlos Laguna[1,2,3], Núria Roglans[1,2,3]. *[1]School of pharmacy and Food Sciences, universitat de Barcelona, Barcelona, Spain; [2]IBUB, Barcelona, Spain; [3]CIBERObn, Barcelona, Spain*
Email: bentanachs@ub.edu

Background and aims: We have previously shown that pemafibrate administration prevents steatosis development in an experimental model of simple metabolic-associated steatotic liver disease (MASL) in Sprague-Dawley (SD) rat (*Biomed&Pharmacother* 177 (2024) 117067), further inducing significant changes in faecal bile acid (BA) metabolome. As we have found that telmisartan also prevents steatosis in the same experimental model, we were interested in determining its possible effect on faecal BA metabolome.
Method: Female Sprague-Dawley rats were randomly distributed into 3 groups (n = 8 each): (1) control (CT; standard rodent chow); (2)

high-fat diet with 10% w/v fructose in drinking water (HFHFr); (3) HFHFr plus telmisartan at 10 mg/Kg/day (Telmi). Rats were fed the HFHFr diet for three months, while the Telmi group received high fat diet supplemented with the corresponding drug for the last month. At the end of the treatment, rats fasted for 2 h were sacrificed and liver tissue and faecal content were collected and properly stored. The concentrations of 10 BA (cholic acid, chenodeoxycholic acid, deoxycholic acid, lithocholic acid, ursodeoxycholic acid, α-muricholic acid, β-muricholic acid, hyocholic acid, hyodeoxycholic acid, and murideoxycholic acid) in rat faeces were determined by ultra-high-performance liquid chromatography coupled to tandem mass spectrometry (UHPLC-MS/MS), as described previously (Biomed&Pharmacother 177 (2024) 117067). Liver expression of pertinent genes related to primary BA synthesis was determined.
Results: After 3 months of dietary intervention, HFHFr showed increases in the following faecal bile acid concentrations: Total BA (x1.4 vs CT), cholic acid (x8.5 vs CT), chenodeoxycholic acid (x2.8 vs CT), Total Secondary BA (x1.3 vs CT), ursodeoxycholic acid (x7.8 vs CT), deoxycholic acid (x1.4 vs CT), and hyocholic acid (x2.6 vs CT). These changes were similar in intensity and direction to the changes induced by the HFHFr diet we have previously described (Biomed&Pharmacother 177 (2024) 117067). Although telmisartan treatment partially restored the liver expression of *cyp7a1* (x4.0 vs HFHFr), a gene coding for the main enzyme regulating primary bile acid synthesis, it did not significantly modify the faecal concentration of any of the BA analyzed.
Conclusion: Anti-steatosis effect of Telmisartan in a SD rat MASL dietary model do not associate with significant changes in faecal BA metabolome. Grants: PID2023-146140OB-I00, funded by MICIU/AEI/10.13039/501100011033 and FEDER-UE, and 2021SGR-00345.

FRI-344

Sexual dimorphism of Sprague-Dawley rats in the liver inflammatory/fibrotic response to a high in sucrose and fat, choline-deficient, L-amino acid CDAA diet

Patricia Ramírez-Carrasco[1,2], Manel Garcia-Díez[1], Jianing Zhou[1], Yanhao Qiu[1], Roger Bentanachs[1,2], Marta Alegret[1,2,3], Laia Vilà[1,2,3], Núria Roglans[1,2,3], Juan Carlos Laguna[1,2,3]. *[1]School of pharmacy and Food Sciences, universitat de Barcelona, Barcelona, Spain; [2]IBUB, Barcelona, Spain; [3]CIBERObn, Barcelona, Spain*
Email: p.ramirezcarrasco@gmail.com

Background and aims: We have shown the efficacy and security of bempedoic acid and pemafibrate in an experimental model of simple metabolic dysfunction-associated steatotic liver in Sprague-Dawley (SD) rat (*Biomedicines* 10 (2022) 1517, *Biomed&Pharmacother* 177 (2024) 117067). We aim to characterize an appropriate SD rat model of metabolic dysfunction associated steatohepatitis (MASH) to test the efficacy and security of these drugs in an advanced stage of metabolic dysfunction-associated steatotic liver disease.
Method: Male and female SD rats were randomly distributed into 2 groups each: (1) control (CT; standard rodent chow, n = 8), and (2) CDAA (n = 16). Half the animals were fed the CT and CDAA diets for three months, and the remaining for an additional 2 moths. At the end of each period, the animals were sacrificed and serum and liver and perigonadal white adipose tissues were obtained. Zoometric, liver histology (Oil-Red O -ORO-, Haematoxylin-Eosin -HE-, and Sirius Red -SR-), serum and liver triglyceride (TG) and cholesterol (C) concentrations, serum analytes, liver hydroxyproline (LHP) content and expression of genes related to inflammatory, redox and fibrotic processes were determined.
Results: After 3 months, CDAA-male SD rats showed liver steatosis (increased liver content of C and TG, and ORO staining), inflammation (increased serum - alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transpeptidase- and liver – tumor necrosis factor alpha (TNFalpha), F4.80, interleukin (IL) 6, IL1b - expression of inflammatory markers, and HE staining), and fibrosis (increased LHP and fibrotic - collagen type I alpha 1 chain (COL1A1), TIMP metallopeptidase inhibitor 1 (TIMP1), tissue growth factor beta (TGFbeta), actin alpha 2, smooth muscle (ACTA2)-markers, and SR staining). These changes were maintained at 5 months without a significant increase in their intensity. On the contrary, 3 and 5 months CDAA-female SD rats, although presenting liver steatosis, and mild changes in inflammatory markers, did not show clear signs of liver fibrosis, specially as assessed by LHP content and SR staining. Significant differing responses to the CDAA diet related to sex were observed for serum TG, C, insulin, ALT, AST, alkaline phosphatase, and growth differentiation factor 15 concentrations, histological assessment, and liver tissue expression of TNFalpha, F4.80, IL6, COL1A1/2, TIMP-1, TGFbeta, and ACTA2.
Conclusion: There is a clear sexual dimorphism in the response of SD rats to a CDAA diet, with males developing MASH after three months of continuous CDAA diet supplementation, while females not showing any clear increase in liver fibrotic markers after five months of CCDA diet supplementation.
Grants: PID2023-146140OB-I00, funded by funded by MICIU/AEI/10.13039/501100011033 and FEDER-UE and 2021SGR-00345.

FRI-349

Quantifying the periportal and lobular fat distribution in metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis with artificial intelligence detection of portal tracts and macrovesicular steatosis

Dylan Windell[1], Alastair Magness[1], Paul Aljabar[1], Kenneth Fleming[2], Eve Fryer[3], Tim Kendall[4], Robert D. Goldin[5], Phil Wakefield[1], Caitlin Langford[1]. *[1]Perspectum Ltd, Oxford, United Kingdom; [2]Green Templeton College, University of Oxford, Oxford, United Kingdom; [3]Department of Cellular Pathology, John Radcliffe Hospital, Oxford, United Kingdom; [4]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [5]Section for Pathology, Imperial College London, London, United Kingdom*
Email: dylan.windell@perspectum.com

Background and aims: Portal Tracts (PTs) are important features to identify when assessing liver histology slides because their morphology, location and related disease features are intrinsic to pathologists' evaluation of the tissue. Identification is also needed to determine biopsy adequacy (>6 PTs required). In addition, measures of steatosis, inflammation and fibrosis are generally reported as averages across the tissue - scored by eye rather than computationally. This averaging results in loss of potentially important information on heterogeneity of distribution of pathological features. To address the first two issues, we have developed an AI detection model for segmenting individual PTs. To show how this can also resolve the "averaging" issue, we have accurately quantified the distribution of steatosis in relation to portal and lobular regions.
Method: Our AI model detects individual features of PTs (bile duct, hepatic artery and portal vein) and associated tissue (foreground and connective tissue). Based on spatial analysis of these features, PTs and lobular regions can be identified. PT segmentations were then paired with segmentations of fat droplets to measure steatosis. Around each PT, concentric zones of ~100 microns thickness were identified to generate metrics across portal, lobular and periportal regions. The model was applied to Haematoxylin and Eosin stained WSIs from Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD) [N = 249] and Metabolic dysfunction-Associated Steatohepatitis (MASH) [N = 104] datasets. Steatosis was measured using the percentage of steatotic tissue in proportion to the total tissue area (Fat Fraction - FF). Comparisons were measured using Mann-Whitney and Kruskal-Wallis tests.
Results: Our model accurately identified steatosis in interface, portal and lobular regions across WSIs. When comparing the FF in portal regions, there was a significant ($p < 0.05$) low level of steatosis in MASLD [0.16%] and MASH [0.20%]. In lobular regions, there was a significant ($p < 0.001$) difference of steatosis between MASLD [4.9%]

and MASH [7.2%]. When delineating periportal regions, there were low levels of steatosis in the closest zone to the PT (Zone 1) in both MASLD and MASH [2.25% vs 2.69%] with increasing levels of steatosis in zones 3–4 [5.2% vs 6.75% and 5.3% vs 7.2% in MASLD and MASH respectively]. Significant differences ($p < 0.01$) in steatosis were apparent between MASLD and MASH in all zones apart from zone 1. When compared to steatosis scores from expert pathologists, there was no significant difference between MASLD and MASH.
Conclusion: PT characterisation is imperative for histological scoring and establishing sample adequacy of liver biopsies. Our AI model can also generate visual overlays on WSIs to assist pathologists by producing automated quantifications of steatosis across whole biopsies. Quantitative measurements of steatosis are not only more accurate and reproducible endpoints but may help differentiate between MASLD and MASH cases.

Effect of high-intensity interval, moderate continuous and voluntary training on body composition, hepatic steatosis and myosteatosis in a preclinical model of metabolic dysfunction-associated steatotic liver disease
Camille Lannoy[1], Sandra Calvo Blanco[2], Laura Fache[1], Isabelle Leclercq[2], Louise Deldicque[1]. [1]*Institute of Neuroscience, Louvain-la-Neuve, Belgium;* [2]*Institute of Experimental and Clinical Research, Bruxelles, Belgium*
Email: camille.lannoy@uclouvain.be

Background and aims: MASLD is defined as hepatic steatosis combined with different levels of inflammation and fibrosis. Recently, myosteatosis has been shown to be linked to the severity of MASLD in preclinical models. On the other hand, physical exercise could be beneficial for decreasing lipid content in the liver and in the skeletal muscle. This study aims to investigate if physical exercise could reduce myosteatosis and the severity of MASLD in a preclinical model, and which training modality would be the most effective.
Method: High fat diet (HFD)-fed fat aussie (FOZ) mice were used as a preclinical model of MASLD. Mice were divided into five groups: control treadmill (CTRL TM, n = 3), control wheel (CTRL W, n = 3), high intensity interval training (HIIT, n = 6), moderate continuous training (MCT, n = 4) and free wheel training (W, n = 3). After 12 weeks of HFD, mice were trained 5 times per week for 8 weeks on a treadmill or during nights on the wheel. Before and after training, body composition and density of the dorsal muscle (DM) and the liver were assessed by micro-computed tomography (µCT-scan). Mice were sacrificed at 20 weeks of HFD. Hindlimb muscles and liver were collected for further analysis. The MASLD activity score (MAS) was determined based on the degree of inflammation, hepatocyte ballooning and steatosis in the liver.
Results: At this point of the study, there is not enough individuals to conclude any comparisons between groups. However, each group can be analyzed individually before and after training. After HIIT, weight was increased ($p = 0.014$) and DM density was decreased ($p = 0.024$). After MCT, DM density and liver density were both increased ($p = 0.019$ and 0.003 respectively). MAS score and its parameters taken individually were not changed by HIIT or MCT so far. Results from the groups CTRL W and W are not available for the moment but will pe presented on the poster.
Conclusion: HIIT and MCT did not reverse the severity of MASLD based on the MAS score. According to the µCT-scan results, HIIT seems to worsen the myosteatosis whereas MCT seems to improve lipid infiltration in the liver and in the DM. Further analysis needs to be conducted to enhance statistical power and to understand the underlying mechanisms of lipid accumulation in the liver and in the skeletal muscles.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing global health concern, strongly influenced by gut dysbiosis. In our prior clinical trial, Qushi Huayu (QSHY), a traditional Chinese medicine, demonstrated efficacy in treating MASLD and correcting gut dysbiosis. This study aims to identify the efficacy response-associated microbial species (RAMS) linked to QSHY intervention and to explore the formulation compounds responsible for modulating RAMS.
Method: We conducted a metagenomic analysis of 44 patients, including high-response individuals (relative decreases in serum alanine transferase > 40% or liver magnetic resonance imaging-derived proton density fat fraction > 30% from baseline at week 24) treated with QSHY or a control (n = 22 per group). RAMS associated with QSHY intervention were verified via fecal microbiota transplantation (FMT) from patients pre- and post-treatment into recipient mice. A high-fat, high-sugar (HFHS) diet-induced model of steatohepatitis (MASH) was used for in vivo evaluation. Compounds from QSHY and cecal contents of MASH mice were analyzed using chromatography-q exactive-orbitrap high resolution mass spectrometry (UHPLC-Q-Orbitrap HRMS) at multiple time points (4, 6, 8, 12, and 24 hours) after continuous QSHY intragastric administration (1.7 g/kg for six weeks, n = 5 per time point). The direct effects of QSHY and its compounds on RAMS were assessed using in vitro co-culture assays.
Results: QSHY significantly increased the abundance of *Roseburia intestinalis* (*R. intestinalis*) in high-response MASLD patients post-intervention. The relative abundance of *R. intestinalis* was negatively correlated with liver fat content, liver injury markers, and insulin resistance. FMT from post-QSHY MASLD patients improved liver lipid deposition and elevated *Roseburia* abundance in recipient mice. Colonization with *R. intestinalis* alleviated hepatic steatosis, inflammation, and metabolic dysfunction in HFHS diet-induced MASH mice. A total of twenty compounds were identified in both QSHY and the cecal contents of MASH mice after six weeks of continuous QSHY intragastric administration. QSHY and eight compounds were found to directly promote *R. intestinalis* growth.
Conclusion: QSHY corrects intestinal dysbiosis in patients with MASLD. QSHY and some of its compounds directly promote the growth of *R. intestinalis*, offering potential therapeutic effects for MASLD.

FRI-352-YI
Spatial multiplex analysis reveals distinct senescence patterns and cellular interactions in mouse models of MASLD and MetALD
Charalampos Pavlidis[1], Pavitra Kumar[1], Marlene Kohlhepp[1], Richard Sittner[1], Juan Wang[1], Julian Pohl[1], Hasan Tarik Cosgun[1,2], Tobias Puengel[1], Frank Tacke[1], Cornelius Engelmann[1]. [1]*Charité – Universitätsmedizin Berlin, corporate member of Freie Universität Berlin and Humboldt-Universität zu Berlin, Department of Hepatology and Gastroenterology, Berlin, Germany;* [2]*Universitätsklinikum Knappschaftskrankenhaus Bochum, Bochum, Germany*
Email: charalampos.pavlidis@charite.de

Background and aims: Hepatocellular senescence, arising from cellular injury, leads to cell cycle arrest in metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic alcohol-related liver disease (MetALD), affecting the tissue microenvironment, including interaction with neighboring hepatocytes, their

distribution, and localization. This study aims to characterize senescence-associated cellular patterns in steatotic liver disease (SLD) to explore their potential role in mediating disease progression.
Method: MASLD and MetALD rodent models were established in wild-type C57BL6/J mice. For MASLD, mice were fed with Choline-Deficient, L-Amino Acid-Defined, High-Fat Diet (CDAHFD) for 8 & 12 weeks and Western Diet (WD) for 7 & 16 weeks. For MetALD, mice received WD plus 10% ethanol in drinking water for 4 weeks plus ethanol binge (6 g/kg) 24 hours before sacrifice. Liver tissues underwent multiplex immunofluorescence (mIF) staining followed by single-cell analysis with CellProfiler and MATLAB/CytoMAP.
Results: The MASLD models demonstrated varying levels of steatosis and inflammation, accompanied by an increased senescence phenotype (elevated SA-beta galactosidase activity, p53, and p21, along with decreased Lamin B1 and phosphorylated Retinoblastoma). Notably, the CDAHFD exhibited more pronounced effects than the WD. Additionally, mIF-based single-cell analyses revealed that DNA damage and senescence were specific to hepatocytes, showing significant results in WD ($p21: p < 0.002$; gamma-H2A.X: $p < 0.04$) and CDAHFD ($p21: p < 0.02$; gamma-H2A.X: $p < 0.006$). Senescent hepatocytes were primarily located in the peribiliary zones, while DNA-damaged and proliferating hepatocytes predominantly occurred in the parenchymal region. The DNA-damaged hepatocytes in the parenchyma (WD: $p < 0.04$; CDAHFD: $p < 0.002$) were often surrounded by proliferative hepatocytes (WD: $p < 0.04$; CDAHFD: $p < 0.03$). This suggests that, in MASLD, senescent hepatocytes in the peribiliary areas may inhibit the proliferation of adjacent cells, whereas DNA-damaged hepatocytes in the parenchyma could promote hepatocellular proliferation in their vicinity. In contrast, the MetALD model was significantly associated with hepatocellular senescence ($p < 0.02$) despite the absence of substantial DNA damage. In this case, senescent hepatocytes were primarily localized in the perivenous region and surrounded by proliferative hepatocytes. This distribution pattern likely reflects the influence of alcohol on the localization of senescent cells.
Conclusion: Hepatocellular senescence is ubiquitous among MASLD (WD and CDAHFD) and MetALD. Refined spatiotemporal patterns of hepatocellular senescence, DNA damage, and proliferation in MASLD and MetALD illuminate the intricate progression of SLD, deepen our understanding of disease mechanisms, and highlight zone-specific therapeutic targets for future interventions.

FRI-353-YI

Tirzepatide reduces diet-induced senescence and NETosis-mediated liver fibrosis in mice

Feng Chen[1], QiQi Nam[1], Torsten Wuestefeld[1,2], Bernett Teck Kwong Lee[1,3,4,5], Siu Ling Wong[1,6]. *[1]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore; [2]Laboratory of In Vivo Genetics and Gene Therapy, Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore, Singapore; [3]Singapore Immunology Network, Agency for Science, Technology and Research, Singapore, Singapore; [4]Infectious Diseases Labs, Agency for Science, Technology and Research, Singapore, Singapore; [5]Khoo Teck Puat Hospital, Singapore, Singapore; [6]Tan Tock Seng Hospital, Singapore, Singapore*
Email: christine.wongsl@ntu.edu.sg

Background and aims: Lipofuscin was found to accumulate in senescent cells and was reported in liver biopsies from patients with liver fibrosis of various etiologies. However, the relationship between lipofuscin and liver fibrosis has not been elucidated. Tirzepatide (TZP), the latest FDA-approved anti-diabetic drug, was recently shown to improve liver fibrosis in patients with obesity. Adopting a mouse model of liver fibrosis with robust lipofuscin accumulation, we aimed to examine if TZP can alleviate liver fibrosis by intercepting senescence and neutrophil activation.
Method: C57BL/6J mice were fed either control diet or choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for up to 10 weeks with TZP (or vehicle) treatment commenced concurrently. Livers were collected and processed for histological staining, bulk RNA sequencing (RNA-seq), immunostaining and western blotting to examine differences in fibrosis severity, lipofuscin accumulation, neutrophil activation and markers of senescence.
Results: Mice developed liver fibrosis starting from week 7 of CDAHFD feeding, while lipofuscin accumulation in hepatocytes was visible as early as at week 2. A strong and significant positive correlation ($r = 0.85$, $p < 0.001$) was observed between liver collagen deposition and lipofuscin accumulation. Among differentially expressed genes revealed by RNA-seq analysis, chemokine- and cytokine-related genes were upregulated in the liver of CDAHFD-fed mice. Further Gene Ontology analysis showed a significant enrichment in neutrophil migration, chemotaxis, and activation pathways. Immunostaining confirmed that more neutrophils infiltrated into the liver of CDAHFD-fed mice. Notably, neutrophil extracellular trap formation (NETosis) occurred mainly in neutrophils that clustered around lipofuscin-laden cells. Mice defective in NETosis (*Vav1-Cre Padi4$^{fl/fl}$*) showed less severe liver fibrosis when fed CDAHFD, indicating a crucial role of NETs in liver fibrosis development. Treatment of TZP decreased lipofuscin accumulation and liver fibrosis, in conjunction with a reduction of chemokine- and cytokine-related genes mediating neutrophil activation. CDAHFD-induced senescence markers, including p21 and p16, senescence-associated secretory phenotype-related genes, loss of hepatocyte identity and increase in polyploidisation in lipofuscin-laden cells, were also reversed by TZP.
Conclusion: TZP reduces senescence, including lipofuscin accumulation, and liver fibrosis in CDAHFD-fed mice. These findings highlight the potential to repurpose TZP for liver fibrosis implicating lipofuscin accumulation in a non-diabetic context.

FRI-354-YI

A dynamic human liver acinus-on-a-chip to model health-to-disease (MASLD-MASH) transitions

Debbie Neill[1], Anabel Martinez Lyons[1], Callum Rafferty[1], Justyna Cholewa-Waclaw[2], Pierre Bagnaninchi[2], Leonard J. Nelson[1,3,4]. *[1]Institute for BioEngineering, School of Engineering, University of Edinburgh, Edinburgh, United Kingdom; [2]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [3]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [4]Center for Inflammation Research, University of Edinburgh, Edinburgh, United Kingdom*
Email: dneill2@ed.ac.uk

Background and aims: The transition from healthy liver to metabolic dysfunction-associated steatotic liver disease (MASLD) and steatohepatitis (MASH) involves complex interactions between hepatocytes, nonparenchymal cells (NPCs), and extracellular matrix (ECM). These processes are poorly captured in standard static 2D cultures. Microfluidic Organ-Chip platforms offer physiologically-relevant microenvironments integrating mechanical forces, fluid dynamics, and cell-cell/cell-matrix interactions. We developed a novel 5-cell-type human liver acinus-on-a-chip to model hypoxia and inflammation-driven transitions from healthy liver to MASLD and MASH.
Method: Using Emulate™ S1-Chips the 5 cell-types of the human liver acinus were co-cultured under dynamic flow. HepaRG116™ cells (hepatocyte:cholangiocytes) were seeded into the S1-Chip upper channel; and monocytes (Kupffer cell analogue), stellates', and endothelial cells in the lower channel. Chips were incubated under flow (30µL/h) for 7 days before challenge with MASLD (Oleate) or MASH (LPON: Lactate, Pyruvate, Octanoate & Ammonia) inducing media for 72 h. Supernatant samples were collected at 0, 24, 48 and

72 h. Lipid accumulation, pro-inflammatory markers, and ECM remodelling were assessed with ELISA, Western blotting, and confocal imaging. Results were compared with conventional, static 2D monolayer and 2.5D Transwell® models.
Results: The liver acinus-on-a-chip displayed self-organization (cell-cell/cell-matrix interactions) with robust biocompatibility/viability. MASLD-MASH conditions induced progressive lipid accumulation and inflammation-driven ECM remodeling. The acinus-chip outperformed conventional systems in recapitulating in vivo-like (patho)physiological/ responses in albumin, ALT, and L-lactate (cell stress) secretion. Pro-inflammatory IL-6 levels and hypoxia-inducible factor 1-alpha nuclear localization were elevated in MASH conditions, aligning with published patient data.
Conclusion: The acinus-on-a-chip model offers a unique physiologically-relevant liver microenvironment to study the pathogenic progression from healthy-MASLD-MASH. It offers enhanced predictive insights compared with static models, enabling temporal tracking of cellular behaviour and secreted factors. Future studies will employ temporal-omics analyses to identify biomarkers and elucidate disease mechanisms - validated against patient data - which could aid diagnostic and therapeutic strategies in chronic liver disease.

FRI-355
Single-cell transcriptomics reveals THR-β agonist treatment increases macrophage proportion and inhibits complement pathway in mice with metabolic dysfunction-associated steatohepatitis
Feng Xue[1], Lan Wang[2], Haoran Xie[1], Peng Zhang[2], Lai Wei[1].
[1]*Hepatopancreatobiliary Center, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, Beijing, China;*
[2]*Department of Automation, Tsinghua University, Beijing, China*
Email: docxuefeng@163.com

Background and aims: Thyroid hormone receptor (THR)-β agonist resmetirom has been approved by the U.S. FDA as the first drug for the treatment of metabolic dysfunction-associated steatohepatitis (MASH). However, the effects of THR-β agonist treatment on different liver cell types and their interactions in the MASH context remain poorly understood.
Method: To explore the effects of the THR-β agonist HSK31679 on liver cell types and their interactions in MASH, we used a mouse model induced by a western diet. Mice were divided into two groups (n = 3 per group). Group A received HSK31679 (5 mg/kg) by gavage, while Group B received the solvent as a control. The treatment lasted for 28 days, after which liver tissue was subjected to single-cell sequencing.
Results: Seven liver cell subsets were identified: hepatocytes, liver macrophages, hepatic stellate cells, liver endothelial cells, B cells, dendritic cells, and plasma cells. Compared to the model group, the proportion of hepatocytes decreased in the HSK31679 treatment group, while proportions of liver macrophages, hepatic stellate cells, liver endothelial cells, B cells, dendritic cells, and plasma cells increased. Notably, liver macrophages showed the most significant increase. Gene ontology enrichment analysis revealed activation of the alternative and classical complement activation pathways in macrophages of the model group, which were suppressed in the HSK31679-treated group. In addition, communication between various liver cell subsets was enhanced in the HSK31679-treated group, particularly between hepatocytes and liver macrophages, hepatic stellate cells, liver endothelial cells, B cells, and dendritic cells. Communication between liver macrophages and other cells (hepatocytes, hepatic stellate cells, and endothelial cells) was also strengthened.
Conclusion: Treatment with the THR-β agonist HSK31679 in MASH mice resulted in an increased proportion of liver macrophages and suppressed complement activation pathways in these cells. Additionally, communication between liver cell subsets, particularly between hepatocytes and macrophages, was enhanced.

FRI-357
Liver disease activity measured with quantitative MRI is associated with major liver and cardiovascular events: a prospective cohort study
Edward Jackson[1], Andrea Dennis[1], Luis Núñez[1], John McGonigle[1], Rajarshi Banerjee[1]. [1]*Perspectum Ltd., Oxford, United Kingdom*
Email: edward.jackson@perspectum.com

Background and aims: Individuals with metabolic-dysfunction associated liver disease (MASLD) experience higher rates of mortality and morbidity. Our aim was to investigate the prognostic value of MRI-derived biomarkers of liver disease activity and liver fat in assessing the risk of experiencing major liver events, at the population level and in individuals with MASLD.
Method: UK biobank participants aged 40–70 years were scanned between 2016 and 2022. LiverMultiScan was used to measure inflammation via iron-corrected T1 (cT1, ms), and liver fat content (LFC, %). Outcomes were all-cause mortality, new-onset major liver and cardiovascular events, and non-infective liver disease-related related hospitalization from hospital and death records. Hazard ratios were reported, adjusted for age, sex and body mass index (BMI), and repeated in a subset of participants with MASLD for cT1 and LFC as continuous, normalised variables and thresholded at clinically relevant cutoffs. (cT1 between 800 ms and 875 ms, cT1 above 875 ms, LFC between 5% and 10% and LFC above 10%).
Results: 45,262 participants had available cT1 data (mean age 65 years, 52% female, 18% BMI ≥30 kg/m^2, 99% with LFC available) with a median follow-up time of 4 years (3–5). 11,560 met the diagnostic criteria for MASLD (mean age 65 years, 40% female, 40% BMI ≥30 kg/m^2). The median time to liver events was 27 months (13–42), and to CVD events was 27 months (14–41). Overall incidence rates per 1000 person-years were 0.4 for liver events (0.5 in MASLD sub-group) and 2.5 for liver hospitalization (4.7 in MASLD); 11 for CV events (14 in MASLD); and 3.2 for all-cause mortality (3.5 in MASLD). As a continuous variable, liver cT1 was associated with major liver events (HR 1.9 [1.6, 2.4]), liver hospitalisation (1.6, [1.5, 1.7]), CVD events (1.1 [1.0, 1.2]) and all-cause mortality (1.2, 1.1, 1.3). Liver fat was associated with liver hospitalization (1.5 [1.4, 1.6]). In the MASLD subset, continuous cT1 and LFC were associated with major liver events (cT1 2.3 [1.5, 3.4], LFC 1.5 [1.0, 2.1]). and liver hospitalisation cT1 between 800 and 875 ms was associated with liver hospitalisation (HR 3.2 [2.4, 4.4]), major liver events (2.6 [1.1, 6.2]), and all-cause mortality (1.7 [1.1, 2.3]). cT1 above 875 ms was associated with major liver events (14.5 [5.8, 36.6]) and liver hospitalisation (6.4 [4.0, 10.2]). LFC between 5 and 10% and LFC above 10% were associated with liver hospitalisation (1.7 [1.3, 2.2], 3.1 [2.4, 4.1]).
Conclusion: In a large-scale prospective study, MRI metrics of liver impairment are associated with liver hospitalisation and liver events in the general population and in a MASLD sub-set. Liver disease activity measured by cT1 is more strongly associated with risk of new-onset liver events than liver fat. cT1 is also associated with new-onset major cardiovascular events and all-cause mortality.

FRI-358
Anti-inflammatory effects of a chemokine receptor mimicking peptide in obesity-associated MASH and atherosclerosis in Ldlr −/− Leiden mice
Simon Ebert[1], Eveline Gart[2], Wim van Duyvenvoorde[2], Markus Brandhofer[1], Hendrik Wunderlich[3], Aphrodite Kapurniotu[3], Robert Kleemann[2], Martine C. Morrison[2], Jürgen Bernhagen[4]. [1]*Ludwig Maximilian University (LMU), Munich, Germany;* [2]*TNO, Leiden, Netherlands;* [3]*Technische Universität München (TUM), Munich, Germany;* [4]*Ludwig Maximilian University (LMU), Munich Cluster for Systems Neurology (SyNergy), Munich Heart Alliance, Munich, Germany*
Email: eveline.gart@tno.nl

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is one of the most prevalent chronic liver diseases, which is closely associated with obesity, dyslipidemia and

atherosclerotic cardiovascular disease. Inflammation is one of the driving forces in MASLD and atherosclerosis progression. Therefore, in this study, we investigated the potential anti-inflammatory effect of a novel peptide-based chemokine receptor ectodomain mimic, msR4M-L1, as a treatment for obesity-associated MASLD and atherosclerosis. msR4M-L1selectively inhibits the MIF/CXCR4 axis and blocks pro-inflammatory MIF activity *in vitro* and *in vivo*, an atypical chemokine known to play a role in both MASLD and atherosclerosis progression. The peptide has high proteolytic stability and spares the dichotomic CXCL12/CXCR4 and cardioprotective MIF/CD74 axis.

Method: Ldlr−/− Leiden mice were fed a high-fat diet (HFD) for 10 weeks to induce obesity dyslipidemia, atherosclerosis and MASLD features and subsequently treated for 14 weeks with msR4M-L1 (3x/week via i.p.) or vehicle (3x/week saline via i.p.) while continuing HFD feeding. Endpoints included plasma lipids, lipoprotein profile and histological analysis of MASLD and atherosclerosis in the aortic root as well as single nuclei RNA sequencing (snRNAseq) of aorta.

Results: After 24 weeks of HFD feeding, Ldlr−/− Leiden mice developed obesity, increased white adipose tissue weight, systemic low-grade inflammation, plasma dyslipidemia, MASLD and atherosclerosis. msR4M-L1 slightly increased body weight compared with the HFD-vehicle group, without affecting food intake or adiposity, an observation sparking future mechanistic studies. The peptide did not affect MASLD or atherosclerotic lesion size but improved circulating inflammatory factors and the vascular inflammatory status by increasing atheroprotective vascular macrophage populations and eliciting an anti-inflammatory transcriptional signature. These systemic and vascular anti-inflammatory effects of msR4M-L1 were associated with an increase in the number of smooth muscle cells (SMCs) within atherosclerotic plaques, contributing to a more stabile plaque phenotype.

Conclusion: Specifically targeting the MIF/CXCR4 axis attenuated HFD-induced low-grade inflammatory state and improved atherosclerotic plaque composition by increasing plaque-stabilizing SMCs, suggesting an overall atheroprotective role.

FRI-359

A 5-week treatment with the GLP-1/GIP/glucagon triple receptor agonist retatrutide demonstrates multiple metabolic benefits and strong reduction in liver steatosis in a diet-induced obese MASH mouse model

Francois Briand[1], Camille Le Cudennec[2], Marjolaine Quinsat[1], Natalia Breyner[1], Claire Bigot[1], Estelle Grasset[1], Pierre Dillard[2], Thierry Sulpice[1]. *[1]PHYSIOGENEX, ESCALQUENS, France; [2]JANVIER LABS, LE GENEST-SAINT-ISLE, France*
Email: f.briand@physiogenex.com

Background and aims: Retatrutide is a novel triple agonist of the glucose-dependent insulinotropic polypeptide, glucagon-like peptide 1 and glucagon receptors that demonstrated significant body weight loss and liver fat reduction in patients with obesity. Our aim was to evaluate the effectiveness of retatrutide in the AMLN-diet induced obese MASH mouse model, a preclinical model routinely used for preclinical drug development.

Method: C57BL/6JRj mice were fed the AMLN-diet for 35 weeks to induce obesity and MASH, before a 5-week treatment with vehicle or retatrutide 15 nmol/kg s.c. Q3D. A group of age-matched/control chow fed mice was included as negative control. Body weight, food/water intake, whole body composition and energy expenditure were monitored during the treatment period, then blood and liver were collected for biochemistry and histology analysis after 5 weeks of treatment.

Results: As expected, 5-week treatment with retatrutide strongly reduced body weight by 31% ($p < 0.0001$ vs. vehicle) with significant reduction in fat and lean mass. The weight loss was also associated with a strong inhibition of food and water intake during the first days of treatment and a significantly greater energy expenditure at the end of the treatment period. Compared with vehicle, retatrutide significantly reduced fasting blood glucose and plasma insulin, leading to a 69% lower HOMA-IR index of insulin resistance ($p < 0.0001$ vs. vehicle). Retatrutide did not alter plasma transaminases levels and fasting plasma triglycerides, but reduced total cholesterol levels (−37%, $p < 0.01$). Compared with vehicle, retatrutide markedly decreased liver mass (−44%, $p < 0.0001$) and strongly reduced hepatic fatty acids, triglycerides and total cholesterol content (-66%, – 75% and 45%, all $p < 0.001$). Although the 5-week treatment period did not reduce hepatic inflammation and portal fibrosis, histology analysis also showed a 2-fold lower steatosis score with retatrutide ($p < 0.0001$ vs. vehicle).

Conclusion: In the AMLN-diet induced obese MASH mouse model, a 5-week treatment with retatrutide demonstrates multiple metabolic benefits and a strong reduction in liver steatosis. This preclinical data set will help to further assess the efficacy of novel therapies targeting obesity and MASH versus retatrutide as reference.

FRI-360

Sex-based differences in immune response and liver damage in MASLD-associated sepsis: role of neutrophil extracellular traps

Flavia Savino[1,2], Carlos Cuño-Gómiz[1,2], Anna Tutusaus[1,3], Patricia Rider[1,2,3], Diba Zare[1,2], Pablo Garcia de Frutos[1,4], Albert Morales[1,3], Montserrat Marí[1,3]. *[1]Institute of Biomedical Research of Barcelona (IIBB-CSIC), Institut d'Investigacions Biomèdiques August Pi I Sunyer (IDIBAPS), Barcelona, Spain; [2]Departament de Biomedicina, Facultat de Medicina, Universitat de Barcelona, Barcelona, Spain; [3]CIBEREHD, ISCIII, Madrid, Spain; [4]CIBERCV, ISCIII, Madrid, Spain*
Email: monmari@clinic.cat

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD), the most prevalent liver disease worldwide, is characterized by liver damage, fibrosis, and inflammation. Its progressive form, MASH, has been recently confirmed as an independent risk factor for sepsis, a life-threatening systemic response to bacterial infection. In sepsis, the participation of neutrophils remains unclear. While neutrophil extracellular traps (NETs) function to remove pathogens, excessive NETs release has been proposed to contribute to organ damage during sepsis. However, the role of NET formation and their clearance in experimental MASLD and following sepsis, as well as potential sex-based immune response differences, have not been reported.

Method: MASLD was induced in 8- to 10-week-old wild-type (WT) C57BL/6J male and female mice using a high-fat, choline-deficient diet (HFCD) with 60% kcal from fat and 0.1% methionine. After four weeks on the HFCD, mild sepsis was induced via intraperitoneal injection of lipopolysaccharide (LPS, 10 mg/kg, LD50). Mice were sacrificed 6- or 16-hours post-injection. Liver damage was assessed by ALT levels. Serum levels of inflammatory cytokines IL-6 and TNF-α, neutrophil elastase (NE), liver tissue IL-1β, and citrullinated histone H3 (H3cit, a marker of NET formation) were measured by ELISA. Inflammatory gene expression was analyzed by qPCR. Immunofluorescence was used to detect NETs in hepatic tissue, acquired in a Leica Stellaris 8 dive confocal microscope, and analyzed with ImageJ/Fiji.

Results: Following LPS administration, hepatic damage (ALT) peaked earlier in male MASLD mice compared to MASLD females, while chow-fed mice of either sex showed no liver damage. Inflammatory cytokines at the 6-hour mark were significantly elevated in males compared to females, both in serum protein levels and liver mRNA expression. However, 16 hours post-LPS, MASLD males exhibited reduced liver damage compared to MASLD females, which displayed persistent hepatic injury that correlated with increased presence of NETs in liver as compared to MASLD males. In accordance, higher H3cit levels in tissue, confirmed the increased presence of NETs in the livers of MASLD females.

Conclusion: This study highlights significant sex-based differences in immune response and liver damage in MASLD-associated sepsis. In

similar MASLD conditions, while males displayed an earlier inflammatory response with quick resolution at later stages, females showed a persistent injury paralleled by enhanced NET formation and aggravated hepatic damage. Our results suggest NET formation as participating mechanism in the susceptibility to sepsis observed in female MASLD patients, underscoring the study of NETs as potential target for personalized strategies in sepsis treatment.

FRI-365

DR10624, a novel FGF21R, GCGR, and GLP-1R tri-agonist, demonstrated extraordinary efficacy in B6-Alms1-del mice, a spontaneous MASH model of mice with obesity, hyperglycemia, and dyslipidemia phenotype

Yongliang Fang[1], Wenwen Duan[1], Yonglu Chen[1], Qianwen Zhao[2], Jie Li[2], Yanshan Huang[1]. [1]*Zhejiang Doer Biologics Co., Ltd., Hangzhou, China;* [2]*Department of Infectious Disease, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China*
Email: fyl323@gmail.com

Background and aims: DR10624 is a novel long-acting tri-specific therapeutic protein with agonistic activity against FGFR1c/Klothoβ coreceptor (FGF21R), Glucagon receptor (GCGR), and GLP-1 receptor (GLP-1R). In non-clinical studies, DR10624 has shown extraordinary potency in terms of reduced body weight, normalized blood lipids, and improved glycemic control, making it a promising candidate for the treatment of metabolic dysfunction-associated steatohepatitis (MASH).

Method: Thirty-five B6-Alms1-del mice, a spontaneous metabolic dysfunction-associated steatohepatitis (MASH) model of mice, were selected for a 6-week study. The mice were randomly divided into five groups of seven: G1 (normal control), G2 (model control), G3 (Semaglutide 30 nmol/kg), G4 (DR10624 3 nmol/kg), G5 (DR10624 10 nmol/kg), and G6 (DR10624 20 nmol/kg). Blood samples were collected at week 3 and 6 to assess liver function and lipid profiles. At the end of the study, liver weights were recorded, liver lipid content (TC and TG) were analysed. Liver tissues from the left, middle, and right lobes were paraffin-embedded for hematoxylin and eosin (H&E) staining to assess the NAFLD Activity Score (NAS) and Picrosirius Red (PSR) staining to evaluate fibrosis.

Results: DR10624 showed dose-dependent liver protection and antihyperlipidemic effects, evidenced by significantly reduced ALT, AST, Choloesterol, and LDL-C levels. Both Semaglutide and significantly reduced liver weight, liver index, and hepatic TC and TG, but DR10624 was more effective at all dose levels. DR10624 (3, 10, and 20 nmol/kg) significantly reduced steatosis, inflammation, and ballooning, leading to a lower NAS score compared to the model control ($p < 0.0001$). While Semaglutide (30 nmol/kg) reduced inflammation and the overall NAS score, DR10624 exhibited superior effects in reducing steatosis and ballooning. Compared to the normal control, all groups (model control, Semaglutide, and DR10624) exhibited mild fibrosis. However, the model control group had a higher proportion of grade 2 fibrosis and a lower proportion of grade 0 fibrosis. Both Semaglutide and DR10624 reduced the proportion of grade 2 and 1C fibrosis and increased the proportion of grade 0 fibrosis, indicating improved fibrosis. While both treatments were effective, DR10624 appeared to have a slightly weaker antifibrotic effect than Semaglutide, as evidenced by a higher proportion of lower-grade fibrosis.

Conclusion: DR10624 significantly improved liver pathology in B6-Alms1-del mice, a spontaneous MASH model of mice. It also effectively reduced body weight, improved liver and blood lipid profiles, and ameliorated liver function, which all outperformed Semaglutide. DR10624's preclinical study demonstrated its great potential as a possible best-in-class biotherapy for the treatment of MASH patients.

FRI-366

Integrated analysis of the liver tissue proteome and transcriptome in metabolic dysfunction-associated steatotic liver disease (MASLD) reveals an evolving pathophysiological milieu that may support identification of novel therapeutic targets

Background and aims: Greater understanding of pathophysiological changes as Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) progresses to cirrhosis will inform the identification of new therapeutic targets. Previous studies have compared the hepatic transcriptome with the circulating proteome, but have been unable to simultaneously survey transcriptomic and proteomic changes within the liver itself. This is the first large-scale multi-omics study to carry out comprehensive analyses of the evolving liver proteome and transcriptome across the full spectrum of MASLD.

Method: Simultaneous extraction of mRNA and proteins was conducted from the same tissue sample in a cohort of 122 well-characterised, histologically confirmed, MASLD cases selected from the European SLD (NAFLD) Registry. Using untargeted LC-MS/MS proteomics, we measured the expression of 4,815 hepatic proteins and conducted global RNA-sequencing, detecting 35,390 mRNA signals in total. These datasets were then integrated with publicly available scRNA-sequencing data to explore correlations between genomic and proteomic expression changes and the expression of potential therapeutic targets during MASLD progression.

Results: We demonstrated a considerable positive correlation between protein and mRNA expression (Spearman's Rho = 0.5, *p*-value = 2.2e-16). The markers exhibiting the strongest correlation were significantly enriched in metabolic processes, with many highly localised to hepatocytes. Proteins linked to lipid, retinol and cholesterol metabolism (AKR1B10, TM7SF2 and SULT2A1) were observed to increase with worsening fibrosis. We also identified proteins enriched in carbohydrate, lipid, homocysteine and glycine metabolism (GALK1, PLIN1, GNMT and BHMT) to decrease particularly at the cirrhotic stage, indicating strong metabolic changes within hepatocytes throughout disease progression. In addition, tissue remodelling and progenitor cell markers (CAPG, TAGLN, FBLN5 and KRT7) were highly correlated between transcriptomic and proteomic levels increasing with advancing fibrosis. We then carried out differential expression analysis comparing milder

(fibrosis stages 0–2) and advanced disease (fibrosis stages 3–4) to investigate significance. We discovered 26 candidates to be differentially expressed at both the transcriptomic and proteomic levels, 9 of which were amongst the most correlated, with an additional 17 proteo-transcriptomic markers significantly changing in advanced MASLD.
Conclusion: The current study provides new insights into the changing proteo-transcriptomic profile of the liver throughout the pathophysiological evolution of MASLD. It suggests optimum treatment targets/drug mechanisms of action may change as the disease progresses and has clinically relevant implications that will help guide future drug development.

FRI-367
Pathophysiological mechanisms involved in liver steatosis in metabolic dysfunction-associated steatotohepatitis over time : a bulk RNAseq data analysis
Guillaume Henin[1,2], Alvy Lamotte[1], Maxime Nachit[1], Axelle Loriot[3], Isabelle Leclercq[1], Nicolas Lanthier[1,2]. Email: ghenin1993@gmail.com

Background and aims: Liver steatosis results from metabolic dysregulations of lipid homeostasis. Drugs targeting lipid metabolism are being evaluated in clinical trials with inconsistent results. We suggest that steatosis pathophysiology evolves with MASLD progression resulting in a mismatch between the deregulated mechanisms and the drug used. Our aim is to analyze the evolution of gene expressions of key lipid metabolism genes during MASH progression in mice.
Method: *Foz/foz* mice (FOZ) were fed normal diet (ND) (3.39 kcal/g, 16% of lipids) or high-fat diet (HFD) (5.24 kcal/g, 60% of lipids). Liver tissue was harvested at baseline (control group, N = 5) and after 4 (HFD = 4), 12 (HFD = 8) or 32 (HFD = 6) weeks. Liver samples were scored histologically (SAF score) using hematoxylin & eosin staining. Total RNA from liver samples was extracted using Qiagen® mini kits prior to bulk RNA sequencing. Sequencing data were normalized according to timepoint and diet (RStudio). Differentially expressed genes (DEG) and enrichment analysis reported by the Normalized Enrichment Score (NES) of FOZ HFD mice were compared at each timepoint with the control group.
Results: Maximal liver weight to body weight ratio was reached at 32 weeks ($p < 0.001$). Insulin resistance assessed by the HOMA-IR index was present at 4 weeks of HFD ($p < 0.01$). Liver histology showed the whole MASH spectrum with transcriptomics changes over time. At week 4, steatosis was observed with 284 DEG notably involved in fatty acid biosynthetic process (NES = 13.9, padj = 1.2e-4), lipid transport (NES = 9.7, padj = 8.0e-8), lipid storage (FES = 21.5, padj = 3.0e-6) and fatty acid oxidation (FAO) (NES = 9.4, padj = 0.02). At week 12, steatohepatitis was observed with 469 DEG involved in 504 enriched pathways including lipid transport (NES = 14.7, padj = 3.6e-15), lipid storage (NES = 24.2, padj = 1.66e-7) and FAO (NES = 22.2, padj = 2.7e-7). At week 32, fibrosing steatohepatitis was observed with 750 DEG involved in 1167 enriched pathways including lipid transport (NES = 11.3, padj = 6.3e-21), lipid storage (NES = 24, padj = 1.4e-15) and FAO (NES = 11, padj = 7.4e-7). At the gene level, the lipid metabolism key regulator Pparɣ was downregulated in a time-dependent manner: Log2FC = – 1.6, padj = 9e-5 at week 4; Log2FC = –1.8, padj = 9e-6 at week 12 and Log2FC = –2.35, padj = 6.6e-9 at week 32. Fatty acid oxidation related genes are all downregulated at week 12, such as Obp2a (Log2FC = –3.17, padj = 0.003) and Acaa1b (Log2FC = –1.64, padj = 9.9e-9). Lipid storage genes expression also greatly change over time. Both Cidec and Fitm1involved in lipid droplet homeostasis are significantly downregulated at week 12 (Log2FC = –2.13, padj = 3e-6; Log2FC = –1.37, padj = 1.68e-7 respectively) and at week 32 (Log2FC = – 2.7, padj = 2e-5; Log2FC = –1.02, padj = 2e-4 respectively).
Conclusion: Gene expression of key-lipid metabolism genes significantly change over time during MASH occurence. These shifts in gene expression of potential therapeutic targets may significantly influence the response to MASLD treatments.

Email: giorgia.benegiamo@epfl.ch

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD), and its more severe form, metabolic dysfunction associated steatohepatitis (MASH), are a public health burden with high unmet therapeutic need. About one quarter of the general population has MASLD, but only about 20% of these patients will progress to develop MASH. The specific pathways involved in the MASLD-to-MASH transition are not fully elucidated. In a previous study we found large variability in MASLD/MASH susceptibility between genetically different mouse strains and identified highly sensitive and completely resistant strains. We used this information to design a 4-way F2 genetic cross to map novel quantitative trait loci (QTL) involved in disease susceptibility and find novel potential therapeutic targets.
Method: We performed a 4-way intercross of the strains with the highest (PWK/PhJ), intermediary (C57BL/6J and 129S1/SvlmJ) and lowest (CAST/EiJ) susceptibility to MASLD/MASH. 500 genetically unique F2 mice (250 males and 250 females) from this cross were fed a "western" style diet (WD) and were housed at thermoneutrality (30°C) for 17 weeks to induce metabolic dysfunction and MASLD/MASH. We measured activity, food intake, energy expenditure and respiratory exchange ratio (by the CLAMS system at week 0 and 13), body composition (by EchoMRI at week 0, 7 and 15) and body weight (bi-weekly). Plasma and urine were collected at week 0, 7 and 15. We quantified several disease biomarkers in the plasma (including ALT, AST, cholesterol and TIMP-1), performed histological analysis of the livers to quantify steatosis and fibrosis, as well as liver RNA-seq and proteomics.
Results: Analysis of the evolution of the body weight and body composition revealed a large variation in body weight and body fat gain in the F2 population, with a subset of mice being completely resistant to body fat gain. Unbiased hierarchical clustering of liver disease phenotypes identified 4 different clusters covering the whole spectrum of MASLD/MASH severity. Analysis of the transcriptomes allowed to identify distinct gene expression signatures that characterize different stages of MASLD and MASH severity. We found several genetic loci associated with obesity phenotypes and liver disease. By combining QTL analysis on clinical phenotypes (cQTL), transcriptome (eQTL) and proteome (pQTL), and validating the results in large human cohorts, we are now refining a list of novel candidate genes involved in MASLD and MASH susceptibility.
Conclusion: The F2 mouse population that we generated covers a very wide range of genetic susceptibility to resistance to MASH. In combination with human genetic data our data is an ideal tool to discover causative genes of both susceptibility to MASLD and the transition to MASH that are generalizable to humans.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a prevalent condition affecting approximately 30% of adults worldwide. It is characterized by hepatic steatosis, obesity, type 2 diabetes, and hypertension. Emerging evidence suggests that epigenetic alterations play a pivotal role in the development of MASLD. Lysine-specific demethylase 1 (LSD1) stands out as a key player in regulating chromatin structure and transcriptional control through the demethylation of histone 3 lysine 4 or lysine 9. Transcriptomic and proteomic analyses have revealed alterations in lipid metabolism gene expression profiles, indicating the involvement of LSD1 in MAFLD pathogenesis.
Method: To investigate the role of LSD1 in MAFLD development, we employed a high-fat diet mouse model. Systemic and hepatocyte-specific LSD1 inhibition were achieved using a LSD1 inhibitor or liver-specific conditional transgenic LSD1 mutation, respectively, after administration of adeno-associated virus (AAV). RNA-seq from these livers and adipose tissue showed a dysregulation in the chemokine expression profile. Additionally, primary hepatocytes were isolated to further explore the functional significance of LSD1 in MAFLD.
Results: Liver histology demonstrated a significant reduction in steatosis, accompanied by notable weight loss and healthy liver enzyme values after systemic LSD1 inhibition. Notably, hepatocyte-specific LSD1 inactivation also resulted in diminished fat accumulation, although to a lesser extent compared to systemic pharmacological LSD1 inhibition. Transcriptomic analysis of liver tissue from systemic LSD1-inhibited mice revealed marked alterations in lipid metabolism, particularly in genes involved in lipid transportation. Furthermore, chemokine expression profiles were reduced after LSD1 inhibition that favors the decrease in steatosis. Moreover, single nuclei-RNA sequencing from liver-specific LSD1 inactivation revealed an imbalance in proteostasis and stress response.
Conclusion: This study underscores the crucial role of LSD1 in MAFLD development. By altering hepatic lipid metabolism, proteostasis and chemokine expression profile.

Hepatoprotective effects of efruxifermin treatment in GAN diet-induced obese and biopsy-confirmed mouse model of MASH

Henrik B. Hansen[1], Susanne Pors[1], Jacob Nøhr-Meldgaard[1], Michael Feigh[1]. [1]*Gubra A/S, Hørsholm, Denmark*
Email: hbh@gubra.dk

Background and aims: Efruxifermin (EFX, a long-acting FGF21 analogue) is currently in phase 3 clinical development for the treatment of metabolic dysfunction-associated steatohepatitis (MASH). This study aimed to investigate the therapeutic benefits of EFX on metabolic, biochemical, histopathological and transcriptomic profile in the Gubra Amylin NASH (GAN) diet-induced obese (DIO) and biopsy-confirmed mouse model of MASH with liver fibrosis.
Methods: Male C57BL/6 mice were fed GAN diet, high in fat, fructose and cholesterol for 36 weeks prior to study start. A liver pre-biopsy was collected 4 weeks before treatment start. Only GAN DIO-MASH mice with NAFLD Activity Score (NAS $\geq$ 5) and fibrosis stage F2–F3 were included and stratified into treatment groups. EFX (1 mg/kg) or vehicle was administered subcutaneously once weekly for 12 weeks. Histopathological pre-to-post individual assessment of NAS and fibrosis stage was performed. Other endpoints included quantitative liver histomorphometry, blood and liver biochemistry and liver RNAsequencing.
Results: EFX promoted vehicle-corrected weight loss of approx. 14% and improved hepatomegaly as well as liver (triglycerides, total cholesterol) and plasma (transaminases, total cholesterol, LDL/HDL cholesterol) biomarkers. EFX promoted a $\geq$2-point statistically significant improvement in NAS, driven by reductions in steatosis and lobular inflammation scores. These findings were supported by quantitative liver histology of steatosis (lipid-laden hepatocytes, lipid droplet size) and inflammation (CD45, galectin-3). EFX did not improve fibrosis stage, albeit reduced histological markers of fibrosis (PSR, Collagen 1a1) in addition to hepatic stellate cell marker (α-SMA) for fibrogenesis. Finally, EFX induces transcriptomic regulation and reduced gene expression involved in inflammation and extracellular matrix production.
Conclusion: EFX treatment improved metabolic and biochemical parameters, as well as histological markers of steatosis, inflammation and fibrosis/fibrogenesis. In addition, EFX improved histopathological NAFLD Activity Score, with longer treatment intervention needed for observing fibrosis stage improvement. The therapeutic effects of EFX highlight the translatability and applicability of the GAN DIO-MASH mouse model in preclinical drug discovery.

FRI-371-YI

Serum lipidome heterogeneity in MASH patients identifies DNA damage as predominant hit in one subtype

Email: patricia.aspichueta@ehu.eus

Background and aims: The heterogeneity of metabolic-associated steatotic liver disease (MASLD), linked to genetic and environmental factors and comorbidities difficulties finding effective treatments. Among the diversity of MASLD, dysregulation of pathways involved in lipid and lipoprotein metabolism play a prominent role. Thus the aims were: 1) to classify patients with MASH according to the serum lipidome of five models of diet-induced MASH, identifying the most prevalent profile; 2) to identify the involvement of the predominant hit in the metabolic dysregulation according to the classification of the serum lipidome, proposing targets for treatment.
Method: Serum lipidome analysis was performed on five diet-induced mouse models of MASH (52 weeks of Choline deficient high-fat diet (HFD); 52 weeks of HFD; 10 weeks of HF/H Sucrose; 17 weeks of HF H Cholesterol (1.5%) and diethylnitrosamine (DEN) followed by 26 weeks of HFD. Serum lipidome was also analyzed in a cohort of biopsy-proven MASH patients (n = 324) and metabolically healthy individuals (n = 302). The 25 most representative metabolites of each mouse model were used to classify MASH patients according to the altered mechanism dividing the patients into five categories. Hepatic lipidome, hepatic proteome analysis, mitochondrial complex activity and serum parameters were analyzed in the biopsy-proven Biobizkaia MASLD cohort (n = 103).
Results: Of the 324 patients, the greater number (n = 109) fell into the DEN-HFD category, the predominant hit being DNA damage (DD) and related DD response. The serum lipidomic signature of "DD-related MASH" was associated with changes in species of sphingolipids and phospholipids. To validate the role of DD in MASH, the Biobizkaia cohort was divided into MASH patients with levels of the DD marker pH2AX above the mean and below the mean. MASH patients with higher pH2AX levels had a worse metabolic status, increased hepatic triglyceride (TG) and dygliceride (DG) species and inefficient fatty acid oxidation despite increased mitochondrial complex IV activity. Accordingly, proteome analysis of patients with MASH and high DD showed remodelling of pathways involved in lipid and lipoprotein metabolism, as well as those involved in the cell cycle. The metabolic and cell cycle regulator E2F2, increased in MASLD, promoted DD and DDR in primary cultures of hepatocytes while its deficiency protected against DD. Upon DD the intracellular lipid deposition promoted by E2F2 overexpression was abolished when hepatocytes were treated with the DDR inhibitor ceralasertib by increasing FAO.
Conclusion: DD is a driving mechanism of MASH, causing metabolic changes that favour the progression of the pathology. MASH-related E2F2 overexpression exacerbates DD-associated progression and targeting DDR when E2F2 levels are high may be a valuable tool to prevent further metabolic dysregulation in this MASH subtype.

FRI-372
MASH-in-a-dish: a multicellular pre-clinical model to identify targetable metabolite crosstalk in MASH

Jung-Chin Chang[1], Annika Sullock Enzlin[1], Saskia van Essen[1], Rachel Thomas[1], Laura Bongiovanni[1,2], Thomas Kluiver[3], Weng Chuan Peng[3], Esther Zaal[1], Bart Westendorp[1], Alain de Bruin[1], Bernd Helms[1], Celia Berkers[1]. *[1]Division Cell Biology, Metabolism & Cancer, Department of Biomolecular Health Sciences, Utrecht University, Utrecht, Netherlands; [2]Department of Veterinary Medicine, University of Teramo, Teramo, Italy; [3]Princess Máxima Center for Pediatric Oncology, Utrecht, Netherlands*
Email: j.chang1@uu.nl

Background and aims: Affecting more than 25% of the world population, metabolic dysfunction-associated steatotic liver disease (MASLD) is becoming the leading cause of liver failure and liver cancers. Progression of MASLD from benign steatosis to metabolic dysfunction-associated steatohepatitis (MASH) is characterized by sterile inflammation and progressive fibrosis. Metabolites are now recognized as potential signaling molecules. For instance, itaconate, an immunometabolite, can signal via protein cysteine alkylation. Metabolite crosstalk amongst steatotic hepatocytes, Kupffer cells (KCs), and hepatic stellate cells (HSCs) underlies MASH pathogenesis but is challenging to study using *in vivo* models. The present study aims to establish a multicellular co-culture model that (1) mimics clinical MASH phenotypes and (2) allows identification of key metabolite crosstalk in MASH.
Method: We developed "MASH-in-a-dish," a Transwell™ co-culture system of primary mouse hepatocyte organoids (HepOrgs), primary mouse KCs, and primary mouse HSCs. MASH-in-a-dish enabled rapid cell type separation in 1 minute, effectively preserving the cell-type-specific metabolomes. MASH was induced by 4-day treatment with a MASH lipid mix, formulated based on lipidomes of human MASH livers and sera. Different cell type combinations were employed to identify crosstalk metabolites. Clinically relevant MASH readouts were used for validation, including steatosis and hepatocyte ballooning (histology), liver damage marker (aspartate transaminase), inflammation (IL-6, TNFα, C-reactive protein), and fibrosis (type I collagen). Liquid-chromatography-mass-spectrometry-based (LC-MS) metabolomics with $^{13}C_6$-glucose tracing was performed to identify crosstalk metabolites in the MASH condition.
Results: Treatment with MASH lipid mix caused steatosis and ballooning-like changes in 90% and 40% of the HepOrgs, respectively. The MASH lipid mix also significantly induced secretion of inflammatory cytokines by KCs and type I collagen by HSCs. Semi-targeted metabolomics showed that MASH lipids enhanced secretion of several Krebs cycle metabolites, urea cycle metabolites, acetyl-L-carnitine, and itaconate in a co-culture dependent manner. Analysis of intracellular metabolomes in MASH-in-a-dish confirmed KCs as the source of itaconate. $^{13}C_6$-Glucose tracing revealed that the MASH lipid mix decreased ^{13}C labelling in itaconate, suggesting that fatty acids replaced glucose as a carbon source for increased itaconate production in MASH. Crosstalk signaling via itaconate from KCs to HepOrgs was supported by increased levels of itaconate and itaconate-cysteine adduct in the HepOrgs.
Conclusion: MASH-in-a-dish models key clinical features of MASH and identifies itaconate as a lipid-driven crosstalk metabolite between Kupffer cells and hepatocytes. Our findings provide mechanistic insights into increased itaconate in livers of MASH patients.

FRI-373
Calciprotein crystallization assay as calcification biomarker in metabolic-dysfunction associated steatotic liver disease population

Joyce Xu[1,2], Stan Driessen[3], Koen van Son[3,4], Joost PH Drenth[4], Maarten Tushuizen[5], Robert de Jonge[1], Marc Vervloet[6], A.G. (Onno) Holleboom[3], Henrike Hamer[1]. *[1]Amsterdam UMC, department of Laboratory Medicine, Laboratory of Specialized Diagnostics and Research (LGDO), Amsterdam, Netherlands; [2]Amsterdam UMC, department of Neprhology, Amsterdam, Netherlands; [3]Amsterdam UMC, department of Vascular Medicine, Amsterdam, Netherlands; [4]Amsterdam UMC, department of Gastroenterology and Hepatology, Amsterdam, Netherlands; [5]LUMC, department of Gastroenterology and Hepatology, Leiden, Netherlands; [6]Radboudumc, department of Nephrology, Nijmegen, Netherlands*
Email: j.y.xu@amsterdamumc.nl

Background and aims: Vascular calcification (VC) is commonly present in patients diagnosed with metabolic-dysfunction associated steatotic liver disease (MASLD). The pathogenesis of VC is multifactorial. One of the pathways is an abnormal metabolism of calciprotein particles (CPP) which is possibly involved in the development of VC in patients with MASLD. Physiological CPP scavenge calcium phosphate salts in the blood circulation. The primary form of CPP is formed around the glycoprotein fetuin A which is produced in the liver. Overload of phosphate/calcium or decrease of fetuin A induces the transition of primary CPP to its crystallized form which drives VC. The novel T50 test measures the transition time to crystalline CPP expressed in minutes. The reference range of T50 ranges from 270 to

470 min. Previous studies have shown that lower T50 values correlate with a greater risk of VC, and cardiovascular and all-cause mortality. In this study, we tested the hypothesis that patients with MASLD with severe liver stiffness suppresses the expression of fetuin A leading to a shorter transition time to crystalline CPP, thus a lower T50.
Method: A retrospective case-control study was conducted including 42 patients at cardiometabolic risk who had been screened for fibrotic MASLD. Two groups were formed based on the liver stiffness measurement (LSM): a group with fibrotic MASLD (high LSM of ≥10 kPa), and a control group without fibrotic MASLD (low LSM of ≤7 kPa). Groups were matched for age, sex, smoking and type 2 diabetes mellitus. The T50 values and fetuin A levels were measured in all patients and statistically analyzed with paired t-test.
Results: The mean LSM for the high and low LSM groups were 14.0 ± 5.3 and 4.9 ± 1.1 kPa, respectively. Additionally, the mean controlled attenuation parameter (CAP) score for the high LSM group was 328.1 ± 42.8 dB/m, and 286.9 ± 58.2 dB/m for the low group. Fetuin A levels were significantly lower in the patients with high LSM (mean = 0.28 ± 0.03 g/L) compared to low LSM (0.32 ± 0.06 g/L; p = 0.041). The mean T50 did not differ between the high (419 ± 67 min) and low LSM groups (376 ± 60 min; p = 0.054).
Conclusion: Fetuin A levels were lower in patients with fibrotic MASLD, but this did not translate into worsening T50 values. The T50 values in patients with MASLD were comparable to those found in the general population. Moreover, the absence of difference in T50 observed in patients with high liver stiffness compared to low liver stiffness argues against a role of abnormal CPP metabolism in the development of VC in patients with MASLD. Therefore, in patient with MASLD the measurement of the T50 does not appear to have added value in the stratification of patients at risk for VC.

Hepatic peroxisome proliferator-activated receptor gamma coactivator-1- alpha impacts the secretion of SerpinA3N in response to obesogenic diets in mice through induction of oxidative stress response in hepatocytes
James Eng[1], Philipa Levesque-Damphousse[1], Aurele Besse-Patin[2], Philippe Besse[3], Daina Avizonis[2], Jennifer Estall[1]. [1]*Institut de recherches cliniques de Montreal (IRCM), Montreal, Canada;* [2]*McGill University, Montreal, Canada;* [3]*Universite de Toulouse, Toulouse, France*
Email: james.eng@ircm.qc.ca

Background and aims: The liver has a critical role in metabolism by maintaining homeostatic levels of circulating macronutrients. For instance, when blood glucose is decreasing, the liver will increase glucose output, while excess blood glucose is absorbed and stored in the liver. Chronic excessive caloric intake will eventually overwhelm the ability of the liver to maintain energetic homeostasis leading to Metabolically Associated Steatotic Liver Disease (MASLD), characterized by lipid accumulation in the liver and progressive loss of hepatic function. It is well understood that regulation of metabolic homeostasis is a highly coordinated process involving many organs working together. This high level of coordination is achieved through organ crosstalk via secreted signaling molecules and proteins. What remains poorly understood is how the signals being sent by the liver change in the development of MASLD, and how this change influences the metabolism and health of other organs. We aim to investigate how the secretome of hepatocytes responds to metabolic challenges to better understand the progression of MASLD and the influence of the liver on extrahepatic organs.
Method: Hepatocytes from mice with a 50% reduction of peroxisome proliferator activated-receptor gamma coactivator 1 - alpha (PGC-1alpha), complete loss of PGC-1alpha, fed chow or high fat, high fructose diet for 6 weeks were isolated and the hepatocyte secretome compared between diets and genotypes. Top candidates were explored at the gene and protein level in primary mouse hepatocytes, liver, and plasma. Western blot and ELISA analysis determined hepatic and circulating hepatokine levels. Primary hepatocytes were treated with various chemical and biological inducers of inflammation and oxidative stress and secreted SERPINA3N was measured by western blot.
Results: SERPINA3N, CCL2, antileukoproteinase, and clusterin were identified as strongly influenced by diet and/or PGC-1alpha *in vitro*. Further analysis showed that circulating SERPINA3N was strongly influenced by diet and genotype in a similar manner *in vivo*, while plasma CCL2, antileukoproteinase, and clusterin were not significantly altered. Liver of PGC-1alpha knockout and high fat, high fructose fed mice demonstrate increased oxidative stress markers. Inducing oxidative stress in primary hepatocytes was sufficient to stimulate SERPINA3N expression and secretion.
Conclusion: Our data identified SERPINA3N as a hepatokine that increases in response to an obesogenic diet, an induction impaired by loss of PGC-1a. These data indicate that changes in hepatic SERPINA3N secretion could be an adaptive response to metabolic oxidative stress.

Background and aims: Fatty acid synthase (FASN) is an enzyme in the de novo lipogenesis (DNL) pathway that converts the metabolites of dietary sugars into the saturated fatty acid palmitate, a precursor of triglycerides and other lipotoxic lipids. The first-generation FASN inhibitor Denifanstat reduces liver steatosis, inflammation, and fibrosis in MASH patients. It is also associated with adverse events, including alopecia, that may limit its clinical utility. Here, we aimed to develop novel targeted FASN inhibitors that retain liver-specific benefits while minimizing exposure to other tissues.
Method: Intrinsic potency was measured using recombinant rat FASN in a fluorescent-based biochemical assay. In vitro DNL inhibition was conducted in primary hepatocytes and other cell types. Initial in vitro safety screen consisted of CYP inhibition and CEREP safety panel of 44 receptors. Predicted clearance was estimated based on metabolic stability in primary hepatocytes. Pharmacokinetic profiling in rats and dogs was used to determine liver exposures, tissue partitioning, and oral bioavailability. Single dose in vivo studies of liver DNL inhibition were conducted in rats.
Results: Lead molecule optimization focused on improving liver-to-plasma partitioning in rodents and enhancing in vitro metabolic stability in multiple species. The resulting candidate, BJT-188, is a potent inhibitor of FASN with an EC_{50} value <100 nM in primary human hepatocytes. Additionally, BJT-188 demonstrated high specificity, showing no inhibition of major CYPs or the 44 human receptors tested, including hERG. In rats, a single oral dose of BJT-188 at 20 mpk resulted in rapid and high exposure to the liver, with minimal levels detected in plasma and other tissues. In a rat PK/PD model, BJT-188 achieved rapid and complete inhibition of hepatic DNL while maintaining low systemic exposures. Lastly, the PK profile of BJT-188 in non-rodent species supports the potential for once-daily dosing in humans.
Conclusion: BJT-188 is a potent and selective FASN inhibitor with high liver-to-plasma partitioning and low potential for alopecia. BJT-188 is currently progressing towards IND enabling studies.

[4]*University Hospital Wales, Wales, United Kingdom*
Email: jeni123@live.com

Background and aims: The non-alcoholic fatty liver disease activity score (NAS) is applied to liver biopsies to adequately diagnosis metabolic dysfunction-associated steatohepatitis (MASH). Whilst NAS scores are not routinely reported, they are often required for research purposes and retrospectively applying scores can be costly and time-consuming. We investigated whether a team of trained non-experts, using dedicated computer software, could score biopsy images with a quality comparable to that of an expert pathologist.
Method: Liver biopsy slides were scanned to a digital image viewing software. A national health service (NHS) Consultant Pathologist, with subspecialty interest in liver pathology, trained a group of non-clinical medical annotators to grade slides using the NAS criteria. The medical annotators used a partially adjusted grading system. Slides were viewed using Zeiss Zen 3.10 software on 24 inch monitors at a resolution of 1920 × 1200 and 5x zoom. Hepatocyte ballooning and inflammation were assessed by randomly selecting three sample regions across the biopsy slide and counting the number of ballooned hepatocytes and lobular inflammation nodes within each sample. Medical annotators also had access to a NAS scoring guide prepared specifically for this project. The pathologist sampled 20% of the images and graded them, to assess inter- and intra-observer (medical image annotator) agreement. A linearly weighted Cohen's kappa was applied for agreement calculations.
Results: Ninety-one liver biopsies were obtained from 85 distinct patients. Agreement was best for steatosis percentage, with 0.78 kappa between the team median and the pathologist, and 0.62–0.83 within the team itself. The number of portal tracts scored 0.55 agreement and 0.45 for fibrosis. Inflammation scored the lowest at 0.41 kappa between the team median and pathologist. Consistency of ballooning score was the lowest within the medical annotator team, 0.07–0.26 kappa, but 0.48 between the team median and pathologist. Overall NAS score agreement was 0.42 (0.19–0.51).
Conclusion: Medical annotators were able to apply NAS scores. Agreements scores were moderate to substantial according to kappa scoring for each component and in some cases similar to previous published intra-observer variability scores between pathologists. This method is effective to off-set time and cost for a training dataset.

FRI-381-YI
Oncostatin M contributes to liver steatosis in experimental metabolic dysfunction - associated steatotic liver disease

Jessica Nurcis[1], Salvatore Sutti[2], Irene Varriale[1], Francesca Protopapa[3], Alessia Provera[4], Cristina Vecchio[2], Stefania Cannito[1], Beatrice Foglia[1], Marina Maggiora[1], Claudia Bocca[1], Emanuele Albano[2], Maurizio Parola[1], Erica Novo[1]. Email: erica.novo@unito.it

Background and aims: Oncostatin M (OSM), a cytokine belonging to the IL-6 family, has been recently proposed as a pro-inflammatory and profibrogenic mediator involved in the progression of experimental and clinical conditions of Metabolic dysfunction – Associated Steatotic Liver Disease (MASLD). The aim of this study is to evaluate whether OSM can contribute to hepatocyte accumulation of triglycerides in MASLD progression.
Method: Morphological, biochemical and molecular biology approaches were used to investigate the role of OSM in: i) mice genetically manipulated to delete the OSM β receptor (OSMβR$^{-/-}$ mice) in hepatocyte and related wild type (WT) control littermates fed for 24 weeks on a Choline-Deficient, AminoAcid-refined (CDAA) lipogenic diet (i.e., to develop a murine model of progressive MASLD); ii) the murine AML12 hepatocyte cell line.
Results: Hepatocyte conditional deletion of OSMβR abrogated OSM/STAT3-related signaling in murine hepatocytes and resulted in a significant reduction of liver steatosis in OSMβR$^{-/-}$ mice vs related WT mice fed on CDAA diet, as for morphological analysis and evaluation of liver triglycerides content. This was accompanied by a number of observations suggesting a correlation of OSM/OSMβR axis and lipid metabolism in hepatocytes, including: i) a reduction of total macrophage infiltration paralleled by a significant increase in TREM2 + macrophages as well as in Osteopontin (OPN) expression observed in OSMβR$^{-/-}$ mice vs WT mice; ii) OSMβR$^{-/-}$ mice, as compared to WT mice, were also characterized by a significantly reduced expression of genes involved in the regulation of lipid metabolism, including CD36, carnitine-palmitoyl transferase 1 (Cpt1) and medium-chain acyl-CoA dehydrogenase (MCAD); iii) recombinant OSM was able to up-regulate the expression of CD36, Cpt1 and MCAD in the AML12 murine hepatocyte cell line.
Conclusion: Results of the present study indicate that the pro-inflammatory and pro-fibrogenic cytokine OSM, by acting on OSMβR expressed by hepatocytes, can also contribute to perpetuate liver steatosis in a murine model of progressive dietary induced MASLD.

The protective effect of dapagliflozin against kidney injuries by tubular mitochondrial preservation in metabolic dysfunction-associated steatohepatitis

Jee-Fu Huang[1], You-Hsien Lin[2], Yu-Min Ko[3], Ming-Lun Yeh[1], Wan-Long Chuang[4], Ming-Lung Yu[1]. [1]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Center of Excellence for Metabolic Associated Fatty Liver Disease and School of Medicine, College of Medicine, National Sun Yet-sen University, Kaohsiung, Taiwan;* [2]*Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Division of Nephrology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan;* [3]*Department of Pharmacy and Master Program, College of Pharmacy and Health Care, Tajen University, Pingtung, Taiwan;* [4]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan*
Email: jf71218@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) contributes to kidney injuries. Sodium-glucose cotransporter-2 inhibitors (SGLT2i) provide renal and cardiac protective effects. This study aimed to explore the renal protective effect by dapagliflozin in MASLD-related kidney injuries.
Method: In a controlled study, MASLD and metabolic dysfunction-associated steatohepatitis (MASH) were induced in 8-week-old C57BL/6 male mice using a high-fat diet (HFD) with 5% fructose for six months. Mice were divided into two groups: one receiving dapagliflozin (1 mg/kg/day) and the other a vehicle. Metabolic parameters and renal function were assessed through biochemical assays and transmission electron microscopy for mitochondrial ultrastructure analysis.
Results: There's no significant weight loss between dapagliflozin group and vehicle group. Dapagliflozin-treated MASH mice had improved glucose handling ($p = 0.03$ for fasting glucose; $p = 0.02$ for glucose tolerance) and alleviated insulin resistance ($p < 0.0001$ for HOMA-IR) compared to vehicle group. Dapagliflozin also mitigated renal function deterioration, evidenced by lower serum creatinine ($p = 0.01$) and proteinuria ($p = 0.01$). Renal histological features demonstrated reduced tubular injury scores ($p = 0.01$), glomerulosclerosis ($p = 0.04$), and tubulointerstitial fibrosis ($p < 0.0001$). Transmission electron microscopy showed decreased aberrant tubular mitochondria, and increased cristae length and numbers. Dapagliflozin

reduced reactive oxygen species production ($p = 0.03$) and renal adiponectin levels ($p = 0.04$).
Conclusion: These findings underscore the mechanistic link between the protective effects of dapagliflozin and renal tubular injury in MASH mice.

FRI-383
Comparative anti-fibrotic action of resmetirom, semaglutide, tirzepatide and efruxifermin in the GAN diet-induced obese and biopsy-confirmed mouse model of MASH
Jacob Nøhr-Meldgaard[1], Gaye Saginc Giannoustas[2], Natalie Pursell[2], Malte H. Nielsen[1], Susanne Pors[1], Michael Feigh[1]. [1]*Gubra A/S, Hørsholm, Denmark;* [2]*e-therapeutics plc, London, United Kingdom*
Email: jnm@gubra.dk

Background and aims: Resmetirom (RES, THR-βR agonist) has recently been FDA-approved for metabolic dysfunction-associated steatohepatitis (MASH). Other drug concepts are in late-stage clinical development for MASH, including semaglutide (SEMA, GLP1R agonist), tirzepatide (TZP, GLP1R-GIPR co-agonist) and efruxifermin (EFX, FGF21 analogue). The present study aimed to compare efficacy of RES, SEMA, TZP and EFX monotherapy on metabolic, biochemically and histopathological outcomes in the translational Gubra Amylin NASH (GAN) diet-induced obese and biopsy-confirmed mouse model of MASH with liver fibrosis.
Method: Male C57BL/6 mice were fed the GAN diet for 31–34 weeks prior to study start. Only GAN DIO-MASH mice with biopsy-confirmed NAFLD Activity Score (NAS≥5) and fibrosis (stage = F2–3) were included and stratified into treatment groups (n = 18 per group). Mice were administered vehicle (SC/PO, QD), RES (3 mg/kg, PO, QD), SEMA (10/30 nmol/kg, SC, QD), TZP (10 nmol/kg, SC, QD) or EFX (1 mg/kg, SC, QW), for 12 and 16 weeks. Pre-to-post individual assessment of NAS and fibrosis stage was performed. Other terminal endpoints included plasma biochemistry and liver histomorphometry expressed as parenchymal (steatosis-adjusted) proportionate area for inflammation (Gal-3) and collagen (PSR, Col1a1).
Results: GAN DIO-MASH mice demonstrated vehicle-corrected weight loss of 15% (EFX), 20% (SEMA) and 25% (TZP), while RES was weight-neutral, after 16 weeks of treatment. All treatment interventions improved hepatomegaly and reduced plasma liver enzymes. Independent of treatment duration, a significant improvement in NAS was achieved with EFX, SEMA and TZP (≥2-point) and RES (≥1-point). Benefits on NAS were supported by quantitative liver histology for steatosis and inflammation. Neither EFX, SEMA, TZP nor RES improved fibrosis stage, albeit all compounds consistently reduced parenchymal collagen proportionate area after 16 weeks of treatment. Notably, EFX, SEMA, TZP and RES effectively reduced fibrogenesis biomarkers (plasma TIMP-1, PIIINP, liver α-SMA) after 12-weeks of treatment.
Conclusion: RES, SEMA, TZP and EFX improved metabolic, biochemical and histopathological endpoints in GAN DIO-MASH mice, highlighting the model clinical translatability. Longer treatment intervention demonstrated histological improvement in fibrosis, highlighting the importance of treatment duration to alleviate fibrosis burden in the GAN DIO-MASH model.

Disease-associated transcriptomic profiles of liver sinusoidal endothelial cells at single nucleus resolution in a non-human primate model of metabolic dysfunction-associated steatohepatitis
Joanne Hsieh[1], Heather Burkart[2], Susan Appt[2], Vinay Kartha[1], Jingshu Chen[1], Hikaru Miyazaki[1], Smitha Shambhu[1], Dimitry Popov[1], Kylie Kavanagh[2], Francisco LePort[1], Martin Borch Jensen[1]. [1]*Gordian Biotechnology, South San Francisco, United States;* [2]*Wake Forest University School of Medicine, Winston-Salem, United States*
Email: joanne@gordian.bio

Background and aims: Hepatic endothelial cells (ECs) play an important role in fibrogenesis and EC dysfunction is also critical to the development of portal hypertension, which is an important complication of cirrhosis. Single cell-level characterization of ECs in human livers has been reported for the healthy and cirrhotic states, with a paucity of information on the intervening disease stages. Our long-term diet-fed non-human primate (NHP) model of MASH therefore offers a unique opportunity to examine the EC transcriptome as the disease progresses from steatosis to advanced fibrosis.
Method: Male, middle-aged African Green Monkeys (*Chlorocebus aethiops sabaeus*) were given a high fat, cholesterol and fructose diet for over 90 weeks, with additional fructose enrichment starting at week 36. After 20 and 54 weeks on diet, liver biopsies were collected and single nucleus RNA-sequencing (snRNA-Seq) was performed, yielding 173,669 analyzable nuclei spanning 11 NHPs over 2 time points. Comprehensive blood work performed at more frequent intervals revealed high heterogeneity in this group of animals. We harnessed this heterogeneity to interrogate how specific metabolic co-morbidities affect the EC transcriptome.
Results: 54 weeks of diet-feeding resulted in an average liver picrosirius red staining area of 9.9% in the NHPs, with the staining concentrated in the periportal region. Between 20 weeks and 54 weeks of diet feeding, hepatic ECs showed an upregulation of endocytic vesicle, collagen-containing extracellular matrix, and lipoprotein particle binding genes. The most fibrotic tertile of livers had ECs that showed increased NRF2 transcriptional activity and cytokine-mediated signaling pathway. The NHPs with the highest low density lipoprotein cholesterol levels had ECs with increased expression of basement membrane genes, consistent with sinusoidal capillarization. This result is in agreement with the beneficial effects observed for statins in portal hypertension. To understand why diabetic patients have a blunted hepatic venous pressure gradient response to non-selective beta blockers, we compared the NHP with elevated HbA1c to the rest and found this animal had hepatic ECs with increased SMAD4 transcriptional activity. Notably, a gene that was commonly upregulated in the hyperlipidemic and diabetic animals' hepatic ECs was *CETP*, which is not expressed by mice and rats.
Conclusion: The diet-fed NHP is a MASH model with high translational relevance. A high-throughput drug discovery screen in such a model could elucidate novel therapies to address unmet needs.

FRI-385
High-throughput in vivo pooled screening can identify therapies applicable across the spectrum of metabolic dysfunction-associated steatohepatitis disease severity
Joanne Hsieh[1], Vinay Kartha[1], Jingshu Chen[1], Hikaru Miyazaki[1], Shengping Wang[1], Ian Driver[1], Chris Carrico[1], Daniel Fuentes[1], Linda Chio[1], Dimitry Popov[1], Jessica Nonora[1], Arnav Gupta[1], Alex Araki[1], Smitha Shambhu[1], Gayathri Donepudi[1], Chris Towne[1], Francisco LePort[1], Martin Borch Jensen[1]. [1]*Gordian Biotechnology, South San Francisco, United States*
Email: joanne@gordian.bio

Background and aims: Despite the continuing evolution of complex *in vitro* liver models, many features of liver biology remain difficult to faithfully recapitulate outside of the living mammal, especially in the diseased state. Such features include the intricate canalicular architecture arising from the hepatocytes' unique multiaxial polarization, hepatocyte zonation due to the concentration gradient of oxygen and nutrients, and the infiltration of diverse bone marrow-derived immune cells. To overcome these shortcomings of culture-based screening, we developed a pooled screening platform that enables us to query hundreds of unique interventions in a single live animal.
Method: We delivered a cocktail of hundreds of uniquely barcoded adeno-associated virus (AAV)-based gene therapies to mice fed the Gubra-Amylin (GAN) diet for an average of 60 weeks. The AAV cocktail

dose was titrated to ensure only about 7% of hepatocytes were transduced, thereby avoiding cross-interaction between different interventions. We examined the hepatocyte response to each intervention at the single nucleus level according to mRNA expression of curated gene sets designed to capture multiple aspects of MASH pathogenesis and resolution. Novel interventions with a transcriptomic response that suggested a therapeutic effect were then administered to mice fed the GAN diet for 44–48 weeks at a saturating dose.

Results: After 60 weeks on diet, the livers of the mice showed F2 fibrosis. Overexpression of *Il6* and the dominant-negative mutant of the IL-6 receptor subunit beta both strongly affected the lipid droplet pathway feature, indicating an important role for this cytokine in modulating steatosis. The *Alb* overexpression intervention showed beneficial transcriptomic shifts despite the very high baseline expression levels of the gene and the low multiplicity of infection of the AAV cocktail. Overexpressing *Alb* reduced expression of protumorigenic features while increasing expression of anti-tumorigenic features. This agrees with observations that long term albumin administration improves outcomes in decompensated cirrhosis. Interestingly, *Alb* overexpression resulted in upregulated expression of farsenoid X receptor signaling and *de novo* lipogenesis. Of the candidate AAV therapies tested at the saturating dose in GAN diet-fed mice, 50% showed a reduction from baseline ALT levels within 8 weeks. One intervention showed a reduction in steatosis along with decreased expression of genes indicative of inflammatory cell infiltration and extracellular matrix gene deposition.

Conclusion: The ability to interrogate the expression of diverse disease features means that *in vivo* pooled screening in an animal model of moderate fibrosis could reveal insights into interventions that have implications for simply steatotic liver disease to decompensated cirrhosis.

FRI-386

HK3, a novel oral anti-obesity MASH drug with direct reduction of liver fibrosis

Elisabeth Rohbeck[1], Juergen Eckel[1]. [1]*CureDiab Metabolic Research GmbH, Düsseldorf, Germany*
Email: juergen.eckel@curediab.de

Background and aims: MASLD has emerged as a global health concern, recognized as the hepatic manifestation of the metabolic syndrome with obesity as the major risk factor. Due to its complexity, a multitarget approach of combined pharmaceuticals may be required. Resmetirom is the only drug that has recently been approved for the treatment of MASH, ehibiting only modest weight reduction. This study aimed to investigate if our allosteric modulator of the GABA-A receptor, HK3, could directly ameliorate fibrosis in different MASH models as well as obesity.

Method: 3D Spheroids of primary human hepatocytes and non-parenchymal cells from MASH patients were treated with insulin and fatty acids, in the presence or absence of HK3 (1, 3, 10 µM) for 1 week. Lipid content, inflammatory cytokines, and fibrosis markers were quantified using specialized assays (AdipoRed, (multiplex) ELISA). Human hepatic stellate cells (LX2) were treated with TGF-β1 (5 ng/ml, 24 h) with HK3 or competitor drugs (semaglutide, lanifibranor and resmetirom, all 10 µM) to assess pro-fibrotic protein levels. Finally, diet-induced obese mice (12 weeks) received HK3 (25 mg/kg, 4 weeks) in addition to high fat diet. Food intake, body weight, body composition and oral glucose tolerance test were measured and serum biomarkers were analyzed.

Results: In the 3D spheroid model, HK3 reduced lipid content, inflammatory cytokine secretion, and pro-collagen level ($p < 0.0001$, $p < 0.05$, $p < 0.05$). HK3 outperformed other MASH drug candidates in reducing fibrotic markers in LX2 cells. In CCl_4-treated mice, HK3 mitigated liver fibrosis progression and reduced inflammatory markers ($p < 0.05$). In addition, HK3 improved liver function markers (ALT, $p < 0.001$; AST $p < 0.0001$), triglyceride ($p < 0.001$) and cholerstol levels ($p < 0.0001$) in the DIO mice, without affecting food intake. HK3 treatment resulted in a significant reduction in body weight (>10%) compared to vehicle-treated animals ($p < 0.0001$), with a marked decrease in fat mass (21%) ($p = 0.001$). Notably, lean mass remained unaffected by HK3 administration. A 28-days GLP-tox study in rats demonstrated the safety of the compound.

Conclusion: This comprehensive study reveals HK3 as a promising candidate for MASH treatment, demonstrating both potent direct anti-fibrotic and anti-obesity effects. Its unique mechanism of action and multi-faceted benefits position HK3 as a potential first-in-class therapy for the concurrent management of MASH and obesity, addressing two critical aspects of metabolic liver disease.

FRI-387

35 kilodalton specific-sized hyaluronan ameliorates high fat diet-induced liver injury in a murine model of moderate

Semanti Ray[1], Emily Huang[1], Megan McMullen[1], Samreen Jatana[1], Carol de la Motte[1], Laura Nagy[2]. [1]*Cleveland Clinic, Cleveland, United States;* [2]*Cleveland Clinic, cleveland, United States*
Email: len2@po.cwru.edu

Background and aims: Obesity is a growing concern in the US and world-wide, associated with an increased risk for several cardiometabolic diseases, including metabolic associated steatotic liver disease (MASLD). Currently, therapeutic interventions to prevent and/or treat MASLD are limited, and research is needed to identify new therapeutic targets. The specific-sized 35 kDa fragment of hyaluronan (HA35), has gut protective and anti-inflammatory properties and a previous pilot clinical study reported it is well tolerated in healthy individuals. Here we tested the hypothesis that HA35 treatment ameliorates high fat diet-induced liver injury.

Method: Five-week-old male C57BL/6J mice were allowed *ad lib* access to control chow or high fat fructose and cholesterol (FFC) diet over a period of 12 weeks. HA35 was administered at 15 mg/kg via oral gavage on the last 6 days of the study as a therapeutic intervention.

Results: Mice on FFC diet-gained more body weight compared to those on chow diet, with final body weights ranging from 30.8–45.6 g. FFC diet caused hepatocyte injury, increased expression of inflammatory cytokine/chemokine mRNA, as well as indicators of liver fibrosis. When mice were stratified based on their final body weight, only mice <40 g were protected by treatment with HA35. In this group, treatment with HA35 also restored tight junction integrity in the colon and increased expression of α -defensins in the small intestine.

Conclusion: Taken together the data suggests that HA35 is an effective therapeutic in ameliorating high fat diet-induced liver inflammation and fibrosis in moderately obese, but not severe, conditions.

FRI-388

Quantitative digital pathology and AI to characterize histological phenotypes of regression in a robust mouse model of human MASH

Li Chen[1], Kenneth Li[2], Adi Lightstone[1], Mathieu Petitjean[1], Scott Friedman[2], Shuang Wang[2]. [1]*PharmaNest, Princeton, United States;* [2]*Icahn School of Medicine at Mount Sinai, New York, United States*
Email: kenneth.li@icahn.mssm.edu

Background and aims: Metabolic Dysfunction-Associated Steatohepatitis (MASH) is a liver disease marked by inflammation and damage resulting from excessive fat accumulation, often associated with metabolic co-morbidities including obesity, diabetes, and hypercholesterolemia. If the disease persists, it can progress to cirrhosis. In this study, we focused on investigating the spontaneous regression of fibrosis after the cessation of a MASH-inducing model ("FAT-MASH"; doi:10.1016/j.jhep.2018.03.011) at an early stage of liver fibrosis. We utilized the FibroNest™ Digital Pathology platform

to quantify the phenotypic features of fibrosis and establish its value in quantifying features of disease regression.
Method: In the FAT-MASH mouse model of MASH, animals (n ≥ 6) were fed a Western diet for 6 wks, with sugar water and low-dose weekly CCl4. Mice were euthanized either at peak fibrosis (6 wks) or 2 and 6 wks following cessation of the MASH model to assess spontaneous fibrosis regression and other histologic features. Liver sections were stained with Sirius red and imaged at 40×. The images were analyzed using a single-fiber, high-content image analysis platform to assess collagen deposition (quantity), fiber morphometry (shape and size), and fibrosis architecture (fiber organization and complexity), generating a Phenotypic Fibrosis Score (Ph-FCS), a continuous, quantitative measure of fibrosis severity.
Results: FAT-MASH mice at 6 wks exhibited a significantly higher Ph-FCS compared to the normal diet control group (mean 5.58 vs. 0.91, p = 0.0026). Similar trends were observed in the three sub-phenotypic analysis layers, including collagen quantity, fiber morphometry, and fibrosis architecture. Liver histology revealed predominantly complete, thin bridging septa, along with hepatic fat accumulation. However, a time-dependent reduction in Ph-FCS was observed at 2 and 6 weeks following the discontinuation of disease model (mean 2.74, p = 0.024 and 2.04, p = 0.01, respectively). This reduction was consistent across the 3 sub-phenotypic quantifications, indicating that the fibrosis phenotypic traits, including collagen fiber quantity, shape, and organization were impacted. Histological examination of the liver revealed reduced and thinning of the bridging fibrosis, with nearly complete resolution of hepatic steatosis. These results suggest that spontaneous regression of liver fibrosis and steatosis occurs following the cessation of MASH (at 6 wks).
Conclusion: Fibrosis phenotypic quantification is valuable to assess the features of spontaneous fibrosis regression. The FibroNest™ digital pathology image analysis tool is highly effective in assessing the histological phenotypes of steatosis as well as fibrosis severity and regression in a robust MASH model. These findings may help clarify the mechanisms underlying fibrosis regression in human disease.

FRI-389

Histological phenotypes of regression in advanced liver fibrosis using quantitative digital pathology in a rodent model of cirrhotic human NASH with HCC

Li Chen[1], Bruno Cogliati[2], Adi Lightstone[1], Mathieu Petitjean[1], Scott Friedman[2]. [1]*PharmaNest, Princeton, United States;* [2]*Icahn School of Medicine at Mount Sinai, New York, United States*
Email: bruno.cogliati@mssm.edu

Background and aims: Metabolic Dysfunction-Associated Steatohepatitis (MASH) is characterized by hepatic inflammation and injury associated with accumulation of fat. MASH can progress to cirrhosis and substantially elevate the risk of liver cancer. In this study, we assessed the spontaneous regression of advanced fibrosis following the cessation of a MASH-inducing model ("FAT-MASH"; doi:10.1016/j.jhep.2018.03.011) at a cirrhotic stage of liver fibrosis associated with hepatocellular carcinoma (HCC). The FibroNest™ Digital Pathology platform was utilized to quantify the phenotypic features of fibrosis and determine its effectiveness in measuring disease regression.
Method: In the FAT-MASH mouse model of MASH, mice (n ≥ 5) were fed a Western diet for 40 wks, supplemented with sugar water and low-dose weekly CCl4. The mice were euthanized either at peak fibrosis (40 wks) or at 2, 8, 16, and 24 wks following the cessation of the MASH model to evaluate spontaneous fibrosis regression and other histological features including steatosis. Liver sections were stained with Sirius red and imaged at 40X. The images were analyzed for both non-tumoral and tumoral areas using a single-fiber, high-content image analysis platform to assess collagen deposition (quantity), fiber morphometry (shape and size), and fibrosis architecture (fiber organization and complexity), generating a Phenotypic Fibrosis Score (Ph-FCS), a continuous, quantitative measure of fibrosis severity.
Results: In FAT-MASH mice at peak fibrosis (40 wks), both Ph-FCS and steatosis were significantly increased compared to the normal diet control group (mean 6.21 vs. 2.69, p = 0.0001 and mean 8.68 vs. 0.69, p = 0.00001, respectively). Similar trends were observed across the 3 sub-phenotypic layers, including collagen quantity, fiber morphometry, and fibrosis architecture. Liver histology revealed mostly branching bridging septa, perisinusoidal fibrosis, and hepatic fat accumulation. No time-dependent reduction in Ph-FCS or the 3 sub-phenotypic layers was observed after discontinuing the disease model, although steatosis exhibited a significant decrease over time (mean values at 2, 8, 16, and 24 wks: 3.51, p = 0.012; 1.87, p = 0.034; 1.7, p = 0.001; 2.09, p = 0.006). Concurrently, FAT-MASH mice developed large liver tumors comprising ~45% of overall tissue area in all disease groups. The fibrosis and steatosis patterns in the tumors were similar to those observed in the non-tumoral liver tissues.
Conclusion: These findings indicate that while spontaneous regression of steatosis is achievable, reversing fibrosis in advanced, cirrhotic MASH associated with HCC is more challenging. This degree of fibrosis may represent a "point of no return" where regression is no longer feasible. The FibroNest™ digital pathology image analysis can significantly aid in understanding the mechanisms underlying the irreversibility of fibrosis.

Transcriptomic analysis reveals alterations in mitochondrial energy metabolism and lipogenesis in GIPR/GLP-1R agonists treated metabolic dysfunction-associated steatohepatitis rodents

Hui Li[1], Jiliang Zhang[1], Miao Yuan[1], Chen Liu[1], Luxia Wei[1], Xiuxiu Shen[1], Yunhan Qiu[1], Lijuan Jiang[1], Zhixiang Zhang[1], Qiangyang Gu[1]. [1]*In Vivo Pharmacology Unit, WuXi Biology, WuXi AppTec, Shanghai, China*
Email: li_hui0122@wuxiapptec.com

Background and aims: Metabolic Dysfunction-Associated Steatotic Liver Disease (MAFLD) and its progressive form, Metabolic Dysfunction-Associated Steatohepatitis (MASH), present a considerable global health challenge. The lack of regulatory-approved MASH medications emphasizes the critical need for innovative treatments. Various gastric inhibitory polypeptide receptor (GIPR) and glucagon-like peptide-1 receptor agonists (GLP-1RAs) are undergoing clinical investigations at different stages for MASH, potentially offering new prospects for MASH therapy. Despite prior research reporting reduced liver enzymes and improved MASH histopathology in response to GLP-1RAs, the fundamental molecular mechanism remains unclear.
Method: In this study, RNA profiling was employed to examine the transcriptome profiles of two distinct MASH rodent models: HFD +CCl4 and CDHFD treated with Semaglutide and Tirzepatide.
Results: Semaglutide notably decreased the liver fibrosis score in the CDHFD model and the NAS score in the HFD+CCl4 model. Nevertheless, the histopathological improvement observed with Tirzepatide treatment was not as pronounced. Comparative analysis revealed more than 3000 differentially expressed genes for both peptides. Gene Set Enrichment Analysis (GSEA) identified common lipogenic, fibrotic, and inflammatory pathways consistent with the unique disease characteristics. In addition, mitochondrial energy metabolism and lipogenesis were the most significantly altered signaling pathways, yet with distinctive patterns in the CDHFD mice between two peptides.
Conclusion: The findings suggest the apparent beneficial effect of Semaglutide, primarily through modulations in mitochondrial function and de novo lipogenesis. Although they share a similar mechanism of action, different GIPR/GLP-1RAs may alter energy metabolism via distinctive effector genes, leading to divergence in their therapeutic efficacy against different pathological features.

FRI-391

NEDD4 regulates TGF-beta/SMAD signaling pathway through ubiquinated decorin to ameliorate metabolic dysfunction-associated steatohepatitis

Rui Jin[1], Nan Geng[1], Qianqian Chen[1], Shengxia Yin[1], Qianwen Zhao, Jie Li. [1]*Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China*
Email: 18810531268@163.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) poses a significant global public health challenge, with its underlying mechanisms yet to be comprehensively elucidated. NEDD4, as an E3 ubiquitin ligase, is implicated in the regulation of multiple metabolism-associated signaling pathways. However, its role in MASH remains inadequately clarified.
Method: Hepatocellular NEDD4 were knocked down or overexpressed in mice via the AAV8 system respectively, and male C57BL/6J mice (six weeks old) were fed either a western diet (WD), or a methionine-choline deficient (MCD) diet for 10 weeks to induce MASH. 293T and AML12 cells were utilized for in vitro studies.
Results: An integrated analysis of human and murine MASH datasets was conduced and NEDD4 was identified as the differentially expressed E3 ubiquitin ligase in hepatocytes. Notably, NEDD4 protein levels were significantly elevated in both in vivo and in vitro MASH models, with this upregulation predominantly observed in hepatocytes. Lipid accumulation was markedly exacerbated in MASH mice fed an MCD or WD diet for 10 weeks in NEDD4-KD mouse. Conversely, overexpression of NEDD4 in hepatocytes significantly ameliorated hepatic lipid accumulation. RNA-seq analysis revealed an upregulation of the TGF-β pathway in NEDD4 knockdown AML12 cells, with decorin (DCN) exhibiting pronounced transcriptional changes. Additionally, predictions from the Ubibrowser website suggested that DCN is a potential substrate of NEDD4.
Conclusion: Collectively, our findings demonstrate that NEDD4 ameliorates MASH by modulating the TGF-β/SMAD signaling pathway through the ubiquitination of decorin.

FRI-392

Myostatin regulates the muscle-liver axis by inducing hepatocyte senescence via SLC7A11 ubiquitination in metabolic dysfunction-associated steatohepatitis

Nan Geng[1], Qianqian Chen[1], Fajuan Rui[1], Wenjing Ni[1], Yixuan Zhu[1], Zhiwen Fan[1], Shengxia Yin[1], Qianwen Zhao, Jie Li[1]. [1]*Department of Infectious Diseases, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, Jiangsu, China, Nanjing, China*
Email: lijier@sina.com

Background and aims: Recent studies suggest that skeletal muscle alterations may contribute to the pathogenesis of Metabolic Dysfunction-Associated Steatohepatitis (MASH). Myokines, bioactive peptides released by skeletal muscle, play a pivotal role in regulating peripheral tissues, including the liver. Among them, myostatin (MSTN) has emerged as a critical regulator of muscle mass and metabolism. However, its specific role and underlying mechanisms in MASH development remain unclear.
Method: MASH was induced in mice using high-fat, high-fructose diet (HFHFD) and choline-deficient, amino acid-restricted, high-fat diet (CDA-HFD). Muscle-specific MSTN knockdown was achieved using an adeno-associated virus 8 (AAV8) system. MSTN expression in the serum of MASH patients was assessed via Elisa. The role of MSTN in MASH progression was investigated using recombinant MSTN protein and co-cultures of C2C12 muscle cells and primary mouse hepatocytes. Additionally, RNA sequencing was employed to analyze the impact of MSTN on the hepatocyte transcriptome.
Results: MSTN was found to be overexpressed at both the transcriptional and protein levels in the skeletal muscle tissues of MASH mice. Muscle-specific MSTN suppression significantly inhibited the progression of HFHFD- and CDAHFD-induced MASH. Recombinant MSTN protein exacerbated hepatocyte steatosis, inflammation, and senescence. Transcriptomic analysis identified the cystine transporter SLC7A11 as a key target of MSTN-induced hepatocyte changes. Furthermore, MSTN promoted the degradation of SLC7A11 via the ubiquitination pathway during MASH progression.
Conclusion: Reducing muscular myostatin expression may represent a promising therapeutic strategy for treating MASH.

Email: lina.jegodzinski@uksh.de

Background and aims: The *PNPLA3* rs738409 (p.I148M) polymorphism is the most important genetic risk factor for the progression of metabolic steatotic liver disease (MASLD) to steatohepatitis (MASH) and fibrosis. Its expression is regulated by fasting and feeding cycles, which are likely to influence disease outcome. However, the underlying mechanisms remain poorly understood.
Method: We analyzed 353 serum samples from patients with MASLD from two German medical centres using NMR metabolomics. Patients were stratified by *PNPLA3* rs738409 C > G genotype into three subgroups: PNPLA3 CC, PNPLA3 CG and PNPLA3 GG. Metabolites, lipoproteins and glycosylation patterns were assessed based on fasting status.
Results: Homozygous PNPLA3 GG carriers displayed a distinct metabolic profile compared to CG or CC carriers, with notable alterations between fasting and non-fasting states. In the latter case, PNPLA3 148M inhibits adipose triglyceride lipase (ATGL), resulting in impaired triglyceride (TG) export from hepatocytes, as evidenced by reduced VLDL-1 lipoproteins. Following an overnight fast, GG carriers exhibited elevated tricarboxylic acid (TCA) cycle metabolites and ketone bodies, reflecting increased beta-oxidation, likely driven by reduced PNPLA3 expression and unrestricted ATGL activity. Additionally, the ketogenic amino acid lysine, which is critical for mitochondrial carnitine transport, was reduced. TG were enriched in LDL and large HDL particles, and an increased number of intermediate density lipoprotein (IDL) particles emerged as a distinct marker in fasted GG carriers. These metabolic changes were enhanced in individuals with T2DM and/or obesity. Finally, glycan structural variations were found in GG carriers, but were not associated with acute-phase inflammation.
Conclusion: Fasting and feeding cycles significantly exacerbate pathophysiological changes in PNPLA3 GG carriers, with implications for biomarker identification and tailored therapeutic interventions to counteract MASLD progression.

FRI-398

SETDB2 promotes the progression of metabolic dysfunction-associated steatohepatitis by regulating liver macrophages polarization via MAPK signaling pathway

Baiyi Liu[1], Wang Zilong[1], Xiaoxiao Wang[1], Feng Liu[1], Huiying Rao[1]. [1]*Peking University People's Hospital, Peking University Hepatology Institute, Infectious Disease and Hepatology Center of Peking University People's Hospital, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation*

Base for Science and Technology on NAFLD Diagnosis, Beijing, China
Email: rao.huiying@163.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is an inflammatory stage of metabolic dysfunction-associated steatotic liver disease (MASLD), which is often accompanied by metabolic disorders, such as obesity, type II diabetes, insulin resistance and dyslipidemia. The histone methyltransferase SETDB2 protein is a member of the KMT1 family of lysine methyltransferases, associated with the regulation of chromosome segregation. SETDB2 was reported involving in innate and adaptive immunity, the proinflammatory response, and hepatic lipid metabolism. Our previous study found that SETDB2 was significantly upregulated in liver macrophages of MASH mice models, indicating it might promote the progression of MASH. However, the potential molecular mechanism of SETDB2 regulating the progression of MASH is unclear.
Method: The expression of SETDB2 was detected in liver tissues from MASH and control patients cohorts, respectively. In vivo, myeloid specific Setdb2 knockout mice($Setdb2^{fl/fl}Lyz2^{cre+}$) and control mice ($Setdb2^{fl/fl}$) were feed with WD(Western diet) and MCD(Methionine-choline deficient) diet to construct MASH mice model. H&E and Sirius Red were performed to detect the hepatic steatosis and inflammation. Liver macrophages were isolated, and the proportion of M1 and M2 macrophages was determined by flow cytometry. In addition, to investigate the direct effects of SETDB2 on the polarization of macrophages, mouse bone marrow-derived macrophages (BMDMs) and Raw264.7 cell line were studied in vitro.
Results: Through the detection of liver tissues from clinical MASH and control patients, we found that SETDB2 was upregulated in macropahges of MASH liver. In vivo, myeloid specific Setdb2 knockout($Setdb2^{fl/fl}Lyz2^{cre+}$) allivated hepatic steatosis and inflammation in mice compared with the control mice($Setdb2^{fl/fl}$). In $Setdb2^{fl/fl}Lyz2^{cre+}$ mice, the deficiency of Setdb2 inhibited M1-polarization and promoted M2-polariztion of liver macrophages. Furethermore, the number of M1-type(inflammatory type) macrophages and the proportion of M1 and M2-type macrophages reduced significantly. In vitro, we found that the decrease or increase of SETDB2 protein level directly affected the expression of pMEK and pERK proteins, showing a positive correlation, indicating that SETDB2 regulates macrophage polarization through the MAPK signaling pathway.
Conclusion: The expression of SETDB2 significatntly incresed in macrophages of MASH livers. Also, it may promote the M1 polarization of inflammation-associated macrophages through the MAPK signaling pathway, and then accelerate the inflammatory response in livers, and ultimately promote the progression of MASH. This result may complement the underlying molecular mechanism of MASLD progression, highlight the important role of macrophages in MASLD.

Email: lorenzonevi@hotmail.it

Background and aims: Excessive lipid accumulation into hepatocytes is a hallmark of metabolic dysfunction-associated Steatotic Liver Disease (MASLD), further features are liver inflammation and fibrosis. Recent findings indicate that cholestasis in MASLD patients serves as a significant predictor of poor prognosis, highlighting the putative role of impaired bile secretion in the pathogenesis and progression of the disease. Interestingly, bile acids could interfere with autophagy, a key process for lipid regulation into hepatocytes. Here, we correlate the alteration in bile duct systems with impaired autophagy flow by anatomical and transcriptomic analysis in MASLD patients with early liver fibrosis.
Method: 21 human liver biopsies and clinical data of MASLD patients with early fibrosis were collected. A cholestatic, mixed or hepatocellular pattern was defined based on serological profiles. Tissues were analyzed by immunohistochemistry for autophagy, and biliary cell markers. We performed gene expression analysis on 58 genes involved in lipid metabolism, bile secretion and autophagy. Finally, we correlated the data obtained with clinical data.
Results: Our data demonstrated that in early human fibrosis the impairment of autophagy flux into hepatocytes is linked to cholestasis-related changes in the biliary system, inducing ductular reaction and the expansion of intermediate hepatobiliary cells. Gene expression analysis confirmed alterations in lipid metabolism and homeostasis, mitochondria biogenesis, autophagy and transcription factors involved bile secretion and uptake processes. We observed an increased levels of impaired autophagy marker p62 correlating with the expansion of hepatic progenitor cells and intermediate hepatobiliary cells ($p < 0.05$). Impaired autophagy was also associated with higher mRNA expression of liver X receptor alpha ($p < 0.05$) and farnesoid X receptor ($p < 0.01$), and a greater expression of cholesterol bile efflux pumps, ATP Binding Cassette Subfamily G Member (ABCG) 5 and 8, was observed in patients with cholestatic pattern compared to those with a mixed or hepatocellular pattern ($p < 0.05$). Furthermore, in patients with cholestatic blood profiles, reduced expression of ABCG5 and ABCG8 was associated with increasing ballooning, a feature of MASLD-related liver damage ($p < 0.05$). Also, expression analysis of all selected genes best identifies the patients with cholestatic pattern respect to others ($p < 0.01$).
Conclusion: Our data linked impaired autophagy, bile efflux system dysregulation, and histological changes in MASLD. In early fibrosis, higher ABCG5/8 expression in cholestatic patients may reflect a compensatory bile efflux response to reduce biliary impairment. This could suggest a novel histological and genetic signature of cholestatic MASLD in early disease potentially helpful in identifying patients at risk of disease progression before severe fibrosis occurs.

FRI-400-YI

Impact of ageing on metabolic dysfunction-associated steatotic liver disease in a murine model: insights into progression, biomarkers, and therapeutic stratification

Lucia Lameroli Mauriz[1], Andrea Scelza[1], Miranda Orellano[1], Juan Bayo Fina[1], Esteban Fiore[1], María José Cantero[1], Bárbara Bueloni[1], Mailín Casadei[1], Luz Andreone[1], Guillermo Mazzolini[1], Catalina Atorrasagasti[1]. [1]*Instituto de investigación en medicina traslacional (IIMT), CONICET-Universidad austral, Buenos Aires, Argentina*
Email: catorrasagasti@austral.edu.ar

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) ranges from steatosis to steatohepatitis, fibrosis, cirrhosis and hepatocarcinoma. It is more prevalent in older individuals, who frequently present severe manifestations. There are no reliable markers to predict disease progression. This study aims to examine the impact of ageing on MASLD progression in a murine model to provide tools for patient stratification and identification of predictive biomarkers of progression.

Method: Male C75BL/6N mice were divided into 4 groups: 2-month-old mice (young, Y) fed with chow diet (Y-CD), or high fat western diet (Y-WD), and 10-month-old mice (middle-aged, MA) fed with CD (MA-CD) or WD (MA-WD). Weight and blood glucose levels were tracked for 20 weeks. Then, liver tissue was collected for histological staining, gene expression analysis by qPCR and RNAseq. Differentially expressed genes (p-adjusted value <0,05 and |logFC| < 0.585) were identified via Limma differential expression analysis. Gene ontology (GO) analysis was performed with significantly regulated genes to identify regulated biological processes (FDR < 0.05).
Results: Mice on the WD gained more weight than those on the CD, with a greater effect in Y mice. Liver mass increased significantly with WD despite age. MA mice became insulin resistant regardless of diet, while WD also caused insulin resistance in Y mice. Serum ALT, AST, and LDH levels were increased in MA-WD mice as well as total cholesterol, LDL and HDL. NAFLD activity score (NAS) showed that WD had a greater effect on MA mice. A different quantity and distribution pattern of hepatic lipid droplets was observed between Y-WD and MA-WD. WD induced hepatocellular hypertrophy, while ageing promoted inflammation and fibrosis, worsened by WD. GO analysis of MA-CD mice revealed an upregulation of genes associated with circadian rhythm processes compared to Y-CD mice. Notably, WD modulated different biological processes in Y and MA mice: in Y-WD mice, genes related to angiogenesis, extracellular matrix organization, cell migration and adhesion were upregulated; in MA-WD mice, upregulated genes were associated with inflammation while downregulated genes were linked to energy metabolism. Moreover, a group of genes were regulated commonly in Y-WD and MA-WD mice.
Conclusion: These results suggest that disease progression is faster in older animals compared to younger ones, which highlights the importance of considering the age factor when evaluating treatments for the disease. These findings also enhance our understanding of MASLD progression, pointing towards potential biomarkers for better patient stratification and therapeutic targets independent of age.

FRI-401

Assessing perilipin-2 as a liver-specific biomarker: lack of correlation between cardiac damage and its levels in heart failure patients

Lucrezia Petrucci[1], Giulia Angelini[1], Isabella Fumarulo[2], Sara Russo[1], Antonio Liguori[1], Marcello Vaccarella[2], Barbara Garramone[2], Massimo Massetti[2], Antonio Gasbarrini[1], Geltrude Mingrone[1], Nadia Aspromonte[2], Luca Miele[1]. *[1]Department of Medical and Surgical Sciences, A. Gemelli University Policlinic Foundation IRCCS, Rome, Italy; [2]Department of Cardiovascular Sciences, A. Gemelli University Policlinic Foundation IRCCS, Rome, Italy*
Email: lucreziapetruccimed@gmail.com

Background and aims: Lipid droplets serve as the primary organelles for lipid storage in liver and host a group of proteins known as perilipins (PLINs), including five members: PLIN1 to PLIN5. Perilipin 2 (PLIN2) is linked to lipid deposition in non-adipose tissues, and its increased expression is associated with various metabolic diseases. Several studies report high levels of PLIN2 in metabolic dysfunction-associated steatotic liver disease (MASLD) and atherosclerosis. Recently, PLIN2 has been proposed as a novel, specific and sensitive biomarker for detecting MASLD and/or liver fibrosis.
The aim of this study is to confirm the role of PLIN2 as a specific biomarker of liver damage, excluding its correlation with cardiac damage in patients with cardiovascular disease.
Method: This is a case-control study to assess the association between PLIN2 levels and cardiac damage in patients affected by heart failure (HF) compared to PLIN2 levels in MASLD patients. A total of 50 patients affected by HF, without history of MASLD as determined by non-invasive scoring methods, were enrolled. Patients were divided into two subgroups based on their to history of coronary artery disease (CAD) and degree of systolic dysfunction, expressed as ejection fraction (EF): patients with a previous history of CAD and EF < 50% (CAD n = 33) and patients without history of CAD and EF ≥ 50% (HFpEF n = 17). A total of 20 controls with histological proven MASLD without history of HF were included. Patients underwent physical examination, blood sample and echocardiography at the time of enrollment. PLIN2 monocyte expression was assess by flow cytometry. Data were analyzed by Mann-Whitney U test and expressed as mean ± SEM.
Results: PLIN2 protein level was significantly lower in subjects with HF-noMASLD (3.68 ± 1.13 MFI; p < 0.0001) compared to MASLD patient (19.10 ± 8.48 MFI; p < 0.0001). Moreover, there was no difference in PLIN2 level between patients with CAD or HFpEF (3.68 ± 0.97 and 3.61 ± 1,30 MFI; p = 0.24), highlighting the lack of association between PLIN2 levels and HF.
Conclusion: Preliminary data show that there is no correlation between HF and PLIN2 levels, regardless of ischemic or non-ischemic etiology. This study reinforces the role of PLIN2 as a specific biomarker of liver damage despite the crucial role of monocytes and lipids accumulation in the pathogenesis of CAD.

FRI-402

The Nlrp3 inflammasome affects Kupffer cell phenotype, proliferation and triglyceride accumulation in the liver

Lukas Geisler[1,2], Pavitra Kumar[1], Marlene Kohlhepp[1], Jana Knorr-Klocke[1], Cornelius Engelmann[1], Frank Tacke[1], Moritz Peiseler[1], Alexander Wree[1]. *[1]Charité - Universitätsmedizin Berlin, Department of Hepatology and Gastroenterology, Berlin, Germany; [2]Humboldt-Universität zu Berlin, Department of Biology, Berlin, Germany*
Email: lukas.geisler@charite.de

Background and aims: The Nlrp3 Inflammasome is an essential mediator of acute and chronic disease. In the liver, constitutive activation of the Nlrp3 complex in immune cells results in “sterile inflammation,” as damaged hepatocytes and bacterial translocation via the portal blood cause ongoing inflammation via TLR4. Research has shown that the resident sinusoid lining KC are essential responders to mediate inflammation and metabolism in the liver. We here aimed to evaluate the role of Nlrp3 specifically in KC in their role in mediating metabolic related liver disease.
Method: We used primary cell isolation, co-culture and in vivo experiments. For readouts we performed multicolor (intracellular) flow cytometry, IF, mitochondrial respiration assays, and qPCR.
Results: Combining Nlrp3 deficient KCs with Nlrp3 sufficient hepatocytes suggested an impact of the KC on FA uptake in cell culture, which came along a nearly unaltered expression of the Nlrp3 regulator and KC marker Tim4 upon activation, but also the FA transporters MRC1/CD206 and CD36. Unsaturated Oleic acid was taken up readily in the presence of wtKC, while saturated Palmitic acid elicited a diminished gene expression response in N3koKC. The presence of N3koKC significantly decreased mitochondrial respiration in co-cultured hepatocytes, while metabolization of FA between wtKC and N3koKC remained unchanged. 10 weeks of feeding WD to mice with KC specific (Clec4f-ASC$^{fl/fl}$/ C4fA) inflammasome inactivation showed a striking decrease in response, while untreated C4fA mice showed higher numbers of KC with higher CD206 and decreased Tim4 expression. Those CD206/Clec4f positive KC accumulated mostly in the portal field of C4fA/ N3ko mice, and were readily visible WD fed wt mice, both in flow cytometry and IF. As the aforementioned KC profile may be prone to induce obesity, we aged those mice to 40 weeks finding increased liver triglycerides alongside higher KC numbers and increased endothelial marker expression alongside decreased inflammation related markers such as Crig, CCR2 but also Tim4 and CD80.
Conclusion: In summary, we found that the KC cell specific inactivation of Nlrp3 lead to an increase in absolute KC number, alongside CD206^{hi} and ESAM1^{hi} KCs that show decreased expression of Tim4 and Crig. The model results in a phenotypical adaptation of

$CD206^{lo}$ and $ESAM1^{lo}$ KC and numerical adaptation of $CD206^{hi}ESAM^{hi}KC$ similarly resulting in proliferation, inducing a metabolic phenotype inducing local accumulation of triglycerides in the liver. It appears conceivable to us, that $CD206^{hi}ESAM^{hi}$ KC are responsible for the accumulation of fatty acids. As those cells lack a potent response to polysaturated fatty acids in vivo and in vitro, they are conductive to a less inflammatory environment that coincides with higher insulin sensitivity alongside lower IL-12 and hence result in a lesser phenotype compared to wild type controls.

FRI-403-YI

Spatial lipidomics applied to human liver across the spectrum of metabolic dysfunction-associated steatotic liver disease using mass spectrometry imaging

Monika Selvakumar[1], Shazia Khan[1], Tim Kendall[2], Damian Mole[2], Dr Xiaozhong Zheng[2], Scott Webster[1], Jonathan Fallowfield[2], Ruth Andrew[1]. [1]*Centre for Cardiovascular Science, Queen's medical research institute, University of Edinburgh, Edinburgh, United Kingdom;* [2]*Centre for Inflammation Research, University of Edinburgh, Edinburgh, United Kingdom*
Email: m.selvakumar@sms.ed.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) results from excessive fat accumulation in the liver while metabolic dysfunction-associated steatohepatitis (MASH) is the progressive, inflammatory form of disease that can lead to fibrosis, cirrhosis, and liver cancer. Patient heterogeneity, variable disease progression and challenges in diagnosis complicate early detection of MASLD. We hypothesized that spatial lipidomics with matrix-assisted laser desorption ionization mass spectrometry imaging (MALDI-MSI) offers a powerful approach for identifying lipid biomarkers in liver tissue. This study aims to reveal spatial lipid patterns that could aid in the early diagnosis of MASH and help identify novel therapeutic targets and biomarkers.
Method: Human liver biopsy samples (n = 30, 32–83 years) from the HepaT1ca study (ClinicalTrials.gov NCT03213314) were categorized into groups with low (< 5%), medium (5–33%), and high (>33%) fat content based on histological assessment, with 5 male and 5 female samples per group. MALDI-MSI was applied to liver tissue for untargeted spatial lipid profiling. Data were collected at a spatial resolution of 75 microns using SYNAPT G2-Si qToF mass spectrometer (Waters Corp.). Mimetic tissue spiked with lipid standards served as an inter-batch quality control. Lipid identification was performed using the LipidMaps database, with data processed using MassLynx™ and Lipostar MSI™ software. Statistical analyses, including normalization (by sum) and Pareto scaling, were conducted using MetaboAnalyst. To identify specific lipid markers between groups and sex, partial least squares discriminant analysis (PLS-DA), orthogonal PLS-DA and variable importance in projection (VIP) scores were applied. VIP scores above 1 were considered significant.
Results: PLS-DA revealed clear separation between the three groups by fat level with component 1 accounted for 12% of the variance, and 16.8% by component 2. The high-fat group showed a distinct lipid profile, while profiles of the mid and low-fat groups overlapped. Sex differences were observed in lipid profiles within each group classified by fat level. Lipid markers distinguishing high- from low-fat groups across sexes included triglycerides (e.g., TG 54:10, VIP score = 1.75), diacylglycerols (e.g., DG 36:2, VIP score = 1.74), and phosphatidylcholines (e.g., PC 32:0, VIP score = 1.13). Within the high-fat group, sex-specific differences were observed. Phosphatidylcholines (e.g., PC 36:1, VIP score = 2.2) and lysophosphatidylcholine (e.g., LPC 18:1, VIP score = 1.8) were more abundant in males, while phosphatidylcholines (e.g., PC 34:2, VIP score = 1.0 and PC 38:5, VIP score = 1.1) were more abundant in females.
Conclusion: MSI has the potential to identify sexually dimorphic biomarkers of liver pathology that may improve future diagnostic screening.

FRI-404-YI

Leucine regulates mitochondrial function in an in vitro model of MASLD

Lizbeth Magnolia Aguilar[1], Manon Buist-Homan[1], Hans Blokzijl[1], Han Moshage[1]. [1]*University Medical Center Groningen, Groningen, Netherlands*
Email: magnoliamarths@gmail.com

Background and aims: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is becoming a global burden worldwide with a prevalence of 38% in the adult population. Metabolic perturbation disrupts lipid synthesis, esterification, and oxidation processes, leading to lipotoxicity that triggers mitochondrial dysfunction, including reactive oxygen species (ROS) production leading to oxidative stress. On the other hand, branched-chain amino acids (BCAAs: leucine (Leu), isoleucine (Ile), and valine (Val)), are essential nutrients that have become notorious as diagnostic (Fisheŕs ratio) and therapeutic tools during chronic liver diseases. During MASLD, they pass from overconcentrated to low concentrated as liver failure progress and they have shown to influence mitochondrial functionality. This study aims to elucidate the effects of BCAAs on mitochondrial function and lipid metabolism, in vitro model of MASLD.
Method: Primary hepatocytes from male Wistar rats were treated with either palmitic acid (PA: 500 µM) or a mixture of oleic acid/palmitic acid (FFA: 750 µM) in the absence or presence of BCAAs. Mitochondrial function was assessed by determining expression of antioxidant- genes (NRF2, GPX, SOD1 and, SOD2) and proteins (NRF2, MnSOD), ROS production, mitochondrial membrane potential (JC-10 assay), and energy production (Seahorse assay). Lipid accumulation (Bodipy staining) and expression of lipid metabolism-related genes (DGAT, SREBP, PPAR, CPT1, CD36, ACADs) were also assessed. Hepatocyte mitochondria were isolated using multiple centrifugation steps and proteomics analysis was performed.
Results: BCAAs significantly improved cell survival, with Ile and Leu being most effective. FFA significantly increased the presence of lipid droplets, which was reduced by BCAAs. BCAAs, particularly Leu, activated mTOR and its downstream targets. Leu and its metabolite keto-isovaleric acid (KIC) both diminished LD accumulation, partially regulated by mTOR since the mTOR inhibitor Rapamycin decreased this effect. The β-oxidation-related genes CPT1 and ACADs, were slightly increased by Leu and KIC and after mTOR inhibition, suggesting that mTOR acts as a negative regulator of β-oxidation mediated by Leu and KIC. Both Leu and KIC reduced ROS production, but no significant changes were observed in the expression of antioxidant-related genes. Interestingly, antioxidant proteins were upregulated by both leucine and KIC, suggesting post-translational regulation by Leu and its metabolite.
Conclusion: Mitochondrial dysfunction plays a crucial role in the progression of MASLD. BCAAs, particularly leucine and its metabolite KIC, enhance fatty acid oxidation and reduce oxidative stress, with these effects being partly mediated by the mTOR signaling pathway. These findings provide insight into the potential therapeutic role of BCAAs in managing MASLD.

FRI-405

Pharmacological decreases in reductive stress ameliorate lipotoxicity in hepatocytes

Mari J. Jokinen[1,2], Meghana Nagaraj[1], Nidhina Haridas[1], Vesa M. Olkkonen[1,3], Panu K. Luukkonen[1,2,4]. [1]*Minerva Foundation Institute for Medical Research, Helsinki, Finland;* [2]*Department of Internal Medicine, University of Helsinki, Helsinki, Finland;* [3]*Department of Anatomy, University of Helsinki, Helsinki, Finland;* [4]*Abdominal Center, Helsinki University Hospital, Helsinki, Finland*
Email: panu.luukkonen@helsinki.fi

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease, but the underlying pathophysiology remains unclear. Recent studies have

shown that the severity of MASLD associates with a high plasma beta-hydroxybutyrate-to-acetoacetate ratio, a well-established marker of hepatic mitochondrial reductive stress. Here, we investigated whether palmitate-mediated lipotoxicity can be prevented by small molecules that ameliorate reductive stress, such as mitochondrial uncouplers, electron acceptors, nicotinamide adenine dinucleotide (NAD^+) boosters and citrate-malate shuttle inhibitors. Furthermore, we studied whether these compounds enhance mitochondrial oxidation.

Method: Cellular reductive stress was determined using Promega NAD/NADH-Glo kit. As a model of lipotoxicity, HepG2 cells were incubated in 200–300 uM palmitate for 24 hours, after which cell viability was determined as live-to-dead cell ratio and ATP content using Promega MultiTox-Fluor and CellTiter-Glo 2.0 kits, respectively. Mitochondrial oxidation was determined as oxygen consumption rate (OCR) using Agilent Seahorse XF96. The small molecules that were studied included mitochondrial uncouplers (carbonyl cyanide 4-(trifluoromethoxy) phenylhydrazone [FCCP, 0.25–1.0 uM]; 2,4-dinitrophenol [DNP, 0.2–100 uM]; aspirin [0.01–1 uM]), an electron acceptor methylene blue [MB, 2.5–40 uM], NAD^+ boosters (SBI-797812, 0.1–10 uM; JBSNF-000088, 1–50 uM; TES-1025, 0.1–10 uM) and a citrate-malate shuttle inhibitor (CTPI-2, 1–50 uM; decreases reductive stress exclusively in mitochondria). HepaRG cell line was used for validation. All experiments were performed in triplicate. P-values were determined using ANOVA.

Results: The mitochondrial uncouplers FCCP, DNP and aspirin, the electron acceptor MB, the NAD^+ boosters SBI-797812, JBSNF-000088 and TES-1025, and the citrate-malate shuttle inhibitor CTPI-2 decreased cellular reductive stress as determined by $NADH/NAD^+$ by 36.6, 19.1, 26.5, 88.9, 20.3, 15.7, 17.7 and 24.1%, respectively (p ranging from < 0.0001 to < 0.05). The same compounds increased hepatocellular viability under palmitate treatment by 91.8, 13.3, 11.4, 82.2, 13.6, 22.2, 12.3 and 62.4%, respectively (p ranging from <0.0001 to <0.05). Similar improvements were observed using ATP content as a measure of viability. FCCP, DNP, MB and CTPI-2 increased OCR by 23.2, 27.0, 112.0 and 6.8%, respectively (p ranging from < 0.0001 to 0.011). Consistent results were observed using the HepaRG cell line.

Conclusion: Palmitate-induced lipotoxicity in hepatocytes can be ameliorated with small molecules that decrease reductive stress, such as mitochondrial uncouplers, electron acceptors, NAD^+ boosters and citrate-malate shuttle inhibitors. Our results suggest hepatic reductive stress as a potential pharmacological target in MASLD.

FRI-406

A quantitative systems pharmacology model identifies mechanisms attenuated by knockdown of HSD17B13 expression and associated with a reduction in hepatocellular ballooning

Mario Giorgi[1], Brandon Swift[2], Scott Siler[3], Vinal Lakhani[3], Mark Harpel[4], Sumanta Mukherjee[5], Marc Goldfinger[1], Itziar Irurzun[6], Hardik Chandasan[4], Stephen Atkinson[1], Nikhil Vergis[1], Anna Sher[7]. *[1]GSK, London, United Kingdom; [2]GSK, Durham, NC, United States; [3]Simulations Plus, Research Triangle Park, United States; [4]GSK, Collegeville, PA, United States; [5]GSK, UP, United States; [6]GSK, San Sebastián, Spain; [7]GSK, Waltham, MA, United States*
Email: mario.g.giorgi@gsk.com

Background and aims: Loss-of-function mutations in *HSD17B13* protect against chronic liver disease, including metabolic dysfunction-associated steatohepatitis (MASH), but mechanisms of action (MoA) underlying this observation are not well understood. ARO-HSD, a hepatocyte-targeted siRNA therapeutic designed to silence HSD17B13 expression, improved markers of liver injury in participants with MASH in a Phase 1/2a clinical trial (NCT04202354). The aim of this study was to utilise quantitative systems pharmacology (QSP) modelling to investigate the MoA by which HSD17B13 modulation impacts clinical biomarkers of MASH.

Method: In the Phase 1/2a trial, ARO-HSD was administered as an open-label treatment on Days 1 and 29 to participants with confirmed/clinically suspected MASH. Liver biopsy was performed pre-dose and on Day 71 to evaluate HSD17B13 expression. Data from the MASH/suspected MASH Phase 1/2a trial cohort were used to calibrate the NAFLDsym QSP model, which was updated to include HSD17B13. A virtual cohort of 135 participants reflective of the Phase 1/2a cohort was generated; this was used to predict changes from baseline in liver fat fraction (Day 71), plasma propeptide of type III collagen (PRO-C3) levels (Week 16) and plasma alanine aminotransferase (ALT; Day 71 and longitudinally to Day 113). Simulations included the following literature-proposed MoA: hepatocellular triglyceride (TG) lipolysis, mitochondrial biogenesis and its downstream effect on lipotoxicity, and neutrophil aggregation. The QSP model was used to predict changes in Non-alcoholic fatty liver disease Activity Score (NAS) following HSD17B13 knockdown.

Results: Consistent with Phase 1/2a data, most (78%) of the virtual cohort demonstrated at least 90% HSD17B13 knockdown and some (22%) had an average of 60% knockdown. No differences in liver fat data between the virtual and clinical cohorts were observed. Simulations invoking TG lipolysis and mitochondrial biogenesis predicted ALT, PRO-C3 and liver fat changes that matched clinical observations. On investigation of each MoA, mitochondrial biogenesis had a major impact on ALT and TG lipolysis had a minor impact on liver fat. Activation of neutrophil aggregation had no effect on the biomarkers of interest. When invoking TG lipolysis and mitochondrial biogenesis, 27% of the virtual cohort were predicted to have ≥ 2 reduction in NAS mostly attributed to an improvement in hepatocyte ballooning.

Conclusion: This QSP study suggests that TG lipolysis and mitochondrial biogenesis may be a key MoA behind HSD17B13 knockdown. The QSP model predicts that HSD17B13 knockdown results in reductions in ALT, as seen in the Phase 1/2a trial, and additionally reduces PRO-C3. The small dataset available for calibration limits the strength of the conclusions that can be drawn. These, and other potential MoA, are being further investigated in the ongoing HORIZON Phase 2b study.

FRI-407

Adding the serotonergic agonist psilocybin to semaglutide as a novel combination therapy to cure MASLD

Martina Colognesi[1], Daniela Gabbia[1], Anna Signor[1], Stefano Comai[1], Andrea Mattarei[1], Gianfranco Pasut[1], Lucia Centofanti[2], Stefano La Rosa[3], Giovanna Finzi[4], Franco Folli[2], Marco Pappagallo[5], Paolo Manfredi[5], Sara De Martin[1]. *[1]University of Padova, Padova, Italy; [2]University of Milano, Milano, Italy; [3]University of Insubria, Varese, Italy; [4]ASST Sette Laghi, Varese, Italy; [5]Relmada Therapeutics Inc., Coral Gables, United States*
Email: sara.demartin@unipd.it

Background and aims: Serotonin and glucagon-like peptide 1 (GLP-1) mutually act in the gut and in the brain to control appetite and feeding behavior. Serotonin modulates the nutrient-induced release of GLP-1 by enteroendocrine cells in the ileum. However, the serotonin/GLP-1 axis has not been exploited so far as a pharmacological target for MASLD. This study investigated the potential therapeutic benefit of targeting both pathways simultaneously through a combination of GLP-1 mimetic semaglutide and serotonergic 5-HT2A agonist psilocybin.

Method: To induce MASLD, C57BL/6J mice were fed with a diet rich in fat (60% kcal from fat) and sugar (30% fructose in drinking water), named high fat-high fructose diet (HFHFD), for 17 weeks. From week 6, HFHFD animals (n = 10 per group) received individual or combined treatments with semaglutide (0.04 mg/kg twice weekly, s.c.) and psilocybin at non-psychedelic doses (0.05 mg/kg daily, p.o.). A group of mice (n = 10) fed with standard diet was used as control. Muscle strength was evaluated by the grid test every two weeks.

Intraperitoneal glucose tolerance test (ipGTT) was performed before sacrifice.
Results: Body weight gain was significantly reduced by all treatments, but more effectively in the group treated with the combination (80% in the untreated HFHFD mice, 60% in psilocybin-treated, 32% in semaglutide-treated, 27% in mice treated with the combination, and 20% in healthy controls). Liver steatosis was also significantly reduced by all treatments, as shown by H&E staining. Although all treated mice showed a significant reduction of fasting glucose and HOMA index ($p < 0.05$ vs. untreated HFHFD mice), during the ipGTT only mice treated with the combination showed a significant reduction of the postprandial plasma glucose and insulin concentration (both $p < 0.05$ vs. placebo). Electron microscopy analysis demonstrated that HFHFD produced a severe damage of insulin-producing beta cells which appear proapoptotic and degranulated, typical of severe type 2 diabetes mellitus. At variance, islets of Langerhans of HFHFD mice treated with either psilocybin or semaglutide or both showed healthy and well granulated insulin producing beta cells. Psilocybin alone or in combination caused a significant delay in the deterioration of mice motor performance, compared to HFHFD untreated mice and those treated with semaglutide only. Accordingly, mRNA levels of perilipin 4, which plays a detrimental role in myosteatosis and other related conditions, were significantly reduced in quadriceps of psilocybin-treated mice with respect to untreated ones.
Conclusion: Adding low non-psychedelic doses of psilocybin to semaglutide further ameliorated insulin sensitivity and preserved muscle function in a mouse model of MASLD, paving the route for a possible combination therapy in MASLD patients with obesity, type 2 diabetes mellitus and sarcopenia.

FRI-408-YI
MASLD-associated changes across the gut-liver-brain axis are not ameliorated by a low-fat diet intervention in an aged mouse model

Matthew Siddle[1], Deepika Goel[1], Christos Konstantinou[1,2], Rajiv Jalan[3], Nathan Davies[3], Lindsey Edwards[1], Debbie L. Shawcross[1], Anna Hadjihambi[1,2]. [1]*King's College London, London, United Kingdom;* [2]*Foundation for Liver Research, London, United Kingdom;* [3]*University College London, London, United Kingdom*
Email: matthew.siddle@kcl.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has increasingly been associated with intestinal microbial dysbiosis, systemic inflammation, cerebral hypoxia, cognitive decline, and increased risk of neurodegenerative disease. MASLD-related changes overlap considerably with age-associated changes, creating an interesting interplay of pathologies which may ultimately drive neurodegeneration. Here, we assessed a low-fat diet (LFD) as a protective intervention against MASLD-associated dysfunction across the gut-liver-brain axis in ageing mice.
Method: 6-week-old male C57BL/6NTac mice were fed control diet (CD) or high-fat high-cholesterol diet (HFD) for 26 weeks to induce MASLD. Half the mice in each group were then placed on the LFD and aged to 18-months. Behavioural tests were performed on all mice. Cortical oxygenation at baseline and in response to systemic hypercapnia (10% CO2) was measured in vivo. Steatosis and fibrosis were assessed by histology. Plasma markers of intestinal dysfunction were measured by enzyme-linked immunosorbent assay, with complementary immunofluorescence ongoing. Cerebrovascular morphology, pericytes, and microglia were characterised by immunofluorescent staining. A qPCR gene panel was used to assess cortical inflammation and mitochondrial function. Cortical metabolites were measured by nuclear magnetic resonance.
Results: Unexpectedly, LFD drove steatosis in CD-LFD mice and fibrosis in some HFD-LFD mice. Both HFD and HFD-LFD mice exhibited anxiety-like behaviours, whilst aged CD-LFD and HFD-LFD mice showed impaired memory. Increased plasma LPS-binding protein indicated intestinal bacterial translocation in CD-LFD and HFD-LFD mice, whilst increased fatty acid-binding protein 2 indicated intestinal epithelial dysfunction in HFD and HFD-LFD mice. HFD, HFD-LFD, and CD-LFD mice exhibited lower baseline cortical oxygenation but preserved cerebrovascular reactivity to systemic hypercapnia. A trend towards reduced vessel volume compared to CD was observed. HFD mice had reduced vascular pericyte coverage. Furthermore, HFD mice had lower cortical nicotinamide and NAD+ compared to CD, indicative of oxidative stress. HFD and HFD-LFD also showed increased microglia density and cell volume, indicating reactive microglia. Interestingly, HFD mice exhibited upregulation of genes associated with inflammation and mitochondrial changes in the cortex, which mirrored the aged groups.
Conclusion: HFD-induced steatosis is associated with intestinal dysfunction, cerebrovascular pathology, and accompanying neuroinflammation. With the additional impact of ageing, these changes may underly the increased risk of neurodegeneration in people with MASLD. The LFD failed to mitigate all MASLD-associated alterations across the gut-liver-brain axis in ageing mice.

FRI-413
Hepatoprotective effects of fatty acid synthase inhibitor TVB-3664 in the GAN diet-induced obese and biopsy-confirmed mouse model of MASH

Michael Feigh[1], Kristoffer Voldum-Clausen[1], Malte H. Nielsen[1], Jacob Nøhr-Meldgaard[1], Susanne Pors[1], Henrik B. Hansen[1]. [1]*Gubra A/S, Hørsholm, Denmark*
Email: mfe@gubra.dk

Background and aims: Denifanstat, an oral fatty acid synthase (FASN) inhibitor, have recently been demonstrated to improve NAFLD Activity Score (NAS) and fibrosis stage in a phase 2b clinical trial (FASCINATE-2) in patients with metabolic dysfunction-associated steatohepatitis (MASH). The present study aimed to investigate metabolic, biochemical, histopathological and transcriptomic effects of TVB-3664, a FASN inhibitor analogue, in the translational Gubra Amylin NASH (GAN) diet-induced obese and biopsy-confirmed mouse model of MASH with liver fibrosis.
Methods: Male C57BL/6 mice were fed the GAN diet high in fat, fructose and cholesterol for 39 weeks prior to study start. A liver pre-biopsy was collected 4 weeks before treatment start. Only GAN DIO-MASH mice with biopsy-confirmed NAFLD Activity Score (NAS≥5) and moderate/advanced fibrosis (stage F2-F3) were included and stratified into treatment groups (n = 16–17 per group). Mice were administered once daily oral vehicle or TVB-3664 (10 mg/kg) for 12 weeks. Histopathological pre-to-post individual assessment of NAS and fibrosis stage was performed. Other terminal endpoints included quantitative liver histomorphometry, blood and liver biochemistry in addition to RNA-sequencing-Bioinformatic analysis.
Results: GAN DIO-MASH mice demonstrated vehicle-corrected weight loss of 12% after 12 weeks of TVB-3664 treatment in conjunction with reduced adiposity and preserved lean tissue mass. Furthermore, TVB-3664 treatment improved hepatomegaly, plasma biomarkers (transaminases, plasma cholesterol and triglyceride levels). TVB-3664 treatment promoted a ≥2-point statistically significant improvement in NAS, driven by reduction in steatosis score. Benefits on NAS were supported by quantitative liver histology on steatosis (hepatocytes with lipids)) and marker of inflammation (galectin-3). TVB-3664 treatment did not improve fibrosis stage, albeit reduced histological markers of fibrosis (PSR, Collagen 1a1) in addition to marker (α-SMA) for fibrogenesis. Finally, TVB-3664 induces transcriptomic regulation and reduced gene expression involved in inflammation and extracellular matrix production.
Conclusion: TVB-3664 improved metabolic, biochemical and histological markers of steatosis, inflammation and fibrosis/fibrogenesis. In addition, TVB-3664 improved histopathological NAFLD Activity Score, with longer treatment intervention needed for fibrosis stage

improvement. The therapeutic effects of TVB-3664 highlight the translatability and applicability of the GAN DIO-MASH mouse model in preclinical drug discovery.

FRI-414

Reproducible hepatoprotective effects and clinical translatability of long-term semaglutide treatment in the GAN diet-induced obese and biopsy-confirmed mouse model of MASH

Michael Feigh[1], Jacob Nøhr-Meldgaard[1], Sanne Skovgård Veidal[2], Jenny Egecioglu Norlin[2], Susanne Pors[1], Kristoffer Voldum-Clausen[1], Henrik B. Hansen[1]. [1]*Gubra A/S, Hørsholm, Denmark;* [2]*Novo Nordisk, Måløv, Denmark*
Email: mfe@gubra.dk

Background and aims: The glucagon-like-peptide (GLP)-1 analogue semaglutide is currently approved for the treatment of type 2 diabetes and obesity. Semaglutide has been reported to promote MASH resolution and improved fibrosis stage in a recent Phase 3 trial (ESSENCE). The present study aimed to evaluate robustness of therapeutic outcomes and clinical backtranslation following long-term treatment with semaglutide in the translational GAN diet-induced obese (DIO) mouse model of biopsy-confirmed MASH and fibrosis.
Methods: Semaglutide was characterized in 3 individual studies. C57BL/6JRj male mice were fed the GAN diet high in fat, fructose, and cholesterol for 34–38 weeks before treatment start. Only animals with biopsy-confirmed MASH (NAFLD Activity Score (NAS) ≥5) and fibrosis (stage ≥F1) were included, randomized and stratified into treatment groups. GAN DIO-MASH mice (n = 14–18 per group) received semaglutide (30 nmol/kg, SC) or vehicle (SC) once daily for 20–24 weeks. Vehicle-dosed chow-fed controls served as healthy controls. Within-subject comparisons (pre- vs. post-treatment) were performed for histopathological NAS and fibrosis stage. Terminal quantitative endpoints included plasma/liver biochemistry and liver histomorphometry.
Results: For all studies in GAN DIO-MASH mice, semaglutide consistently reduced body weight and improved hepatomegaly, plasma transaminases and hypercholesterolemia. For all studies, semaglutide promoted a ≥2-point significant improvement in NAS, primarily driven by reduced steatosis scores. Benefits on NAS were supported by quantitative liver histology on steatosis (% lipid-laden hepatocytes) and inflammation (macrophage marker galectin-3). A significant 1-stage improvement in fibrosis was observed when data was pooled across the 3 studies (20% vehicle adjusted), supported by reduced quantitative fibrosis markers (PSR, Col1a1) in addition to α-SMA levels, a marker of hepatic stellated cell activation (fibrogenesis).
Conclusion: Semaglutide consistently improved metabolic and biochemical parameters, as well as histological markers for steatosis, inflammation and fibrosis/fibrogenesis. In addition, semaglutide improved clinical-derived histopathological scoring in the GAN DIO-MASH mouse, resembling findings reported in recent phase 3 trial (ESSENCE). The highly reproducible therapeutic effects of semaglutide highlight the translatability, robustness and applicability of the GAN DIO-MASH mouse model in preclinical drug discovery.

Email: michelangelo.trucchi01@universitadipavia.it

Background and aims: Metabotropic glutamate receptor type 5 (mGluR5) is involved in lipid metabolism and intracellular signaling, particularly through protein kinase C (PKC) activation. mGluR5 regulates PKC, which in turn can inhibit AMP-activated protein kinase (AMPK) via phosphorylation, impairing its ability to prevent lipid accumulation (Chen et al., 2011; Heathcote et al., 2016). Additionally, mGluR5 hyperactivation in hepatic stellate cells promotes hepatocyte fat accumulation (Choi et al., 2019). In our previous studies, the mGluR5 negative allosteric modulator 2-methyl-6-(phenylethynyl)pyridine (MPEP) reduced lipid deposition in oleate/palmitate-induced steatotic HepG2 cells (Ferrigno et al., 2020), and depleted ATP in hepatocytes (Ferrigno et al., 2018), suggesting potential effects on both PKC and AMPK pathways. To further investigate mGluR5′s role, we used negative allosteric modulators (MPEP, Fenobam), the orthosteric antagonist 2-methyl-4-carboxyphenylglycine (CPG), and the orthosteric agonist 3,5-dihydroxyphenylglycine (DHPG). Phorbol 12-myristate 13-acetate (PMA), a PKC activator, was included to explore the interplay between mGluR5, PKC, and AMPK in steatosis.
Method: steatosis in HepG2 was induced by 2 mM O/P for 24 h. Cells were pre-treated with 0.3–3–30 μM MPEP, 1-25-50 μM Fenobam, or 100-150-200 μM CPG, alone or combined with 0.1-1-10 μM AMPK inhibitor Compound C. To assess mGluR5-PKC interaction, steatotic cells were treated with 0.01-0.1-0.5-1 μM PMA, with or without MPEP or Fenobam. Non-steatotic cells received 100–200-300 μM DHPG, alone or with 30 μM MPEP. Lipid accumulation was assessed using Nile Red dye and quantified by ImageJ; viability was evaluated by MTT. ATP content was measured by luciferin-luciferase assay, and p-AMPK/AMPK levels were analyzed via Western blot.
Results: In O/P-treated steatotic HepG2 cells, MPEP, Fenobam, and CPG reduced lipid accumulation dose-dependently. In non-steatotic cells, DHPG increased lipid accumulation, while MPEP co-treatment neutralized this effect, confirming mGluR5′s role. Only MPEP depleted ATP in HepG2 cells. Since AMPK is activated by ATP depletion, we hypothesized that MPEP's defatting effect involved AMPK; in fact, Western blot showed increased p-AMPK/AMPK levels in steatotic cells treated with MPEP. Co-treatment with Compound C reduced MPEP's effect, supporting this mechanism. Also PMA reversed MPEP's lipid-lowering effect, confirming PKC's role in lipid modulation. Thus, MPEP modulates lipid metabolism via ATP depletion-driven AMPK activation and inhibition of PKC-mediated suppression.
Conclusion: mGluR5 negative allosteric modulators and antagonists reduce fatty acid accumulation in an in vitro steatosis model via selective receptor inhibition. MPEP uniquely modulates both PKC and AMPK, the former with a receptor-independent mechanism.

FRI-416

Patatin-like phosphatase domain-containing 3 (PNPLA3) genotype and dietary fat modify the liver adiposity

Background and aims: Patatin-like phosphatase domain-containing 3 (*PNPLA3*) GG genotype and bad quality of dietary fat are causal for metabolic dysfunction-associated steatotic liver disease (MASLD). We studied the impact of dietary fat quality modification on liver adiposity in men homozygotes of *PNPLA*3.
Method: Ninety-nine randomly assigned men (age: 67.8 ± 4.2 years, body mass index: 27.2 ± 2.5 kg/m^2), homozygous for *PNPLA3* rs738409 variant (I148M), participated in a 12-week diet intervention. The quality of dietary fat was planned according to the National and Nordic nutrition recommendations in the recommended diet (RD) arm, and according to the average fat intake in Finland in the average diet (AD) arm. Liver imaging was performed by ultrasound with 2D-shear wave elastography (2D-SWE) and magnetic resonance imaging (MRI) in combination with magnetic resonance spectroscopy (MRS).
Results: MRI-based liver fat decreased in the RD arm (CC: from 3.8 ± 3.2% to 3.2 ± 3.3% and GG: from 3.9 ± 3.3% to 3.5 ± 3.1%, *p time* = 0.032) and increased in the AD arm (CC: from 4.1 ± 3.6% to 4.8 ± 3.9% and GG: from 4.7 ± 3.7% to 6.7 ± 5.3%, *p time* = 0.015). Liver elasticity decreased in the AD arm with the *PNPLA3* CC genotype and increased with the GG genotype (from 6.1 ± 1.5 kPa to 6.5 ± 1.4 kPa and from 6.2 ± 1.4 kPa to 5.8 ± 1.0 kPa, respectively, time and genotype interaction *p* = 0.013). MRS-quantified liver saturated fat content increased with AD (lipid methylene CC from 5899 ± 6534 a.u. to 8252 ± 8714 a.u. and GG from 6621 ± 3689 a.u. to 9663 ± 6168 a.u., *p time* = 0.010). Liver triglyceride concentration did not change in either arm with the CC genotype but increased in the AD arm with the GG genotype (for time *p* = 0.082 and for time and genotype interaction *p* = 0.027).
Conclusion: The *PNPLA3* genotype modifies the response of dietary fat quality modification to both the content and composition of liver fat.

Email: nils.haep@charite.de

Background and aims: The HSD17B13 rs72613567:A variant displays strong, reproducible protective effects against MASLD. HSD17B13 is a lipid droplet-associated protein predominantly expressed in hepatocytes. However, the effects of the rs72613567:A variant in the liver tissue of normal-weight individuals have not been investigated. We aimed to examine potential changes in lipid metabolism associated with rs72613567.
Method: Human liver tissue was acquired during routine liver resection with informed consent. Taqman SNP Genotyping was performed on 504 cryopreserved liver tissues without a history of chemotherapy or significant fibrosis (>F2). 6 cases with minor homozygosity for rs72613567:A were chosen for further analyses. All liver tissues analyzed were major homozygous (WT) for the previously described MASLD-related genetic variants (PNPLA3 rs738409, TM6SF2 rs58542926, MTARC1 rs2642438). Carrier and non-carrier groups of rs72613567:A were matched for age, sex, BMI, steatosis, and fibrosis grade. Mass spectrometry-based lipid analyses of selected liver tissues (n = 12) were performed and analyzed with Lipid R (Version 2.20.0). Differential lipid analysis was performed, and results were visualized using lipid set enrichment analysis. Additionally, Liquid Chromatography-Mass spectrometry-based proteomics was performed on 22 human liver tissues comprising samples from the lipidomic analysis and FragPipe visualized proteomic data.
Results: The allele frequency of rs72613567:A was 24% among patients undergoing liver resections. After matching there were no significant differences in mean age (control: 63.5 vs. HSD17B13: 63.3), mean BMI (23.2 vs. 25.6), mean steatosis (11.7% vs. 6.67%), and fibrosis grade. Carriers of rs72613567:A exhibited significantly reduced HSD17B13 protein expression in liver tissue (p = 0.008). Lipidomic analysis revealed enrichment of phospholipids (phosphatidylcholine [PC], phosphatidylinositol [PI], sphingomyelin [SM]) in carriers of rs72613567:A, while glycolipids (diacylglycerol [DAG] and triacylglycerol [TAG]) were significantly reduced.
Conclusion: This study provides the first lipidomic analysis of human liver tissue in non-obese individuals with the HSD17B13 rs72613567:A variant. We conclude that carriers of the HSD17B13 rs72613567:A variant have a phospholipid surplus (PC, PI, SM) in the liver. In addition to previous findings, hepatic glycolipids (DAG and TAG) were reduced in carriers of rs72613567:A.

FRI-418
Plasma proteomics identifies pathways to target in metabolic dysfunction-associated steatotic liver disease
Niharika Jakhar[1], Benjamin P.M. Laevens[1], Tobias Seibel[1], Yazhou Chen[1], Thriveni Raju[1], Feng Cao[1], Yuanyuan Liu[1], Kai Markus Schneider[1], Carolin V. Schneider[1]. [1]*Uniklinik RWTH Aachen, Aachen, Germany*
Email: njakhar@ukaachen.de

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) involves a variety of complex mechanisms such as inflammation, oxidative stress, and metabolic dysregulation. Plasma proteomics offers an opportunity to explore disease-specific pathways. This study evaluates the plasma proteome in MASLD patients compared to controls.
Method: Proteomics data from the UK Biobank were linked to MASLD diagnosis determined using liver MRI scans and a proton density fat fraction (PDFF) value of > = 5%. Differential OLINK protein expression analysis was performed to identify proteins of interest. Pathway enrichment analysis was conducted using EnrichR, with pathways annotated using Reactome 2022 and WikiPathways 2024 databases.
Results: Among 40,189 participants with OLINK plasma protein data, 9,692 were diagnosed with MASLD and 29,303 as controls. Differential protein expression analysis revealed: Downregulated pathways: Reactome analysis identified disruptions in glycosaminoglycan metabolism, extracellular matrix organization, and dermatan sulfate biosynthesis, indicative of altered structural and metabolic functions. IGFBP-2 (Insulin-like Growth Factor Binding Protein 2) was found to be downregulated, suggesting its potential involvement in sarcopenia amid metabolic dysregulation in MASLD. WikiPathways further highlighted impairments in lipid metabolism and PI3K-Akt signaling pathways. Upregulated pathways: Reactome findings showed enrichment in immune system processes, including interleukin-10 signaling and neutrophil degranulation. WikiPathways highlighted proinflammatory and oxidative stress-related pathways, such as cytokine receptor interactions and NRF2 activation, suggesting a role for immune-inflammatory responses in MASLD pathophysiology.
Conclusion: This study provides an exploratory analysis of the plasma proteome in MASLD, identifying potentially dysregulated biological pathways. While the findings suggest disruptions in extracellular matrix remodeling, lipid metabolism, and immune-inflammatory processes, further validation in independent cohorts is essential to confirm these results and select drugs that target these pathways.

FRI-419-YI

Therapeutic potential of targeting processing-bodies in metabolic dysfunction-associated steatohepatitis and hepatocellular carcinoma

Noémie Gellée[1,2,3,4], Noémie Legrand[1,2,3,4], Mickaël Jouve[1,2,3,4], Fabrice Bray[5], Pierre-Jean Devaux[1,2,3,4], Viviane Gnemmi[6], Laurent Dubuquoy[1,2,3,4], Cyril Sobolewski[1,2,3,4]. *[1]Université de Lille, Lille, France; [2]chu lille, Lille, France; [3]Inserm, Lille, France; [4]INFINITE U1286, Lille, France; [5]Miniaturisation pour la Synthèse, l'Analyse et la Protéomique (MSAP) UAR 3290, Lille, France; [6]CHU Lille, Service d'Anatomopathologie, F-59000 Lille, France, Lille, France*
Email: noemie.gellee.etu@univ-lille.fr

Background and aims: Processing-Bodies (P-bodies) are small cytoplasmic compartments composed of untranslated mRNAs and proteins involved RNA decay (i.e., decapping enzymes, deadenylases, exonucleases). P-bodies control the expression of a wide range of genes associated with inflammatory, metabolic, and cancer-related processes. Accordingly, alterations of P-bodies assembly or P-bodies components contribute to the development of a wide range of diseases, including cancers. Although previous works have reported that some P-bodies-related proteins (e.g., TTP, CNOT6L) are involved in metabolic dysfunction-associated steatotic liver disease (MASLD) and hepatocellular carcinoma (HCC), the role of P-bodies remains largely unexplored. Herein, we aim at characterizing the role of P-bodies in MASLD and HCC.
Method: The expression of specific P-bodies markers (EDC4, DCP1A, DDX6, TTP) was investigated in liver tissues from patients or mouse models of MASLD, HCC. The impact of different stress (oxidative stress, lipotoxicity) and anti-cancerous drugs (sorafenib) on P-bodies assembly was investigated by immunofluorescence staining of P-bodies proteins (EDC4) in hepatic cancer cells and primary hepatocytes. Loss of function analyses (siRNA) were performed in a panel of hepatic cancer cell lines to assess the impact of P-bodies proteins deficiency (EDC4) on cancer cells proliferation, survival and sensitivity to stress. In vivo experiments were carried out to decipher the impact of TTP or EDC4 silencing (i.e., AAV8 encoding shRNAs) in MASLD development, in mice fed a CSAA (choline supplemented L amino acid defined) or a CDAHFD (choline deficient L amino acid defined, high-fat diet).
Results: The expression of TTP is downregulated in HCC as compared to adjacent hepatic tissues. Although EDC4 is heterogeneously expressed in HCC, the high expression of EDC4 correlates with a poor clinical outcome. Interestingly, an increase of P-bodies number was observed in sorafenib/hydrogen peroxide-treated cells, thus suggesting that P-bodies assembly is part of a stress response. Moreover, EDC4 is upregulated in sorafenib-resistant HCC patients as compared to responders. EDC4 silencing reduces P-bodies number and hinders hepatic cancer cells proliferation and viability, thus suggesting a tumor promoting function. Preliminary findings suggest that EDC4 silencing in vivo markedly reduces hepatic steatosis in mice fed a CSAA or a CDAHFD.
Conclusion: Our study suggest that P-bodies assembly contribute to the development of MASLD and HCC and may represent a resistance mechanism against harmful conditions and sorafenib. Targeting P-bodies may therefore represent an efficient therapeutic approach for the management of MASLD and HCC.

FRI-420

Low frequency, mild gradient intermittent hypoxia still induces liver fibrogenesis in mice fed a high-fed diet

Shogo Ohkoshi[1], Junpei Kudo[1], Kosuke Kushiro[1], Haruka Hirono[1]. *[1]Clinical Examination, Graduate School of Life Dentistry at Niigata, The Nippon Dental University, Niigata, Japan, Niigata, Japan*
Email: okoshi@ngt.ndu.ac.jp

Background and aims: Fibrogenesis in metabolic dysfunction-associated steatohepatitis (MASH) may progress when complicated by obstructive sleep apnea (OSA). High-frequency intermittent hypoxia (IH) exposure, mimicking human OSA (e.g., nadir oxygen concentration of 5%, with rapid cycles of 60 times/hour), is commonly used to study OSA pathogenesis in animal models. However, IH is not always harmful and may exert health-protective effects under milder conditions. This study investigated whether low-frequency, mild-gradient IH exposure could aggravate liver injury and fibrosis in a mouse model of fatty liver.
Method: Control (n = 16; room air 8, IH 8) and high-fat diet (HFD) mice (n = 16; room air 8, IH 8) were exposed to low-frequency, long-duration IH (12 minutes/cycle) for 12 hours/day over four weeks. The groups were compared for laboratory data, liver fibrosis levels via Sirius red staining, hydroxyproline assay, quantification of liver 8-OHdG, and serum nitric oxide (nitrite/nitrate) levels as markers of oxidative stress. Cytokine arrays were used to identify specific cytokines induced under fatty liver and IH conditions. Real-time RT-PCR and immunohistochemistry determined gene expression levels.
Results: ALT/AST and lipid levels were not significantly higher in the HFD + IH group compared to the HFD + room air (RA) group. However, the serum albumin/globulin (A/G) ratio, liver fibrosis levels, liver 8-OHdG, and nitrite/nitrate as oxidative stress markers were elevated in the HFD + IH group, indicating that even low-frequency, mild-gradient IH exposure accelerated fibrogenesis in fatty liver. Conversely, systemic insulin resistance levels were decreased in the HFD + IH group, suggesting mild IH had bidirectional effects. Intercellular adhesion molecule (ICAM-1) and osteopontin (OPN) were upregulated under HFD + IH conditions.
Conclusion: Low-frequency, mild-gradient IH accelerated fibrogenesis in HFD mice by inducing oxidative stress without significant increases in liver injury, independent of insulin resistance. ICAM-1 and OPN may be involved in this pathogenesis.

FRI-421

Differential fatty acid metabolism in the liver and adipose tissue in metabolic dysfunction-associated steatotic liver disease

Saana Palomurto[1,2], Kirsi Virtanen[3], Vesa Kärjä[4], Ursula Schwab[5,6], Pirjo Käkelä[1,7], Jussi Pihlajamaki[5,8], Ville Männistö[9,10]. *[1]Kuopio University Hospital, Department of Surgery, Kuopio, Finland; [2]University of Eastern Finland, Faculty of Health Sciences, School of Medicine, Institute of Clinical Medicine, Kuopio, Finland; [3]Turku PET Center, Turku Univeristy Hospital, Turku, Finland; [4]Kuopio University Hospital, Department of Clinical Pathology, Kuopio, Finland; [5]University of Eastern Finland, Institute of Public Health and Clinical Nutrition, Kuopio, Finland; [6]Kuopio University Hospital, Department of Medicine, Endocrinology and Nutrition, Kuopio, Finland; [7]University of Eastern Finland, Faculty of Health Sciences, School of Medicine, Department of Clinical Medicine, Kuopio, Finland; [8]Kuopio University Hospital, Department of Medicine, Endocrinology and Clinical Nutrition, Kuopio, Finland; [9]University of Eastern Finland, Institute of Clinical Medicine, Kuopio, Finland; [10]Kuopio University Hospital, Department of Medicine, Internal Medicine, Kuopio, Finland*
Email: palomurt@uef.fi

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease. The hallmark of MASLD is hepatic steatosis, which can progress in some patients to metabolic dysfunction-associated steatohepatitis (MASH). Fatty acids (FAs) are mainly stored in adipose tissue and mobilized through lipolysis to the liver. They can also be synthesized in the liver via *de novo* lipogenesis. The liver esterifies FAs into lipoproteins for circulation, but when its capacity is exceeded, excess FAs accumulate, causing steatosis. To assess inter-tissue crosstalk in FA metabolism in those with MASLD, we compared FA profiles in the liver, serum, and visceral and subcutaneous adipose tissue samples from severely obese patients with either normal liver, simple steatosis or MASH. This comprehensive approach provided a unique opportunity to explore depot-specific alterations in FA profiles in those with MASH, which has not been previously studied.

Method: Samples were collected from the liver, subcutaneous, and visceral adipose tissue during laparoscopic bariatric surgery together with preoperative serum samples from 183 severely obese patients (122 women, mean age 46.9 ± 9.7 years, and body mass index 43.5 ± 5.7 kg/m^2). Liver histology was assessed by one pathologist according to the standard criteria. FA composition in different tissue depots was analyzed with gas-liquid chromatography. The enzyme activities were estimated using the product-to-precursor-ratios of individual FAs.
Results: In general, the differences observed in the liver based on the histology were more distinct than those in adipose tissue. Proportion of all polyunsaturated FAs were significantly lower in liver in patients with MASH compared to those with normal liver (all adjusted $p < 0.01$). In contrast, dihomo-gamma-linoleic acid, adrenic acid and arachidonic acid proportions were higher in subcutaneous and visceral adipose tissue in patients with MASH compared to those with normal liver (all adjusted $p < 0.001$). Interestingly, monounsaturated and saturated FAs exhibited opposite trends between liver and adipose tissue. Estimated delta-5-desaturase activity was lower (adjusted $p = 0.02$) and elongase activity was higher (adjusted $p = 0.006$) in liver in those with simple steatosis compared to those with normal liver. In visceral adipose tissue, the elongase activity was lower in patients with MASH compared to those with normal liver (adjusted $p = 0.04$).
Conclusion: The lower proportion of arachidonic acid in the liver suggests its increased utilization in eicosanoid production or decreased synthesis due to a reduced linoleic acid proportion or diminished delta-5-desaturase activity. These findings highlight distinct differences in FA metabolism between the liver and adipose tissue in patients with MASLD, emphasizing tissue-specific regulatory mechanisms.

FRI-422-YI
Taurine reprograms hepatocyte metabolism and its plasma levels are inversely associated with the progression of MASLD
Pavitra Kumar[1], Juan Wang[1], Hasan Tarik Cosgun[1], Münevver Demir[1], Frank Tacke[1], Cornelius Engelmann[1,2]. *[1]Department of Hepatology and Gastroenterology, Charité—Universitätsmedizin Berlin, 13353 Berlin, Germany, Berlin, Germany; [2]Berlin Institute of Health (BIH), 10178 Berlin, Germany, Berlin, Germany*
Email: pavitra.kumar@charite.de

Background and aims: Liver diseases, particularly those related to metabolic disorders like Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD), pose a significant global health challenge. Identifying reliable biomarkers for early diagnosis and understanding metabolic changes is essential for effective management. Taurine, a semi-essential micronutrient synthesized in the liver, declines with aging. Hepatocytes, the primary cells for fat accumulation and metabolism in the liver, interact with immune cells, influencing the progression of MASLD. This study investigates taurine as a potential biomarker for MASLD and explores its regulatory role in hepatic metabolism-related to this condition.
Method: The study examined polar metabolomics in EDTA-plasma from age-matched healthy subjects (n = 5) and MASLD patients at stages F0-F2 (n = 10) and F3-F4 (n = 10). Primary mouse hepatocytes were treated with 1 mM taurine for 24 hours, followed by 0.3 mM free fatty acids (FFA) (1:1, palmitic and oleic acid) for another 24 hours. Neutrophils were isolated using negative selection microbeads, while bone marrow-derived macrophages were obtained with anti-F4/80 microbeads. Cellular bioenergetics were assessed using 10 mM glucose, 2 mM pyruvate, and 1 mM glutamine, with fuel preference evaluated via the XF Seahorse analyzer.
Results: Levels of taurine decreased 2-fold in MASLD patients at stages F0-F2 ($p < 0.05$), and further decreased by 2.5-fold from F0-F2 to F3-F4 ($p < 0.05$). This decline in taurine levels correlates with the progression of chronic liver disease severity toward fibrosis and cirrhosis, as confirmed in a validation cohort that showed a 50% reduction in taurine between healthy individuals (n = 29) and those with compensated cirrhosis (n = 43, $p < 0.0001$). Since taurine is primarily synthesized in the liver, we aim to examine its role and mechanism in steatotic hepatocytes. Our findings indicate that taurine reduces fatty acid uptake and lipogenesis by downregulating CD36, FATP2, and FATP5, maintaining its effects even with FFA treatment. Taurine supplementation halved lipid accumulation ($p < 0.001$) without increasing fatty acid oxidation, suggesting its benefits arise from reduced FFA uptake and lipogenesis. FFA-exposed steatotic hepatocytes preferred glucose over fatty acids for ATP production, but taurine decreased glucose-dependent oxidative phosphorylation by 2-fold ($p < 0.001$). Additionally, taurine reduced the attraction of neutrophils and bone marrow-derived macrophages (BMDMs) to steatotic hepatocytes by 1.5-fold and 2-fold, respectively ($p < 0.001$), indicating its potential to mitigate liver inflammation.
Conclusion: Taurine functions as an early biomarker for liver disease, with significant decreases in plasma levels observed across various disease stages. Additionally, taurine supplementation reduces fatty acid uptake and lipid accumulation while also modulating inflammatory response, highlighting its potential therapeutic benefits in managing MASLD.

FRI-423
Targeting activated fibroblasts in metabolic-associated steatotic liver disease with Nintedanib
Pil Soo Sung, Gil Won Lee[1], Mi Hyun Kwon[1], Kwon Yong Tak[2], Seung Kew Yoon[2]. *[1]The Catholic University Liver Research Center, Department of Biomedical Sciences, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea, Seoul, Korea, Rep. of South; [2]The Catholic University Liver Research Center, Department of Biomedical Sciences, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea, Division of Hepatology, Department of Internal Medicine, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Republic of Korea, Seoul, Korea, Rep. of South*
Email: pssung@catholic.ac.kr

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) represents a significant health challenge, with activated fibroblasts playing a crucial role in its progression. Targeting and eliminating these fibroblasts could be key in managing MASLD. This study aimed to evaluate the potential of nintedanib, an established treatment for idiopathic pulmonary fibrosis (IPF), in alleviating MASLD through its effects on activated fibroblasts.
Method: Fibroblasts isolated from the livers of MASLD patients were treated with nintedanib and compared to sorafenib for efficacy. Hepatic stellate cell line LX2 was activated with TGF-β1 and treated with varying concentrations of nintedanib. Bulk RNA sequencing was used to examine RNA changes in response to treatment. To assess the role of PDGFR suppression, siPDGFR was transfected into LX2 cells. In vivo, a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) mouse model was employed to study nintedanib's effects using FACS analysis, Sirius red staining, H&E staining, IHC, and single-cell sequencing.
Results: In vitro, nintedanib significantly reduced the viability of activated fibroblasts compared to sorafenib. Western blotting revealed decreased levels of phosphorylated-AKT and phosphorylated-ERK in nintedanib-treated fibroblasts, indicating reduced inflammation and fibrosis. Bulk RNA sequencing reveled that PDGFR, the target of nintedanib, decreased in dose-dependent manner with nintedanib treatment. Additionally, fibrosis markers such as FN1 and Col1a1 were also found to decrease in a dose-dependent manner. After transfecting LX2 cells with siPDGFR and inducing activation with TGF-β1, a reduction in fibrosis marker FN1, FAP and α-SMA was observed. Additionally, phosphorylated-AKT levels was also found to decreased. In the CDAHFD mouse model, nintedanib treatment selectively eliminated FAP+PD-L1+ activated

fibroblasts at low concentrations, suggesting its potential as a therapeutic option for MASLD.
Conclusion: Nintedanib effectively reduces activated fibroblasts in both in vitro and in vivo MASLD models. By targeting PDGFR, nintedanib suppresses fibrosis markers and selectively eliminates key fibroblast populations. These results support nintedanib as a promising therapeutic option for MASLD by addressing the fibroblast-driven progression of liver fibrosis.

FRI-424
Differential activation and clonal expansion of T cells by PNPLA3 I148 M genetic variant is associated with the progression of metabolic dysfunction-associated steatotic liver disease
Jaejun Lee[1], Jung Hoon Cha[2], Hyun Yang[1], Seung Kew Yoon[1], Seong Wook Yang[3], Seok Keun Cho[4], Mi Young Byun[4], Pil Soo Sung[1], Si Hyun Bae[1]. *[1]Division of Hepatology, Department of Internal Medicine, College of Medicine, The Catholic University of Korea, The Catholic University Liver Research Center, Department of Biomedicine & Health Sciences, College of Medicine, The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]The Catholic University Liver Research Center, Department of Biomedicine & Health Sciences, College of Medicine, The Catholic University of Korea, Seoul, Korea, Rep. of South; [3]Department of Systems Biology, Institute of Life Science and Biotechnology, Yonsei University, Seoul, Korea, Rep. of South; [4]Xenohelix Research Institute, Incheon, Korea, Rep. of South*
Email: pssung@catholic.ac.kr

Background and aims: Increasing evidence highlights the pivotal role of T cells in the progression of metabolic dysfunction-associated steatotic liver disease (MASLD). The *PNPLA3 I148M* variant has been linked to hepatic inflammation and fibrosis, but its role in T cell infiltration, activation, and clonal expansion within the liver remains unclear.
Method: A total of 70 patients with MASLD were prospectively enrolled. Genomic DNA was extracted from buccal swabs or liver biopsy samples, and SNP genotyping was performed to determine the rs738409 SNP genotype at codon 148 of PNPLA3 using the XENOHELIX PNPLA3 genotyping kit. Immunohistochemistry was conducted using CD3 and CD68 antibodies to quantify T cell and macrophage infiltration, respectively. Cell counts were assessed in three periportal regions, normalized to a unit area (20,000 μm²), and averaged. Additionally, total RNA extracted from biopsy specimens was used for quantitative RT-PCR to assess the expression of specific markers associated with T cell activation and clonal expansion.
Results: Among the 70 MASLD patients, 34 carried the GG genotype, while 21 and 15 carried the GC and CC genotypes, respectively. GG genotype carriers exhibited significantly higher CD3+ and CD68+ cell counts in the periportal region compared to GC/CC carriers ($P < 0.05$). Increased CD3+ and CD68+ cell number was positively correlated with advanced fibrosis stages and higher NAS scores (5–8 vs. 0–4, $P < 0.05$). In sensitivity analysis comprising fibrosis stage 0–2, GG genotype still exhibited higher CD3+ and CD68+ cell counts compared to GC/CC carriers ($P < 0.05$). Interestingly, the transcriptional profile of these clonally immune cells differed based on genotype. MASLD livers with GG genotype showed stronger expression of markers of chronic Ag stimulation (KLRG1, CD160, CD244, TIGIT, TOX, and PDCD1) than those with GC and CC genotypes.
Conclusion: This study demonstrates a significant correlation between the PNPLA3 I148M variant and increased T cell infiltration, activation, and clonal expansion within the MASLD liver. Further study is on-going regarding TCR sequencing and in-vitro co-culture experiments. Funding: This research was supported by the Bio&Medical Technology Development Program of the National Research Foundation (NRF) funded by the Korean government (MSIT) (RS-2024-00438542).

Thrombospondin-2 reflects improved metabolism and attenuated liver fibrogenesis in severely obese patients undergoing an intensive weight-loss therapy
Rambabu Surabattula[1], Nathalie Rohmann[2,3], Julia Koppenhagen[4], Alexia Beckmann[3], Perdita Wietzke-Braun[3], Tim Hollstein[2,3], Sudha Rani Myneni[5], Katharina Hartmann[2], Lucy Kruse[2], Kristina Schlicht[2], Corinna Geisler[2], Kathrin Türk[2], Dominik Schulte[2,3], Matthias Laudes[2,3], Detlef Schuppan[6,7]. *[1]1Institute of Translational Immunology, University Medical Center Mainz, Mainz, Germany; [2]Institute of Diabetes and Clinical Metabolic Research, University Medical Center Schleswig-Holstein (UKSH) Campus Kiel, Kiel, Germany; [3]Division of Endocrinology, Diabetes and Clinical Nutrition, Department of Internal Medicine, University Medical Center Schleswig-Holstein Campus Kiel, Kiel, Germany; [4]Institute of Diabetes and Clinical Medical Research, University Medical Center Schleswig-Holstein Campus Kiel, Kiel, Germany; [5]Institute of Translational Immunology, University Medical Mainz, Mainz, Germany; [6]Institute of Translational Immunology, University Medical Center of the Johannes Gutenberg University, Mainz, Mainz, Germany; [7]Division of Gastroenterology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, United States*
Email: detlef.schuppan@unimedizin-mainz.de

Background and aims: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is common in the severely obese population, with a global prevalence of up to 30%. Lifestyle interventions aimed at weight loss are the cornerstone of MASLD management. However, non-invasive assessment of response to intervention is not yet established. Here, we investigated a novel fibrogenesis marker, thrombospondin-2 (TSP2), in association with intensive weight loss and with special attention to markers of liver inflammation, metabolism and fibrosis after lifestyle intervention in a severely obese population.
Method: The Kiel intervention cohort consists of 160 patients with severe obesity (BMI≥40) who underwent a multimodal, intensive interdisciplinary weight loss program at the UKSH in Kiel (Germany) for six months, which includes guideline-based recommendations. Clinical and biochemical parameters were assessed at baseline, after a 10-week very low-calorie diet (VLCD) and after a further 16-week normo-caloric diet (NCD). Serum TSP2 was measured using a validated ELISA and compared with metabolic markers and liver stiffness measurement (LSM) by transient elastography.
Results: TSP2 levels decreased significantly after weight loss therapy ($-14.8 \pm 18.6\%$, $p < 10^{-5}$), which correlated significantly with the decrease in BMI ($-17.1 \pm 5.9\%$, $p < 10^{-5}$; $r = 0.19$, $p = 0.04$). BMI and fat mass continuously decreased in both arms (VLCD & NCD), while TSP2 and liver stiffness along with other metabolic markers decreased significantly after VLCD and maintained at low levels after NCD. TSP-2 correlated with anthropometric values, liver enzymes, fat mass, visceral fat and liver stiffness at baseline and during the intervention. TSP2 levels were higher in men ($p = 7.1 \times 10^{-3}$) and in patients with pre- and manifest diabetes ($p = 9.3 \times 10^{-4}$) and also correlating with the HOMA index for insulin resistance, triglycerides and HDL-Cholesterol levels. Based on baseline liver stiffness, subjects were classified as normal-mild (<7.5 kPa, n = 65), elevated (7.5–13 kPa, n = 38), and cirrhotic (>13 kPa, n = 14). Interestingly, TSP2 was significantly reduced in all groups during VLCD.
Conclusion: Circulating TSP2 levels showed significant changes in individuals with severe obesity who achieved weight loss through diet and may be a useful tool to assess metabolic improvements and liver fibrosis in patients undergoing lifestyle and therapeutic interventions. Ongoing further analyses will investigate its possible connection with body composition, metabolic status and inflammatory activity.

Email: rferrerl@recerca.clinic.cat

Background and aims: Metabolic-associated steatotic liver disease (MASLD) is a complex disease with a high degree of population and individual variability. Therefore, it is important to develop human-based preclinical models that recapitulate patient heterogeneity to fine new and personalized therapeutic strategies. Here, we aim to generate patient-derived liver biopsy organoids (b-Orgs) from MASLD patients for precision disease modelling.
Method: A portion of a liver tru-cut biopsy from patients with different stages of MASLD (n = 53) was seeded in Matrigel to generate b-Orgs. b-Orgs were characterised by immunofluorescence, functional analysis and bulk RNA sequencing. b-Orgs were stimulated with lipotoxic media to model MASLD and the response was assessed by lipidomic and RNASeq analysis and imaging. Hyperpolarised magnetic resonance (HPMR) was used for real-time metabolic assessment of b-Orgs.
Results: Our methodology allowed the successful generation of b-Orgs with a high efficiency (87%), ranging from 100% for early stages (MASLD F0) to 83% for advanced stages (MASH F3/F4). b-Orgs showed an enriched hepatocyte-like phenotype as assessed by immunofluorescence, bulk transcriptomics and functional studies. b-Orgs expressed high levels of albumin and HNF4A, but also EpCAM, SOX9, and KRT7. In addition, b-Orgs produced albumin and alpha-1-antitrypsin and contained functional bile canaliculi as stained with MRP2. b-Orgs retain disease stage characteristics, b-Orgs from advanced MASLD patients showed a tendency to lose the hepatocyte-like identity, with increased ductular reaction and epithelial-to-mesenchymal transition markers. When stimulated with a lipotoxic media, b-Orgs showed morphological changes, increased lipid accumulation and upregulated inflammatory markers. Finally, metabolic imaging of b-Orgs was assessed by HPMR after injection of hyperpolarised [1-13C]-pyruvate (PA) and downstream metabolites were examined. Real-time monitoring of PA metabolism revealed the conversion of PA to lactate via LDH in MASLD b-Orgs, indicating the potential of b-Orgs and HPMR for real-time assessment of metabolic response.
Conclusion: Overall, we have successfully developed a methodology to generate patient-derived b-Orgs from different stages of MASLD. b-Orgs allow modelling MASLD while incorporating patient characteristics and disease stage features, highlighting their potential as a tool for personalised medicine studies.

FRI-430

Hepatic estrogen receptor alpha drives liver metabolic adaptation during pregnancy

Arianna Dolce[1], Clara Meda[2], Sara Della Torre[1]. *[1]Department of Pharmaceutical Sciences, Università degli Studi di Milano, Milano, Italy; [2]Department of Health Sciences, Università degli Studi di Milano, Milano, Italy*
Email: sara.dellatorre@unimi.it

Background and aims: Pregnancy is a unique physiological state marked by extensive metabolic adaptations, particularly in the liver, to meet the increased energy and nutrient demands of both the mother and the developing fetus. The liver dynamically adjusts glucose, lipid, and protein metabolism in response to hormonal signals, with estrogen receptor alpha (ERa) playing a key regulatory role. In the liver of female mice, ERa not only supports metabolic demands but also integrates reproductive and metabolic processes to maintain homeostasis. Disruptions in hepatic ERα regulatory network can contribute to pregnancy-related liver disorders, such as intrahepatic cholestasis of pregnancy (ICP) and acute fatty liver of pregnancy (AFLP). ICP is characterized by impaired bile acid transport and accumulation, while AFLP results from defective fatty acid oxidation, potentially leading to liver failure. Despite its pivotal role in metabolic homeostasis, the mechanisms by which hepatic ERa drives metabolic adaptations during pregnancy and its potential contribution to pregnancy-related liver diseases remain poorly understood. Unraveling how ERa coordinates liver metabolism during pregnancy could offer new insights into therapeutic strategies to prevent or mitigate these conditions. This study aims to explore the role of hepatic ERa in metabolic adaptation during pregnancy and its potential involvement in the pathogenesis of pregnancy-related liver disorders.
Method: To evaluate the relevance of hepatic ERa in metabolic adaptation during pregnancy, we compared liver-specific ERa-knockout (LERKO) and control (CTRL) female mice at gestational days 6.5, 14.5, and 17.5. Virgin females at the proestrus phase (when circulating 17β-estradiol levels are highest) were used as the reference group.
Results: Pregnancy induced significant changes in the hepatic transcriptome, with the most pronounced alterations occurring at mid-pregnancy compared to virgin controls. Each gestational timepoint exhibited distinct transcriptomic patterns, especially enriched in genes involved in lipid, bile acid, and steroid metabolism, as well as hepatokine signaling. Although pregnancy rates were comparable between LERKO and control females, LERKO mice displayed altered

gene expression patterns, indicating that hepatic ERa is essential to fully optimize liver metabolic adaptations during pregnancy.
Conclusion: Hepatic ERa is crucial for orchestrating metabolic adaptations across different stages of pregnancy, likely supporting the energy demands of the developing fetus. These findings suggest that dysregulated hepatic ERa signaling may contribute to an increased risk of pregnancy-related liver disorders, including ICP, AFLP, and metabolic dysfunction-associated steatotic liver disease (MASLD). Targeting ERa could offer a novel approach to preventing or mitigating these conditions.

Background and aims: QL1005, a glucagon-like-protein-1/growth differentiation factor 15 (GLP-1/GDF15) dual-agonist, shows significant effects in reducing body weight and metabolic disorders in human and animal models with low-toxicity. This study aimed to explore the effects of QL1005 against hepatic fibrosis.
Method: The chemical-induced liver fibrosis model was established in male mice by intraperitoneal injections of 10% CCl4 for 7 weeks. The MASH model was created by feeding mice a Western diet supplemented with fructose (WDF) for 26 weeks. During the last 3 or 6 weeks, mice received daily subcutaneous injections of QL1005, GLP-1 (QL1005 with inactive GDF15), GDF15 (QL1005 with inactive GLP-1), or Vehicle at a dose of 30 nmol/kg. At the end of the experiments, plasma and liver samples were collected for analysis.
Results: During both hepatic injury and resolution phases (24 and 72 hours after last injection, respectively), QL1005 and GLP-1 significantly reduced ALT and AST levels compared to Vehicle, while GDF15 showed no effect. QL1005 uniquely lowered TNF-α and MCP-1 levels in both phases. No significant anti-fibrotic effects were observed during the injury phase for QL1005 or the mono-agonists. In the resolution phase, QL1005 reduced tissue injury and fibrosis, as shown by Sirius Red staining, with a 38.2% decrease in α-SMA-positive regions and downregulation of α-SMA, type 1, and type 3 collagen mRNA levels. RNAseq analysis revealed decreased expression of genes related to fibrosis, inflammation, apoptosis, and oxidative stress. In the MASH model, treatment with all three agonists significantly reduced weight gain and liver size. Liver enzymes, fasting blood glucose, triglycerides, and cholesterol levels were also notably improved, with QL1005 showing the greatest effect. QL1005 significantly reduced the hepatic expression of a-SMA and COL1a1 as confirmed by immunohistochemistry and pro-inflammatory cytokines including IL-6, TNFα and IL-1, as confirmed by qPCR. In HSC of scRNA-seq analysis, KEGG enrichment analysis revealed that QL1005 may influence apoptosis、oxidative phosphorylation、fatty acid metabolism and interferon-α response pathways. In QL1005-treated mice, macrophage counts were significantly reduced, accompanied by downregulation of TGF-β and p53-related pathways.
Conclusion: GLP-1/GDF15 dual-agonist showed a synergistic effect in reducing hepatic inflammation and fibrosis was observed in chemical-induced fibrosis and MASH models, highlighting its potential as a therapeutic candidate for treating liver fibrosis.

FRI-432
Role of TOX3 in regulating the progression of metabolic dysfunction-associated steatotic liver disease
Shaoping She[1], Hongsong Chen[1]. [1]*Peking University People's Hospital, Peking University Hepatology Institute, Infectious Disease and Hepatology Center of Peking University People's Hospital, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis, Beijing, China*
Email: sheshaoping@126.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is now the most common cause of chronic liver disease globally, affecting over 30% of adults. Thymocyte selection-associated high mobility group box factor 3 (TOX3) is a member of an evolutionarily conserved DNA-binding protein family. Our previous study found that TOX3 could promote the progression of hepatocellular carcinoma (HCC) through the PPAR signaling pathway. However, the role and mechanism of TOX3 in MASLD have not yet been elucidated.
Method: The expression of TOX3 was detected in patients with chronic liver diseases and several murine models of MASLD induced by methionine-choline deficiency (MCD) diet, western diet (WD) and carbon tetrachloride (CCl_4) injection. The role of TOX3 was evaluated in heterozygous Tox3 gene knockout (*Tox3*$^{+/-}$) mice and hepatocyte-specific Tox3 knockout (*Tox3*^{Hep}) mice in vivo. Direct effects of TOX3 on hepatocytes (AML12 and THLE-2) and hepatic stellate cells (HSCs) (LX-2) were studied in vitro. Single-cell sequencing was used to explore the molecular mechanism of TOX3 regulation of MASLD progression.
Results: In this study, we found that TOX3 was highly expressed in fibrotic/cirrhotic tissues from patients with multiple etiologies and in mice treated with MCD diet, WD or CCl_4 injection. PSMP deficiency resulted in a marked amelioration of hepatic injury and steatosis in mouse models of MASLD. At the same time, the secretion of various proinflammatory cytokines in the serum and tissue of *Tox3*$^{+/-}$ and *Tox3*^{Hep} mice was also significantly reduced. *In vitro*, we found that the overexpression of TOX3 could directly promote the activation and survival of human LX-2 cells, while knockdown of TOX3 inhibits the activation and survival of LX-2 cells.
Conclusion: Taken together, TOX3 promotes hepatic injury and steatosis by activating the HSCs. The results are expected to clarify the role and mechanism of TOX3 in the liver immune microenvironment for the first time and indicate that TOX3 may be a potential therapeutic target for the treatment of MASLD.

FRI-433
Beneficial effects of milk-derived extracellular vesicles on liver fibrosis progression by restoring intestinal barrier integrity
Shinya Sato[1], Hiroyuki Masuda[1], Norihisa Nishimura[1], Kosuke Kaji[1], Tadashi Namisaki[1], Hitoshi Yoshiji[1]. [1]*Nara Medical University, Kashihara, Japan*
Email: shinyasato@naramed-u.ac.jp

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD) has emerged as the most prevalent chronic liver disease, leading to metabolic dysfunction associated steatohepatitis (MASH), cirrhosis, and hepatocellular carcinoma (HCC). However, no treatment for MASH-related fibrosis is available for clinical use. Extracellular vehicles (EVs) are bilayer membrane vesicles released from various cells into the extracellular space, participating in multiple life processes. Recent studies have indicated that bovine milk-derived EVs (B-mEVs) suppress inflammation, have anti-tumor effects, and protect the intestinal barrier in an in vivo model. Whether EVs from bovine milk exert a beneficial effect against MASH is worth investigating. We explored the effect of B-mEVs on MASH-related liver fibrosis by modulating the gut barrier function.
Method: MASH-related liver fibrosis was induced in female C57BL/6J mice by feeding them a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for eight weeks. B-mEVs (1.2 mg/kg) were orally administered every two days for four weeks. Seven-week-old female C57BL/6J mice were randomly divided into four groups and treated for 12 weeks as follows, n = 5 for each; i) normal chow with vehicle; ii) normal chow with B-mEVs; iii) CDAHFD diet with vehicle; iv) CDAHFD diet with B-mEVs. The mice were then sacrificed for histological analyses to assess the effect of B-mEVs on steatohepatitis

and fibrosis. Intestinal barrier integrity was also evaluated by the intestinal permeability using FITC-dextran and immunohistochemistry of tight junction proteins (TJPs). The effect of B-mEVs on the Caco-2 cell line barrier function was similarly evaluated in vitro using the permeability assay.
Results: B-mEVs significantly suppressed macrophage expansion, proinflammatory responses, and liver fibrosis in CDAHFD-fed mice by blocking hepatic translocation of lipopolysaccharide (LPS) and activating toll-like receptor (TLR) 4 signaling. Moreover, B-mEVs improved intestinal permeability by restoring TJPs like ZO-1, Occludin, and Claudin-2. B-mEVs also directly suppressed LPS-induced barrier dysfunction and TJP depletion in Caco-2 cells.
Conclusion: B-mEVs reduced MASH-related fibrosis by inhibiting lipid accumulation and macrophage expansion and suppressing LPS/TLR4/NF-κB-mediated inflammatory responses by restoring intestinal barrier function.

FRI-434
Investigating the pharmacological potential of a new investigational drug- AD64 for treating metabolic dysfunction-associated steatohepatitis induced by a hepatopathogenic diet in rats
Subheet Jain[1], Shiran Shetty[2], Arpitha Malhan[1]. *[1]Guru Nanak Dev University, Amritsar, India; [2]Kasturba Medical College, Manipal, India*
Email: s.jain@bioplus.in

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a progressive liver disorder marked by inflammation, fibrosis, and metabolic irregularities. Globally, metabolic dysfunction-associated liver disease (MASLD) affects approximately 32.4% of the population, with MASH impacting 3%–5%. This study investigates the therapeutic efficacy of AD64, a xanthine derivative, in a rat model of MASH induced by a high-fat/high-fructose (HF/HFr) diet.
Method: MASH was induced in Wistar rats (n = 6/group) through a 12-week diet consisting of 60% kcal from fat and supplemented with fructose. Rats were subsequently treated with AD64 at doses of 41.3, 82.6, or 124 mg/kg body weight for 12 weeks. Key outcomes included liver histopathology, body weight, serum liver enzymes (ALT, AST), abdominal ultrasonography (USG), lipid profiles, hydroxyproline content, and oxidative stress markers.
Results: MASH development in HF/HFr-fed rats was characterized by increased liver steatosis, inflammation, and hepatocyte ballooning. AD64 treatment resulted in significant improvements, with all dose groups achieving a ≥3-point reduction in NAS scores. At the highest dose, body weight decreased by 30%, AST levels by 40%, and ALT levels by 35%. USG findings indicated a reversal of stage III steatosis to near-normal levels. Lipid profile improvements included a 67% reduction in triglycerides. AD64 also reduced hydroxyproline content, indicating antifibrotic activity, and enhanced glutathione levels while suppressing reactive oxygen species, mitigating oxidative stress. A linear dose-response relationship was observed, further supporting AD64's efficacy.
Conclusion: AD64 demonstrated significant efficacy in alleviating MASH by improving liver histopathology, enzyme levels, ultrasonographic findings, lipid profiles, and oxidative stress markers while reducing inflammation and fibrosis progression. These findings position AD64 as a promising therapeutic agent for MASH, likely mediated through adenosinergic receptor modulation and PDE inhibition.

FRI-435
Increased nuclear localization of small heterodimer partner despite incresed serum BA profile in patients with metabolic dysfunction-associated steatohepatitis
Shih-Chieh Chien[1,2], Chiung-Yu Chen[3], Hong-Wen Tsai[4], Yih-Jyh Lin[5], Shu-Chu Shiesh[6], Pin-Nan Cheng[3], Chiu Hung-Chih[3], Yencheng Chiu[3], Mei-Juan Zheng[2], Ming- Shan Wu[2], Kung-Chia Young[7], Yau-Sheng Tsai[2]. *[1]Department of Internal Medicine, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, 138 Sheng Li Road, Tainan 70401, Taiwan, Institute of Clinical Medicine, College of Medicine, National Cheng Kung University, Tainan 70401, Taiwan, Tainan, Taiwan; [2]Clinical Medicine Research Center, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan; [3]Department of Internal Medicine, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan; [4]Department of Pathology, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan, Tainan, Taiwan; [5]Division of General and Transplant Surgery, Department of Surgery, National Cheng Kung University Hospital, College of Medicine, National Cheng Kung University, Tainan, Taiwan; [6]Department of Medical Laboratory Science and Biotechnology, Tainan, Taiwan; [7]Department of Medical Laboratory Science and Biotechnology, College of Medicine, National Cheng Kung University, Tainan, Taiwan*
Email: slamdunk9031137@gmail.com

Background and aims: Elevated serum bile acid (BA) levels have been documented in individuals with metabolic-dysfunction steatohepatitis (MASH), yet the underlying pathogenesis remains elusive. The nuclear factor small heterodimer partner (SHP) serves as a critical regulator in maintaining BA homeostasis. In this study, we investigated the associations of hepatic subcellular distribution of SHP and BA dysregulation in MASH patients.
Method: Hepatic tissues and serum samples were collected from MASH patients and healthy participants. Subcellular distribution of hepatic SHP protein was investigated by immunofluorescence staining. Serum BA levels were measured by liquid chromatography–mass spectrometry (LC-MS/MS) and tissue mRNA of BA-related genes were determined through quantitative reverse transcription-PCR (RT-PCR). Results were correlated to hepatic SHP subcellular distribution.
Results: We enrolled 68 patients with biopsy-proven MASH and 10 healthy participants. Patients with MASH exhibited elevated serum primary and conjugated BAs while having similar serum secondary BAs compared to healthy participants. Patients with MASH also demonstrated a markedly increased hepatic cytochrome P450 family 7 subfamily A member 1 (CYP7A1) mRNA and genes related to BA conjugation and transporters. Immunofluorescent staining revealed a marked increase in hepatocellular SHP nuclear ratio in patients with MASH (nuclear ratio of SHP in patients with MASH vs. control participants: 50.36% vs. 1.55%, $p < 0.001$), which is correlated with serum hepatitis markers, tissue NF-κB signaling intensity, and degree of hepatic steatosis, but not with serum BAs or BA-related genes.
Conclusion: Increased SHP nuclear localization represents a distinct characteristic of MASH liver that is linked to hepatic inflammation and steatosis. In patients with MASH, SHP may have deficiency in its canonical role to suppress BA synthesis.

FRI-436
Inhibition of hepatic bile salt uptake using the anti-HDV drug Bulevirtide attenuates inflammation in mouse models for colitis and diet-induced steatohepatitis
Thuc-Anh Nguyen[1], Claire Groenen[1], Reinout Roscam Abbing[1], Joost Lamboojj[2], Pim Koelink[1], Dirk de Waart[1], Isabelle Bolt[1], Esther Vogels[1], Suzanne Duijst[1], Joanne Verheij[3], Bruno Guigas[2], Manon Wildenberg[1], Coen Paulusma[1], Wietse In het Panhuis[1], Stan F.J. van de Graaf. *[1]Tytgat Institute for Liver and Intestinal Research, Amsterdam University Medical Centers, Amsterdam, Netherlands; [2]Leiden University Center for Infectious Diseases, Leiden University Medical Center, Leiden, Netherlands; [3]Department of Pathology, Amsterdam University Medical Centers, Amsterdam, Netherlands*
Email: t.a.nguyen@amsterdamumc.nl

Background and aims: Although activation of the bile salt receptor Takeda G protein-coupled receptor 5 (TGR5) leads to reduced pro-inflammatory cytokine production in macrophages and attenuated

inflammation in mice, synthetic agonists of TGR5 did not reach clinical application. Instead, we aimed to exploit systemic bile salt signaling by using Bulevirtide, a clinically applied inhibitor of the main hepatic uptake transporter of bile salts-Na^+ Taurocholate Co-transporting Polypeptide (NTCP). We investigated if NTCP inhibition could attenuate intestinal and hepatic inflammation and the role of TGR5 and the nuclear receptor FXR in bile salt-immunosuppressive effects.

Method: Mice that lack the Organic Anion Transporting Polypeptide (OATP)1a/1b gene cluster were used to mimic human (NTCP-centered) hepatic bile salt dynamics. Acute inflammation and colitis were induced using lipopolysaccharide (LPS) and dextran sodium sulfate (DSS), respectively, and metabolic dysfunction-associated steatohepatitis (MASH) was induced by a high-fat-high-cholesterol diet and fructose water. Mice were treated with vehicle or Bulevirtide once (LPS), 5-days (DSS) or 6 weeks (MASH). Additionally, bone marrow-derived macrophages (BMDM) from wild-type (WT), $TGR5^{-/-}$, and $FXR^{-/-}$ mice were stimulated with LPS and treated with taurochenodeoxycholic acid (TCDCA) *in vitro*.

Results: Bulevirtide increased plasma bile salt levels ~10-fold in all mouse models. In LPS-treated mice, Bulevirtide reduced plasma levels of the inflammatory cytokine TNFα and increased the anti-inflammatory cytokine IL10 increased, both 2-fold. In the colitis model, Bulevirtide prevented body weight loss, attenuated intestinal damage, and reduced intestinal gene expression of inflammatory cytokines TNFα, IL1β and IFNγ 2–3 fold. In the MASH model, Bulevirtide lowered liver weight, tended to reduce histological signs of steatosis and lobular inflammation, lowered abundance of $CD45^+$ $CD11b^+$ monocytes in plasma and liver and caused a shift towards a less inflammatory ($Ly6C^{high}TREML4^{low}$) and more regulatory ($Ly6C^{low}TREML4^{high}$) profile. In LPS-stimulated WT BMDM, TCDCA administration reduced TNFα and IL1β secretion. This effect was preserved in $TGR5^{-/-}$ and $FXR^{-/-}$ BMDM.

Conclusion: NTCP inhibition reduces intestinal inflammation and steatohepatitis, suggesting novel clinical applications of Bulevirtide and NTCP targeting small molecules. Interestingly, the effects of bile salts on BMDM *in vitro* were independent of TGR5 and FXR, suggesting the involvement of additional bile salt receptors underlying the beneficial effects of NTCP inhibition.

FRI-437

Liver sinusoidal endothelial cells affect lipid metabolism in hepatocytes and form lipid droplets under steatotic conditions

Ting Chen[1,2], Quinten Augustijn[1,2], Aldo Grefhorst[1,2], Max Nieuwdorp[1,2], A.G. (Onno) Holleboom[1,2]. [1]*Department of (Experimental) Vascular Medicine, Amsterdam University Medical Centers, Location AMC, Amsterdam, Netherlands;* [2]*Amsterdam Gastroenterology Endocrinology Metabolism (AGEM) Institute, Amsterdam UMC, University of Amsterdam, Amsterdam, Netherlands*
Email: t.chen@amsterdamumc.nl

Background and aims: Increasing evidence emphasizes the regulatory effect of liver sinusoidal endothelial cells (LSECs) in metabolic dysfunction-associated steatotic liver disease (MASLD). Dysfunctional LSECs aggravate MASLD progression, already from the stage of early stage of isolated steatosis. We aimed to characterize the role of LSECs in regulating lipid metabolism in hepatocytes under steatotic conditions by deploying a co-culture of lipid-laden human hepatocytes (HepG2) and immortalized LSECs (HLEC), using human aortic endothelial cells (HAECs) as control.

Method: HepG2 cells were cultured in 12-well-plates, HLECs and HAECs were in separate transwell inserts. HepG2 were treated with a mixture of fatty acids (250 µM oleic acid and 125 µM palmitate acid, OA/PA) or BSA for 24 hours, with or without the transwells of HLECs/HAECs above, creating a setting to study paracrine effects and mimicking the space of Disse. The intracellular lipid droplets in both hepatocytes and endothelial cells were stained and measured, and mRNA expression was studied.

Results: Upon OA/PA loading, co-culturing with HLECs resulted in smaller lipid droplets in HepG2 cells and 68% reduced intracellular triglyceride content. In HepG2 treated with OA/PA, lipogenic mRNA expression was inhibited upon co-incubation with HLECs but not with HAECs, including those encoding fatty acid synthase (*Fasn*), acetyl-CoA carboxylase alpha (*Acaca*), and sterol regulatory element-binding protein 1 (*Srebp1*). The mRNA expression of the genes encoding carnitine palmitoyl transferase 1A (*Cpt1a*) involved in fatty acid oxidation as well as the lipid transporter CD36 was down-regulated upon co-culture with HLECs but not with HAECs. Of interest, *Cd36* mRNA expression was upregulated in HLECs but was reduced in HAECs when co-cultured with HepG2 cells. In line, co-culturing with HepG2 cells resulted in more lipid droplets in the HLECs.

Conclusion: Co-culturing of hepatocytes with LSECs resulted in a less severe steatotic phenotype of the former cells, a feature that's absent in the presence of HAECs. These data strongly suggest that LSECs have a protective effects on hepatocytes via a paracrine factor. Future research aims to explore this paracrine LSEC-hepatocyte axis.

FRI-438

Identification of differences in therapeutic mechanisms between Resmetirom and Semaglutide on metabolic dysfunction-associated steatohepatitis treatment in western diet-fed melanocortin 4 receptor knockout mice

Takumi Sugawara[1], Kosuke Hitaka[1], Mitsuharu Matsumoto[1], Yumiko Miyamoto[1], Hitoshi Kandori[1], Kotaro Yokoyama[1], Yasunori Nio[1]. [1]*Axcelead drug discovery partners, Inc., 26-1, Muraoka-Higashi 2, Fujisawa, Kanagawa, 251-0012, Japan*
Email: takumi.sugawara@axcelead.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is strongly associated with metabolic abnormalities such as obesity and insulin resistance, and MASLD develops into metabolic dysfunction-associated steatohepatitis (MASH). Recently, Resmetirom, a thyroid hormone receptor (THR)-beta agonist, was approved for first MASH therapeutic drug. There are some reports of Resmetirom using diet-induced obese (DIO) mice. However, DIO mice models show only mild liver fibrosis and do not fully reflect human MASH pathology. Melanocortin 4 receptor (MC4R) expressed in hypothalamus regulates appetite and energy expenditure and MC4R KO mice gain appetite and body weight. Western diet (WD)-fed MC4R KO mice show multiple aspects of pathophysiology of MASH patients such as liver injury, steatosis, and fibrosis. Therefore, WD-fed MC4R KO mice are an attractive MASH model with significant fibrosis as compared with DIO mice model. For treatment of MASH, recently, it was reported that Gulcagon-like peptide-1 (GLP-1) analogue, Semaglutide, also has ameliorative effects on MASH. In this study, we confirmed and compared anti-MASH effects of Resmetirom and Semaglutide respectively using this mouse.

Method: To induce disease conditions, MC4R KO mice were fed with WD for 6 weeks before treatment. Resmetirom (5 mg/kg) was orally administered and Semaglutide (0.1 mg/kg) was subcutaneously injected daily for 7 weeks. Energy expenditure was analyzed after 6 weeks treatment. On the 7 weeks of treatment, body composition was measured using Magnetic Resonance Imaging. Then, mice were anesthetized and then blood was collected, and the liver was harvested. Plasma and liver were used for biochemical and pathological analyses.

Results: WD-fed MC4R KO mice showed increase in liver weight, plasma AST and ALT. Both Resmetirom and Semagluride treatments significantly improved these parameters. LDL-cholesterol in plasma was also increased in this model, however only Resmetirom lowered the level of LDL-cholesterol in accordance with the mechanism of THR-beta. Although Resmetirom and Semagluride ameliorated liver

fibrosis and fat mass, Semaglutide significantly suppressed lean mass. Moreover, regarding energy expenditure, Resmetirom enhanced oxygen consumption but Semaglutide reduced energy expenditure. The results of gene expressions and pathological analysis are also explained in this conference.
Conclusion: These results revealed that the different mechanisms of anti-MASH effects between Resmetirom and Semaglutide. Similar to clinical evidence, Semaglutide treatment might have a problem on muscle mass reduction by food intake suppression. This study provides the first evaluation to compare Resmetirom and Semaglutide simultaneously on MASH phenotypes and revealed their mechanism of action using WD-fed MC4R KO mice.

FRI-439

Shallow-deep neural networks reveal extracellular vesicles as robust biomarkers for liver steatosis stages S0 vs. S1-S3 in metabolic dysfunction-associated steatotic liver disease patients

Email: trif.lena@gmail.com

Background and aims: Extracellular vesicles (EV) have emerged as promising biomarkers in liver diseases. This study explores their utility in distinguishing the steatosis (S1-S3) stages in metabolic dysfunction-associated steatotic liver disease (MASLD) from non-steatosis (S0). Additionally, we evaluated the performance of a shallow-deep neural network (sDNN) architecture in leveraging EV data, showcasing its potential in handling limited sample volumes effectively.
Method: We included 74 MASLD patients with ultrasound-confirmed steatosis and at least one cardiometabolic risk factor after excluding other causes of steatosis. We performed transient elastography via the "iLivTouch" FT100 device by Wuxi Hisky Medical Technologies Co., Ltd. (Hisky Med), China by which we acquired Ultrasound Attenuation Parameter (UAP) values. Patients were categorized into S0, S1, S2 and S3 steatosis stages based on the UAP (dB/dl) thresholds, <S0 244 dB/dl, ≥S1 244 dB/dl, ≥S2 269 dB/dl, ≥S3 296 dB/dl. Plasma samples were collected and further processed for the isolation and characterization of EVs with differential centrifugation and Nanoparticle Tracking Analysis, respectively. We used data exclusively from EV characterization, with steatosis stages categorized as S0 versus S1-S3. The dataset was partitioned into training and testing subsets with 80/20%. Model performance was assessed via three-fold cross-validation (3CV), employing a custom-designed DNN architecture with shallow-deep layers to balance interpretability, feature representation and avoid over-fitting. Metrics included specificity, sensitivity, receiver operating characteristic (AUROC) area, and F1 score, averaged across CV folds.
Results: The sDNN achieved outstanding test performance: specificity of 0.6, sensitivity of 0.9, AUROC of 0.75, and an F1 score of 0.86. Cross-validation results demonstrated robustness, with mean specificity of 0.65 ± 0.16, sensitivity of 0.82 ± 0.20, AUROC of 0.73 ± 0.06, and F1 score of 0.80 ± 0.10. Notably, even with the minimal dataset size of 74 patients (59/15), the architecture effectively captured the discriminative power of EV, underscoring their relevance as biomarkers.
Conclusion: This study highlights extracellular vesicles as viable non-invasive biomarkers for staging liver steatosis. The shallow-deep architecture demonstrated excellent performance despite the limited data size, paving the way for scalable and interpretable artificial intelligent applications in biomarker-driven diagnostics.

Background and aims: Extracellular ATP (eATP) is a damage-associated molecule that triggers the inflammatory response, leading to immune cell infiltration and cytokine release. ENTPD1/CD39 is an ectonucleotidase which is responsible for metabolizing ATP, decreasing circulating ATP levels, allowing a regulation of inflammation. In addition, P2RX7 is also an ATP receptor which triggers de NLRP3 inflammasome pathway, increasing the release of IL-1B. The aim of this study was to determine the role of eATP and the pathways in which it is involved in the progression of MASLD.
Method: Thirty-six male C57BL/6J mice were fed a High Fat High Carbohydrate and Cholesterol (HFHCC) diet (5TJT Test Diet) (n = 29) or chow (n = 7) for 52 weeks and thirty male C5BL/6J mice were fed a CDACHFD diet (Teklad Rodent Maintenance 2014) (n = 20) or chow (n = 10) diet for 8 weeks. *Entpd1* gene and Entpd1 and P2rx7 protein expression were assessed by PCR and IHC assays. Moreover, one-hundred three biopsy proven MASLD patients were included and classified according to SAF and NAS Score as bland steatosis (n = 42) or MASH (N = 61). Patients with at least 1 point in each parameter of SAF score and NAS Score > 4 were classified as MASH. Serum CD39 levels were measured by ELISA.
Results: In mice fed a HFHCC diet for 52 weeks 5 times higher levels of Entpd1 were observed compared to controls ($p < 0.0001$). Moreover, in mice fed with a CDAC-HFD diet, an increase of Entpd1 levels were observed (fold change of 1 ± 0.37 vs 4.3 ± 2.08; $p < 0.0001$). Entpd1 protein expression is observed around the central vein in the control group, while there is no expression around the

portal vein. However, in both HFHCC and CDACHFD diet mice, the expression presented a shift towards the portal vein, showing a heightened expression in the portal vein region and a decline in the central vein region. Regarding P2rx7 expression, there is an elevated number of positive cells per area in mice fed HFHCC diet *vs.* controls, indicating an increased expression of P2RX7 in this group (272.4 ± 79.82 *vs.* 391.8 ± 121.8; p = 0.0035). Patients with MASH (1368 ± 1094 pg/ml) had increased ENTPD1 levels compared to patients with bland steatosis (925 ± 474 pg/ml) (p = 0.006). Based on inflammation, an increase in ENTPD1 serum levels were observed as inflammation increased [none (n = 19), 879 ± 484 pg/ml; mild (n = 56), 1164 ± 757 pg/ml; moderate (n = 28), 1444 ± 1312 pg/ml; p = 0.112]. In addition, a correlation between ENTPD1 levels and SAF Score's activity was found (p = 0.03). ENTPD1 levels did not show significant differences in fibrosis [F0 (n = 22), 947 ± 563 pg/ml; F1 (n = 22), 1404 ± 1536 pg/ml; F2 (n = 17), 1263 ± 656 pg/ml; F3 (n = 33), 1227 ± 749 pg/ml; F4 (n = 9), 960 ± 490 pg/ml; p = 0.491].
Conclusion: Entpd1 mRNA and protein levels and P2rx7 protein levels were increased along with the progression of the disease, suggesting that eATP related pathways play an important role in the progression of MASLD, mainly in the transition steatosis to steatohepatitis.

FRI-445
Deep learning analysis reveals the impact of steatosis size and density on the progression of non-alcohol-related liver disease in severe obesity
Vicente Cambra-Cortes[1], Alina-Iuliana Onoiu[1], Andrea Jiménez-Franco[1], Juan Manuel Jiménez-Aguilar[1], Núria Montalà-Palau[1], Jordi Camps[2], Jorge Joven[1]. [1]*Universitat Rovira i Virgili, Unitat de Recerca Biomèdica, Reus, Spain;* [2]*Hospital Sant Joan de Reus, Unitat de Recerca Biomèdica, Reus, Spain*
Email: vicentecambra2697@gmail.com

Background and aims: Over the last few decades, the worldwide prevalence of obesity and Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) has grown significantly. Metabolic Dysfunction-Associated Steatohepatitis (MASH) represents the progressive form of MASLD, and suffering from it can result in a higher risk of premature death. It has been shown that steatosis has an important role in the pathogenesis of the disease. This study aims to determine the effect of steatosis percentage, size and density on the presence of MASH-associated comorbidities and liver damage, influencing the severity and progression of MASH in people with severe obesity.
Method: A cohort of 354 patients with severe obesity undergoing bariatric surgery at Hospital Universitari Sant Joan de Reus were recruited and classified based on liver biopsies into non-MASH (134), uncertain (132) and MASH (88). Blood samples were collected pre-surgery, and liver biopsies were processed for histological analysis using Haematoxylin & Eosin and Masson's Trichrome staining. Biochemical parameters were assessed using an automatic analyzer, and clinical variables were obtained from medical history. A deep learning-based method quantified steatosis in digitalized liver slides.
Results: Comparing the deep learning-based approach with pathologists' assessments, we found that pathologists tended to overestimate the severity of steatosis. Our analysis revealed that not only does the percentage of steatosis increase, but lipid droplet size and density also rise as the disease progresses. In our study of variables impacting steatosis development, we observed a link between age and increased steatosis. Factors such as male sex, structured diet schedules, hypertension, type 2 diabetes, and metabolic syndrome were also shown to play a significant role in the pathogenesis of the disease. Additionally, liver damage enzymes increased with the progression of steatosis.
Conclusion: Significant differences were found between groups regarding steatosis percentage, size, and density. Moreover, sex, age, and metabolic disorders significantly influenced the prevalence of steatosis. Altered levels of liver enzymes were also observed with the progression of the disease. Our findings highlight the complex interplay between metabolic dysfunction, hepatic steatosis, and the progression of MASLD to MASH in individuals with severe obesity.

FRI-446
Metabolomic profiling reveals early biomarkers of gestational diabetes mellitus with MASLD as a mediator
Won Kim[1], Saekyung Joo[1], Young Ho So[1], Yong Jin Jung[1]. [1]*Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, Korea, Rep. of South*
Email: wonshiri@yahoo.com

Background and aims: This study aims to identify early metabolomic biomarkers of gestational diabetes mellitus (GDM) and evaluate their association with hepatic steatosis.
Method: We compared maternal serum metabolomic profiles between women who developed GDM (n = 118) and matched controls (n = 118) during the first (10~14 gestational weeks) and second (24~28 gestational weeks) trimesters using ultra-performance liquid chromatography coupled with mass spectrometry. Mediation analysis was performed to evaluate the mediating role of metabolic dysfunction-associated steatotic liver disease (MASLD) in the relationship between metabolites and subsequent development of GDM. A refined prediction model was developed to predict GDM using established clinical factors and selected metabolites.
Results: Significant alterations in circulating metabolites, including amino acids, bile acids, and phospholipids, were observed in the GDM group compared to controls during early pregnancy. Mediation analysis revealed that several metabolites, including glycocholic acid (proportion mediated (PM) = 31.9%), butanoyl carnitine (PM = 25.7%), and uric acid (PM = 22.4%), had significant indirect effects on GDM incidence mediated by hepatic steatosis. The refined prediction model composed of clinical factors and selected metabolites in the first trimester demonstrated higher performance in predicting GDM development than the established prediction model composed solely of clinical factors (AUC, 0.85 vs. 0.63, p < 0.001).
Conclusion: Women who developed GDM exhibited altered metabolomic profiles from early pregnancy, which showed a significant correlation with GDM, with MASLD as a mediator. Selected metabolomic biomarkers may serve as predictive markers and potential targets for early risk assessment and intervention in GDM.

FRI-447
Preclinical studies of a novel hydrolysis-based prodrug for treating metabolic dysfunction associated steatohepatitis
Gongxin He[1], Xiubo Tang[1], Jia Meng[1], Hao Wu[1], Kai Hou[1], Wenyuan Fan[1], Chunyan Yao[1], Xiaowu Chen[1]. [1]*Shanghai CureGene Pharmaceutical Co. Ltd, Shanghai, China*
Email: gongxin.he@curegene.com.cn

Background and aims: Approval of resmetirom for treating Metabolic dysfunction associated steatohepatitis validated thyroid hormone receptor beta (THR-b) as an effective therapeutic target. VK-2809, another THR-b-targeting drug, showed significant reductions in cholesterol, liver fat and fibrosis in a phase II study. It is a prodrug relying on cytochromes P450 (CYP) for bioactivation to its active metabolite (MB07344) in the liver. We designed and synthesized novel prodrugs based on MB07344 but using fast hydrolysis by esterases for bioactivation and avoiding CYP related issues.
Method: Our prodrugs were tested in a HepG2 assay for *in vitro* activity and evaluated in rats and dogs for pharmacokinetics (PK) and distribution. CG-025016 was selected for efficacy testing in a hypercholesterolemia rat model, fed with either a normal diet (11% kcal fat, lean control) or a 60% high-fat diet (HFD) for 2 weeks prior to dosing. Serum cholesterol levels (total cholesterol, TC and LDL-cholesterol, LDL-C) were measured at baseline and 24 h post-dose.
Results: CG-025013 and CG-025016 showed EC50 of 39.3 and 44.5 nM, respectively, in HepG2 vs 662 nM for VK-2809. For oral PK

study in rats, both CG-025013 and CG-025016 at 1 mg/kg dose were barely detectable (Cmax <1 nM) in the plasma, liver, and heart. In contrast, VK-2809 at same dose was found at a much higher concentration with Cmax around ~100 nM in the same tissues. For the active metabolite, the Cmax was much higher in the liver for CG-025013 and CG-025016: 5,000 and 3,335 nM, respectively, vs 464 nM for VK-2809. Area under the curve (AUC) values were similarly differentiated. Similar results were observed in dogs. Rats on HFD treated with 1.5 mg/kg CG-025016 led to significantly greater declines in plasma TC (87.1%) and LDL-C (69.5%), compared to declines in plasma TC (21.3%) and LDL-C (16.6%) with resmetiron treatment at same dose. At 0.3 mg/kg, CG-025016 resulted in slightly higher reductions compared with VK-2809 at same dose in plasma TC (55.0% vs 45.9%, respectively) and LDL-C (52.0% vs 47.4%, respectively). The dose-dependent reductions were also observed for CG-025016. CG-025016 was safe and well tolerated in 7-day rat safety study.

Conclusion: Our prodrugs showed a ~15-fold *in vitro* activity increase over VK-2809 in HepG2 assay. *In vivo* PK studies showed that they were barely detectable while the active metabolite was preferentially concentrated in the liver compared to VK-2809. The ratio of the active metabolite AUC between liver and heart was 116 (CG-025013), 158 (CG-025016) vs 63 (VK-2809). These findings suggest that our novel prodrugs based on esterase hydrolysis can indeed enrich the active metabolite more efficiently in the liver, resulting in higher potency while reducing the exposure outside the liver. *In vivo* efficacy in rats was also observed. Overall, CG-025016 is a highly potent THR-b agonist with an excellent PK and safety profile, making it a promising clinical candidate to address the limitations of current treatment options.

FRI-448

Genipin 1-β-D-gentiobioside alleviates MASH by inhibiting hepatocyte PP2A enzymatic activity

Xin Xin[1], Xu Xiao[2], Tian Xiaoting[3], Huang Chenggang[3], Xie Cen[3], Yiyang Hu[2], Qin Feng[2]. *[1]Key Laboratory of Liver and Kidney Diseases (Ministry of Education), Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China, SHANGHAI, China; [2]Institute of Liver Diseases, Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China, Shanghai, China; [3]Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China*
Email: xinxinliver@yeah.net

Background and aims: Genipin 1-β-D-gentiobioside (GG) is one of the important natural components from the herb Gardenia jasminoides. The aim of this study is to explore the potential therapeutic targets of GG against metabolic-associated steatohepatitis (MASH) and elucidate its potential pharmacological mechanism.

Method: In this study, two MASH mouse models induced by high trans-fatty acid and high-sugar diet (HFHC) and methionine/choline deficient diet (MCD) and the rat model induced by high-fat diet (HFD) were used to investigate the anti-MASH effect of GG. Concurrently, we used an FFAs (Free Fatty Acids)-induced THLE2 cell model for in vitro observations. The potential GG-binding proteins were screened by HuProt protein chip and pull-down mass spectrometry. Surface Plasmon Resonance (SPR), Drug Affinity Responsive Target Stability (DARTS), and Cell-based Thermal Shift Assay (CETSA) techniques were used to verify the interaction between GG and the target protein. Phosphorylated protein chip technology was used to screen the downstream substrates of the binding protein. Ultimately, both in vivo and in vitro models of liver-specific gene editing were used to ascertain the mechanism of effect of GG against MASH.

Results: We demonstrated that GG significantly reduced hepatic lipid accumulation, inflammation, and early liver fibrosis in the MASH models. GG could substantially reverse lipid deposition under metabolic stress in FFAs-induced cells models. Importantly, the combined analysis results suggested that Protein phosphatase 2 (PP2A) was the direct binding proteins of GG, which was strongly verified by SPR (KD = 7.99E-06 mol/L). Interestingly, we further observed in liver tissues and hepatocytes that GG did not alter PP2A expression but significantly inhibited PP2A enzyme activity that was significantly elevated under metabolic stress. The phosphoprotein screening results showed that ACC1, the key enzyme regulating de novo lipid synthesis, was the most likely downstream substrate of PP2A, and CO-IP experiments confirmed that the two could interact. With the decrease of PP2A enzyme activity after GG intervention, the phosphate level of ACC1 was significantly increased. Hepatocyte-specific gene deletion of PP2A in vitro and in vivo blunted the therapeutic effect of GG in the MASH model.

Conclusion: Our study clearly showed that GG could inhibit de novo lipogenesis and improve MASH liver lipid deposition by targeting hepatocyte PP2A and then up-regulating ACC1 phosphorylation, which provided evidence for the clinical practice of natural active ingredients in MASH field.

FRI-449

Caffeine ameliorates metabolic-associated steatohepatitis by rescuing hepatic Dusp9

Xin Xin[1], Cheng Chen[2], Qin Feng[3], Yiyang Hu[4]. *[1]Key Laboratory of Liver and Kidney Diseases (Ministry of Education), Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China, Shanghai, China; [2]Laboratory of Liver Diseases, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Bethesda, MD, USA, bethesda, United States; [3]Central Laboratory, Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China, shanghai, China; [4]Institute of Liver Diseases, Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China, shanghai, China*
Email: xinxinliver@yeah.net

Background and aims: Caffeine (CAFF) is abundant in black coffee and is known for its antioxidant properties. As one of the most widely consumed beverages globally, coffee has been the focus of increasing clinical and basic research, particularly regarding its benefits in alleviating metabolic dysfunction-associated steatotic liver disease (MASLD). However, the therapeutic effects of CAFF on metabolic-associated steatohepatitis (MASH) and the underlying mechanisms remain unclear. The objective of this research is to investigate the targets of CAFF against MASH and to clarify the mechanisms involved.

Method: Utilizing a high trans-fatty acid and high-sugar diet to induce MASH in mice, along with high-fat combined carbon tetrachloride injections to establish MASH models, we observed the effects of CAFF on pharmacodynamic indicators. Concurrently, we used an FFAs (Free Fatty Acids)-induced THLE2 cell model for in vitro observations. Subsequently, we conducted combined transcriptomic analysis of the liver samples from the mice with GEO (Gene Expression Omnibus) database to screen potential targets of CAFF. Following this, we validated the potential binding targets using SPR (Surface Plasmon Resonance), DARTS (Drug Affinity Responsive Target Stability), and CETSA (Cell-based Thermal Shift Assay). Finally, we utilized liver-specific gene-edited mouse models and gene-edited cell models to observe whether CAFF intervention leads to changes in MASH phenotype and pharmacological mechanisms.

Results: In this study, we demonstrated that CAFF significantly reduced hepatic lipid accumulation, inflammation, and early-stage liver fibrosis in MASH mice induced by HFHC diets and HFD combined with CCl_4 injections. Through sequencing analysis and drug target screening validation, we identified dual-specificity phosphatase 9 (Dusp9) as a key therapeutic target directly bound by CAFF (KD = 1.860E-4 mol/L), which was diminished by HFHC but restored with CAFF treatment. Furthermore, CAFF inactivated the ASK1-p38/JNK, a downstream signaling pathway of Dusp9, which regulates inflammation and apoptosis. In vivo and in vitro

knockdown of Dusp9 exacerbated glycolipid metabolism disorders and unexpectedly diminished the systemic therapeutic effects of CAFF in the MASH model.
Conclusion: Our study highlights the multi-faceted benefits of CAFF in treating MASH by rescuing hepatic Dusp9 expression, thereby reversing glycolipid metabolism disorders, liver inflammation, and fibrosis. These findings provide foundational evidence supporting the clinical and daily use of CAFF and black coffee in MASH patients.

FRI-450
ALG-055009, a potent and selective thyroid hormone receptor beta agonist for the treatment of metabolic dysfunction-associated steatohepatitis, induces pro-metabolic and anti-fibrotic gene expression in the liver of diet-induced obese mice
Peter Althoff[1], Jieun Song[1], Lillian Adame[1], Tse-I Lin[2], Kusum Gupta[1], Koen Vandyck[2], David McGowan[2], Sarah Stevens[1], Andreas Jekle[1], Dinah Misner[1], Sushmita Chanda[1], Caroline Williams[1], Antitsa Stoycheva[1], Lawrence Blatt[1], Leonid Beigelman[1], Julian Symons[1], Pierre Raboisson[2], Jerome Deval[1], Xuan Luong[1].
[1]Aligos Therapeutics, Inc., South San Francisco, United States, [2]Aligos Belgium BV, Leuven, Belgium
Email: xluong@aligos.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) encompasses a heterogenous series of disorders ranging from fatty liver to more severe metabolic dysfunction-associated steatohepatitis (MASH). Thyroid hormone receptor beta (THRbeta) is a clinically validated target for the treatment of MASH, with THRbeta agonists able to selectively reduce fat deposits in the liver and potentially prevent the downstream consequences of MASLD (inflammation, fibrosis, hepatocellular carcinoma). ALG-055009 is a THRbeta agonist that has demonstrated significant reductions in liver fat (placebo-adjusted median relative reductions up to 46.2%) and atherogenic lipids in patients with presumed MASH and stage 1–3 liver fibrosis. Here, we present the effects of ALG-055009 in a diet-induced obese (DIO) mouse efficacy model and primary human liver cells.
Method: C57BL/6J mice were fed with a high fat diet (HFD) for 14 weeks, followed by drug treatment for 4 weeks. ALG-055009 treatment groups included two QD doses of 0.5 and 1.5 mg/kg/day, and four BID doses ranging from 0.075 to 0.35 mg/kg/dose. Pharmacodynamic endpoints included serum lipids and liver gene expression monitored by RT-qPCR. Primary liver cells were used to study in vitro gene expression changes associated with ALG-055009.
Results: We previously reported significant, dose-dependent reductions in serum lipid levels in parallel with significant increases in *Dio1* liver gene expression in DIO mice after treatment with ALG-055009. Newly generated data further elucidate the compound's mechanism of action. ALG-055009 significantly upregulated *Fgf21* expression in the liver of DIO mice (2.8- to 10.3-fold), while significantly downregulating liver *Dio3* expression (0.4- to 0.1-fold). Concurrently, liver expression of pro-fibrotic gene markers, *Enpp2* and *Lgals1*, significantly decreased (0.7- to 0.4-fold and 0.6- to 0.2-fold, respectively) in response to ALG-055009 treatment in a dose-dependent manner.
Conclusion: Preclinical and clinical data demonstrate that ALG-055009 is positioned as a potential best-in-class THRbeta agonist for the treatment of MASH. Here, we offer new evidence for the compound's mechanism of action. The resulting increased Fgf21 expression, another emerging therapeutic target for MASH, suggests improved lipid metabolism and insulin sensitivity from treatment with ALG-055009. Dio1 encodes a selenoenzyme that supports the production of active thyroid hormone (TH) and the clearance of inactive TH, while Dio3 inactivates TH. We hypothesize that by decreasing Dio3 together with upregulation of Dio1, ALG-055009 may increase local availability and activity of TH, leading to reduced hepatosteatosis and curbed MASH progression. Additionally, treatment with ALG-055009 downregulated the expression of known pro-fibrotic/cancer prognostic gene markers in the liver.

FRI-451
Comparative analysis of NAD+ boosters reveals the role of liver-nerve axis in metabolic health
Yasmine Liu[1], Qi Wang[1], Jonathan Sulc[1], Wenyu Liu[1], Angelique Scantlebery[2], Sylvia Andrzejewski[3], Karen Smith[3], Jeffrey Ciavarri[3], Riekelt Houtkooper[2], Johan Auwerx[1].
[1]École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [2]Amsterdam UMC, Amsterdam, Netherlands; [3]Astellas Engineered Small Molecules, Boston, United States
Email: yasmine.liu@epfl.ch

Background and aims: Nicotinamide adenine dinucleotide (NAD+) is an essential metabolite for cellular redox reactions and a substrate for several classes of non-redox enzymes, regulating metabolism, DNA repair and nerve degeneration. NAD+ levels decline in a range of metabolic diseases and upon aging. Enhancing NAD+ improves metabolic health. Despite considerable interest in boosting NAD+ levels for health, the mechanistic understanding of its metabolic benefits remains incomplete, particularly in relation to its consumption by enzymes such as poly(ADP-ribose) polymerases (PARPs) and the NAD+ hydrolase, SARM1. In a diet-induced mouse model of metabolic dysfunction-associated steatohepatitis (MASH), we compared the metabolic benefits of inhibiting PARP and SARM1 to the benchmark treatment of supplementing the NAD+ precursor nicotinamide riboside (NR).
Method: C57BL/6J mice were fed a western-style diet (WD) or chow at thermoneutrality (30°C) for 23 weeks with therapeutic treatment of NR (500 mg/kg/day), SARM1i (60 mg/kg/day), or olaparib (50 mg/kg/day) during the final 14 weeks. Body weight, composition, energy expenditure, and plasma factors were measured using EcoMRI, Promethion, and Luminex. Hepatic fibrosis and inflammation were analyzed histologically. Gene expression and metabolites was measured by RNA sequencing and mass spectrometry.
Results: SARM1 inhibition increased energy expenditure and reduced liver inflammation similarly to NR, but more effectively decreased liver steatosis and obesity, mitigated liver damage, and improved insulin sensitivity. In contrast, PARP inhibition showed less improvement compared to NR and SARM1 inhibition. Bulk liver transcriptome changes reflected these physiological improvements, with both NR and SARM1 inhibition strongly reversing pathological gene expression patterns. Liver metabolomics revealed that while NAD+ levels were similarly elevated across different treatments, glycolysis and TCA cycle metabolites were differentially enhanced by NR and SARM1 inhibition, correlating with their distinct effects on insulin sensitivity.
Conclusion: These findings suggest that increasing NAD+ levels through SARM1 inhibition alone can lead to comparable or greater metabolic benefits than NR, highlighting the importance of preserving nerve health for these effects. Furthermore, NR supplementation in vitro protects against nerve degeneration. Thus, preserving nerve health, including the function of the hepatic sympathetic nervous system, which is impaired in MASH, is central to the metabolic benefits of NAD+ elevation. SARM1 inhibition, therefore, offers a very targeted therapeutic approach for managing metabolic diseases.

FRI-452
Bispecific small interfering RNA targeting YAP1/WWTR1 reduces low-density lipoprotein-cholesterol via proprotein convertase subtilisin/kexin type 9 transcriptional regulation in metabolic dysfunction-associated steatotic liver diseases
Tatsuki Sato[1], Yuki Yamada[1], Kaito Ueda[1], Misa Yoshida[1], Sachiko Sakamoto[1], Masashi Kamiyama[1], Hiroyuki Tanaka[1], Kenjiro Minomi[1], Hiroshi Yamada[1], Masayuki Sugimoto[1].
[1]Nitto Denko Corporation, Drug Delivery Research and Development Department, Osaka, Japan
Email: masayuki.sugimoto@nitto.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has become the leading cause of chronic liver

disease worldwide. MASLD affects not only liver-related mortality but also cardiovascular disease (CVD). It is known that YAP (Yes-associated protein, encoded by *YAP1*) and TAZ (transcriptional coactivator with PDZ-binding motif, encoded by *WWTR1*) contribute to MASLD via various transcriptional factors. However, the therapeutic potential of YAP/TAZ inhibition for MASLD-associated metabolic disorders and CVD remains unclear due to the lack of approved agents. We established bispecific small interfering RNA (bsiRNA) targeting *YAP1* and *WWTR1*, causing selective RNA interference. This study aimed to explore the therapeutic potential of *YAP1*/*WWTR1* silencing on MASLD-related dyslipidemia and clarify the mode of action in mice.

Method: Negative control siRNA (siNC), siRNA targeting *Yap1* (siY) or *Wwtr1* (siW), and bsiRNA targeting *Yap1*/*Wwtr1* (bsiYW) were chemically modified and encapsulated in lipid nanoparticles (LNP). Each formulation and vehicle were administered to mice fed a choline-deficient L-amino-acid-defined high-fat diet (CDAHFD). RNA sequencing (RNA-seq) and assay for transposase-accessible chromatin sequencing (ATAC-seq) were performed. Each formulation was also administered to mice fed with or without CDAHFD and ob/ob mice fed with or without the Gubra-Amylin (GAN) diet. Gene expressions and biochemistry were evaluated. In vitro studies involved transfecting AML12 cells with siNC, siY, siW, or bsiYW, followed by gene expression analysis. Expression levels of *YAP1*/*WWTR1* and their responsive genes were explored in publicly available datasets of bulk RNA-seq from MASLD patients (GSE167523).

Results: RNA-seq revealed 122 differentially expressed genes (DEGs) in the livers of bsiYW-administered mice fed a CDAHFD, compared to siNC, with *Pcsk9* identified as one of the most significant DEGs. ATAC-seq also revealed decreased chromatin accessibility of Exon1 in *Pcsk9* promoter region. Reduction of *Pcsk9* was observed in the liver of mice administered bsiYW but not siY or siW alone. Similarly, bsiYW, but not siY or siW alone, decreased *Pcsk9* in AML12 cells. The reduction of *Pcsk9* in the liver was associated with decreased plasma proprotein convertase subtilisin/kexin type 9 (PCSK9) and low-density lipoprotein cholesterol (LDL-C) levels in mice fed with or without a CDAHFD and ob/ob mice fed with or without a GAN diet. Furthermore, a significant correlation between *YAP1* or *WWTR1* and *PCSK9* was observed, similar to other YAP/TAZ-responsive genes, *CCN1* and *CCN2*, in the MASLD cohort.

Conclusion: Dual silencing of *Yap1*/*Wwtr1* lowers plasma LDL-C levels by decreasing *Pcsk9* transcription in mice. bsiYW is a potential therapeutic agent for preventing and treating MASLD-related CVD. Blood PCSK9 levels could serve as proof of mechanism for YAP/TAZ inhibition in the liver and as a biomarker to identify responsive patients.

FRI-453

Proteomics reveals the effect of liraglutide in enhancing fatty acid metabolism and reducing fibrosis in metabolic dysfunction-associated steatotic liver disease

Yuxuan Chen[1], Chendong Liu[1], Qian Yang[1], He Zhang[2], Jingyi Yang[1], Dapeng Li[1]. *[1]West china school of pharmacy, Sichuan University, Chengdu, China; [2]Department of laboratory medicine, West China Hospital, Sichuan University, Chengdu, China*
Email: dpli@scu.edu.cn

Background and aims: Liraglutide, a glucagon-like peptide-1 receptor agonist (GLP-1 RA) approved by the FDA for the treatment of obesity and type 2 diabetes, has demonstrated significant potential in improving metabolic dysfunction-associated steatotic liver disease (MASLD). As the most common chronic liver disease worldwide, MASLD is a leading cause of liver-related morbidity and mortality, with its prevalence driven by the rising rates of obesity and type 2 diabetes. Despite liraglutide's promising therapeutic effects, its precise molecular mechanisms in MASLD remain unclear. In this study, we used a high-fat diet (HFD)-induced MASLD mouse model to explore liraglutide's regulatory effects on the hepatic proteome, aiming to identify key pathways and molecules involved in its amelioration of MASLD.

Method: C57BL/6J mice were fed a HFD for three months to develop a MASLD model, with a control group maintained on a normal diet (ND). Liraglutide was administered via injection for one week in the treatment group (HFDL). Liver samples were sectioned and stained with Oil Red O to evaluate lipid accumulation. Serum biochemical parameters, including alanine aminotransferase (ALT) and total cholesterol (TC), were measured. Equal amounts of liver tissue were collected for protein extraction. After trypsin digestion, the resulting peptides were analyzed using nano-LC-MS/MS to characterize the liver proteome.

Results: Liver morphology, tissue staining, and serum indicators confirmed the MASLD mouse model's success and showed liraglutide significantly improved liver pathology. The proteomic analysis yielded significant insights into the molecular mechanisms underlying liraglutide's effects on MASLD. A total of 4,636 proteins were identified across 3 groups, with 1,799 proteins retained for quantitative analysis after filtering for accuracy. Principal component analysis (PCA) demonstrated that liraglutide partially normalized the proteome disrupted by HFD. Differentially expressed proteins (DEPs) analysis identified 161 DEPs in the HFDL group compared to the HFD group. Gene Ontology (GO) and KEGG pathway analysis indicated that liraglutide significantly regulated fatty acid degradation. Additionally, extracellular matrix-receptor interactions were notably affected. Protein-protein interaction (PPI) analysis highlighted Acaa2 and Lamc1 as key regulatory molecules, and their gene and protein expression levels were confirmed by qPCR and Western blot, validating the proteomic findings.

Conclusion: Our study demonstrated that liraglutide significantly improves MASLD by regulating specific fatty acid metabolism and extracellular matrix interactions. Acaa2 and Lamc1 were identified and validated as potential regulatory molecules. These findings provide valuable insights into liraglutide's therapeutic mechanisms and highlight its potential for treatment. These findings contribute to advancing the clinical potential of liraglutide in treating MASLD.

FRI-454

BTB and CNC homology 1 aggravates metabolic dysfunction-associated steatohepatitis by activating calreticulin

Zhiping Wan[1], Fengjuan Chen[2], Xiang Cai[1], Xiaoman Chen[1], Xiaoquan Liu[1], Hong Deng[1], Qingxian Cai[2]. *[1]Department of Infectious Diseases, the Third Affiliated Hospital of Sun Yat-sen University, Guangdong Key laboratory of Liver Disease Research, the Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China; [2]Department of Hepatopathy, The Third People's Hospital of Shenzhen, The Second Affiliated Hospital of Southern University of Science and Technology, Shenzhen, China*
Email: zssywzp@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has become the most common chronic liver disease, and metabolic dysfunction-associated steatohepatitis (MASH) is the more severe form of MASLD. BTB and CNC homology 1 (BACH1) is associated with the progression of MASLD, but its role in the MASH process remains unclear. We aimed to explore the role of BACH1 in the MASH process.

Method: The BACH1 expression was analyzed in MASH patient livers, MASH mouse livers, and macrophages. Liver specimens confirmed pathologically as MASH were collected at the Third Affiliated Hospital of Sun Yat-sen University. 6-week-old male C57BL/6 mice were fed a choline-deficient, l-amino acid-defined, high-fat diet (CDAHFD) for 9 weeks to construct a MASH mouse model. Liver tissue sections were used for H&E staining, Oil Red O staining, and immunofluorescence staining. BACH1-plasmid or small interfering RNA targeting BACH1 was used to upregulate or downregulate BACH1 expression in macrophages. Real-time quantitative polymerase chain reaction,

Western blot, Enzyme linked immunosorbent assay, and flow cytometry were also performed.
Results: The expression of BACH1 in the livers of MASH patients and MASH mice was higher than that in the control group. Importantly, BACH1 was mainly localized in liver macrophages, and the expression of BACH1 was increased in M1 macrophages. Besides, the levels of Bach1 were positively correlated with alanine transaminase content, aspartate aminotransferase content, and nonalcoholic fatty liver disease (NAFLD) activity score. Calreticulin (CALR) was identified as the target of BACH1, and there was a binding site between BACH1 and CALR. Upregulation of BACH1 promoted the expression of CALR, while knockdown of BACH1 inhibited the expression of CALR. Upregulation of BACH1 in macrophages promoted the increased expression of interleukin-1 beta (IL-1β) and tumor necrosis factor-alpha (TNF-α). Upregulation of BACH1 also increased the proportion of CD86-positive cells. Moreover, knockdown of BACH1 resulted in decreased expression of IL-1β and TNF-α in macrophages, as well as a reduction in the proportion of CD86-positive cells.
Conclusion: BACH1 is upregulated during MASH. BACH1 activates CALR to promote the polarization of M1 macrophages, thereby aggravating MASH.

Email: rallerf@saludcastillayleon.es

Background and aims: The Mediterranean diet and physical activity promote the regression of metabolic-associated steatotic liver disease (MASLD). We aimed to evaluate liver outcomes using magnetic resonance-imaging (MRI) after a lifestyle program.
Method: 96 patients with histologically confirmed MASLD were subjected to a hypocaloric Mediterranean diet and randomized to engage in structured and supervised physical activity or follow clinical practice guideline recommendations (EASL 2021) for 12 weeks, with an additional 12 weeks of follow-up. We defined response as follows: a) Steatosis if ≥30% fat infiltration by PDFF; b) Steatohepatitis if normalization of ALT or a decrease of 17 U/L along with a reduction >30% PDFF; c) Fibrosis: improvement ≥ one fibrosis stage assessed by MR elastography using published cut-off points: significant fibrosis, 3.14 kPa; advanced fibrosis, 3.53 kPa; and cirrhosis, 4.45 kPa (J Hepatol 2023); complete response: >30% PDFF reduction and regression of at least one fibrosis stage with resolution of steatohepatitis.
Results: Regression of at least one stage of fibrosis was achieved in 11/30 (36.7%) patients with fibrosis >F2. Resolution of steatohepatitis occurred in 39/89 (43.8%) and improvement of steatosis in 24/66 (36.4%). Fibrosis regression was 9/22 (40%) in patients with advanced fibrosis (F3-F4) vs 4/22 (18.18%) in F1-F2; p = 0.057. Resolution of MASH was 13/30 (43.3%) vs 24/56 (42.85%); p = 0.966, steatosis 12/23 (52.17%) vs 11/40 (27.5%); p = 0.05, and complete response 6/19 (31.5%) vs 2/43 (4.6%), p = 0.008. In univariate analysis, nut consumption was significantly higher in patients with resolution of steatohepatitis (6.8 ± 4.87 vs. 4.14 ± 4.69; p < 0.008). Improvement in steatosis was associated with increased physical activity in MET/min/week (2,499 ± 1086 vs. 1257 ± 807; p < 0.007) and lower wine consumption (0.66 ± 1.92 vs. 3.56 ± 5.52; p < 0.011). Fibrosis regression was associated with higher coffee consumption (19.4 ± 12.4 vs 29.2 ± 10.9; p < 0.049). In multivariate analysis, independent predictive variables of response were: Fibrosis regression was associated with increased coffee consumption [1.172; 95% CI: 1.002–1.370; p < 0.046]. Resolution of steatohepatitis was independently associated with age [1.195 (1.027–1.390); p < 0.021] and nut consumption [1.616 (95% CI: 1.103–2.366)]. Improvement in steatosis was associated with increased METs/min/week of physical activity: 1.001; 95% CI: 1.000–1.003; p = 0.05.
Conclusion: Intervention with the Mediterranean diet and structured physical exercise promotes the resolution of steatohepatitis, fibrosis regression, and steatosis improvement. The response is significantly higher in individuals with advanced fibrosis. It would be highly recommended to increase coffee and nut consumption, avoid alcohol consumption, and increase physical activity to improve MRI-assessed features.

Statin, but not aspirin use, is inversely associated with steatotic liver disease and liver fibrosis: results from two large population based studies

Jesse Pustjens[1], Laurens A. van Kleef[1], Harry L.A. Janssen[1,2], Maarten Leening[3], Bruno Stricker[4], Willem Pieter Brouwer[1]. *[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Centre, Rotterdam, Netherlands; [2]Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada; [3]Department of Cardiology, Erasmus MC University Medical Centre, Department of Epidemiology, Erasmus MC University Medical Centre, Department of Radiology, Erasmus MC University Medical Centre, Rotterdam, Netherlands; [4]Department of Epidemiology, Erasmus MC, University Medical Centre, Rotterdam, Netherlands*
Email: j.pustjens@erasmusmc.nl

Background and aims: Liver disease is a growing public health concern, mainly due to the increasing prevalence of steatotic liver disease (SLD). As therapeutics targeting steatosis and fibrosis are limited, drugs used in cardiovascular disease are increasingly being explored for their potential hepatoprotective effects. Here we investigate associations of statin and aspirin with liver disease in the general population.
Method: Data were used from two population-based cohorts: the Rotterdam Study (RS; the Netherlands) and the NHANES (2017–2020 cycle; United States). Participants aged ≥40 years with reliable liver stiffness measurements (LSM) and data on statin and aspirin use were included. Those with excessive alcohol consumption (≥50/60 g/day F/M), viral hepatitis, or heart failure were excluded. Fibrosis was defined as LSM ≥8.0 kPa, and SLD by ultrasound or CAP ≥280 dB/m. Logistic regression models were used to evaluate associations between statin, aspirin and liver outcomes. Models were adjusted

for age, sex, ethnicity, triglycerides, cholesterol, waist circumference, diabetes, hypertension and the number of metabolic risk factors. Interaction and multicollinearity were explored via interaction terms and variance inflation factors. Non-linearity was assessed in the pooled cohort by restricted cubic splines for the duration of statin use.
Results: 11.197 participants were included. 6.055 participants were included from the RS (median age 64 years [56–71], 44% male) and 5.142 from the NHANES (median age 60 years [50–69], 50% male). SLD prevalence was 33% in the RS and 48% in the NHANES and fibrosis was present in 4.7% in the RS and 11% in NHANES. In the RS, 22% used statin and 15% aspirin, compared to 30% and 29% in the NHANES. Statin was associated with SLD in the RS (aOR 0.47; 95%CI: 0.38–0.58) and fibrosis in the RS (aOR 0.57; 95%CI 0.38–0.86) and NHANES (aOR 0.60; 95%CI 0.47–0.78). Non-linear effects were observed for SLD (p = 0.033) and fibrosis (p = 0.002). Risk reduction during the first three years of statin use was 20% for steatosis and 40% for fibrosis. Thereafter, this effect stabilized in statin users for up to 20 years. Aspirin was not significantly associated with steatosis (RS: aOR 1.05; 95% CI 0.87–1.28; NHANES: aOR 1.19; 95% CI 0.95–1.49) nor fibrosis (RS: aOR 0.94; 95% CI 0.65–1.36; NHANES: aOR 0.94; 95% CI 0.69–1.26. There was no significant interaction or multicollinearity between statin and aspirin. The significant inverse association of statin therapy with SLD and fibrosis was consistently observed among subgroups with metabolic dysfunction.
Conclusion: Statin, but not aspirin, was independently inversely associated with SLD and fibrosis in a population-based settings. Risk reduction increased up to three years of treatment and remained stable thereafter. These result warrant further evaluation of statin therapy for liver disease in a randomized, controlled setting.

qFibrosis enables earlier detection of fibrosis response in Efruxifermin-treated patients with F2-F3 MASH in 96-week HARMONY study

Jörn M. Schattenberg[1], Dean Tai[2], Elaine Chng[2], Yukti Choudhury[2], Galvin Gan[2], Cynthia Behling[3], Pierre Bedossa[4], Doreen Chan[5], Jimmie Zhang[5], Erica Fong[5], Brittany de Temple[5], Matthew Minerva[5], Mark Burch[5], Kimberly Barrett[5], Reshma Shringarpure[5], Erik Tillman[5], Tim Rolph[5], Andrew Cheng[5], Kitty Yale[5], Mazen Noureddin[6]. *[1]Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany; [2]HistoIndex Pte Ltd, Singapore, Singapore; [3]University of California, San Diego, United States; [4]Liverpat, Paris, France; [5]Akero Therapeutics, South SF, United States; [6]Houston Research Institute; Houston Methodist Hospital, Houston, United States*
Email: joern.schattenberg@uks.eu

Background and aims: Efruxifermin (EFX) has been observed to improve fibrosis without worsening MASH, by conventional histopathology, with a doubling of response rates between week 24 and week 96 for the 50 mg EFX group, with a slight increase observed for the 28 mg EFX group. The placebo-adjusted effect sizes for fibrosis improvement without worsening of MASH grew from 21% to 52% between week 24 and week 96 for 50 mg EFX and from 20% to 22% for 28 mg EFX. This post-hoc analysis investigates changes in fibrosis using AI-based qFibrosis that can detect subtle intra-stage changes by using collagen morphometry for precise quantification on a continuous scale.
Method: Subjects with unstained biopsies at baseline (BL), week 24 (W24), and week 96 (W96) (n = 82) were available for qFibrosis analysis using SHG/TPEF imaging. The qFibrosis score incorporated a correction to account for a significant reduction in hepatic fat observed with EFX treatment, as well as offering a detailed assessment of fibrosis dynamics across the following defined hepatic zones: portal, peri-portal (zone 1), peri-sinusoidal (zone 2), central, and peri-central (zone 3).
Results: In this analysis, for the 28 mg EFX group, CRN staging identified most responders at W24 (n = 9), with 2 new responders captured at W96. In contrast, qFibrosis captures statistically significant ≥1 stage fibrosis improvement at W24 (60–70%) which converges with the 1-stage fibrosis improvement by CRN staging at W96 (70–80%), demonstrating the capability of qFibrosis to capture earlier W24 fibrosis regression, which may not be sufficient to be captured as a 1-stage improvement by conventional histopathology. The earlier capture of W24 responders by qFibrosis is evident in the statistically significant regression of fibrosis in Zones 1 and 2 in EFX arms compared to placebo, which was sustained in EFX arms at W96. The quantitative regression in Zones 1 and 2 was observed in subjects whether or not improvements in fibrosis had been seen by conventional histopathology staging, highlighting the consistency and sensitivity of qFibrosis in capturing subtle but significant fibrosis reductions for EFX-treated subjects.
Conclusion: Analysis of fibrosis response at W24 with qFibrosis resulted in a higher proportion of early responders that later become fibrosis responders by conventional histopathology at W96, compared with conventional histopathology at W24. This finding supports the potential utility of using qFibrosis zonal analysis provided by digital pathology to identify potential early improvements in zonal fibrosis patterns for interventional trials in subjects with F2 and F3 MASH to support drug development.

Efficacy of lower carbohydrate diets for reducing liver fat and improving metabolic dysfunction: a systematic review and meta-analysis

Aslihan Ozdemir[1,2], Xiaomian Tan[1,3], J Bernadette Moore[1,3]. *[1]School of Food Science and Nutrition, University of Leeds, Leeds, United Kingdom; [2]Faculty of Health Sciences, Department of Nutrition and Dietetics, Hacettepe University, Ankara, Türkiye; [3]Institute of Systems, Molecular and Integrative Biology, University of Liverpool, Liverpool, United Kingdom*
Email: j.bernadette.moore@liverpool.ac.uk

Background and aims: Weight loss through dietary and lifestyle changes is advised in the clinical management of metabolic dysfunction-associated steatotic liver disease (MASLD) for reducing liver fat and improving other markers of metabolic health. However, the recommended 5–10% weight loss can be difficult for many patients to achieve, and questions remain about optimal dietary interventions for MASLD treatment. Therefore, the aim of this work was to evaluate the relative efficacy of lower carbohydrate diets (LCD) for reducing liver fat (intrahepatocellular triglyceride, IHTG) and improving parameters of metabolic dysfunction in MASLD.
Method: In accordance with PRISMA guidelines and prospectively registered at Prospero (CRD42021223085), the MEDLINE, Scopus, Cochrane Library and EMBASE electronic databases were systematically searched from inception through May 31, 2024, for randomized or crossover intervention trials assessing the effects of LCD on IHTG (assessed by MRS, MRI or ultrasound) versus lower fat (LFD) types in adults aged 18 or older. Secondary outcomes included liver stiffness, body weight, fasting glucose, insulin, and HOMA-IR. The R software environment (v4.3.0) was used to conduct meta-analyses using the inverse variance method and random effects models. Heterogeneity between studies was evaluated with Cochran's Q-test and the I-squared index. Comparison between subgroups was done using a plural, fixed effects, model.
Results: From 10,537 records screened, 321 were eligible for full-text review, 26 studies were included in the qualitative synthesis, and 20 studies (n = 786 participants) could be meta-analysed for IHTG. Examining effect sizes as weighted mean difference (WMD) from baseline to intervention endpoint showed that, although both LCD and LFD significantly reduced IHTG (WMD [95% confidence intervals]: LCD: −2.76% [−3.93,−1.58] versus LFD: −1.54% [−2.52,−0.56]; p

= 0.12), there were no significant differences between groups in the plural model. Similarly, for body weight (19 studies, n = 708; p = 0.27), fasting glucose (15 studies, n = 609; p = 0.48), fasting insulin (13 studies, n = 623; p = 0.91), HOMA-IR (11 studies, n = 564; p = 0.33), there were no significant differences between the reductions observed in both LCD and LFD. No improvements in liver stiffness (6 studies, n = 458) were observed in either group (LCD: −0.56 kPA [−1.20, −0.12]; LFD: −0.12 kPA [−0.32, −0.08]). On the other hand, much more pronounced reductions were observed in hypocaloric trials for both IHTG (HYPO: −3.82% [−5.01,−2.63] versus ISO: −0.67% [−1.17, −0.18]; p < 0.01) and body weight (HYPO: −5.23 kg [−7.21, −3.26] versus ISO: −1.71 kg [−3.44, 0.02]; p < 0.009).
Conclusion: In conclusion these data show dietary interventions decreasing either carbohydrate or fat intakes were similarly effective for lowering IHTG and body weight and improving markers of insulin sensitivity in MASLD.

SAT-406
Role of glucagon-like peptide-1 receptor agonists (GLP-1 RAs) in mortality reduction among patients with obesity and metabolic dysfunction-associated steatotic liver disease (MASLD) cirrhosis: a global retrospective analysis
Varun Aitharaju[1], Humza Aamir-Khan[2], Jamile Wakim-Fleming[1].
[1]*Cleveland Clinic Main Campus, Cleveland, United States;* [2]*MetroHealth Medical Center - Main Campus, Cleveland, United States*
Email: aitharv2@ccf.org

Background and aims: Glucagon-like peptide-1 receptor agonists (GLP-1 RAs) are approved for managing type 2 diabetes mellitus (T2DM) and promoting weight loss. These agents have demonstrated efficacy in reducing hepatic fat content and the production of inflammatory cytokines, thereby alleviating liver inflammation and fibrosis in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). However, their effects on MASLD complicated by cirrhosis remain inadequately understood.
This study aims to compare mortality and incidence of hepatocellular carcinoma in patients who were and were not prescribed GLP-1 RAs after diagnosis of MASLD cirrhosis. Secondary outcomes include decompensating events, sepsis, obesity-associated malignancies, inpatient admissions, and liver transplants.
Method: A retrospective analysis was conducted using the multi-institutional research network TriNetX that compiled data from 2004–2024. Patients with cirrhosis who have never been prescribed a GLP-1 RA (nonusers) were compared to patients with cirrhosis who were prescribed a GLP-1 RA (users) after diagnosis. Patients with decompensated cirrhosis and cirrhosis from other aetiologies were excluded. The patients were propensity matched to control for confounding factors. Multivariable-adjusted Cox proportional hazards models were used to compare the outcomes between GLP-1 RA nonusers and users.
Results: 40,646 patients were included in the analysis, of which 4,328 patients were prescribed a GLP-1 RA after diagnosis of cirrhosis. After propensity score matching, 3,846 patients were included from both groups. Five years after initiation of GLP-1 RA, there was a decrease in mortality (Hazard Ratio [HR] 0.37; 95% Confidence Interval [CI], 0.27 to 0.50) and incidence of hepatocellular carcinoma (HCC) (Hazard Ratio [HR] 0.57; 95% Confidence Interval [CI], 0.36 to 0.89) among users. Additionally, compared with the nonuser group, the user group had a lower incidence of sepsis (HR 0.52; 95% CI, 0.36 to 0.76), obesity-associated malignancies (HR 0.64; 95% CI, 0.54 to 0.76), major adverse cardiovascular events (MACE) (HR 0.84; 95% CI, 0.72 to 0.98), incidence of liver transplants (HR 0.45; 95% CI, 24 to 0.82), and inpatient admissions (HR 0.54, 95% CI 0.47 to 0.62).
Conclusion: In patients with obesity and MASLD cirrhosis, GLP-1 RAs were associated with a lower risk of HCC, sepsis, obesity-associated malignancy, hospital admission, MACE, liver transplantantation, and death. Future prospective studies may be beneficial in understanding more clearly the role of GLP-1 RAs in MASLD cirrhosis.

SAT-407-YI
Assessing early changes and responses to resmetirom therapy using real world single center data
Allysa Saggese[1], Adam Buckholz[1], Robert Schwartz[1], Tibor Krisko[1], Mallory Ianelli[1], Lindsay Rogers[1], Jessica Siguencia[1], Sonal Kumar[1].
[1]*Weill Cornell Medicine, New York, United States*
Email: als9267@med.cornell.edu

Background and aims: Metabolic-dysfunction associated steatotic liver disease (MASLD) affects an estimated 30% of the world's population, and metabolic-dysfunction associated steatohepatitis (MASH) is the leading cause of cirrhosis worldwide. In March 2024, resmetirom received conditional United States Food and Drug Administration approval as the first medication for MASH and is currently under evaluation with the European Medicines Agency for approval in the European Union. However, real-world use is limited; some early guidance suggests assessing at 12 months for treatment response. We aimed to assess whether treatment response can be evaluated at an earlier (3-month) timepoint.
Method: Single-center data from a New York City-based academic institution were collected on patients with F2 or F3 fibrosis, identified by non-invasive tests, who were initiated on resmetirom therapy between March 2024 and November 2024. Liver enzymes, lipids, hemoglobin A1c (HbgA1c) and Fibrosis-4 were collected at months 1, 3, and 6. Liver stiffness measurement (LSM) by transient elastography was reassessed at 3 months. Baseline and 3-month values were compared using two-sided Wilcoxon matched-pairs signed-rank test.
Results: Our center initiated 36 patients on resmetirom, with 3-month follow up available for 19 patients: 16 on 80 mg daily and 3 on 100 mg daily. Pre-treatment mean LSM was 10.9 kPa and controlled attenuation parameter (CAP) was 292 dB/m. Follow up LSM was performed at a mean of 99.4 (IQR 11) days after initiation of therapy. The 3-month mean LSM significantly decreased to 8.2 kPa (−2.7 kPa, p = 0.02) and CAP trended towards improvement (mean 271 dB/m, −21.2 dB/m, p = 0.06). 10 (52%) participants had ≥25% reduction in LSM from baseline, and 1 (5%) had ≥25% increase from baseline. There was a trend towards reduction in low-density lipoprotein at 3 months (79.2 mg/dL to 70.6 mg/dL, p = 0.09) and in triglycerides (133 mg/dL to 116 mg/dL p = 0.42). No significant changes were seen in body mass index (BMI) (31.1 kg/m^2 to 30.9 kg/m^2); HgbA1c% (6.0% to 6.1%); aspartate aminotransferase (39.6 U/L to 38.9 U/L); or alanine amino-transferase (58.2 U/L to 57.7 U/L). Patients on concomitant glucagon-like peptide-1 receptor agonists (GLP-1 RA) (n = 11) did not have a significant difference in percent LSM change compared to those not on GLP-1 RAs (n = 8). Six-month data will also be reported.
Conclusion: In the first 19 patients to reach three months of treatment on resmetirom, LSM reduced from pre-treatment levels, independent of liver enzymes, weight/BMI change, diabetes control or GLP-1 RA use. These data suggest that response to therapy may be assessable at the 3-month timepoint, helping to guide future management in high-risk patients. Limitations include a small cohort and the lack of a control population. Our follow-up data will assess whether these changes persist to one year and identify potential predictors of early response.

SAT-408
Effectiveness of bariatric surgery versus glucagon-like peptide-1 receptor agonists for prevention of adverse cardiovascular outcomes among patients with metabolic dysfunction-associated steatotic liver disease, diabetes, and obesity

Email: dr.arunkumar.krishnan@gmail.com

Background and aims: Cardiovascular disease (CVD) is the leading cause of death in individuals with metabolic dysfunction-associated fatty liver disease (MAFLD). Risk factors for CVD and MAFLD overlap and are linked to metabolic syndrome. Weight loss and reduced cardiovascular events have been observed in type 2 diabetes (T2DM) patients treated with GLP-1 receptor agonists (GLP-1RAs). Bariatric surgery (BS) also significantly lowers cardiovascular risks and improves metabolic health. However, limited evidence compares the impact of BS and GLP-1RAs on mortality and major adverse cardiovascular events (MACEs). This study assessed the incidence of major CVD in patients with MAFLD, T2DM, and obesity, without prior CVD, treated with BS versus GLP-1RAs at a population level.
Method: This population-based, retrospective cohort study utilized the TriNetX database to analyze adult patients (>18 years) with MAFLD, T2DM, and obesity, excluding other chronic liver diseases and prior CVD history. A 1:1 propensity score matching (PSM) adjusted for demographics, BMI, comorbidities, lab parameters, and medications. Bariatric surgery (BS) included Roux-en-Y gastric bypass and sleeve gastrectomy. The GLP-1RA cohort was defined by the first-ever use date, with a 6-month lag for both groups to reduce protopathic bias. The primary outcome was CVD incidence, a composite of heart failure (HF), MACE, or cerebrovascular disease. The secondary outcome was all-cause mortality. Sensitivity analyses ensured result robustness, and hazard ratios (HRs) compared BS outcomes with controls.
Results: A total of 167,895 individuals with MASLD, T2DM, and obesity were identified. Of those, 6898 patients had a history of BS, whereas 49,767 newly received GLP-1RAs. After PSM, each cohort included 6,430 patients, with BS patients being younger (49.1 vs. 54.6 years) and having a higher mean BMI (45.1 vs. 41.2). Both groups were predominantly female and white, with a mean follow-up of 4.6 years (up to 10 years). At 1 year, BS significantly reduced the incidence of HF (HR 0.67), MACE (HR 0.75), and cerebrovascular disease (HR 0.59). Adjusted analyses showed lower risks for MACE (HR 0.87), HF (HR 0.67), and cerebrovascular disease (HR 0.70) in the BS group compared to GLP-1RAs. Mortality rates were similar at 1 year (HR 0.92; 95% CI, 0.77–1.02), but BS showed a lower all-cause mortality risk (HR 0.34) and composite CVD outcomes over longer follow-ups (3, 5, and 7 years). Sensitivity analyses confirmed the consistency of these findings.
Conclusion: BS demonstrated a stronger and sustained reduction in cardiovascular events and all-cause mortality compared with GLP-1RAs among patients with MASLD, T2DM, and obesity. These findings suggest that BS may serve as a more effective intervention for reducing adverse outcomes in this high-risk population. Given the increasing adoption of GLP-1RAs, further long-term, comparative studies are warranted to guide evidence-based treatment decisions and optimize patient outcomes.

SAT-413

Cardiovascular disease risk, liver outcomes, and statin use among adults with metabolic dysfunction-associated steatotic liver disease

Arunkumar Krishnan[1,2], Diptasree Mukherjee[3], Aldanah Althwanay[4], Faisal Abaalkhail[5,6], Waleed K Al-Hamoudi[7,8], Saleh A Alqahtani[9,10].
[1]Atrium Health Levine Cancer, Department of Supportive Oncology, Charlotte, NC, United States; [2]Wake Forest University School of Medicine, Department of Medicine, Winston Salem, NC, United States; [3]Apex Institute of Medical Sciences, Department of Medicine, Kolkata, India; [4]University of Maryland Medical Center, Internal Medicine Department, Baltimore, MD, United States; [5]King Faisal Specialist Hospital and Research Center, Gastroenterology Section, Department of Medicine, Riyadh, Saudi Arabia; [6]Alfaisal University, College of Medicine, Riyadh, Saudi Arabia; [7]King Faisal Specialist Hospital and Research Center, Organ Transplant Center of Excellence, Riyadh, United States; [8]King Saud University, College of Medicine, Department of Medicine, Liver Disease Research Center, Riyadh, Saudi Arabia; [9]King Faisal Specialist Hospital and Research Center, Liver, Digestive, and Lifestyle Health Research Section, and Organ Transplant Center of Excellence, Riyadh, Saudi Arabia; [10]Weill Cornell Medicine, Division of Gastroenterology & Hepatology, New York, United States
Email: dr.arunkumar.krishnan@gmail.com

Background and aims: Cardiovascular disease (CVD) remains the leading cause of morbidity and mortality in patients with metabolic dysfunction–associated steatotic liver disease (MASLD). Statins reduce cardiovascular events and are considered safe for patients with liver disease. However, limited population-level data exist regarding their impact on adverse CVD events and liver-related outcomes in patients with MASLD. This study aimed to assess the association of statin use with major adverse cardiovascular events (MACE), liver disease progression, and all-cause mortality in this population.
Method: This was a population-based cohort study with consecutive patients diagnosed with MASLD using TriNetx. The cohort included adults (>18 years) without other chronic liver disease etiologies. Statin users were identified based on first-ever statin prescriptions, with a 6-month exposure lag to minimize protopathic bias. Propensity score matching (PSM) (1:1) balanced baseline covariates between cohorts. Primary outcomes included new-onset heart failure (HF), MACE, composite cerebrovascular disease, and liver disease progression (decompensation, hepatocellular carcinoma [HCC]), and secondary outcomes assessed all-cause mortality. Hazard ratios (HR) with 95% confidence intervals (CI) were calculated using Cox proportional hazards models. Sensitivity analyses assessed robustness by excluding patients with events within two years post-index.
Results: We identified 176,983 patients with MASLD. Among these, 51,481 received statins, and 125,502 did not, with a median follow-up time of 5.1 years. PSM resulted in well-matched groups (42,227 each). Statin use was associated with significantly lower risks of MACE (HR 0.29, 95% CI: 0.25–0.33), HF (HR 0.94, 95% CI: 0.91–0.98), cerebrovascular diseases (HR 0.87, 95% CI: 0.83–0.91), liver-related outcomes (HR 0.77, 95% CI: 0.71–0.84), and all-cause mortality (HR 0.85, 95% CI: 0.81–0.89). Interaction analysis revealed a greater benefit for women in reducing MACE (HR 0.66) than men (HR 1.09). Sensitivity analyses confirmed consistent findings. Statin use was also associated with lowering the risk of cardiovascular outcomes, such as MACE (HR, 0.29), HF (HR, 0.94), and cerebrovascular diseases (HR, 0.87). All-cause mortality (HR, 0.85) was significantly lower in statin users. However, there was a significant interaction with sex with a decreased risk of MACE for women (HR 0.66 vs. HR 1.09). The sensitivity analysis results were consistent, and all statistically significant associations remained unchanged.
Conclusion: Statin use in patients with MASLD significantly reduces the risk of adverse cardiovascular events, liver disease progression, and mortality, underscoring its role as a cornerstone therapy in high-risk populations. These findings highlight the dual benefits of statins in cardiometabolic and liver disease management while emphasizing the need for personalized strategies to mitigate metabolic side effects.

SAT-414-YI

Can non-diabetic patients with metabolic dysfunction associated steatotic liver disease benefit from glucagon-like peptide-1 analogs? A multicenter cohort study

Ritu Singh[1], Harishankar Gopakumar[2], Sonu Dhillon[2]. [1]*University of Illinois College of Medicine, Johns Hopkins University Bloomberg School of Public Health, Peoria, United States;* [2]*University of Illinois College of Medicine, Peoria, United States*
Email: drhrituraj83@gmail.com

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD) has evolved into the most common cause of chronic liver disease affecting more than a third of the global population and is a leading cause of liver-related mortality. Treatment of MASLD relies on weight management and control of insulin resistance, and the most effective treatment to achieve these outcomes is either bariatric surgery or use of glucagon-like peptide-1 (GLP-1) analogs. While GLP-1 analogs are increasingly used for diabetes mellitus and weight loss; the evidence to support their use in MASLD is limited. We aim to investigate the effectiveness of GLP-1 analogs in patients with MASLD without diabetes mellitus in reducing the risk of cirrhosis with decompensation, hepatocellular carcinoma and 4-year mortality.
Method: We performed retrospective cohort study utilizing a large research network (TriNetX) comprising data of over 115 million patients. Study period was January 2016 to December 2021. Patients ³18 years with steatotic liver disease along and at least one of the cardiometabolic factors were identified. Patients with diabetes mellitus (or HBA1C ³6.5%) cirrhosis and other etiologies of chronic liver disease, and alcoholic liver disease, history of bariatric surgery were excluded. Patients were followed up to four years. Primary outcome were development of decompensated cirrhosis, hepatocellular carcinoma (HCC) and overall survival (OS) in patients treated with GLP-1 analogs compared to patients not treated with GLP-1 analogs. Propensity score (1:1) matching was performed to control for confounding variables.
Results: 271,125 (49.66%) out of 545,911 patients with MASLD did not have diabetes mellitus and 16,464 (6.07%) of them were treated with GLP-1 analogs. Females (65.74% vs. 52.17%), obese (85.02% vs. 38.01%) and patients with cardiovascular morbidity and obstructive sleep apnea (46.65% vs. 18.55%) were more like to receive a GLP-1 analog, while Hispanics (11.81% vs. 14.86%) were less likely to receive GLP-1 analogs. In an age-, gender-, race-, and comorbidity matched cohort of MASLD patients, the rate of developing decompensated cirrhosis (0.94% vs. 2.64%, hazard ratio [HR] 0.47, 95% confidence interval [CI] 0.39–0.56) and all-cause mortality (0.67% vs. 3.66%, HR 0.24, 95% CI 0.19–0.29) was lower in patients who received GLP-1 analogs compared to those who did not receive GLP-1 analogs. However, there was no difference in HCC incidence (HR 0.67, 95% CI 0.32–1.38) between the two groups.
Conclusion: Our study using real-world evidence shows that while half of patients with MASLD may not have diabetes mellitus, this cohort of patients can benefit from GLP-1 analogs with lower risk of decompensated cirrhosis and overall mortality. Prospective studies on the use of GLP-1 analogs targeting MASLD patients without diabetes are needed to provide policymakers with concrete evidence to approve these novel therapeutics for this patient population.

SAT-415

Are glucagon-like peptide-1 analogs better answer for obese patients with metabolic dysfunction associated steatotic liver disease than bariatric surgery? Real-world evidence

Ritu Singh[1], Sonu Dhillon[1]. [1]*University of Illinois College of Medicine, Peoria, United States*
Email: drhrituraj83@gmail.com

Background and aims: Bariatric surgery is an established treatment for morbid obesity and there has been growing interest in and use of glucagon-like peptide-1 (GLP-1) analogs for the same indication with promising results. However, GLP-1 analogs have not been routinely prescribed or widely accepted for primary use in metabolic dysfunction-associated steatotic liver disease (MASLD). Moreover, there is limited data comparing GLP-1 analogs and bariatric surgery for the treatment of MASLD. We aim to explore the trends in the use of GLP-1 analogs and bariatric surgery and compare the effectiveness of the two treatment options in reducing the risk of developing cirrhosis with decompensation, hepatocellular carcinoma, and 4-year mortality.
Method: We performed a retrospective cohort study utilizing a large research network (TriNetX) comprising data from over 115 million patients. The study period was January 2016 to December 2021. Patients ≥18 years with steatotic liver disease and at least one of the cardiometabolic factors were identified. Patients with cirrhosis and other etiologies of chronic liver disease were excluded. Patients were followed up to four years. Primary outcomes were the development of decompensated cirrhosis and all-cause mortality in patients treated with GLP-1 analogs (semaglutide, tirzepatide, dulaglutide, exenatide, lixisenatide) compared to patients treated with bariatric surgery (gastric bypass, sleeve gastrectomy, biliopancreatic diversion with duodenal switch, vertical band gastroplasty). Propensity score (1:1) matching was performed to control confounding variables.
Results: Out of 545,931 patients with MASLD, 73,339 (13.44%, median 733 days) patients were treated with GLP1 analog, 38,541 (7.06%, median 690 days) sodium-glucose cotransporter 2 (SGLT 2) inhibitors and 29,917 (5.48%, median 832 days) received other weight loss medications (naltrexone, topiramate or phentermine). 33,738 (6.18%) underwent bariatric surgery. The median follow-up was 46.43 months. Patients treated with GLP-1 analogs were older (53.89 vs. 47.70) and had more comorbidities but sleep apnea (54.97% vs. 43.85%) was more common in patients treated with bariatric surgery. After propensity score matching for confounding variables, the rate of decompensation (1.56% vs. 3.87%, risk ratio [RR] 0.43, 95% confidence interval [CI] 0.39–0.48) and all-cause mortality (1.67% vs. 2.97%, RR 0.56, 95% CI 0.51–0.62) were lower in patients treated with GLP-1 analogs compared with patients who had bariatric surgery.
Conclusion: GLP-1 analogs are increasingly being used in patients with MASLD. GLP-1 analogs and bariatric surgery reduce the risk of decompensated cirrhosis in obese patients with MASLD. Our results indicate that patients with MASLD treated with GLP-1 analogs have a lower risk of decompensated cirrhosis and better overall survival than patients treated with bariatric surgery despite being older and having more comorbidities.

SAT-416

The impact of SGLT-2i and GLP-1RA on liver-related events in patients with metabolic dysfunction-associated steatotic liver disease: a systematic review and network meta-analysis

Lu Li[1], Ka Shing Cheung[1], Xianhua Mao[1], Lung-Yi Mak[1], Rex Wan-Hin Hui[1], Man-Fung Yuen[1], Wai-Kay Seto[1]. [1]*Department of Medicine, The University of Hong Kong, Hong Kong, China*
Email: ellie825@connect.hku.hk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has emerged as a major global health issue. Potential benefits of glucose-lowering agents in preventing liver-related events in MASLD patients with type 2 diabetes (T2D) have been reported, but the comparative efficacy of these glucose-lowering agents remains inconclusive, especially for long-term liver-related events. This study aimed to systematically review and compare the efficacy of glucose-lowering agents on liver-related events in patients with MASLD and T2D using a network meta-analysis (NMA).
Method: Data from observational studies were collected through PubMed, EMBASE, Cochrane Library and Web of Science from inception to October 2024. We evaluated the efficacy of glucose-lowering agents, including glucagon-like peptide-1 receptor agonists (GLP-1RAs), sodium–glucose cotransporter 2 inhibitors (SGLT-2is),

dipeptidyl peptidase-4 inhibitors (DPP-4is), sulfonylureas, and thiazolidinediones, on liver-related events (defined by cirrhosis, hepatic decompensation, liver failure, liver transplantation, hepatocellular carcinoma, or liver-related death) using a frequentist NMA approach, with results expressed as estimated pooled hazard ratios (HRs) and 95% confidence intervals (CIs). Treatment ranking in the frequentist NMA were presented as a P-score.

Results: A total of 12 eligible studies with 656,629 patients with MASLD and T2D were included. Among five glucose-lowering agents, SGLT2is and GLP-1RAs are the most effective classes for preventing liver-related events, with P-score 0.8845 and 0.8677, respectively. while other glucose-lowering agents had P-scores below 0.5. In addition, GLP-1RAs were shown to have comparable effects to SGLT2is for liver-related events (pooled HR 1.01; 95%CI 0.87–1.18). SGLT2is were significantly associated with a decreased risk of liver-related events compared with DPP4is (pooled HR 0.69; 95%CI 0.54–0.87), thiazolidinediones (pooled HR 0.58; 95%CI 0.45–0.74), and sulfonylureas (pooled HR 0.56; 95%CI 0.42–0.76). Consistent risk reduction was observed in GLP-1RAs users when compared with DPP4is (pooled HR 0.69; 95%CI 0.56–0.85), thiazolidinediones (pooled HR 0.59; 95%CI 0.45–0.77), and sulfonylureas (pooled HR 0.57; 95%CI 0.43–0.75).

Conclusion: Both SGLT2is and GLP1RAs are promising glucose-lowering agents for preventing liver-related events in patients with MASLD and T2D. These findings may help guide therapeutic strategies for managing patients with MASLD and T2D.

SAT-417-YI

Sex disparities in response to low-carb, high-fat diet in MASLD

Ellen Elise Petersen[1], Johanne Kragh Hansen[2], Nikolaj Torp, Katrine Lindvig, Peter Andersen[2], Stine Johansen[2], Ida Falk Villesen[2], Katrine Bech[2], Katrine Thorhauge[2], Helle Schnefeld[2], Sönke Detlefsen[2], Maja Thiele, Mads Israelsen[2], Camilla Dalby Hansen[2], Aleksander Krag. [1]*University of Southern Denmark, Odense University Hospital, Odense, Denmark;* [2]*Odense University Hospital, Odense, Denmark*
Email: elpet19@student.sdu.dk

Background and aims: Dietary approaches affect women and men differently, in relation to both quality of life (QOL) and clinical outcomes. To improve adherence, it is essential to identify who benefits most in both aspects. This study compares QOL and clinical outcomes between the Low Carbohydrate High Fat (LCHF) diet and the high-carbohydrate, low-fat (HCLF) diets, with a focus on potential gender differences.

Method: These results are from a six-month randomized controlled trial in people with type 2 diabetes. Participants were randomized in a 2:1 ratio to follow either a LCHF diet or a HCLF diet. Both diets were based on non-processed, isocaloric and healthy foods. Liver biopsies, standard clinical assessments, and the Diabetes-39 QOL questionnaire were conducted at baseline and after six months. We used one question from the questionnaire to evaluate overall QOL, called "Please mark the box that represents your overall assessment of your quality of life," the score was from 1–7, with 1 being lowest quality. Liver biopsies were scored according to the NAS CRN scoring system. Subgroup analyses were performed to evaluate sex-specific differences in clinical and QOL response to the dietary interventions.

Results: We included 165 participants, 96 (58%) were women and 69 (42%) were men, median age was 56 (IQR, 50–63) years, mean BMI was 33 ± 7 kg/m^2, mean HbA1c was 56 ± 10 mmol/mol, 141 had MASLD with a median NAS score of 3 (IQR, 2–4) and a median overall QOL score of 5 (IQR, 4–6). QOL improved in both groups with 0.60 (95% CI: 0.05 to 1.16) on the LCHF diet and with 0.80 (95% CI: 0.00 to 1.60) on the HCLF diet (p = 0.692). The impact on QOL did not differ between sexes (p = 0.338). However, looking at the clinical impact between men and women, we saw significant differences. Women on the LCHF diet improved liver steatosis with −2.79 (95% CI: −4.16 to −1.42) compared to −0.74 (95% CI: −2,07 to 0.59) on the HCLF diet (p-value = 0.02), and lobular inflammation with −1.45 (95% CI: −2.52 to −0.38) compared to 0.19 (95% CI: −1.11 to 1.48) on the HCLF diet (p = 0.059). Men did not improve within-group or between-group in liver steatosis or lobular inflammation (steatosis: p-value = 0.764, inflammation: p-value = 0.901). Both sexes improved their HbA1c and weight more on the LCHF diet compared to the HCLF diet (Mean difference in change; women, HbA1c: −5.21 mmol/mol (95% CI: −8.74 to −1.68), weight: −4.76 kg (95% CI: −6.71 to −2.81), men: −7.84 mmol/mol (95% CI: −13.42 to −2.27), weight: −2.33 kg (95% CI: −4.47 to −0.20).

Conclusion: The LCHF diet significantly reduced liver steatosis and inflammation in women, whereas men did not experience similar benefits, despite comparable reductions in weight and HbA1c levels. Notably, neither diet had a negative impact on QOL.

SAT-418-YI

Indication of resmetirom in patients with metabolic dysfunction associated steatohepatitis in the real-world setting - data from the german SLD-registry

Eva Messer[1], David Petroff[2], Jörn M. Email: eva.messer@medizin.uni-leipzig.de

Background and aims: The THR-β agonist resmetirom is the first and only treatment approved for metabolic dysfunction-associated steatohepatitis (MASH) in the US so far. The indication for prescribing resmetirom is MASH and moderate to advanced fibrosis consistent with F2/F3 ("at-risk MASH"). This definition is biopsy driven, although biopsy is only available in selected patients and not necessary in accordance with the US prescribing information. We therefore analyzed how many patients would qualify for resmetirom in the real-world scenario of the German Steatotic Liver Disease (SLD)-Registry.

Method: Indication for resmetirom was assessed by three different approaches: (i) biopsy proven MASH with F2/3 fibrosis and NAS-score ≥ 4; (ii) FibroScan-AST (FAST)-score > 0.67 and vibration controlled transient elastography (VCTE) < 15 kPa; (iii) US expert recommendation with VCTE 10–15 kPa and platelets ≥ 140 109/L (Noureddin et al., Clin Gastroenterol Hepatol 2024).

Results: 1113 patients were recruited across 8 academic and 12 non-academic centers. NAS grading and fibrosis staging were available for 180 cases (16%) with 179/180 conducted at academic centers. Of these, 61 (34%) qualified for resmetirom based on approach (i). FAST score and VCTE, but not histology were available for 638 cases (57%), of which 612 (98%) were from academic and 26 (2%) from non-academic centers. Based on approach (ii), 41 (6.4%) individuals qualified for resmetirom. VCTE was performed in 744 patients (67%) with 624 (84%) at academic and 120 (16%) at non-academic centers. Using approach (iii), 129 (17.3%) individuals qualified for resmetirom. Overall, 201 (31%) patients met the criteria for resmetirom if either VCTE values between 10–15 kPa and platelets ≥ 140 109/L or FAST

score > 0.67 were present. A direct comparison of biopsy results and FAST scores was available for 170 patients, although a substantial amount of time often elapsed between the two assessments. Of these, resmetirom was not indicated by FAST score in 150 cases, however, 47 (31%) would have qualified based on biopsy results.
Conclusion: The selection of eligible patients for resmetirom treatment depends on the method used to identify "at-risk MASH." The availability of diagnostic approaches differs between academic and non-academic centers. Non-invasive assessment may miss patients who would qualify for resmetirom according to biopsy.

SAT-419-YI
A postbiotics and metabiotics reduces the hepatic steatosis indices and aminotransferase activity in MASLD patients: a randomized clinical trial (DELI_MASLD study)
Maryana Savytska[1], Yeva Ilkiv[2], Olena Baka[3], Elina Manzhalii[2], Tetyana Falalyeyeva[4], Viktoriia Yerokhovych[2], Liubov Sichel[5], Nazarii Kobyliak[2]. *[1]Danylo Halytsky Lviv National Medical University, Lviv, Ukraine; [2]Bogomolets National Medical University, Kyiv, Ukraine; [3]Center for Innovative Medical Technologies of the National Academy of Sciences of Ukraine, Kyiv, Ukraine; [4]Taras Shevchenko National University of Kyiv, Kyiv, Ukraine; [5]Stellar Biotics, Rockleigh, United States*
Email: nazariikobyliak@gmail.com

Background and aims: The background for current study was previously reported by our team in pilot study (EASL 2024; Milan, Italy; SAT-213) findings that postbiotic supplementation for 3 months can reduce hepatic fat content in NAFLD patients as measured by MRI-PDFF. The aim of the current study was to conduct a placebo controlled randomized clinical trial (RCT) to assess the short-term efficacy and safety of the same formulation on the main serum parameters which characterized hepatic fat accumulation and transaminases activity in patients with MASLD according to new EASL–EASD–EASO criteria.
Method: A total of 52 patients met the criteria for inclusion. The study included 3 periods. A screening period of up to 1 week was used to assess eligibility for the inclusion/exclusion criteria. The treatment and follow-up periods were 3 months each. The participants received a twice-daily oral dose of postbiotics/metabiotics containing cell lysate and DNA fragments of the probiotic strain *L. rhamnosus DV - NRRLB-68023* at the assigned dose of 100 mg or placebo in capsules. The primary main outcomes were the change of biochemical steatosis indices: fatty liver index (FLI), hepatic steatosis index (HSI) and triglyceride to glucose (TyG) index. Secondary outcomes were the changes in serum lipid content, transaminase activity, markers of chronic inflammation (Il-6, hs-CRP) and anthropomorphic variables. Trial registration: NCT06352697.
Results: Postbiotic/metabiotics supplementation for 3 months was associated with significant reductions in FLI (78.23 ± 14.47 to 71.95 ± 21.62; p = 0.016) and HSI (45.48 ± 5.05 to 42.75 ± 4.98; p = 0.001). For TyG index decreasing trend was observed (4.92 ± 0.39 to 4.84 ± 0.34; p = 0.081). In secondary outcomes analysis, from abovementioned endpoints, only transaminase activity (ALT - 43.15 ± 29.2 to 27.75 ± 18.22 IU/L; p = 0.001 and AST - 31.34 ± 17.98 to 23.88 ± 8.11 IU/L; p = 0.006) and anthropometric parameters changes significantly after 3 months of probiotic lysate administration. In the placebo group, in both outcomes analysis only HSI significantly decrease at the end of treatment period (43.50 ± 4.59 to 42.43 ± 4.79; p = 0.015). After intervention discontinuation, at follow-up visits (6 months), the endpoints increased compared to those at the end of the treatment visits. However, the parameters did not achieve the baseline level.
Conclusion: The present RCT demonstrated the beneficial effects of postbiotic/ metabiotics supplementation on the biochemical steatosis indices, anthropometric parameters and transaminases activity in MASLD patients. However, larger studies are needed to confirm these findings.

SAT-420
Natural explant with dihydromiricetin in metabolic associated steatotic liver disease (MASLD): a double-blind, placebo controlled, randomized clinical trial
Elisavet Michailidou[1], Stavros Papadakos[1], Eleni Koukoulioti[2], Maria Mela[3], Paraskevi Fytili[1], Panagiota Ioannidou[1], Evangelos Cholongitas[1], Konstantinos Triantafyllou[2], George Papatheodoridis[1]. *[1]1st Department of Gastroenterology, Medical School of National and Kapodistrian University of Athens, General Hospital of Athens "Laiko," Athens, Greece; [2]2nd Department of Gastroenterology, Medical School of National and Kapodistrian University of Athens, University General Hospital "Attikon," Athens, Greece; [3]Gastroenterology Department, General Hospital of Athens "Evangelismos," Athens, Greece*
Email: gepapath@med.uoa.gr

Background and aims: MASLD has a prevalence of 25–30% globally representing the most common current cause of cirrhosis and liver transplantation in Western countries. However, effective treatment options for MASLD are limited. The aim of this prospective, double-blind, placebo controlled trial was to assess the efficacy of a dietary supplement containing dihydromyricetin (Hepatrat®) in patients with MASLD.
Method: Adult patients with MASLD seen at our liver clinics were included. All patients should have had elevated ALT and/or GGT and radiologically diagnosed hepatic steatosis, but no other cause of liver injury. Enrolled patients were randomized to receive Hepatrat® (dietary supplement in tablet form containing dihydromyricetin from Ampelopsis grossedentata extract, along with essential nutrients such as vitamins C and E, and choline) or placebo for 12 months (NCT05052515). Patients were assessed every 3 months and the primary end-point of the study was biochemical responses at 12 months.
Results: In total, 55 patients were randomized to active treatment (Group A, n = 28) or placebo (Group B, n = 27), but 9 patients (Group A/B = 2/7) withdrawn early for personal reasons. Baseline characteristics were not different between patients of Group A vs B except for gender distribution. Patients of Group A vs B did not differ in the normalization rates of ALT or GGT alone, but they achieved higher 12-month rates of combined ALT and GGT normalization (ITT analysis:32% vs 4%, p = 0.012, PP analysis:35% vs 5%, p = 0.028). Patients with normal both ALT and GGT compared to those with elevated ALT and/or GGT at 12 months did not differ in baseline age, gender, BMI, diabetes, platelets, liver stiffness or CAP values. Median weight was numerically reduced at 12 months (−1.2 kg, p = 0.103). Weight reduction at 12 months did not differ between patients of Group A vs B (p = 0.571), while it was greater in patients with than without normalization of ALT+GGT (−5.0 vs −1.0 kg, p = 0.035). In multivariable analysis, Group A was the main factor associated with normalization of ALT+GGT at 12 months (OR:11.76, 95%CI:1.15–120.41, p = 0.038) independently of weight reduction (p = 0.059).
Conclusion: The 12-month use of Hepatrat® seems to result in increased rates of normalization of both ALT and GGT in patients with MASLD regardless of their baseline characteristics. Therefore, the use of Hepatrat® in MASLD needs further evaluation.

SAT-421
The reversal of MASH cirrhosis. Pooled analysis from RCTs
Henrik Hee Seung Yang[1], Cheng Han Ng[2], Donghyun Ko[3], Daniel Huang[4], Mazen Moureddin[5], Wenhao Li[6], Hirokazu Takahashi[7], Asahiro Morshita[8], Mark Muthiah[9]. *[1]Singapore General Hospital, Singapore, Singapore; [2]Kurume University, Fukuoka, Japan; [3]Universidad Francisco Marroquin, Guatemala City, Guatemala; [4]YONG LOO LIN SCH OF MEDICINE, Singapore, Singapore; [5]Houston Methodist Hospital, Houston, TX, United States; [6]Queen Mary, University of London, London, United Kingdom; [7]Saga University Hospital, Saga City, Japan; [8]Kagawa University, Kagawa, Japan; [9]National University*

Health System, Singapore, Singapore
Email: chenhanng@gmail.com

Background and aims: Metabolic-associated steatohepatitis (MASH) is a progressive liver disease characterized by liver fibrosis and inflammation, posing significant risks for liver-related complications and mortality. This meta-analysis synthesises data relating only to MASH Cirrhosis to examine the effect of regression using the placebo arm from randomised controlled trials.
Method: A comprehensive strategy was done on Embase and Medline (Ovid) for MASH randomized controlled trials (RCT) from inception to Dec. 26, 2023, with placebo treatment arms. Primary outcomes were defined as at least one point reduction in fibrosis as per the National Institutes of Health Nonalcoholic Steatohepatitis Clinical Research Network (NIH NASH CERN) criteria, and/or two point reduction via Non-alcoholic fatty liver disease (NAFLD) activity score without worsening fibrosis, or resolution of NASH.
Results: Among MASH patients, a ≥1 stage improvement in fibrosis per NASH CRN criteria was observed in 17.23% (95% CI: 10.18–27.67%), with Ishak fibrosis stage improvement reported in 23.88% (95% CI: 15.34–35.20%). Fibrosis improvement without worsening of MASH occurred in 17.19% (95% CI: 11.54–24.83%), while histological resolution was rare at 3.82% (95% CI: 1.14–12.08%). Liver-related complications were notable. Variceal bleeding was observed in 0.19% (95% CI: 0.01–5.18%), ascites in 1.23% (95% CI: 0.27–5.41%), hepatic encephalopathy in 1.22% (95% CI: 0.55–2.69%), and spontaneous bacterial peritonitis (SBP) in 1.61% (95% CI: 0.40–6.22%). Patients with Model for End-Stage Liver Disease (MELD) scores ≥15 demonstrated an elevated risk of adverse outcomes, with a pooled proportion of 4.64% (95% CI: 2.43–8.67%). Liver-related mortality was recorded at 0.68% (95% CI: 0.13–3.38%).
Conclusion: MASH may have spontaneous regression without pharmacotherapy, with histological resolution. This study demonstrates the first pooled evidence of placebo arm related MASH progression. Further characterisation of natural MASH regression and effect of placebo on histological response may aid in further pharmacological profiling and designing of targeted demographic clinical trials.

SAT-422

Effect of hepatic impairment on the pharmacokinetics of Miricorilant: results from a phase 1, open-label, adaptive-design study

Joseph M. Custodio[1], Kirsteen Donaldson[2], Jeevan Kunta[1], Kavita Juneja[1], Hazel J. Hunt[1]. [1]*Corcept Therapeutics Incorporated, Redwood City, CA, United States;* [2]*Jade Consultants (Cambridge) Limited, Cambridge, United Kingdom*
Email: jcustodio@corcept.com

Background and aims: Miricorilant is a nonsteroidal selective glucocorticoid receptor modulator (SGRM) that acts as a mixed agonist/antagonist of the GR and a modest antagonist of the mineralocorticorticoid receptor. Miricorilant is currently being evaluated in the phase 2 MONARCH trial (NCT06108219) for the treatment of noncirrhotic (F1-3) metabolic dysfunction-associated steatohepatitis (MASH). In a previous phase 1b trial, patients (pts) with presumed MASH treated with twice-weekly miricorilant 100 mg had reduction in liver fat content as well as improvements in hepatic, lipid, and glycemic markers (Alkhouri et al. *Hepatology* 2024). As the primary route of elimination for miricorilant is hepatic (Custodio et al. EASL 2024), our objective here was to evaluate the effect of hepatic impairment on the pharmacokinetic (PK) profile of miricorilant.
Method: In this phase 1, open-label, adaptive-design study (NCT05553470), adult pts with moderate (Child-Pugh Class B; including pts with MASH) or severe (Child-Pugh Class C) hepatic impairment were matched with healthy control volunteers based on gender, age (±10 years), and weight (±20%). All participants received a single oral dose of miricorilant 600 mg under fed conditions. Plasma concentrations of miricorilant were determined with a validated LC-MS/MS bioanalytical method at pre-dose and 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4, 6, 8, 12, 24, 48, 72, 96, 120, and 144 hours post-dose. Safety and tolerability were monitored throughout the study.
Results: The study enrolled pts with moderate hepatic impairment (n = 10, including 4 pts with MASH), severe hepatic impairment (n = 9), and healthy volunteers (n = 10). The observed effect of moderate and severe hepatic impairment on miricorilant PK was small. Following a single dose of miricorilant, the geometric mean ratios (90% CI) of miricorilant AUC_{inf} and C_{max} were 133% (97.9–179.9%) and 82% (65.7–101.5%), respectively, in pts with moderate hepatic impairment compared to healthy matched volunteers. The geometric mean ratios (90% CI) of miricorilant AUC_{inf} and C_{max} were 136% (91.4–202.6%) and 30% (24.2–37.5%), respectively, in pts with severe hepatic impairment compared to healthy matched volunteers. The half-life of miricorilant in pts with moderate and severe hepatic impairment was 36.0 and 76.7 hours, respectively, as compared with a half-life of 25.5 hours in healthy matched volunteers. No grade ≥3 treatment-emergent AEs or laboratory abnormalities were observed, and no new safety concerns were identified.
Conclusion: Miricorilant 600 mg was generally well tolerated in pts with moderate and severe hepatic impairment and in matched healthy volunteers. Hepatic impairment had minimal impact on the systemic plasma exposures (as measured by AUC) of miricorilant. These findings support future inclusion of pts with compensated cirrhotic (F4) MASH in the miricorilant clinical development program.

SAT-423

Survodutide, a glucagon/GLP-1 receptor dual agonist, in people with MASH with moderate-to-advanced liver fibrosis (stage F2-F3): rationale and design of an event-driven, multinational, randomised, placebo-controlled, phase 3 trial (LIVERAGE™)

Jörn M. Schattenberg[1], Mazen Noureddin[2], Naim Alkhouri[3], Luiza Borowska[4], Daniel F. Mazo[4], Martina Brueckmann[4,5], Mandy Fraessdorf[4], Samina Ajaz Hussain[4], Ramy Younes[4], Arun J. Sanyal[6]. [1]*Department of Internal Medicine II, University Medical Center Homburg, Homburg and Saarland University, Saarbrücken, Germany;* [2]*Houston Research Institute, Houston Methodist Hospital, Houston, United States;* [3]*Hepatology Division, Arizona Liver Health, Phoenix, United States;* [4]*Boehringer Ingelheim, Ingelheim, Germany;* [5]*First Department of Medicine, Faculty of Medicine Mannheim, University of Heidelberg, Mannheim, Germany;* [6]*Division of Gastroenterology, Hepatology and Nutrition, Department of Medicine, Virginia Commonwealth University, Richmond, United States*
Email: joern.schattenberg@uks.eu

Background and aims: Dual agonism of the glucagon (GCGR) and glucagon-like peptide-1 (GLP-1R) receptors may be effective for treating metabolic dysfunction-associated steatohepatitis (MASH). Survodutide, a GCGR/GLP-1R dual agonist with a receptor ratio of ~1:8 in vitro, markedly improved both steatohepatitis and liver fibrosis in a 48-week phase 2 trial in people with MASH and fibrosis stages F1-F3. We describe here the design of an ongoing phase 3 trial of survodutide for treatment of non-cirrhotic MASH (LIVERAGE™).
Method: In this 2-part trial in ~1800 participants in ~40 countries (NCT06632444), the main eligibility criteria include age ≥18 years, a biopsy-proven diagnosis of MASH and F2-F3 fibrosis (by MASH Clinical Research Network [CRN] stage), screened through the following parameters: aspartate aminotransferase (AST) >20 U/L, liver stiffness by FibroScan vibration-controlled transient elastography (VCTE) ≥7.5 kPa, FibroScan-AST (FAST) score >0.36, and liver fat

fraction ≥8% by magnetic resonance imaging-proton density fat fraction. Exclusion criteria include AST and/or alanine aminotransferase ≥5x upper limit of normal [ULN], platelets <140,000/mm^3, albumin <3.5 g/dL, international normalised ratio of prothrombin time >1.3, bilirubin ≥1.5x ULN, acute or other chronic liver disease, cirrhosis, portal hypertension, decompensated liver disease, hepatocellular carcinoma, Model for End-stage Liver Disease (MELD) score ≥12, or liver transplant. Participants are randomised 2:1 to double-blind, once-weekly, subcutaneous injections of survodutide uptitrated to 6.0 mg or placebo. In part 1, the two primary endpoints will be assessed in the first 700 participants at week 52: 1) resolution of MASH without worsening of liver fibrosis by MASH CRN stage and 2) ≥1-point improvement in fibrosis stage with no worsening of MASH. Key secondary endpoints are % change from baseline in body weight, absolute change from baseline in glycated haemoglobin (in participants with type 2 diabetes), Enhanced Liver Fibrosis score and liver stiffness by VCTE, and achievement of no progression of fibrosis. In part 2, the primary endpoint evaluated in all participants is a composite outcome of time to first event of progression to cirrhosis, all-cause mortality, liver transplant, hepatic decompensation event (s), worsening of MELD score to ≥15, or progression to clinically significant portal hypertension. Safety evaluation is based on treatment-emergent adverse events and laboratory tests.
Results: Recruitment of participants began in October 2024. Follow-up is estimated to end in 2031.
Conclusion: The phase 3 LIVERAGE™ trial will elucidate the long-term effects of survodutide on steatohepatitis, fibrosis, liver outcomes, and all-cause mortality in people with fibrotic MASH without cirrhosis, as well as its tolerability and safety.

SAT-424

Baseline characteristics in well-compensated NASH cirrhosis patients diagnosed with or without a liver biopsy in MAESTRO-NASH-OUTCOMES, a clinical outcome phase 3 study assessing the effect of resmetirom in well compensated NASH cirrhosis

Jörn M. Schattenberg[1], Meena Bansal[2], Rebecca Taub[3], Dominic Labriola[3], David Schneider[3], Michael Charlton[3], Vlad Ratziu[4], Mazen Noureddin[5]. *[1]Metabolic Liver Research Program, I. Department of Medicine, University Medical Center of Johannes Gutenburg University Mainz, Mainz, the Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany, Homburg, Germany; [2]Ichan School of Medicine at Mount Sinai, New York, United States, [3]Madrigal Pharmaceuticals, West Conshohocken, United States; [4]Sorbonne Université, ICAN Institute for Cardiometabolism and Nutrition, Assistance Publique–Hôpitaux de Paris (APHP), INSERM, UMRS 1138, Centre de Recherche des Cordeliers, Paris, France, Paris, France; [5]Houston Methodist Hospital, Houston, United States*
Email: joern.schattenberg@uks.eu

Background and aims: MAESTRO-NASH Outcomes (NCT05500222) is a multi-national, multicenter, double-blind, randomized, placebo-controlled study in well-compensated NASH cirrhosis. Patients were randomized 3:1 in a blinded manner to receive resmetirom 80 mg or matching placebo given orally once daily in the morning for the duration of the study (until the required number of Composite Clinical Outcome events are achieved). Composite Clinical Outcome events are defined as any of the following: mortality, liver transplant, and significant hepatic events, including potential hepatic decompensation events (ascites, hepatic encephalopathy, or gastroesophageal variceal haemorrhage), and confirmed increase of Model for End-stage Liver Disease (MELD) score from <12 to ≥15. The study comprises an up to 60-day screening period and an approximately 3-year treatment period. Baseline factors in patients who were diagnosed with NASH cirrhosis on liver biopsy were compared with those diagnosed with NASH cirrhosis who did not receive a liver biopsy.
Method: The study enrolls NASH cirrhosis patients with confirmed F4 fibrosis on biopsy with 3 metabolic risk factors, meeting other non-invasive testing and eligibility requirements, or NASH cirrhosis diagnosed non-invasively requiring at least 2 non- invasive testing requirements for screening: FibroScan VCTE ≥15 kPa and/or if FibroScan VCTE <15 kPa; at least two other non- invasive tests (MRE ≥4.2, platelets <140 K, ELF ≥10.25, FIB-4 ≥3). Other screening tests include blood tests, MRE, MRI-PDFF and assessments for HCC and ascites, with MELD <12 (except for Gilbert).
Results: A total of 845 patients are enrolled, including 392 with NASH cirrhosis with biopsy-confirmed F4 fibrosis, and 453 with NASH cirrhosis diagnosed non-invasively. Baseline factors were generally similar between patients diagnosed as NASH cirrhosis on liver biopsy or diagnosed as NASH cirrhosis without a liver biopsy: mean age 63 years; 32–35% males; mean BMI of 35 kg/m^2, 70–79% with hypertension, 65–77% with T2DM. Approximately one third of patients had more advanced disease based on MRE ≥ 6, ELF ≥ 11.3, MRI-PDFF < 5%. A higher percentage of NASH cirrhosis patients diagnosed without a liver biopsy had baseline characteristics suggestive of more advanced portal hypertension (Platelets <140 K, higher MRE, ELF and FibroScan VCTE), 67% and 83% meeting Baveno VII criteria for probable or possible clinically significant portal hypertension (CSPH) in the biopsy and no biopsy groups, respectively.
Conclusion: These data support the accuracy of using non-invasive testing to accurately diagnose well-compensated NASH cirrhosis.

SAT-425

Evaluating the efficacy of a carnitine orotate and biphenyl dimethyl dicarboxylate complex in the pathogenetic treatment of metabolic-associated fatty liver disease: midterm data

Aliya Kaisina[1], Almagul Jumabayeva[1], Jamilya Kaibullayeva[1], Balzhan Nugmanova[1], Aliya Balabek[2], Aizhan Muratbekova[2], Assya Yergaliyeva[2], Tamilya Reshidova[3]. *[1]JSC "Research institute of cardiology and internal diseases", Almaty, Kazakhstan; [2]State Enterprise on the Right of Economic Management "City Polyclinic No. 5", Almaty, Kazakhstan; [3]Yenbekshikazakh interdistrict multidisciplinary hospital, Yesik, Kazakhstan*
Email: almusa010@mail.ru

Background and aims: Nowadays the prevalence of metabolic-associated fatty liver disease (MAFLD) is increasing rapidly, whereas clinicians all over the world still have serious limitations in the treatment of MAFLD. Several investigations showed the effectiveness of drugs based on carnitine orotate and biphenyl dimethyl dicarboxylate (COC and BDD) in the complex therapy of patients with MAFLD. The main purpose of this study was to evaluate the effectiveness of the carnitine orotate and BDD complex in the pathogenetic therapy of BDD.
Method: A prospective cohort study of MAFLD patients has been ongoing in Kazakhstan since February 2023. From February 2023 to July 2024, 121 participants aged 18–75, taking COC and BDD, were included in the study in Almaty and the surrounding region. Participants were observed for 48 weeks, with 24 weeks of COC and BDD treatment. The analysis included 78 participants who completed the treatment by September 2024. Anthropometric data (BMI, waist circumference), steatosis and fibrosis levels (measured by transient elastography [FibroScan] with Controlled Attenuation Parameter), alanine aminotransferase (ALT), aspartate aminotransferase (AST), total cholesterol, triglycerides, and FIB-4 (a non-invasive fibrosis marker) were assessed at baseline and at week 24. Statistical analysis was performed using Jamovi 2.4.8.
Results: After 24 weeks of treatment, significant reductions were observed in ALT (32.4 [19–51.5] U/l to 20.1 [14.9–28.4] U/l, $p < 0.001$), triglycerides (1.4 [1.1–2.2] to 1.3 [1.0–2.0] mmol/L, $p = 0.007$), steatosis (304 [268–325] to 283 [246–312] dB/m, $p < 0.001$), and fibrosis (6.5 [5.3–8.3] to 6 [4.7–7.2] kPa, $p = 0.022$). ALT showed a slight increase over time (from 23.3 [17.9–38.6] U/l at baseline to 23.5 [19.1–28.4] U/l at week 24, $p = 0.021$), but remained within the

reference range. The median BMI decreased from 30.4 to 29.8 kg/m² (p = 0.214), with no significant changes in waist circumference (p = 0.943), indicating that weight loss did not significantly impact steatosis, fibrosis, or ALT levels. The frequency of severe fibrosis (F3) decreased from 8.1% to 1.4%, while F2 decreased from 27% to 21.4% (p = 0.022). The frequencies of F1 and F0 increased, indicating improvements in fibrosis. Severe steatosis (S3) decreased from 52.7% to 45.7%, and mild steatosis (S1) increased from 17.6% to 21.4%, with new cases of S0 (10%) appearing at week 24 (p = 0.001). No significant changes were found in total cholesterol levels or FIB-4 scores (p = 0.071).
Conclusion: COC and BDD treatment in MAFLD patients resulted in regression of ALT, triglycerides, steatosis, and fibrosis over 24 weeks, with a slight increase in AST within the reference range. Despite these promising results, further studies are needed to fully assess the efficacy of COC and BDD.

SAT-429

The synergistic effects of 4 weeks of resistance exercise and whey protein supplementation on liver health in individuals with metabolic dysfunction-associated liver disease

Jung-Jun Park[1], Chae-Been Kim[1], Hong Soo Kim[2]. *[1]Department of Sports Science, Pusan National University, Busan, Korea, Rep. of South; [2]Department of Internal Medicine, Soon Chun Hyang University Cheonan Hospital, Cheonan, Korea, Rep. of South*
Email: jjparkpnu@pusan.ac.kr

Background and aims: Exercise and diet are effective non-pharmacological treatments for metabolic dysfunction-associated liver disease (MASLD), reducing hepatic fat. Resistance exercise helps prevent muscle loss in MASLD patients, while whey protein reduces hepatic fat accumulation. However, the combined effects of exercise and whey protein supplementation are unclear. This study examines their individual and combined effects on hepatic fat and liver enzymes in MASLD.
Method: Individuals with MASLD (n = 45) were randomly assigned to four groups: exercise protein (ExPro, n = 14), exercise placebo (ExPla, n = 12), control protein (ConPro, n = 11), and control placebo (ConPla, n = 8). ExPro and ConPro consumed 0.7 g of whey protein/kg of body weight, while ExPla and ConPla consumed an equal amount of placebo for 4 weeks. ExPro and ExPla performed supervised resistance exercise five times per week for 40 minutes, with intensity gradually increasing from 50% to 75% of 1-RM. All participants received packed meals containing 30% fewer calories than their daily requirement (measured by gas analysis of RMR multiplied by physical activity level), containing 0.8 g of protein/kg of body weight. Hepatic fat content was assessed weekly by controlled attenuation parameter (CAP) and plasma samples were collected biweekly to analyze AST, ALT, and GGT. Data were analyzed using generalized estimating equations with a log-gamma model, with ConPla as the reference.
Results: A significant time-by-group interaction was observed for CAP. In the ExPro, reductions were significant at 1 week (beta = −0.061, p = 0.028), 2 weeks (beta = −0.092, p = 0.001), 3 weeks (beta = −0.083, p = 0.008), and 4 weeks (beta = −0.111, p < 0.001). In ExPla, reductions occurred at 2 weeks (beta = −0.054, p = 0.041) and 4 weeks (beta = −0.082, p = 0.011). ConPro showed a reduction at 4 weeks (beta = −0.089, p = 0.002). For ALT, significant reductions in ConPro occurred at 2 weeks (beta = −0.311, p = 0.026) and 4 weeks (beta = −0.322, p = 0.002). AST showed significant time-by-group interaction, with a reduction in ConPro at 2 weeks (beta = −0.198, p = 0.040), but increase in ExPro at 2 weeks (beta = 0.327, p = 0.044). No significant interaction was found for GGT.
Conclusion: Both resistance exercise and whey protein supplementation, both individually and in combination, improve liver health in individuals with MASLD. The combination may offer synergistic benefits compared to each treatment alone.

SAT-430

Population pharmacokinetic/pharmacodynamic modelling of novel thyroid hormone receptor beta agonist ALG-055009 reveals statistically significant correlation between exposure and key efficacy endpoints

Kha Le[1], Russ Wada[2], Paul Ko[2], Stanley Wang[1], Rohit Loomba[3], Megan Fitzgerald[1], Min Wu[1], Ifong Kan-Eng[1], Doug Clark[1], Tse-I Lin[1], Hardean Achneck[1], Lawrence Blatt[1], Sushmita Chanda[1]. *[1]Aligos Therapeutics, South San Francisco, United States; [2]QuanTx Consulting, Mountain View, United States; [3]UCSD, La Jolla, United States*
Email: kle@aligos.com

Background and aims: ALG-055009 is a novel next generation thyroid hormone receptor (THR)-beta agonist with beta selectivity and in vitro potency exceeding that of first-generation drugs. In the randomized, double-blind, placebo-controlled Phase 2a HERALD study, 12 weeks of once daily ALG-055009 treatment in subjects with presumed metabolic dysfunction-associated steatohepatitis (MASH) and F1-F3 fibrosis was well-tolerated and met the primary endpoint, demonstrating significant reductions in liver fat (Loomba et al. AASLD 2024). This analysis was conducted to inform Phase 2b dose selection.
Method: ALG-055009 pharmacokinetic (PK) data were collected from two healthy volunteer studies (n = 91 subjects and 2233 samples) and one MASH patient study (n = 78 subjects and 726 samples), after single or multiple once-daily dosing of 0.1–4.0 mg ALG-055009. Nonlinear mixed effects modeling was used to characterize the population PK. Individual exposure parameters were used to investigate the relationship with efficacy parameters and key safety parameters. The exposure-efficacy dataset consisted of 97 subjects receiving daily oral administration of ALG-055009 at 0.3 (n = 18), 0.5 (n = 21), 0.7 (n = 20) or 0.9 mg (n = 17) or placebo (n = 21). Non-linear regression and logistic regression were used to model the exposure-response relationships. Key efficacy endpoints included change from baseline in liver fat as measured by MRI-PDFF and proportion of responders of ≥30% relative liver fat reduction. Covariate analysis was conducted on the population PK and exposure-response relationship.
Results: Greater change from baseline in liver fat at Week 12 ($p < 2.35 \times 10^{-6}$) and proportion of subjects achieving more than 30% relative liver fat reduction (p < 0.001) showed statistically significant association with increased ALG-055009 exposure. ALG-055009 steady-state area under the plasma concentration-time curve (AUC) between 500–1500 ng.h/mL appeared to have optimal efficacy profile. Covariates included demographics, weight, baseline liver fat, and relevant concomitant medication use (statins or GLP-1 receptor agonists) did not have a statistically significant effect on the exposure-efficacy relationship. A simulation study of PK and key efficacy endpoints in a virtual population of 1000 subjects with covariate distributions from the HERALD study provided rank order of efficacy for dosing regimens with and without dose cut-offs at selected body weights.
Conclusion: Population PK and exposure-response models were developed for ALG-055009. There was a statistically significant correlation between exposure and key efficacy endpoints of change from baseline in liver fat and proportion of responders of ≥30% relative liver fat reduction. These models will be used to provide guidance for dose selection for a Phase 2b study in patients with MASH.

SAT-431

Effectiveness of a smartphone app in promoting weight loss in patients with metabolic dysfunction-associated steatotic liver disease: a pilot randomized controlled trial

Lung Yi Loey Mak[1,2], Teresa Hu[3], Rex Wan-Hin Hui[3], Tat Wing Chim[3], Lu Li[3], Wai Pan To[3], Cynthia Hui[3], Kwan Lung Ko[3,3], Jimmy Louie[4], Daphne Wu[3], Chi Ho Lee[3], Wai-Kay Seto[1], Man-Fung Yuen[1]. *[1]The University of Hong Kong, State Key Laboratory of Liver Research, Hong*

Kong, China; [2]Queen Mary University of London, London, United Kingdom; [3]The University of Hong Kong, Hong Kong, China; [4]Swinburne University of Technology, Melbourne, Australia
Email: loeymak@gmail.com

Background and aims: Although achieving weight loss is the cornerstone of treatment for patients with metabolic dysfunction-associated steatotic liver disease (MASLD), it is only achieved in <20% of patients. Mobile technology is being increasingly used to promote health. We aimed to evaluate the effectiveness of a self-developed smartphone app (*AppLiver*) for promoting weight loss in Chinese adults with MASLD.
Method: We conducted a non-blinded two-arm parallel 1:1 randomized controlled trial (NCT05180760) and recruited adult MASLD patients age <70 who could operate a smartphone and understand Chinese or English. Patients with decompensated cirrhosis were excluded. The control arm consisted of standard of care (SOC) with intensive group counselling and monitoring by non-invasive tests (NITs). The interventional arm consisted of the use of *AppLiver* + SOC. *AppLiver* is a smartphone app developed by our study team which consisted of data tracking function (anthropometric, liver and metabolic parameters), interactive function (dietary log and feedback, activities log) and knowledge enrichment. At baseline and 6-monthly intervals, all patients were monitored by NITs including vibration-controlled transient elastography to determine controlled attenuation parameter (CAP) and liver stiffness (LS), and bioelectrical impedance analysis (BIA) to determine skeletal muscle index (SMI), visceral fat index (VFI) and visceral body fat % (VBF). The primary outcome was weight loss ≥5% at 6 months.
Results: In this interim analysis, a total of 141 participants were recruited, with 72 in SOC arm and 69 in the app arm, who were matched in baseline age (median 56 years, IQR 47–62), gender (53.2% male), body mass index (BMI, 27.3 kg/m^2, IQR 25–30), diabetes (38.3%), steatosis and fibrosis stage. The baseline SMI, VFI and VBF was 7.8 kg/m^2(IQR 6.9–8.6), 13 and 34.6%, respectively. At 6 months, the primary outcome was achieved in 9.1% in the SOC arm and 7.9% in the app arm ($p = 0.533$). Significant CAP reduction (defined as ≥40 dB/m decline), downstaging of steatosis and fibrosis was seen in 13.2%, 15.9% and 14.3% in the app arm and 19.4%, 18.2% and 21.2% in the SOC arm, respectively, (all $p > 0.05$). Compared to baseline, the whole group demonstrated significant increase in SMI (+7.6 kg/m^2, IQR 0–9.4, $p < 0.001$), decrease in LS (-0.6 kPa, IQR −1.7 to +0.5 $p = 0.004$), reduced total cholesterol (-0.15 mmol/L, IQR −0.6 to +0.3, $p = 0.035$), reduced LDL-cholesterol (-0.1 mmol/L, IQR −0.5 to +0.2, $p = 0.018$) and reduced HbA1c (-0.1%, IQR −0.3 to +0.1, $p = 0.014$) at 6 months, while no significant change in body weight, BMI, CAP, ALT, VFI and VBF was observed. No patients dropped out from the study at 6 months.
Conclusion: Intensive group counselling and monitoring with NITs promoted changes in SMI, LS and metabolic profile with or without the aid of mobile technology in Chinese adult patients with MASLD.

SAT-432
Effects of Berberine Ursodeoxcholate (HTD1801) in chinese patients with T2DM and presumed MASLD

Jianhua Ma[1], Zhifeng Cheng[2], Shenglian Gan[3], Kui Liu[4], Meng Yu[4], Leigh MacConell[5]. *[1]Nanjing First Hospital, Nanjing, China; [2]The Fourth Affiliated Hospital of Harbin Medical University, Harbin, China; [3]Changde First People's Hospital, Changde, China; [4]HighTide Therapeutics, Inc., Shenzhen, China; [5]HighTide Therapeutics, Inc., Rockville, United States*
Email: lmacconell@hightidetx.com

Background and aims: T2DM typically coexists with other metabolic abnormalities such as hyperlipidemia, obesity, and MASH that can exacerbate T2DM and lead to a worse prognosis with increased risk for mortality and cardiovascular outcomes. As such, treatments are needed that can be simultaneously effective across multiple metabolic abnormalities. Berberine ursodeoxycholate (HTD1801) is a gut-liver anti-inflammatory metabolic modulator being developed for the treatment of T2DM and MASH. HTD1801 was effective in improving key cardiometabolic parameters in a Phase 2, double-blind, placebo (PBO)-controlled study in Chinese patients with T2DM (NCT06411275). Based on the latest diagnostic criteria, it is likely that a substantial subgroup in this study may have had concurrent MASLD. The purpose of this analysis is to evaluate the benefits of HTD1801 in Chinese patients with T2DM and presumed MASLD.
Method: 113 patients were randomized 1:1:1 to PBO (n = 38), HTD1801 500 mg BID (n = 37), and 1000 mg BID (n = 38) for 12 weeks. The primary endpoint was change from baseline in HbA1c at Week 12. The presence of MASLD was identified by baseline controlled attention parameter (CAP) values >288 dB/M (correlated to 5% liver fat content) and T2DM.
Results: Presumed MASLD, occurring in 40% of patients at baseline, was evenly distributed between treatment groups (PBO, n = 16; HTD1801 500 mg BID, n = 14; HTD1801 1000 mg BID, n = 15). At baseline, HbA1c was 8.1–8.5%, GGT was 40–43 U/L and LDL-C was 119–124 mg/dL. After 12 weeks of treatment, HbA1c was reduced by −0.4% (0.7), −0.8% (0.8), and −1.0% (0.5) in the PBO, HTD1801 500 mg BID and 1000 mg BID groups, respectively. Substantial improvements in GGT were observed with changes of 2.7 U/L (10.8), −8.7 U/L (6.9), and −9.9 U/L (17.6) and the change from baseline in LDL-C was 1.7 mg/dL (16.8), −7.5 mg/dL (15.9), and −9.4 mg/dL (19.1), in the PBO, HTD1801 500 mg BID and 1000 mg BID groups, respectively.
Conclusion: HTD1801 treatment has demonstrated both cardiometabolic and hepatic benefits in Chinese patients with T2DM and presumed MASLD with dose dependent improvements in HbA1c, GGT and LDL-C. These data suggest HTD1801 can comprehensively address metabolic and cardiovascular risk factors beyond glycemic control. Further evaluation of HTD1801 continues in 3 Phase 3 studies of T2DM and a Phase 2b study of patients with MASH and T2DM/pre-diabetes.

SAT-433-YI
Multidisciplinary management combining hepatologist counseling, cognitive/behavioral therapy, and nutritional support (the "CoCoNut" protocol) significantly improves metabolic and clinical outcomes of MASLD patients

Mario Romeo[1], Marcello Dallio[1], Fiammetta Di Nardo[1], Annachiara Coppola[1], Paolo Vaia[1], Carmine Napolitano[1], Alessia Silvestrin[1], Marco Niosi[1], Alessandro Federico[1].
[1]Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples, Italy, Naples, Italy
Email: marcello.dallio@unicampania.it

Background and aims: Metabolic dysfunction-associated Steatotic Liver disease (MASLD) is a systemic disorder severely burdened by various extra-hepatic complications. In this context, acute cardiovascular events (ACE) represent a real plague dramatically affecting mortality, suggesting the cruciality of holistic approaches. Although several drugs have been tested to target dysmetabolic comorbidities, lifestyle modifications remain the cornerstone intervention. Unfortunately, the dietary-behavioral prescription is constantly limited by poor compliance, and, despite emerging evidence supporting behavioral therapy's relevance, the real benefits of offering motivational support to MASLD individuals remain unexplored in real life. Considering this, we aimed to evaluate the effectiveness of a multidisciplinary (hepatologist-nutritionist-psychologist- "CoCoNut") management in improving clinical outcomes in MASLD, via ameliorating adherence to specialistic tailored indications.
Method: MASLD patients (n.286) were consecutively enrolled and randomized in three cohorts: 72 followed generic hepatologist-provided advice ("H"), 71 also received a nutritionists-prescribed individualized intervention ("HN") (H+N = "standard of care"), and 143 were treated with an approach additionally involving cognitive/

behavioral-based psychological support ("HNP") ("experimental-group"). Baseline anthropometric, biochemical, clinical, liver stiffness (LSM), controlled attenuation parameter (CAP), lifestyle habits, and body composition values were recorded. Along 18 months, semestral hepatological (for all), nutritional (H and HN), and psychological (HNP) follow-ups reassessed parameters and evaluated compliance.
Results: After 18 months, the prevalence of patients achieving a ≥10% decrease in body weight was significantly higher in HNP (HNP:62.09%; HN:44.9%; H:35.8%; HNP vs HN, p:0.01; HNP vs H, p:0.0002). In HNP, a significant improvement in Homeostatic-model-assessment-for-insulin-resistance (p:0.001), HDL (p < 0.0001), LSM (p:0.007), CAP (p:0.002), and fat-mass (p < 0.0001) was observed. Loss of compliance rate was significantly lower in HNP (HNP:12.08%; HN:34.7%; H:45.8%; HNP vs HN, HNP vs H, p:0.001) Relevantly, HNP patients presented a significantly lower risk of ACEs [HR: 0.497, IC (0.236–0.751) 95%, p:0.04)]. Logistic regression analysis (adjusted for sex, age, drug administration, and cardiovascular risk factors) revealed that HNP adherence was significantly associated with lower ACE occurrence (aOR: 0.81; C.I. 95%: 0.55–0.97; p:0.02). Large family, dynamic work, and city life emerged as social factors influencing compliance (OR: 2.11, 1.78, 1.12) (all p < 0.05).
Conclusion: Integrating standard hepatological-nutritional with psychological support significantly improves the metabolic and clinical outcomes of MASLD patients.

SAT-434-YI

Efficacy of pharmacotherapy in improvement of liver fibrosis and steatohepatitis in patients with metabolic dysfunction associated steatotic liver disease (MASLD): a network meta-analysis

Shubham Mehta[1], Pranjal Singh[1], Ayush Agarwal[1], Abhinav Sengupta[1], Parul Berry[2], Ishan Gupta[1], Sagnik Biswas[1], Shekhar Swaroop[1], Arnav Aggarwal[1], Shalimar Shalimar[1]. *[1]All India Institute of Medical Sciences, New Delhi, India; [2]Mayo Clinic, Minnesota, United States*
Email: drshalimar@gmail.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is common cause of chronic liver disease. Apart from lifestyle changes including dietary restriction and exercise, several pharmacologic therapies are in pipeline and there is a major need to clarify the comparative efficacy of these therapies. The aim of this study was to estimate the relative rank-order efficacy of different pharmacological therapies in metabolic dysfunction–associated steatohepatitis (MASH) resolution and fibrosis improvement.
Method: Randomized-controlled-trials (RCTs) comparing pharmacological interventions in patients with biopsy-proven MASH and assessing fibrosis improvement or MASH resolution were included. The primary outcome was ≥ 1 stage improvement in fibrosis. Secondary outcomes were comparing different pharmacological interventions for MASH resolution and assessing different interventions for fibrosis improvement and MASH resolution in patients with liver cirrhosis.
Results: Total 44 trials (with a total of 9779 patients and comparing 28 different drugs) met the eligibility criteria. Pegozafermin, Lanafibrinor, Obeticholic acid, Resmetirom, Vitamin E and Pioglitazone were significantly better than placebo in achieving ≥ 1 stage fibrosis improvement. Pegozafermin (P-score = 0.91), Pebelfermin (P-score = 0.72), and Lanafibrinor (P-score = 0.71), had the highest probability of being ranked the most effective intervention for achieving ≥ 1 stage of fibrosis improvement, respectively. Efruxifermin, Pegozafermin, Tirzepatide, Semaglutide, Aldafermin, Pioglitazone, Resmetirom and Lanafibrinor were significantly better than placebo in achieving MASH resolution. Efruxifermin (P-score = 0.94), Pegozafermin (P-score = 0.92), Tirzepatide (P-score = 0.91) and Semaglutide (P-score = 0.75) had the highest probability of being ranked the most effective intervention for achieving MASH resolution. In cirrhotic patients, none of the therapies were found to be better than placebo in achieving fibrosis improvement or MASH resolution.
Conclusion: This study provides an updated relative rank-order of various therapies in terms of their efficacy in fibrosis improvement and MASH resolution. In future, therapies that improve liver fibrosis in patients with MASLD may be combined with therapies which achieve MASH resolution for better treatment response.

SAT-435-YI

A comparative analysis of metabolic dysfunction-associated steatotic liver disease and Mediterranean diet across different races

Meng-Lun Hsieh[1], Vivian Chia-Rong Hsieh[2], Yen-Chun Peng[1]. *[1]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung City, Taiwan; [2]Department of Health Services Administration, China Medical University, Taichung City, Taiwan*
Email: hsiehchiarong@gmail.com

Background and aims: While previous studies have highlighted the benefits of Mediterranean diet in reducing liver steatosis, these investigations have primarily been conducted in Western populations, overlooking the unique dietary factors of other populations. This study aims to evaluate the association between steatotic liver disease (SLD) and adherence to the Mediterranean diet across different racial groups, with a particular focus on Asians.
Method: This case-control study utilized a nationally representative dataset from the National Health and Nutrition Examination Survey 2017–March 2020, which included vibration-controlled transient elastography measurements for quantifying liver steatosis and fibrosis. Our inclusion criteria include age 18 years or older and complete controlled attenuation parameter, alcohol and nutrient intake data. Case group comprised participants meeting the consensus nomenclature for metabolic dysfunction-associated steatotic liver disease (MASLD), defined as CAP ≧ 288 dB/m with at least 1 metabolic factor. Control group consisted of individuals with a CAP < 288 dB/m (non-SLD). For predictor variable, we extracted information from NHANES dietary questionnaires to evaluate participants' adherence to the Mediterranean diet. Adherence was quantified into aMED score, ranging from 0 to 9, with higher scores indicating greater adherence, categorized into three groups: 0–2, 3–4, and 5–9. Effect modification by race was examined. Confounding factors considered in the multivariate analysis include age, sex, anti-HBC, HCV RNA, alcohol intake, physical activity, ALT, total bilirubin, platelet, and liver stiffness.
Results: Of the 15,560 participants, 3,600 MASLD (case) and 2,777 non-SLD (control) individuals were selected. The MASLD group was predominantly non-Hispanic white (37.2%), followed by Hispanic (25.9%) and Asian (8.5%). The non-SLD group comprised primarily non-Hispanic white (36.2%), followed by non-Hispanic black (31.2%) and Asian (9.7%). While there was little difference in the number of people with high aMED scores between the two groups, the MASLD group had a higher proportion of people with middle aMED scores (3–4) compared to the non-SLD group (42.2% vs. 39.3%). Because a significant effect modification by race was observed, results from adjusted analysis with an interaction term showed a significantly lower MASLD risk among non-Hispanic white individuals compared to Hispanic individuals with high aMED scores (aOR: 0.53, p = 0.002). This association was absent in other races, including non-Hispanic Asians (aOR: 0.66, p = 0.23).
Conclusion: A lower risk of MASLD was observed among non-Hispanic Whites with high adherence to the Mediterranean diet, but this association was not evident in other racial groups. Future research should explore how the Mediterranean diet affects MASLD risk across different races and ethnicities.

SAT-436

Efficacy of Imeglimin in MASLD with type 2 diabetes: a multicenter study

Asahiro Morishita[1], Kyoko Oura[1], Kei Takuma[1], Mai Nakahara[1], Tomoko Tadokoro[1], Koji Fujita[1], Joji Tani[1], Hideki Kobara[1]. [1]*Kagawa University, Kagawa, Japan*
Email: morishita.asahiro@kagawa-u.ac.jp

Background and aims: Imeglimin is a novel oral hypoglycemic agent for the treatment of type 2 diabetes mellitus (T2DM) that protects mitochondrial function from oxidative stress and promotes lipid oxidation, thereby normalizing glucose tolerance and insulin sensitivity. Metabolic dysfunction-associated steatotic liver disease (MASLD) is associated with metabolic risk factors such as insulin resistance, T2DM, obesity, and dyslipidemia, and represents a significant public health concern. To date, various medications have been utilized for MASLD, but no definitive therapeutic agent has been established. Therefere, this study aimed to investigate the therapeutic efficacy of imeglimin for MASLD in patients with T2DM across multiple centers.
Method: This study included 131 patients with MASLD and T2DM who received imeglimin treatment at our institution and affiliated facilities. Among them, 40 patients who continued treatment for at least six months were analyzed. To evaluate the effects of imeglimin, changes in liver function markers such as AST, ALT, γ-GTP, controlled attenuation parameter (CAP), liver stiffness measurement (LSM), and FibroScan-aspartate aminotransferase (FAST) score were assessed. Furthermore, changes in these markers were evaluated monthly, from baseline up to six months, to examine early effects.
Results: AST and ALT levels significantly decreased at four weeks after imeglimin administration. γ-GTP also showed a significant decrease at four weeks. Although other biomarkers, including type IV collagen, autotaxin, and the AST-platelet ratio index, did not show significant reductions after imeglimin treatment, the FIB-4 index showed a significant decrease at six months. CAP and LSM did not exhibit significant reductions, but the FAST score significantly decreased at 24 weeks. Additionally, in a subgroup analysis based on baseline HbA1c levels (≥8 vs. <8), AST, ALT, and γ-GTP significantly decreased from four weeks after treatment in the HbA1c <8 group, while the FIB-4 index significantly decreased at 12 weeks. These results represent the first multicenter report indicating that imeglimin improves liver function and fibrosis markers and is effective against hepatic steatosis, inflammation, and fibrosis in patients with MASLD and T2DM.
Conclusion: Imeglimine may be a novel treatment for T2DM complicated by MASLD.

SAT-437

Denifanstat improves multiple qFibrosis-based collagen features linked to major adverse liver outcomes in patients with metabolic dysfunction-associated steatohepatitis patients and high polygenic risk

Email: mrinella@bsd.uchicago.edu

Background and aims: Denifanstat (DENI) is a fatty acid synthase inhibitor in development for metabolic dysfunction-associated steatohepatitis (MASH). It met statistical significance in histology endpoints in a phase 2b trial, showing antifibrotic effect. Liver fibrosis, several genetic variants, and 5 qFibrosis parameters features in the periportal and portal zones (digital pathology) have been associated at baseline with major adverse liver outcomes (MALO). We assessed the antifibrotic effect of DENI in different genotypes.
Method: The FASCINATE-2 phase 2b trial (NCT04906421) randomized 168 patients with biopsy-proven MASH, NAS ≥ 4, and NASH-CRN fibrosis stage 2 or 3, to receive either oral once-daily DENI 50 mg or placebo (PBO) (2:1) for 52 weeks. *PNPLA3* rs738409, *MBOAT7* rs641738, and *TM6SF2* rs58542926 were genotyped in consenting patients. Relative changes from baseline in qFibrosis were calculated using steatosis correction as well as features previously linked to MALO: IntersectionPT (#1), LongStrPeriPortalAgg (#2), ThinStrPeriPortal (#3), ThinStrPeriPortalDis (#4), and StrLengthPeriPortal (#5). Treatment by polygenic risk strata (≤1 risk allele vs > 1 risk allele of the 3 above variants) interaction was tested in an ANCOVA model including terms for treatment, polygenic risk strata, interaction, and (log-transformed) baseline parameter.
Results: At week 52, in accordance with NASH-CRN scores, continuous qFibrosis was significantly decreased in DENI group (−1.0) vs PBO (−0.1, $p < 0.0001$). PBO-corrected treatment effect of DENI on qFibrosis was similar across polygenic risk strata. PBO-corrected relative change from baseline of DENI was −30% ($p = 0.03$), −31% ($p = 0.02$), −27% ($p = 0.01$), −25% ($p = 0.02$), and −30% ($p = 0.01$) in qFibrosis features previously linked to MALO #1, #2, #3, #4, and #5, respectively. Notably, the PBO-corrected treatment effect of DENI on these features was more pronounced in carriers of at least 2 risk alleles vs non-carriers or carriers of 1 risk allele (#2: $p = 0.01$, #3: $p = 0.04$, #4: $p = 0.06$, #5: $p = 0.01$). In the subgroup of patients classified as "no change" by conventional pathology, continuous qFibrosis provided more granularity on DENI effect showing a significant decrease (−0.9) vs PBO (−0.1; $n = 52$, $p < 0.001$). Within this subgroup, 4 out of 5 qFibrosis-based collagen features were significantly decreased compared to PBO: −30% ($p = 0.02$), −32% ($p = 0.02$), −30% ($p = 0.03$), and −29% ($p = 0.02$) in features #2, #3, #4, and #5, respectively.
Conclusion: Digital pathology showed antifibrotic effect of DENI in qFibrosis-based collagen features previously linked to MALO and recapitulated NASH-CRN fibrosis staging. Pronounced changes were seen with DENI in the difficult-to-treat population with several risk variants associated with MALO. Further research is warranted to discern the specific effect related to DENI mechanism of action within the polygenic risk population.

SAT-438

General characteristics of the patients prescribed Resmetirom: data derived from six tertiary care centers in the United States

Naim Alkhouri[1], Ashwani K. Singal[2], Imad Asaad[3], Edward Mena[4], Amreen Dinani[5], Rida Nadeem[6], Sari Alothman[7], Iryna Kalinina[8], Sonal Kumar[9], Madhavi Rudraraju[10], Celine Sakkal[6], Himanshi Kapoor[6], Erfan Asadipour[6], Sirmad Chaudhary[2], Kristina Cabanezwinner[2], Mazen Noureddin[11], Winston Dunn[12]. [1]*Arizona Liver Health, Phoenix, United States;* [2]*University of Louisville, Louisville, United States;* [3]*Firelands Health, Sandusky, United States;* [4]*Pasadena Research Institute, Pasadena, United States;* [5]*Duke University, Durham, United States;* [6]*Arizona Liver Health, Chandler, United States;* [7]*Northshore Gastroenterology, Westlake, United States;* [8]*Clinical Research Institute of Ohio, Westlake, United States;* [9]*Weill Cornell Medicine, New York, United States;* [10]*Pinnacle Research, San Antonio,*

United States; [11]Houston Research Institute, Houston, United States; [12]University of Kansas, Kansas City, United States
Email: naim.alkhouri@gmail.com

Background and aims: Resmetirom was recently approved by the FDA as the first medication intended for non-cirrhotic patients with metabolic dysfunction-associated steatohepatitis (MASH) and stage F2-F3 fibrosis. The approval was based on histological improvement and patients were selected for the phase 3 trial based on liver biopsy. However, in the real world, most patients with MASH do not undergo liver biopsy and the diagnosis is based on noninvasive tests. Here, we aimed to describe the general characteristics of the MASH patients prescribed resmetirom including noninvasive tests and concomitant medications derived from six hepatology clinics in the United States.
Method: The data of MASLD patients derived from six tertiary care centers were collected between March and Nov 2024 (265, 15, 32, 48, 27, and 37 patients from six centers, respectively, total 424 patients). The demographic and laboratory data were recorded during the baseline visit.
Results: The cohort had a median age of 58 years (IQR: 49–67), with 179 males (42.0%). A total of 88 patients (20.8%) were diagnosed via liver biopsy, while the majority (88.9%) were assessed using transient elastography; 56 (13.2%) had ELF testing. The median liver stiffness measurement (LSM) was 11.0 kPa (IQR: 8.9–13.4) and the median ELF was 9.7 (IQR: 9.4–10.3). Obesity was prevalent in 356 patients (84.0%), while 185 patients (43.6%) had type 2 diabetes (T2D). Cardiometabolic comorbidities were common, with 40.3% on statins, 19.3% on GLP-1 analogs, and 33.3% on metformin. Patients prescribed resmetirom were predominantly on 80 mg (50.9%) or 100 mg (47.2%) doses. Only 1.9% were prescribed 60 mg. The number of patients with 0, 1, 2, 3, and ≥4 cardiometabolic risk factors were 6.8%, 23.3%, 28.3%, 29.2%, and 12.3%, respectively.
Conclusion: This large real-world cohort of MASH patients prescribed resmetirom reflects the high burden of cardiometabolic comorbidities typical of MASLD populations, with obesity and T2D being especially prevalent. Most patients were diagnosed with advanced fibrosis (F2-F3) using noninvasive methods, such as transient elastography, highlighting a shift from biopsy reliance in clinical trials to real-world practice. These findings underline the importance of integrated management of cardiometabolic risk factors and reinforce the potential of resmetirom as a critical therapy for MASH in real-world settings.

SAT-439

The impact of metabolic surgery on metabolic dysfunction-associated steatotic liver disease

Hiromasa Namba[1], Sachiyo Yoshio[2], Taizo Mori[2], Eiji Kakazu[3], Tatsuya Kanto[3], Taketomi Akinobu[4], Susumu Inamine[5], Takumi Kawaguchi[6]. *[1]Department of Liver Diseases, National Center for Global Health and Medicine, Ichikawa, Japan; [2]Department of Human Immunology and Translational Research, National Center for Global Health and Medicine, Tokyo, Japan; [3]Department of Liver Diseases, National Center for Global Health and Medicine, Chiba, Japan; [4]Department of Gastroenterological Surgery I, Hokkaido University Hospital, Hokkaido, Japan; [5]Metabolic Surgery Center, Ohama Dai-ichi Hospital, Okinawa, Japan; [6]Division of Gastroenterology, Kurume University School of Medicine, Fukuoka, Japan*
Email: namba624@gmail.com

Background and aims: Obese people with fatty liver are diagnosed as MASLD. Chronic liver inflammation can progress to cirrhosis and liver cancer. Therefore, controlling persistent inflammation is crucial for improving the prognosis of patients with MASLD. Metabolic surgery is known to induce dramatic weight loss and significant metabolic improvements. This study aimed to examine the impact of obesity-related metabolic abnormalities on MASLD and evaluate the effects of metabolic surgery on MASLD.
Method: We enrolled 66 severely obese patients with MASLD undergoing laparoscopic sleeve gastrectomy from July 2020 to April 2022. Blood samples were obtained preoperatively and one year after surgery. Blood cytokines were analyzed using multiplex assay, adiponectin and leptin by ELISA, BCAA by HPLC, liver stiffness by shear wave elastography (SWE), and visceral/subcutaneous fat areas by CT. Liver biopsies were performed intraoperatively, and histological evaluation was performed.
Results: Fourty-two patients (64%) were female. The median age was 45 years, body mass index (BMI) was 43.6 kg/m², systolic blood pressure (sBP) was 143 mmHg, ALT was 47 (10–231) U/L, and the HbA1c was 6.2 (5.2–11.1) %. Compared to non-obese healthy age-mathced adults, 25 blood cytokines, including TNF-α, were higher in the obese patients, indicating that systemic inflammation exists in obese patients. One year after metabolic surgery, there was a decrease in BW, BMI, visceral and subcutaneous fat area, and sBP, ASL, ALT, SWE, type-4 collagen, HbA1c, HOMA-IR, TG and BCAA. After surgery, Leptin decreased, while adiponectin increased. We observed the effects of metabolic surgery on metabolic factors and liver inflammation. Next, we tried to investigate the factors associated with liver inflammation in obese patients. Preoperative ALT > 30 U/L group (45 cases) was compared to preoperative ALT ≦ 30 group (21 cases). The ALT > 30 group was characterized by younger age, a higher proportion of men, elevated systolic blood pressure (sBP), higher AST and gamma-GTP (GGT), increased HbA1c and HOMA-IR, higher BCAA, lower HDL cholesterol (HDL-C), and reduced adiponectin levels. Advanced fibrosis (F2 or higher) was significantly more common in the ALT > 30 group (76%) than in the ALT ≦ 30 group (48%), suggesting an association between liver inflammation and metabolic abnormalities. Among the patients with the preoperative ALT > 30, 5 cases were still ALT > 30 at 1 years after metabolic surgery. To explore the factors contributing to postoperative ALT > 30, we analyzed the preoperative factors in the postoperative ALT > 30 group. In the multivariate analysis, high preoperative HbA1c was an independent contributing factor for postoperative ALT > 30.
Conclusion: Liver inflammation in severely obese MASLD patients was associated with metabolic abnormalities, and metabolic surgery showed beneficial effects.

SAT-440

Effects of Berberine Ursodeoxycholate (HTD1801) in patients with at-risk MASH and T2DM

Nadege Gunn[1], Guy W. Neff[2], Alexander Liberman[3], Leigh MacConell[3]. *[1]Impact Research Institute, Waco, United States; [2]Covenant Metabolic Specialists, LLC, Sarasota, United States; [3]HighTide Therapeutics, Inc., Rockville, United States*
Email: lmacconell@hightidetx.com

Background and aims: Berberine ursodeoxycholate (HTD1801) is a gut-liver anti-inflammatory metabolic modulator with a unique molecular structure which has been shown to significantly reduce liver fat content (LFC) as determined by MRI-PDFF in an 18-week, placebo (PBO)-controlled Phase 2 study in patients with MASH and T2DM (NCT03656744). The primary focus of clinical development in MASH due to the ongoing unmet medical need focuses on patients who are at a higher risk of disease progression and outcomes due to the presence of moderate to advanced fibrosis (defined as at-risk MASH). The purpose of this analysis was to assess the effects of HTD1801 in patients with at-risk MASH and T2DM.
Method: 100 patients were randomized and treated with PBO (n = 33), HTD1801 500 mg BID (n = 33), or HTD1801 1000 mg BID (n = 34) for 18 weeks. The primary endpoint was change in LFC. This analysis focused on patients with at-risk MASH as identified by baseline MRI cT1 > 875 ms and was only assessed in patients randomized to PBO and HTD1801 1000 mg BID.
Results: 66% of patients were considered as having at-risk MASH at baseline, and were evenly distributed between the PBO (n = 23) and HTD1801 1000 mg BID (n = 21) groups. At baseline, LFC, cT1, and body weight were all generally balanced between groups at approximately 20%, 970 ms, and 100 kg, respectively. After 18 weeks of treatment,

the relative change from baseline in LFC was −7.3% (25.0) and −26.2% (21.7) with 22% vs 43% of patients achieving ≥30% reduction in LFC for PBO and HTD1801 1000 mg BID, respectively. The change from baseline in cT1 was −28.7 ms (70.6) and −67.1 ms (83.1) with 17% vs 48% of patients achieving ≥80 ms reduction in cT1 for PBO and HTD1801 1000 mg BID, respectively. In addition, after 18 weeks of treatment the change from baseline in body weight was −1.5 kg (3.2) and −4.2 kg (4.5) in the PBO and HTD1801 1000 mg BID groups. Improvements were also observed in ALT, HbA1c, and LDL-C with HTD1801 treatment.

Conclusion: Eighteen weeks of treatment with HTD1801 resulted in substantial improvements in key hepatic and cardiometabolic parameters in patients with probable at-risk MASH and twice as many patients achieved a reduction in LFC or fibroinflammation that have been associated with improvements in liver histology. These data are particularly insightful as HTD1801 continues to be evaluated in an ongoing paired biopsy study of patients with at-risk MASH and pre-diabetes or diabetes.

SAT-445

Sustained improvements in non-invasive biomarkers with the novel glucagon receptor/glucagon-like peptide-1 receptor dual agonist survodutide: longitudinal analysis from a phase 2 trial in people with metabolic dysfunction-associated steatohepatitis and fibrosis

Email: NoureddinMD@houstonresearchinstitute.com

Background and aims: We performed a longitudinal analysis of the effects of survodutide, a novel glucagon receptor/glucagon-like peptide-1 receptor dual agonist, on non-invasive biomarkers in a phase 2 trial in participants with biopsy-confirmed metabolic dysfunction-associated steatohepatitis (MASH) and F1–F3 liver fibrosis (NCT04771273).

Method: 295 people aged 18–80 years were randomised to once-weekly subcutaneous injections of survodutide 2.4, 4.8, or 6.0 mg or placebo (PBO) (escalated over up to 24 weeks). In this analysis, we evaluated absolute change in enhanced liver fibrosis (ELF™) score and its components, relative change in propeptide of type III collagen (PRO-C3), total cytokeratin 18 (M65) (CK18-M65), Fibrosis-4 index (FIB-4), and glucagon longitudinally from baseline (BL) up to Week 48. Longitudinal analyses were performed on treated participants with BL and ≥ 1 post-BL biomarker value. Changes in biomarker levels over time were analysed using restricted maximum likelihood based mixed model for repeated measures (MMRM) with visit as the repeated measure and an unstructured covariance matrix. Due to their skewed distribution, a logarithmic transformation was applied to all biomarkers (except for the ELF score). Model estimates were back transformed and are reported in the original scale. The MMRM included fixed categorical effects of sex and diabetes at BL, fixed continuous effects of BL body weight, age, and magnetic resonance imaging proton density fat fraction liver fat fraction, and interaction terms for visit and BL biomarker values and for visit and actual treatment (dose at start of maintenance or planned dose up from that received at pre-maintenance discontinuation). P-values are nominal.

Results: Longitudinal absolute reduction in ELF score from BL was 0.57–0.61 with survodutide vs 0.05 for PBO at Week 48 ($p < 0.0001$ all doses). There was a significant reduction in the 3 components of the ELF score with survodutide vs PBO ($p < 0.01$ all doses). The estimated relative change in PRO-C3 was 0.71–0.74 (BL: 39.52–41.73 micrograms/L) with survodutide vs 1.01 (BL: 41.67 micrograms/L) with PBO ($p < 0.001$ all doses). Estimated relative change in total CK18 was 0.29–0.40 (BL: 640.51–672.27 U/L) with survodutide vs 0.90 (BL: 722.72 U/L) with PBO ($p < 0.0001$ all doses). Estimated relative change in FIB-4 was 0.80–0.85 (BL: 1.06–1.12) with survodutide vs 1.04 (BL: 1.22) with PBO ($p < 0.01$ all doses). Estimated relative change in glucagon was 0.73–0.84 (BL: 60.87–65.24 pmol/L) with survodutide vs 1.01 (BL: 61.18 pmol/L) with PBO ($p < 0.0001$ all doses).

Conclusion: Participants who received survodutide vs PBO had significant improvement in multiple non-invasive biomarkers for MASH and liver fibrosis (ELF score and its components, PRO-C3, glucagon, and FIB-4) and significantly reduced levels of total CK18, suggesting increased hepatocyte survival with survodutide treatment.

SAT-446

Survodutide activates cAMP signaling and reduces steatosis and fibrosis through its glucagon component in human liver spheroids

Philip Vonschallen[1], Lisa Hoelting[1], Angelina Breen[1], Mafalda Pereira[2], Radina Kostadinova[1], Joel Zvick[1], Jesus Glaus[1], Robert Augustin[2], Heike Neubauer[2], Francisco Verdeguer[1], Thomas Klein[2]. *[1]Insphero, Schlieren, Switzerland; [2]Boehringer Ingelheim Pharma, GmbH & Co. KG, Biberach/Riss, Germany*
Email: philip.vonschallen@insphero.com

Background and aims: Survodutide, a novel glucagon receptor/glucagon-like peptide-1 receptor dual agonist is currently in Phase 3 clinical trials in people with metabolic dysfunction-associated steatohepatitis (MASH) and for people living with obesity. Recent Phase 2 trials in people with MASH demonstrated anti-steatotic and anti-fibrotic effects of survodutide. Here we report the in vitro characterisation of survodutide in liver spheroids as models for healthy and diseased human liver.

Method: Human liver spheroids resembling phenotypes of healthy and MASLD human livers were investigated for dose-responsive increases in intracellular cAMP upon treatment with survodutide; semaglutide (mono GLP-1R agonist) and tirzepatide (dual GLP-1R/GIPR agonist) were included for comparison. In addition, increases in cAMP was assessed in hepatocytes monolayers from multiple healthy donors. Healthy control and MASH spheroids were incubated with survodutide and total triglyceride content and secretion of pro-collagen 1 (PC-1) were determined after 10 days.

Results: Survodutide increased cAMP in primary hepatocytes mono layers with EC_{50} = 0.581 micromolar. Survodutide (at 1 micromolar) significantly increased cAMP levels in control and MASLD spheroids showing a 3-fold higher potency in MASLD spheroids. Semaglutide and tirzepatide (both 1 micromolar) did not increase cAMP. Compared to control spheroids, MASH spheroids showed a statistically significant increase (9.8 fold, $p < 0.0001$) of triglyceride content and PC-1 secretion (10.3 fold, $p < 0.0001$). In MASH liver spheroids, survodutide significantly reduced intracellular triglyceride content by 23.8% ($p < 0.05$) at a concentration of 0.3 micromolar (EC_{50} = 0. 655 micromolar) and PC-1 secretion by 35.0% ($p < 0.05$) at 1 micromolar (EC_{50} = 0.662 micromolar).

Conclusion: Survodutide showed increased cAMP signalling in spheroids as a model for healthy and MASLD human hepatocytes, while the incretin analogues semaglutide and tirzepatide did not show a response. Survodutide significantly lowered triglyceride as well as PC-1 secretion in MASH spheroids. Human liver spheroids represent a robust in vitro model for human liver cells to study glucagon receptor agonism.

SAT-447

Comprehensive intensive lifestyle intervention to reverse significant liver fibrosis in overweight and obese patients with metabolic dysfunction-associated steatotic liver disease: data from a multicenter randomized controlled trial

Xiaolong Qi[1,2], Yuping Chen[1,2], Zhong Liu[3], Shanghao Liu[1], Qiang Zeng[4], Xiangming Wu[5], Feng Su[6]. *[1]Zhongda Hospital, Medical School, Southeast University, Nurturing Center of Jiangsu Province for State Laboratory of AI Imaging & Interventional Radiology (Southeast University), Nanjing, China; [2]Basic Medicine Research and Innovation Center of Ministry of Education, Zhongda Hospital, Southeast University; State Key Laboratory of Digital Medical Engineering, Nanjing, China; [3]Health Management Center, the First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; [4]Health Management Institute, the Second Medical Center & National Clinical Research Center for Geriatric Diseases, Chinese PLA General Hospital, Beijing, China; [5]Zhejiang Nutriease Health Technology Company Limited, Hangzhou, China; [6]Zhejiang Chinese Medical University, Hangzhou, China*

Background and aims: Liver fibrosis, rather than steatosis, is the vital driver of adverse outcomes in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). This study aimed to evaluate the effectiveness of a 12-week comprehensive intensive lifestyle intervention (ILI) to reverse significant liver fibrosis among overweight/obese patients diagnosed with MASLD.

Method: We analyzed participants with significant liver fibrosis, defined as liver stiffness measurement (LSM, by transient elastography) ≥8 kPa, from a 12-week randomized controlled trial (ClinicalTrials.gov identifier: NCT03972631) involving well-characterized overweight/obese patients with MASLD (aged 18–65 years, BMI 25–35 kg/m²). Eligible participants were assigned to the ILI or control groups in a 1:1 ratio. During the 12 weeks of the trial, patients in both groups were asked to follow a restricted-energy content (initial weight × 25 kcal/kg × 0.7); after randomization, the ILI group received an intensive intervention, following a low-carbohydrate, high-protein diet (20–25 energy percent [E%] carbohydrates, 30–35 E % fat, and 40–45 E% protein), while the control group adhered to a balanced CRD (45–55 E% carbohydrates, 20–30 E% fat, and 20–30 E% protein). All outcomes were collected at baseline and 12 weeks after the intervention started. The primary outcome was the proportion of patients who reversed significant fibrosis from baseline to week 12. Secondary outcomes including changes in weight, liver enzymes and other metabolic indicators.

Results: A total of 33 participants from six university hospitals were enrolled, with 18 in the ILI group and 15 in the control group. Baseline characteristics were comparable between the two groups. The mean ± SD age and BMI in the ILI group (12 [63.2%] male) were 38.0 ± 9.5 years and 29.38 ± 2.41 kg/m², respectively, and in the control group (17 [85.0%] male), they were 38.9 ± 6.5 years and 30.95 ± 2.75 kg/m², respectively. Both groups showed significant changes from baseline to week 12 in LSM, BMI, alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), triglycerides (TG), fasting insulin (FINS), HOMA-IR, and HOMA-β (all $p < 0.05$). Notably, the ILI group achieved a significant higher proportion of reversal in significant liver fibrosis compared to the control group (88.9% vs. 53.5%, $p = 0.047$). Additionally, the ILI group showed greater improvements in key metabolic and liver-related parameters, with mean differences of BMI: −1.53 kg/m² (95% CI: −2.41 to −0.65), ALT: −10.25 IU/L (95% CI: −20.42 to −0.09), GGT: −8.67 IU/L (95% CI: −16.45 to −0.90), fasting insulin: −3.04 μU/mL (95% CI: −5.88 to −2.12), HOMA-β: −42.95 (95% CI: −78.65 to −7.24), all with $p < 0.05$.

Conclusion: The ILI approach was more effective than the traditional balanced diet to reverse significant liver fibrosis in overweight/obese patients with MASLD.

SAT-448

A 10-week, randomized, double blind, placebo-controlled exploratory proof of concept study of Utreglutide (GL0034) in individuals with overweight and obesity

Rajamannar Thennati[1], Vinod Burade[1], Muthukumaran Natarajan[1], Pradeep Shahi[1], Ravishankara Nagaraja[1], Paolo Battisti[2], Thierry Duvauchelle[3], Bernard Thorens[4], Richard E Pratley[5], Tina Vilsbøll[6], Rohit Loomba[7]. *[1]High Impact Innovations – Sustainable Health Solutions (HISHS), Sun Pharmaceutical Industries Limited, Vadodara, Gujarat, India; [2]Inokura, CHU Liège, Avenue de l'Hôpital 1, Liège, Belgium; [3]Phaster1, Le Plessis-Trévise, Paris, France; [4]Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; [5]AdventHealth Translational Research Institute, Orlando, United States; [6]Clinical Research, Steno Diabetes Center Copenhagen, Herlev, University of Copenhagen, Copenhagen, Denmark; [7]Chief, Division of Gastroenterology and Hepatology, Professor of Medicine, University of California at San Diego, San Diego, United States*
Email: rajamannarthennati@yahoo.com

Background and aims: Utreglutide (UTG, GL0034), a potent glucagon-like peptide-1 receptor agonist, has been demonstrated to be safe in a phase 1 program in individuals with obesity. A reduction of body weight (BW) up to 3.3 kg resulted upon single dose administration in obese subjects and sustained till day 22. Further, in multiple ascending dose studies, improvements in liver injury, metabolic and lipid biomarkers were observed. Here, we present safety and efficacy data in a 10-week, randomized, double blind, placebo (PBO) controlled exploratory Proof of Concept study of UTG in individuals with overweight and obesity.

Method: The study was carried out in 20 male and female individuals with overweight or obesity and BMI between ≥ 28 and ≤45 kg/m², which were randomized (16:4) to weekly subcutaneous UTG (400, 2 × 800, 3 × 1400, 4 × 2000 μg) or placebo following an up-titration scheme. Safety along with efficacy biomarkers were assessed viz., liver enzymes [alkaline phosphatase (ALP), alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ-glutamyl transferase (GGT)], lipids [low-density lipoprotein cholesterol (LDL-C), Apolipoprotein B (ApoB), fatty liver index (FLI), very-low density lipoprotein cholesterol (VLDL-C)], free fatty acids (FFA), and β-hydroxybutyrate as well as BW.

Results: Most common adverse events were gastrointestinal including nausea, decreased appetite and vomiting. BMI (kg/m²) at baseline was 33.7 ± 3.1 for UTG treatment group and 34.5 ± 3.5 for PBO. UTG treatment for 10 weeks caused a significant improvement in liver enzymes, lipids, and ApoB. The change in liver enzymes were, ALT [42.6 to 29.5 U/L ($p = 0.02$)], AST [28.9 to 22.9 U/L ($p = 0.004$)], GGT [29.7 to 22.3 U/L($p < 0.001$)], and ALP [75.9 to 71.6 U/L($p > 0.05$)]. These changes reflected in as a significant decrease in the non-invasive marker of fatty liver disease, FLI [77.6 to 62.1 ($p < 0.001$)] along with LDL-C [128.0 to 110.2 mg/dL ($p = 0.03$)], ApoB [0.99 to 0.81 g/L ($p = 0.001$) and VLDL-C [29.9 to 29.4 mg/dL ($p > 0.05$)]. No significant change was observed in FFA (0.34 to 0.33 mmol/L) and β-hydroxybutyrate (0.43 to 0.50 mmol/L). Reduction in BW from baseline was sustained with significance until the end of study [UTG: − 5.9 ± 3.2 kg ($p < 0.001$); PBO: 0.3 ± 0.9 kg].

Conclusion: Utreglutide was safe and well tolerated by individuals with overweight and obesity. The observed pharmacodynamic effects

on liver enzymes and lipid profile, FLI along with body weight reduction at a total dose of 14.2 mg in 10-weeks, suggest potential therapeutic benefits in MASLD patients.

SAT-449

Saroglitazar vs. vitamin E in metabolic-dysfunction associated fatty liver disease related compensated chronic liver disease- a cohort study

Rakhi Maiwall[1], Fagun Sharma[1], Priyanka Sharma[1], Charvi Nayyar[1], Sherin Thomas[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: rakhi_2011@yahoo.co.in

Background and aims: Metabolic dysfunction-associated fatty liver disease (MAFLD) is an emerging cause of chronic liver disease with limited pharmacotherapeutic options. We aimed to investigate the efficacy of saroglitazar (SARO) compared to vitamin E (VitE) on non-invasive surrogates of liver fibrosis and portal hypertension in patients with MAFLD-related compensated chronic liver disease (CLD).

Method: Retrospective cohort of patients with MAFLD, all having liver stiffness measurements (LSM ≥ 10; n = 264, 39% biopsy-proven), were treated with either SARO (n = 92) or VitE (n = 172). Patients were followed with assessments of LSM and spleen stiffness measurement (SSM) performed at baseline and follow-up of every 3–6 months. Progression was defined as a worsening of LSM by 10% and SSM by 20% from baseline at 6 months, while response was defined as a reduction by 20% from baseline to last assessment.

Results: Patients with MAFLD, mean age 48.8 ± 11.2 years, 76% males, 15% hypothyroid, 80% with body mass index (BMI) >23.5, 6% with a family history, and patatin-like phospholipase domain-containing 3 (PNPLA3 rs738409; n = 117) (43%-GG, 34% CG, 22.2% CC genotype) were enrolled. These patients had a mean controlled attenuation parameter (CAP) of 245.5 ± 51.1, LSM 32.9 ± 19.5, SSM 49.9 ± 27.2, HOMA-IR 2.8 ± 2.7, Fib-4 4.7 ± 3.7, and CRP 5.1 ± 10.5, and were followed. Of the 102 patients with hepatic venous pressure gradient (HVPG) measurement, the majority (76%) had HVPG >10 mm Hg (mean 13.2 ± 5 mm Hg).Patients in the VitE group had significantly higher LSM [(29 ± 17.32) vs (34.99 ± 20.29); p = 0.01], FIB4 [(4.14 ± 3.07) vs. (5.05 ± 3.92); p = 0.05], AST [(47.1 ± 24.2) vs. (63.2 ± 57.9); p = 0.01], and lower LDL [(89.8 ± 49.5) vs. (78.9 ± 32.2); p = 0.005] compared to SARO, respectively. The proportion of patients with weight reduction was also similar [(≥10%) 6% vs. 11%, (5–9%) 15% vs.15%; (<5%) 38% vs. 35%; p = 0.65) including response in LSM (50% vs. 41%; p = 0.60) and SSM (14% vs. 15%; p = 0.83) at last assessment; median follow-up of 301(180–642) days. At 6-months, 12% had progression of disease which was comparable (8% vs. 14%; p = 0.24) between SARO and VitE, respectively. Binary logistic regression analysis showed lower ALT (p = 0.02, OR 0.96, 0.93–0.99), presence of hypothyroidism (p = 0.008, OR 4.19, 1.46–12.01), higher BMI (p = 0.03, OR 1.11, 1.01–1.22), and fasting blood sugar (p = 0.04, OR 1.01, 1.00–1.02) were independent determinants of disease progression.

Conclusion: Saroglitazar is comparable to vitamin E in improving metabolic and clinical outcomes, as well as non-invasive surrogates of liver fibrosis and portal hypertension in patients with MAFLD-related cirrhosis. Patients with hypothyroidism, lower ALT, higher BMI, and higher fasting blood sugar are at a higher risk of disease progression and require targeted pharmacotherapy.

Email: mfitzgerald@aligos.com

Background and aims: ALG-055009, a next generation THR-beta agonist with enhanced beta selectivity and in vitro potency, previously demonstrated favorable Ph1 safety, pharmacokinetic (PK) and pharmacodynamic (PD) effects in healthy volunteers/hyperlipidemic subjects. In the Ph2a HERALD (NCT06342947) randomized, double-blind, placebo-controlled study, the efficacy, safety, PK and PD of 12-week once daily ALG-055009 were evaluated in non-cirrhotic adults with presumed MASH and F1-F3 fibrosis. As reported previously, the primary endpoint was met, demonstrating significant reductions in liver fat (Loomba et al. AASLD 2024). Subgroup analyses for the primary endpoint are reported here, including those associated with a worse prognosis (e.g., type 2 diabetes).

Method: 102 subjects (~20/arm) were randomized to receive 0.3, 0.5, 0.7 or 0.9 mg ALG-055009 or placebo, orally once daily for 12 weeks. Only subjects with body weight >85 kg were enrolled in the 0.9 mg arm, with no weight restrictions for other arms. The primary endpoint was relative change from baseline in liver fat by MRI-PDFF at Week 12 and was analyzed across subgroups, defined according to baseline characteristics, e.g., gender, body weight, GLP-1 agonist use, statin use and type 2 diabetes status. Subjects on glucagon-like peptide-1 (GLP-1) receptor agonists at a stable dose for ≥12 weeks prior to dosing were included.

Results: Baseline characteristics were generally similar across arms and representative of the MASH patient population: 62% female, mean age 50 yrs, mean BMI 39 kg/m2, 47% Hispanic, 18% GLP-1 use, 35% statin use, 46% Type 2 diabetes. The mean time of GLP-1 use before first dose of ALG-055009 was 130 weeks. ALG-055009 dose groups met the primary endpoint, with statistically significant placebo-adjusted median relative reductions in liver fat of up to 46.2% at Week 12. Median placebo-adjusted liver fat reduction by selected subgroups were as follows: gender (male: up to 49%; female: up to 48%), body weight (up to 39% for >100 kg and up to 52% ≤100 kg), statin use (yes: up to 55%, no: up to 36%), GLP-1 agonist use (yes: up to 52%; no: up to 36%), or type 2 diabetes status (yes: up to 46%; no: up to 39%). Notably, subgroup analysis indicated that there were no clinically relevant differences in liver fat reduction among participants with or without GLP-1 agonist use.

Conclusion: 12 weeks of once daily ALG-055009 treatment in MASH subjects demonstrated significant reductions in liver fat, with efficacy observed across the baseline factors evaluated. This supports evaluation of longer durations of ALG-055009 and its effects on liver histology and indicates liver fat reductions with the next generation THR-beta agonist ALG-055009 may be observed across various baseline characteristics in the MASH patient population, including those associated with a worse prognosis.

SAT-451

ALG-055009, a novel thyroid hormone receptor beta agonist, demonstrated significant reductions in atherogenic lipids/lipoproteins, including lipoprotein (a), in patients with presumed metabolic dysfunction-associated steatohepatitis in the Phase 2a HERALD study

Rohit Loomba[1], Dimple Desai[2], Daniel Santillano[3], Kathryn Lucas[4], Naim Alkhouri[5], Guy W. Neff[6], Antonio Bianco[7], Eveline Bruinstroop[8], Stanley Wang[9], Kha Le[9], Megan Fitzgerald[9], Min Wu[9], Ifong Kan-Eng[9], Genevieve Harrington[9], Chris Burnett[9], Jen Rito[9], Naqvi Mohammed[9], Meenakshi Venkatraman[9], Tse-I Lin[9], Sushmita Chanda[9], Hardean Achneck[9], Lawrence Blatt[9], Christos Mantzoros[10]. [1]*University of California, San Diego, La Jolla, United States;* [2]*Pinnacle Clinical Research, Edinburg, United States;* [3]*Pinnacle Clinical Research, San Antonio, United States;* [4]*Lucas Research – Diabetes & Endocrinology Consultants, Morehead, United States;* [5]*Arizona Liver Health, Tucson, United States;* [6]*Covenant Metabolic Specialists, LLC, Sarasota, United States;* [7]*University of Texas Medical Branch, Galveston, United States;* [8]*Amsterdam University Medical Center, Amsterdam, Netherlands;* [9]*Aligos Therapeutics, Inc., South San Francisco, United States;* [10]*Harvard Medical School, Boston, United States*
Email: swang@aligos.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction-associated steatohepatitis (MASH) are associated with atherogenic dyslipidemia, with cardiovascular disease (CVD) being the leading cause of mortality in this patient population. While statins reduce low density lipoprotein cholesterol (LDL-C), they have no effect on lipoprotein (a) (Lp(a)). ALG-055009 is a novel next generation thyroid hormone receptor (THR)-beta agonist with beta selectivity and in vitro potency exceeding that of first generation THR-beta drugs. In the randomized, double-blind, placebo-controlled Phase 2a HERALD study, 12 weeks of once daily ALG-055009 treatment in subjects with presumed MASH and F1-F3 fibrosis was well-tolerated and met the primary endpoint, demonstrating significant reductions in liver fat (Loomba et al. AASLD 2024). An analysis of the effects of ALG-055009 compared to placebo on lipid/lipoprotein levels, including Lp(a), a key secondary endpoint, is reported here.
Method: 102 subjects (~20/arm) were randomized to receive 0.3, 0.5, 0.7 or 0.9 mg ALG-055009 or placebo orally once daily for 12 weeks. Only subjects with body weight >85 kg were enrolled in the 0.9 mg arm, with no weight restrictions for other arms. Blood samples were collected to evaluate change from baseline in levels of the following lipid/lipoproteins: total cholesterol, high density lipoprotein cholesterol (HDL-C), LDL-C, non-HDL-C, triglycerides, apolipoprotein B (apoB), A1 and CIII (apoCIII), Lp(a), and very low-density lipoprotein cholesterol (VLDL).
Results: Baseline characteristics were generally similar across arms: 38% male, mean age 50 yrs, mean BMI 39 kg/m^2, 46% with Type 2 diabetes, 54% with dyslipidemia, 18% with stable glucagon-like peptide-1 (GLP-1) agonist use (mean duration of 33 months prior to dose), and 35% with stable statin use. Significant median reductions compared to baseline at Week 12 in levels of LDL-C (up to –15.9% vs. –3.6%; $p < 0.05$), Lp(a) (up to –26.8% vs. +6.1%; $p < 0.005$) and apoB (up to –18.3% vs. –1.5%; $p < 0.005$) for ALG-055009 vs. placebo, respectively, were observed at the highest ALG-055009 dose levels evaluated; reductions in triglycerides (up to –15.4% vs. –5.9%), VLDL (up to –14.8% vs. –6.3%) and apoCIII (up to –12.8% vs. –3.5%) were also observed. These lipids/lipoproteins reductions were observed with or without stable GLP-1 agonist or statin use.
Conclusion: The statistically significant improvements in atherogenic lipids achieved with 12 weeks of ALG-055009 treatment may suggest an added benefit for patients at risk for CVD in addition to the previously reported liver fat lowering properties in a MASLD/MASH population. This data supports evaluation of longer duration ALG-055009 treatment in a dedicated clinical trial of patients with dyslipidemia (including those with MASLD/MASH) to better characterize the extent of reduction in atherogenic lipids/lipoproteins.

SAT-452

GLP1 agonist and metabolic dysfunction-associated steatohepatitis (MASH): systematic review and meta-analysis

Ryan YanZhe Lim[1], Cheng Han Ng[2,3], Ethan Kai Jun Tham[1], Pojsakorn Danpanichkul[4], Daniel Huang[1,3,5], Daniel Tung[3], Mark Muthiah[1,3,5]. [1]*Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore;* [2]*Division of Gastroenterology, Department of Medicine, Kurume University School of Medicine, Kurume, Japan;* [3]*Division of Gastroenterology and Hepatology, Department of Medicine, National University Hospital, Singapore, Singapore;* [4]*Department of Internal Medicine, Texas Tech University Health Sciences Center, Lubbock, Texas, United States;* [5]*National University Centre for Organ Transplantation, National University Health System, Singapore, Singapore*
Email: ryanlimyanzhe21@gmail.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is one of the most prevalent liver diseases. However, pharmacological treatments for this disease have been limited. This meta-analysis aims to evaluate the benefits and limitations of Glucagon-Like Peptide 1 Receptor Agonists (GLP-1 RA) in the treatment of MASH.
Method: MEDLINE and EMBASE was searched on 17th May 2024 for articles comparing GLP-RA with placebo or active comparators. Outcomes included resolution of MASH and ≥1 point reduction in fibrosis stage without worsening of MASH after administration of the drug. Pairwise meta-analysis was conducted to obtain the odds ratio (OR) and mean difference (MD) for dichotomous and continuous outcomes respectively.
Results: In total, 16 studies and 2557 patients were included in the analysis, with 924 MASH patients and 1633 MASLD patients. GLP-1 RA significantly increased the odds of MASH resolution (OR: 5.36, 95% CI: 3.08–9.34, $p < 0.01$, $I^2 = 36.80\%$) and improved fibrosis stage (OR: 2.08, 95% CI: 1.40–3.07, $p < 0.01$, $I^2 = 4.40\%$). However, improvement in fibrosis was only significant for non-cirrhotic patients. There was a reduction in liver fat content (MD = –3.82, 95% CI: –5.4 to –2.23, $p < 0.01$, $I^2 = 0.00\%$), AST (MD = –18.32 U/L, $p = 0.02$, $I^2 = 98.50\%$), ALT (MD = –27.34 U/L, $p < 0.01$, $I^2 = 98.80\%$), and GGT (MD = –35.57 U/L, $p = 0.01$, $I^2 = 98.80\%$) and other metabolic indices.
Conclusion: This meta-analysis has provided strong evidence for the use of GLP-1 based therapies for treatment of MASH/MASLD.

SAT-453

MASH resolution index, a novel, highly sensitive non-invasive measure of histologic improvement, predicts high rates of MASH resolution with pemvidutide treatment of metabolic dysfunction-associated steatohepatitis (MASH)

Rohit Loomba[1], John Suschak[2], Julio Gutierrez[2,3], Jay Yang[2], M. Scot Roberts[2], M. Scott Harris[2], Sarah Browne[2], Daniel Huang[4], Shaheen Tomah[2]. [1]*University of California, San Diego, San Diego, United States;* [2]*Altimmune, Inc., Gaithersburg, United States;* [3]*Scripps Clinic, La Jolla, United States;* [4]*National University of Singapore, Queenstown, Singapore*
Email: stomah@altimmune.com

Background and aims: Pemvidutide is a long-acting, GLP-1/glucagon dual receptor agonist under development for the treatment of metabolic dysfunction-associated steatohepatitis (MASH) and obesity. We previously reported that pemvidutide led to >75% relative reduction in liver fat content (LFC) by MRI-PDFF after 24 weeks, with up to 50% of subjects achieving LFC normalization. Here, we utilized the MASH resolution index (MASHResInd), a novel score based on changes in non-invasive measures of MRI-PDFF, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) with high sensitivity for detecting MASH resolution without worsening of

fibrosis (area under the curve [AUC] 0.81 for MASHResInd ≥−0.67), to predict MASH resolution with pemvidutide treatment.
Method: 64 subjects with metabolic dysfunction-associated steatotic liver disease (MASLD), defined as LFC ≥ 10% by MRI-PDFF, were randomized (1:1:1:1) to receive 1.2 mg, 1.8 mg, 2.4 mg pemvidutide, or placebo weekly for 24 weeks. Subjects with baseline ALT > 75 IU/L or evidence of advanced fibrosis, defined as liver stiffness measurement (LSM) by Fibroscan® ≥ 10 kPa, were excluded. The outcome measure was the proportion of subjects who achieved a MASHResInd response (≥−0.67, Loomba 2024) at Week 24. Combined MASHResInd response and corrected (c)T1 response (≥80 ms reduction, AUC 0.72, Alkhouri 2024) was assessed in a subset of 19 subjects who also underwent cT1 imaging.
Results: Median baseline BMI, LFC, ALT, and LSM, were 36.8 kg/m^2, 20.6%, 31.0 IU/L, and 6.5 kPa, respectively. 53% were female and 27% had diabetes. MASHResInd response was achieved by 22.2%, 69.2%, 92.3%, and 90.9% of subjects receiving placebo, pemvidutide 1.2 mg, 1.8 mg, and 2.4 mg, respectively ($p < 0.05$, $p < 0.001$, $p < 0.001$ vs. placebo) at Week 24. Combined MASHResInd with cT1 responses were achieved in 0.0% of placebo vs. 71.4%, 75%, and 100% of pemvidutide-treated subjects, respectively ($p < 0.05$) at Week 24, further discriminating placebo from active treatment.
Conclusion: Pemvidutide administered for 24 weeks was associated with significantly greater MASHResInd and cT1 responses. These findings suggest a high probability of achieving MASH resolution with pemvidutide in biopsy-driven trials.

Therapeutic Effects of GLP-1 agonist versus SGLT2-i on patients with T2D and MASLD

Ermina Stratina[1], Robert Nastasa[1], Remus Stafie[1], Adrian Rotaru[1], Sebastian Zenovia[1], Cristina-Maria Muzica, Laura Huiban, Irina Girleanu[1], Catalin Sfarti[1], Cojocariu Salloum[1], Horia Minea[1], Ana-Maria Singeap[1], Carol Stanciu[1], Anca Trifan. [1]*Department of Gastroenterology, Grigore T. Popa University of Medicine and Pharmacy, 700115 Iasi, Romania, "St. Spiridon" Emergency Hospital, Institute of Gastroenterology and Hepatology, 700111 Iasi, Romania, Iasi, Romania*
Email: stratina.ermina@yahoo.com

Background and aims: Type 2 diabetes (T2D) has a bidirectional relationship with metabolic dysfunction-associated steatotic liver disease (MASLD). Common pathophysiological pathways, such as insulin resistance, both adipose tissue and mitochondrial dysfunction, low-grade inflammation, and dysbiosis, are the cause of this strong correlation. It remains unclear how the coexistence of MASLD and T2D influences each disease's prognosis in both directions. Considering this, research on the medications that lower glucose affect MASLD has been significant. The aim was to evaluate the comparative effects of oral Semaglutide therapy (GLP-1 agonist) versus Dapagliflozin (SGLT2 inhibitor) in patients with T2D and MASLD.
Method: This was a prospective study. Thus, 72 consecutive patients with MASLD and T2D received oral Semaglutide, and 76 consecutive patients received Dapagliflozin therapy. The median follow-up period was 24 weeks. Dose adjustments of oral Semaglutide and Dapagliflozin were determined by each physician while monitoring efficacy and adverse events.
Results: At 24 weeks, there were notable improvements in body weight, lipid profile, liver enzymes, and glycemic control when compared to baseline values in both groups ($p < 0.01$). Regarding glycated hemoglobin, a notable decrease was observed in the Semaglutide group ($p < 0.001$) when compared to the Dapagliflozin group ($p = 0.011$). Between baseline and 24 weeks, the values of the Controlled Attenuation Parameter (CAP) lowered significantly in Semaglutide group ($p < 0.01$). The variation of body weight index and abdominal circumference were strongly correlated with changes in alanine aminotransferase concentrations ($r = 0.36$, $p < 0.01$) and CAP values ($r = 0.44$, $p < 0.01$). The liver stiffness measurement (LSM) according to Vibration Controlled Transient Elastography was improved significantly in the Semaglutide group from 9.06 ± 1.80 kPa at baseline to 7.41 ± 2.06 kPa ($p < 0.001$). Regarding the factors associated with improving LSM, it was observed that the decrease of CAP by one unit determined a decrease of LSM values by 0.08 kPa, and the decrease of blood glucose by one unit determined the decrease of LSM by 0.07 kPa.
Conclusion: Therefore, the metabolic effects were superior in the group treated with Semaglutide in contrast to the group that received Dapagliflozin. This can be explained by the more important weight loss and improved glycemic control in the first group. Further studies conducted in an ideal time frame are needed to confirm the evidence presented in this research.

SAT-455

A single centre, comparative study of Saroglitazar combined with vitamin E versus Saroglitazar alone in managing steatotic liver disease and/or metabolic dysfunction among liver transplant recipients

Swapnil Dhampalwar[1], Narendra S Choudhary[1], Neeraj Saraf[1], Kunwar Ashish Singh[1], Arvinder Singh Soin[1]. [1]*Institute of Liver Transplantation & Regenerative Medicine, Medanta The Medicity, Gurugram, India*
Email: swapnildhampalwar@gmail.com

Background and aims: The prevalence of post-transplant metabolic dysfunction (MD) has been rising as advancements in the long-term care of liver transplant (LT) recipients enhance survival rates. Management strategies remain centered on lifestyle interventions and pharmacological treatments to address the associated metabolic risks. Saroglitazar, a dual peroxisome proliferator-activated receptor α/γ agonist, is a potential therapeutic option for MASLD or metabolic associated steatohepatitis (MASH).
Method: This single-center retrospective analysis focuses on liver transplant (LT) recipients treated with Saroglitazar for managing MASLD or metabolic dysfunction (MD), including diabetes and/or dyslipidemia. Post-transplant steatotic liver disease (SLD) was diagnosed through imaging (ultrasonography) and/or liver biopsy. Patients were prescribed lifestyle modifications along with pharmacotherapy, which included Vitamin E, Saroglitazar, or a combination of both. The study included 54 patients who had been on Saroglitazar therapy for a minimum of 3 months.
Results: 54 individuals(50 Male and 4 Female) with the mean age of 52.7 ± 8.8 years were included in this study. Out of 54 patients 72.3% patients received Saroglitazar along with Vitamin E, and 27.7% received Saroglitazar alone. MASLD was seen in 38 (70%) patients [de novo in 21(55.3%) and recurrent in 17(44.7%) patients]. Saroglitazar (4 mg/day) was initiated at a median period of 56(IQR 33–82) months after LT. Biochemical and metabolic parameters before and after Saroglitazar initiation are shown in Table 1. Over a median follow-up of 9 months(IQR 5–16.5), notable reductions were observed in total cholesterol, TG, BMI, HbA1C and LDL levels across both groups treated with Saroglitazar. Saroglitazar was generally well tolerated, with no significant adverse events reported.
Conclusion: Saroglitazar, when used independently of Vitamin E, has shown effectiveness in mitigating metabolic risk factors associated with steatotic liver disease in liver transplant recipients. Further studies including MR-PDFF are needed to assess reduction in hepatic fat content with Saroglitazar.

SAT-456

Current evidence on dietary interventions in people with metabolic-dysfunction associated fatty liver disease and MetALD – a systematic review and meta-analysis of randomized controlled trials

Ute Stern[1], Maurice Michel[1], Gudrun Wagenpfeil[2], Verena Keller[1], Jörn M. Schattenberg[1]. [1]*Department of Internal Medicine II, Saarland University Medical Center, Saarland University, Homburg, Germany;* [2]*Institute of Medical Biometry, Epidemiology and Medical Informatics, Homburg, Germany*
Email: ute.stern@uni-saarland.de

Background and aims: Metabolic-dysfunction associated fatty liver disease (MASLD) and MetALD are highly prevalent. The management relies on lifestyle changes. Dietary interventions are recommended as first line treatment. A number of them, including mediterranean diet, intermittent fasting, low-fat high-carbohydrate diet and vice versa, and the DASH diet have been suggested to be beneficial. The aim of this systematic review with meta-analysis was to provide a comprehensive description and quantitative assessment of the evidence of dietary interventions in improving MASLD and MetALD.
Method: In August 2024, a systematic literature search was performed across multiple databases, including Medline, Embase, the International Clinical Trials Registry Platform, ClinicalTrials.gov, and Web of Science. The review focuses on randomized controlled trials published between 2018 and 2024.
Results: The search yielded n = 1459 records, of which n = 182 were selected for full-text screening by two independent reviewers. Records were grouped into different categories according to dietary patterns. Identified studies included the Mediterranean Diet (n = 23), the DASH diet (n = 6), plant-based diets (n = 3), low-carbohydrate (n = 7) or low-fat diets (n = 2), and ketogenic diet (n = 10). Additional interventions include fasting protocols (n = 20), only focusing caloric restriction (n = 2), the utilisation of diverse plant-oils (n = 8) and supplementation with vitamins and minerals (n = 6), omega 3 fatty acids (n = 8), pre- and probiotics (n = 14), and nutraceuticals (n = 6) such as Silymarin. Moreover, the influence of antioxidant-rich substances (n = 13) e.g. resveratrol, was also investigated. However, no trials focusing on MetALD could be identified. Liver-related endpoints included were enzymes (ALT, AST, GGT) in 85%, liver stiffness in 26.7%, controlled attenuation parameter (CAP) in 25%, and magnetic resonance imaging-derived proton density fat fraction (MRI-PDFF) in 11.7% of studies. Furthermore, the duration of the interventions was highly variable ranging from four weeks up to 24 months. Quality of life was only incompletely assessed.
Conclusion: A large number of dietary interventions in MASLD have been published. Overall, the heterogeneity is high. Studies vary significantly with regards to duration and endpoints. Standardization of these interventions will be required to allow to compare and grade recommendations for patients with MASLD.

SAT-461-YI

The early impact of bariatric surgery on liver fibrosis and steatosis in MASLD patients

Valentina Cossiga[1], Mario Capasso[1], Concetta Accongiagioco[1], Luisa Ranieri[1], Vincenzo Schiavone[1], Simona Albano[1], Alon Gregory Rutigliano[1], Antonio Franzese[2], Francesco Capozzi[1], Maria Guarino[1], Mario Musella[2], Filomena Morisco[1]. [1]*Department of Clinical Medicine and Surgery, Diseases of the Liver and Biliary System Unit, University of Naples "Federico II", Naples, Italy, Naples, Italy;* [2]*Department of Advanced Biomedical Science, University of Naples "Federico II", Naples, Italy, Naples, Italy*
Email: valentina.cossiga@gmail.com

Background and aims: Metabolic-dysfunction-associated-liver disease (MASLD) affects more than half of obese subjects. To date, weight reduction by diet and physical activity is recommended to improve liver injury. Recent studies have shown that bariatric surgery induces stable weight loss and ameliorates metabolic parameters. The aim of this study is to evaluate the effect of bariatric surgery on liver steatosis and fibrosis.
Method: This is a monocentric prospective study including all patients with severe obesity and MASLD candidates for bariatric surgery in a single Italian-center. Other causes of chronic liver disease were exclusion criteria. Clinical and biochemical data were collected. Liver fibrosis and steatosis were non-invasively assessed with Liver Stiffness Measurements (LSM) and Controlled Attenuation Parameter (CAP) by Fibroscan at three time-points: before surgery, 6- and 12-months after surgery.
Results: A total of 112 patients (63.4% female, mean age 41.5 years) were enrolled. Before bariatric surgery, the BMI was 43.6 ± 6.2 kg/m², the LSM was 8 ± 5.8 kPa and the CAP was 319.7 ± 57.8 dB/m. Ninety-six patients continued follow-up up after surgery. These patients demonstrated a significant reduction in BMI and CAP as early as 6-months post-surgery, while a significant decrease in LSM was observed only after 12-months. Specifically, the mean BMI was 31.9 ± 5.1 kg/m² after 6 months and 28.0 ± 3.5 kg/m² after 12-months, representing an overall decrease of 35.9% from baseline ($p < 0.0001$). The mean CAP was 264.5 ± 57 dB/m after 6-months and 214.8 ± 47.8 dB/m after 12-months, reflecting an overall decrease of 32.8% from baseline ($p < 0.0001$). Finally, the mean LSM was 6.3 ± 2.5 kPa after 6-months and 5.8 ± 1.9 kPa after 12-months, showing an overall decrease of 21.6% from baseline ($p = 0.02$).
Conclusion: This study demonstrated a significant weight loss and liver steatosis decrease already at 6-months after surgery, while liver fibrosis reduction takes longer at 12-months after surgery. Therefore, in adults with MASLD and severe obesity, bariatric surgery should be considered as a valid therapeutic option for improving liver damage.

Email: vian.azzu@astrazeneca.com

Background and aims: Fibroblast activation protein (FAP) is an endopeptidase whose increased hepatic expression correlates with liver fibrosis severity and development. FAP cleaves proteins that regulate extracellular matrix turnover and metabolism, such as denatured collagens, α2-antiplasmin, and FGF21. Pharmacological inhibition of FAP in animal models of liver fibrosis shows anti-fibrosis benefit. This study reports the safety, tolerability, pharmacokinetics (PK), and pharmacodynamics of AZD2389, a potent FAP inhibitor, in healthy participants.
Method: In a single-blind, phase 1 study with single-ascending (SAD) and multiple-ascending dose (MAD) parts, AZD2389 was evaluated in participants (18–55 years). Each cohort had 6 active and 2 placebo participants. In the SAD, 35 participants across 6 cohorts received from low to high single doses of AZD2389, including one cohort of 5 participants which were dosed twice with AZD2389 to explore effect of food upon PK. In the MAD, 24 participants received AZD2389 or placebo for 10 days at low, medium and high repeated doses across 3 cohorts. FAP inhibition was assessed by percentage inhibition, and mechanistic insights were evaluated through the FAP cleavage product α2-antiplasmin (Asn-α2AP).
Results: AZD2389 was well tolerated with no safety concerns at all doses. No serious adverse events, discontinuations, or clinically significant adverse events (AEs) related to AZD2389 were reported. In the SAD part, one mild AE was observed, and in the MAD part, five mild AEs were reported, all resolving without issues. No clinically relevant trends in ECGs, physical exams, or lab results were found. AZD2389 was rapidly absorbed (Cmax 0.5 to 1 hours post-dose). Systemic exposure increased proportionally with dose across single and repeated dosing. Following administration of AZD2389 with food, AUC was similar and Cmax was 33% lower in fed state compared to fasting state. There was no accumulation in plasma Cmax or AUCtau or time-dependency in AZD2389 PK. AZD2389 inhibited FAP activity by >90% at Cmax in both SAD and MAD parts, with 47%, 74%, and 92% inhibition at trough after low, medium, and high doses, respectively. AZD2389 caused dose-dependently reduced %Asn-α2AP, returning to baseline after washout.
Conclusion: In healthy participants, there were no safety or tolerability concerns up to the highest dose of AZD2389 tested in both the SAD and MAD parts. AZD2389 is a selective FAP inhibitor and is being studied further as a treatment for liver fibrosis.

Non-invasive assesment of liver disease except MASLD

TOP-505
Evaluation of a non-invasive pathway for advanced fibrosis detection and liver-related outcomes prognosis in the general population from China, United Kingdom, and United States

Email: qixiaolong@vip.163.com

Background and aims: Population-based management of chronic diseases is of paramount importance, as this could identify undiagnosed cases at early disease stages. Recently, EASL-EASD-EASO proposed a non-invasive pathway for case finding of advanced fibrosis. This study aims to evaluate the diagnostic accuracy of the pathway for fibrosis detection and its association with liver-related events (LREs) in the general population.
Method: We included 468999 adult general population (age ≥18 years) from four prospective cohorts: China cross-sectional cohort (n = 8943), United States (US) cross-sectional cohort (n = 6756), United Kingdom (UK) prognosis cohort (n = 411120, median follow-up time: 14.7 years), and US prognosis cohort (n = 42180, median follow-up time: 10.4 years). According to the latest EASL-EASD-EASO guideline, the first step was to screen for primary risk factors. Individuals without type 2 diabetes, or elevated liver enzymes, or the simultaneous presence of obesity and one or more additional cardiometabolic risk factor(s) are classified as minimal-risk group. Further, individuals were categorized into low-, medium-, and high-risk groups according to fibrosis-4 index. Advanced fibrosis was defined by liver stiffness measurement ≥10 kPa, assessed using FibroScan®. Associations with LREs (comprising liver-related hospitalization, cirrhosis, liver cancer, and liver-related death), and cardiovascular-related death were investigated.
Results: The prevalence of advanced fibrosis in minimal-, low-, medium-, and high-risk groups was 1.1%, 2.9%, 6.4%, and 20.9% in the China cross-sectional cohort, and 0.8%, 6.9%, 9.8%, and 37.1% in the US cross-sectional cohort. In the UK prognosis cohort, hazard ratios (HRs) for LREs compared to the minimal-risk group were 2.25 (95% CI 2.14–2.36), 2.95 (95% CI 2.79–3.10), and 11.15 (95% CI 10.29–12.08) for the low-, medium-, and high-risk groups, respectively. Compared with the minimal-risk group, HRs for liver-related hospitalization, cirrhosis, liver cancer, and liver-related death in the high-risk group were 11.1 (95% CI 10.23–12.04), 50.75 (95% CI 43.73–58.91), 20.72 (95% CI 16.3–26.34), and 42.39 (95% CI 35.47–50.67), respectively. The risk groups within the pathway were associated with a progressively increasing risk of cardiovascular-related death, with HRs of high-risk group reaching 6.43 (95% CI 5.86–7.06) in the UK prognosis cohort and 11.89 (95% CI 9.67–14.61) in the US prognosis cohort. Notably, subgroup analysis indicated that among participants with and without high alcohol consumption, increased risk stratification was also associated with a higher prevalence of advanced fibrosis and a higher incidence of LREs and cardiovascular-related death.
Conclusion: The stepwise non-invasive pathway appears suitable for identifying individuals at risk for advanced fibrosis and future LREs in the general population.

Email: pgines@clinic.cat

Background and aims: International guidelines recommend early identification of liver fibrosis as an attempt to decrease the burden of chronic liver diseases. Vibration controlled transient elastography (VCTE) on FibroScan devices is one of the most accurate tests to assess liver stiffness (LSM) in general population as well as in high-risk populations. However, VCTE is not widely available in a primary care setting. FibroScan 230 device (FS230) is a new model of Fibroscan (CE marked in April 2021 by Echosens) able to pilot from a personal computer, more accessible, smaller and with smarter connectivity than the conventional VCTE (FS530). The aim of this study was to assess the concordance between both devices in evaluating the presence of liver fibrosis by LSM and steatosis by controlled attenuation parameter (CAP) in the general population.

Method: Prospective cross-sectional population-based study that included subjects above 40 years without previous known liver disease. A medical history, physical examination, VCTE and blood tests were performed. LSM and CAP were measured with FS530 and FS230 in random order. Patients with LSM ≥8 kPa with at least one of the devices or with ALT ≥1.5 UNL were considered as high-risk group and were referred to a hepatologist. Only reliable values of LSM were included in the analysis. Categoric and quantitative variables were represented in percentages, median and interquartile range (IQR). Pearson's correlation was used to assess concordance between devices.

Results: 1962 patients were screened in 5 primary care centers in Catalonia during an 18-month period from 2021 to 2022: 47 met exclusion criteria, 173 did not have available blood tests and 106 had an unreliable VCTE value in any or both devices. Finally, 1628 patients were included for the analysis. Median age 61 years (IQR 52–69), 55% women, 7% at-risk alcohol consumption (≥20 g/day women and ≥30 g/day men), 28% type 2 diabetes (T2DM), 41% arterial hypertension and 42% dyslipidemia. Median LSM was 4.7 Kpa (IQR 3.8–5.8) in FS530 and 4.7 Kpa (IQR 3.8–5.7) in FS230 and CAP 251 dB/m^2 (IQR 218–296) in FS530 and 249 dB/m^2 (IQR 216–292) in FS230. The number of subjects with LSM ≥8 kPa was 109 (7%) in FS530 and 96 (6%) in FS230. The correlation between both devices was R = 0.88 for LSM (CI 95% 0.87–0.89, p < 0.001) and R = 0.84 for CAP (CI 95% 0.83–0.86, p < 0.001). A closer look to subjects with risk factors for chronic liver diseases (T2DM, obesity, at-risk alcohol consumption) showed that correlation for LSM and CAP was above 0.85 and 0.81 respectively in all subgroups (p < 0.05).

Conclusion: There is a good correlation between LSM and CAP values with FS230 and FS530 devices. Repeated measurements showed low variability and good reproducibility in patients with and without risk factors for chronic liver diseases suggesting that both devices may be good tools to screen for liver fibrosis and steatosis in a primary care setting.

WED-500-YI

Evaluation of novel point-of-care ultrasound for hepatitis "PUSH" for healthcare workers managing hepatitis B infection in Zambia

Costanza Bertoni[1,2], Annie Kanunga[3,4], Edford Sinkala[3,5], Enock Syabbalo[3,5], Helen Chitundu[3], Carolyn Chibundi[4], Guy Muula[4], Samuel Bosomprah[4], Giulia Morsica[1], Antonella Castagna[1,2], Claudia Wallrauch[6,7], Tom Heller[6,8], Michael Vinikoor[4,5,9]. *[1]Division of Infectious Diseases, IRCCS San Raffaele Scientific Institute, Milan, Italy; [2]Faculty of Medicine and Surgery, Vita-Salute San Raffaele University, Milan, Italy; [3]University Teaching Hospital, Lusaka, Zambia; [4]Centre for Infectious Disease Research in Zambia, Lusaka, Zambia; [5]Department of Medicine, University of Zambia, Lusaka, Zambia; [6]Lighthouse Clinic Trust, Lilongwe, Malawi; [7]Institute of Infectious Diseases and Tropical Medicine, LMU University Hospital, Munich, Germany; [8]International Training and Education Center for Health, University of Washington, Seattle, United States; [9]University of Alabama at Birmingham, Birmingham, United States*
Email: bertoni.costanza@hsr.it

Background and aims: Hepatitis B is a leading cause of mortality in Africa. However, many people with chronic hepatitis B (CHB) in Africa cannot access treatment because key laboratory tests required for eligibility are lacking at some health facilities. Point-of-care ultrasound (POCUS) has emerged globally as a versatile, inexpensive tool used by various healthcare professionals. To support HBV guidelines implementation, a new POCUS for hepatitis (PUSH) was created. Here we evaluated the accuracy of PUSH in Zambia.

Method: We performed a real world validation study of PUSH at a hepatitis clinic at University Teaching Hospital in Lusaka, Zambia, from March to June 2024. Over 3 days, we trained 4 nurses and 6

physicians not experienced in ultrasound in the PUSH protocol. Trainees learned to visualize 3 liver windows (epigastric, subcostal, and right transverse), identify 4 cirrhosis-suggestive liver features (enlarged caudate lobe, nodular liver surface, coarse echotexture, tortuous vascularity), and liver lesions suspicious for hepatocellular carcinoma. Post-training, participants were evaluated with PUSH if had CHB assessed by HBV S antigen positivity, and 18+ years of age. They were excluded if currently/recently pregnant, with hepatitis C or in the acute phase of HBV infection. Participants also underwent reference standard tests (RST) for cirrhosis: liver stiffness (LS), and a comprehensive abdominal ultrasound by an experienced radiographer. Trainees performing PUSH and staff performing the RST were blinded to participants ' clinical information. The performance of PUSH was calculated for cirrhosis (LS >12.5 kPa), significant fibrosis (>7.0 kPa), and lesions, and we used nonparametric analysis of ROC curve, adjusted for PUSH operator (doctor vs. nurse), sex, and HIV status to examine diagnostic performance.

Results: The participants included were 202. Median age was 38 years, 57% males, 28% HIV-positive, 69% on HBV antiviral therapy. Physicians did 61% of PUSH assessments. According to RSTs, 12% of participants had cirrhosis, 30% had significant fibrosis, and 4% had lesions. Alpha fetoprotein in participants with lesions ranged from 350 to 5,703 ng/mL. PUSH had moderate accuracy for cirrhosis, with sensitivity of 56% (34.9–75.6), specificity of 97.7% (94.3–99.4), and an overall ROC area under the curve (ROC-AUC) of 0.77(0.70–0.82). For significant fibrosis, accuracy was poor with sensitivity of 28.3% (17.5–41.4), specificity of 99.3% (96.1–100), and ROC-AUC of 0.64 (0.57–0.70). PUSH excelled in diagnosing lesions, with 85.7% (42.1–99.6) sensitivity, 93.5% (88.9–96.6) specificity, and ROC-AUC of 0.90 (0.84–0.94).

Conclusion: Newly trained nurses and physicians at an HBV clinic in Zambia identified cirrhosis with moderate accuracy and lesions with high accuracy using PUSH, suggesting that this approach could identify advanced cases of HBV disease. To eliminate HBV in Africa, new strategies like liver POCUS are needed to face challenges in applying international treatment guidelines.

WED-501

Prognostication of liver disease patients via ARFI-based liver stiffness measurement using the WFUMB "Rule-of-4" algorithm

Christian Sebesta[1,2,3], Georg Kramer[1,2,3,4], Nina Dominik[1,2,3], Benedikt Hofer[1,2,3,4], Lorenz Balcar[1,2,3], Paul Thöne[1,2,3], Mathias Jachs[1,2,3], Lukas Hartl[1,2,3,4], Benedikt Simbrunner[1,2,3,4], Till Schöchtner[1], Nicolas Balutsch[1], Friedrich Haimberger[1], Michael Trauner[1,4], Albert Friedrich Stättermayer[1,2], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3,4], David Bauer[1,2,5].

Email: christian.a.sebesta@meduniwien.ac.at

Background and aims: Shear wave elastography (2D-SWE) is a novel ARFI-based technology for measuring liver stiffness (LSM), emerging as a valuable risk assessment tool for portal hypertension (PH). The WFUMB proposed a "rule-of-4" for ARFI-LSM, categorizing patients with advanced chronic liver disease (ACLD) using LSM cut-offs at 5, 9, 13, 17, and 21 kPa. ACLD can be ruled in at ≥13 kPa, while LSM > 21 kPa indicates a high probability of clinically significant portal hypertension (CSPH). We aimed to validate the prognostic value of the WFUMB "rule-of-4".

Method: We prospectively enrolled 125 patients with compensated (cACLD) and decompensated (dACLD) ACLD who underwent same-day 2D-SWE-LSM using the Aixplorer SuperSonic Imagine system and measurement of hepatic venous pressure gradient (HVPG). Patients were stratified via "rule-of-4" kPa into three groups, <13 kPa, 13–21 kPa and >21 kPa. Demographic, clinical, and laboratory as well as follow-up data on decompensation events (cACLD: first decompensation; dACLD: further decompensation/ACLF) were collected.

Results: 22 (17.6%) patients had LSM <13 kPa (non-ACLD); 25 (20%) LSM 13–21 kPa (ACLD); while 78 (62.4%) exhibited LSM > 21 kPa (CSPH) - the corresponding median HVPG were 6.00 [IQR: 4.25–8.00] vs. 10.0 [7.00–12.00] vs 17.0 [13.00–20.00] mmHg, respectively. The CSPH prevalence was 18.2%, 64% and 94.9%. During a median follow-up period of 18.5 months [7.56–24.00], the rate of decompensation significantly increased with the ARFI-LSM rule-of-4 categories: 4.5% in the non-ACLD group, 20% in the ACLD group, and 34.6% in the CSPH group ($p = 0.013$). In ROC analysis for predicting decompensation, HVPG (AUC: 0.78) performed best, while ARFI-LSM (AUC: 0.67) performed similarly to LSM via vibration-controlled transient elastography (VCTE: AUC: 0.72; $p = 0.225$). In competing risk regression, we observed a hazard ratio of 1.01 (95% CI: 1.00–1.02) per kPa for ARFI-LSM ($p = 0.007$), indicating a continuous increase in the risk of decompensation with increasing ARFI-LSM.

Conclusion: The recently proposed WFUMB "rule-of-4" allows for ARFI-LSM based risk assessment in patients with chronic liver disease. Specifically, the risk of decompensation starts to increase at ARFI-LSM 13–21 kPa and is significant at ARFI-LSM > 21 kPa (indicating a high risk for CSPH). Since ARFI-LSM provides comparable prognostic accuracy as VCTE, a wider application of ARFI-LSM in clinical practice should be encouraged.

WED-502

Patient-reported experience measures of EUS-guided and percutaneous liver biopsy. A prospective observational study

Feras Sanoubara[1], Dina Khalil[1], Markus Kimmann[1], Juliana Goediker[1], Janina Schulz[1], Zeyu Wang[1], Silvia Letmathe[1], Sara Noemi Reinartz Groba[1], Franziska Weppelmann[1], Jörn Arne Meier[1], Barbara Braden[1], Wim Laleman[1], Jonel Trebicka[1], Michael Praktiknjo[1]. *[1]University Hospital Muenster, Muenster, Germany*
Email: feras.sanoubara@ukmuenster.de

Background and aims: Liver biopsy is a critical procedure for diagnosing and staging liver diseases. Traditionally, percutaneous liver biopsy (PC-LB) has been the standard method. Endoscopic ultrasound-guided liver biopsy (EUS-LB) has emerged as a promising alternative. While clinical efficacy and safety have been well-documented, less is known about the patient-reported experience associated with this approach. This study aims to compare patient-reported experience measures between EUS-LB and PC-LB, providing insight into its impact on patient comfort and satisfaction.

Method: This is a prospective observational study. Within the study period from January to August 2024, we included all consecutive non-targeted EUS-LB and PC-LB at our tertiary liver center. A modified questionnaire based on the validated Newcastle ENDOPREM was used. The questionnaire comprises multiple domains including general demographic information, pain severity (scale 1–10) and duration (scale 1–5), patient discomfort (scale 1–10), well-being, as well as patient satisfaction. Clinical data were recorded from electronic hospital files.

Results: This study included 87 patients, of whom 56 underwent EUS-LB and 31 PC-LB. Median age was 54 years (18–74), most patients were male (n = 46, 53%). Most common indications for biopsy were either after liver transplantion (n = 33, 39%) or for diagnosis of liver disease (n = 33, 39%). Technical success was 100%. There was only one major postinterventional complication in the EUS-LB group (bleeding without need for transfusion). Patients in the EUS-LB group (0(0–8)) reported significantly ($p < 0.001$) less pain during and after the procedure compared to PC-LB group (3(0–10)). Also, duration of pain was significantly ($p < 0.001$) shorter in EUS-LB (1(1–4)) compared to

PC-LB (2(1–4)). Finally, patients reported significantly ($p = 0.006$) lower rate of overall discomfort after EUS-LB (0 (0–7)) vs. PC-LB (2(0–8)), while no significant differences were observed in the other domains of the questionnaire.
Conclusion: Pain severity, duration and overall discomfort was significantly reduced in EUS-LB compared to PC-LB. The results support the use of EUS-LB as a patient-preferred method for liver biopsy, which could enhance patient compliance and satisfaction.

WED-503
Clinical decision tree for non-invasive diagnosis of graft steatosis in liver transplant patients
Dominik Lüttgen[1], Vivien Renée Castedello[1], Michael Praktiknjo[1], Frank Erhard Uschner[1], Jonel Trebicka[1,2], Maximilian Joseph Brol[1]. *[1]Department of Internal Medicine B, University Hospital Münster, Münster, Germany; [2]European Foundation for the Study of Chronic Liver Failure – EF Clif, Barcelona, Spain*
Email: dominik.luettgen@ukmuenster.de

Background and aims: Patients after liver transplantation (LT) are at high risk of developing hepatic steatosis, an early form of pathological graft alterations. While liver biopsy remains the gold standard for detecting graft steatosis, it carries risks of peri-interventional complications such as bleeding and pain, necessitating non-invasive alternatives. This study aims to develop an algorithm for non-invasive detection of graft steatosis.
Method: LT patients with available liver histology were included. Three ultrasound-based methods were evaluated: Attenuation PLUS (AttPLUS) and Speed of Sound PLUS (SSpPLUS) using the Hologic Mach 30 ultrasound machine, and the Controlled Attenuation Parameter (CAP) using the Fibroscan 630 Expert. Additionally, the serum-based Hepatic Steatosis Index (HSI) was calculated. Histopathological assessment of steatosis served as the reference standard.
Results: A total of 111 patients were included in the study (39% female, median age 59 years [45–68], median time since LT 7 years [2–21]). All methods showed significant correlations with histological steatosis grades ($p < 0.05$). For detecting any steatosis ($S \geq 1$), SSpPLUS demonstrated the highest accuracy with an AUC of 0.758, followed by CAP (0.718), AttPLUS (0.715), and HSI (0.715). When assessing significant steatosis ($S \geq 2$), AttPLUS outperformed other methods, achieving an AUC of 0.801, with CAP (0.763), HSI (0.700), and SSpPLUS (0.672). For severe steatosis ($S \geq 3$), AttPLUS again showed the best performance (AUC: 0.749), followed by CAP (0.747), while HSI (0.535) and SSpPLUS (0.453) exhibited poor results. Consequently, the decision tree was developed using AttPLUS and SSpPLUS. First, the cut-off value for S1 steatosis was determined using the maximum Youden index (if SSpPLUS <1572 m/s, then S1 steatosis; otherwise, no steatosis). Subsequently, the threshold for S2/S3 steatosis was identified (if AttPLUS > 0.568 dB/cm/MHz, then S3 steatosis; otherwise, S2 steatosis.
Conclusion: This study demonstrates that ultrasound-based methods, particularly AttPLUS and SSpPLUS, show promising potential in detecting and grading graft steatosis in liver transplant recipients. By providing a decision tree algorithm, we might demonstrate a feasible alternative to liver biopsy, maintaining diagnostic reliability.

WED-504
Multi-omic machine learning for risk prediction of cholangiocarcinoma in population-based cohorts
Felix Van Haag[1], Jan Clusmann[1,2], Paul-Henry Koop[1], Anna Saborowski[3], Kai Markus Schneider, Jakob Nikolas Kather[4,5,6], Carolin V. Schneider. *[1]Medical Department III - Gastroenterology, Metabolic Diseases & Intensive Care, University Hospital RWTH Aachen, Aachen, Germany; [2]Else Kroener Fresenius Center for Digital Health, Faculty of Medicine and University Hospital Carl Gustav Carus, TUD Dresden University of Technology, Dresden, Germany, Dresden, Germany; [3]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany, Hannover, Germany; [4]Department of Medical Oncology, National Center for Tumor Diseases (NCT), Heidelberg University Hospital, Heidelberg, Germany, Heidelberg, Germany; [5]Department of Medicine I, University Hospital Dresden, Dresden, Germany, Dresden, Germany; [6]Else Kroener Fresenius Center for Digital Health, Technical University Dresden, Dresden, Germany, Dresden, Germany*
Email: fvanhaag@ukaachen.de

Background and aims: Cholangiocarcinoma (CCA) is a highly fatal malignancy most frequently diagnosed at advanced stages, presenting with dismal prognosis. We previously reported a highly accurate machine learning model for HCC-risk prediction and aimed to apply similar methodology to stratify and assess CCA-risk, given the complete lack of risk scores and screening except for patients with primary sclerosing cholangitis.
Method: We trained machine learning models using multimodal data from the UK Biobank (UKB), a population-based cohort encompassing over 500,000 participants. The UKB provides extensive phenotypic characterization, including lifestyle and physical measurements, genomic data (~500,000 participants each), and metabolomic data (~250,000 participants), as well as linkage to electronic health records (EHR)and death registries, with up to 15 years of follow-up. We trained random forest classifiers using a five-fold cross-validation approach on participants from England, with independent validation performed on participants from Scotland and Wales. To address the heterogeneity of CCA($n = 666$), we further developed separate models for intrahepatic CCA (iCCA, $n = 428$) and extrahepatic CCA (eCCA, $n = 113$). Demographic variables, EHR, blood parameters, genomics (18 single nucleotide polymorphisms associated with CCA) and metabolomics were hereby incrementally incorporated into our models to reflect clinically relevant scenarios, ranging from daily clinical practice data to comprehensive multi-omics perspectives. From these, we then derived a final model comprising of only the 10 most relevant features throughout demographics, lifestyle-, EHR- and blood data using systematic ablation studies.
Results: Our models achieved AUROCs of 0.7 in the validation set, with no additional benefit of addition of genomics or metabolomics over a model consisting of demographic variables, EHR and blood parameters alone. The iCCA-only and eCCA-only models achieved AUROCs of 0.7 and 0.66, respectively. Interpretability analysis highlighted age as the most relevant feature, followed by ICD-codes like "complication of cirrhosis," "obstruction of bile duct," and blood parameters, e.g. "HbA1c," "Gamma-GT," "IGF-1," "AP," but also lifestyle factors such as "Pack years." The final model, comprising only 10 ubiquitously available and affordable clinical features showed similar performance to more complex scenarios and is currently undergoing external validation in the All Of Us Research Program (849,000+ participants) as well as the Penn Medicine Biobank (~60,000 Participants).
Conclusion: Our work presents the first-ever risk score for CCA in a general population by using machine learning. Our model, for which we provide all code and weights, can hereby serve as baseline for further prediction efforts for early detection of CCA in the general population.

WED-509
Decoding the dynamics: minimal detectable difference in non-invasive tests may exceed proposed thresholds for meaningful changes
Georg Semmler[1,2,3,4], Chunsen Wu[3,4], Katrine Lindvig[3,4], Lucie Simonis[1,2], Jan Embacher[1,2], Philipp Hruska[1,2], Peter Andersen[3,4], Lorenz Balcar[1,2], Mathias Jachs[1,2], Michael Trauner[1,2], Aleksander Krag[3,4], Thomas Reiberger[1,2], Thomas Scherzer[5], Mattias Mandorfer[1,2], Maja Thiele[3,4]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical*

University of Vienna, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [3]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark; [4]Institute of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark; [5]Health and Prevention Center, Sanatorium Hera, Vienna, Austria
Email: georg.semmler@meduniwien.ac.at

Background and aims: Non-invasive fibrosis tests (NITs) are widely used in primary, secondary and tertiary care. As monitoring becomes increasingly important, robust NITs with minimal random variation are essential for evaluating true changes in disease state over time. This study aimed to evaluate the test-retest reliability and minimal detectable change (MDC) of commonly used NITs across different clinical settings and patient populations.
Method: We retrospectively studied test-retest reliability of VCTE, Agile 3+, Agile 4, FIB-4, APRI, LiverPRO, CORE score, ELF and LiverRisk score in the following clinical scenarios: Cohort I: n = 52 patients with hepatic steatosis and metabolic dysfunction. Cohort II: n = 146 patients undergoing liver biopsy for suspected hepatic fibrosis. Cohort III: n = 45 patients with clinically significant portal hypertension undergoing repeated hepatic venous pressure gradient (HVPG) measurement to assess response to non-selective betablockers.
Laboratory parameters and VCTE were measured in fasting condition on the same day within 14 days (cohort I), 90 days (cohort II) and 28 days (cohort III). We used intraclass correlation coefficient (ICC) to study agreement, and quantified the minimal detectable change (MDC, i.e., minimal difference exceeding measurement error with 95% confidence) with the absolute and relative repeatability coefficient.
Results: Median VCTE was 5.3 kPa (IQR: 4.4–5.9), 10.5 kPa (9.1–14.2) and 55.7 kPa (32.9–75.0) in cohorts I, II and III. All NITs exhibited good to excellent agreement, with the lowest ICC for VCTE and highest for FIB-4: VCTE 0.623–0.846, Agile 3+ 0.704–0.889, Agile4 0.672–0.887, FIB-4 0.898–0.957, LiverPRO 0.900–0.955, CORE 0.652–0.935, LiverRisk score 0.924 (cohort I), and ELF 0.875 (cohort II). The MDC (original scale) in cohorts I, II and III was: 2.1/6.6/32.6 kPa for LSM; 8.6/11.5/4.1% for Agile 3+; 2.0/8.7/17.4% for Agile 4; 0.21/0.22/2.62 points for FIB-4; 6.2/5.0/19.0% for LiverPRO; 0.4/1.4/11.9% for CORE; 0.59 for LiverRisk score (cohort I); 0.64 points for ELF (cohort II). On a relative scale, this translated into a MDC of 38.3/88.3/70.8% for LSM; 93.3/124.9/4.3% for Agile 3+; 137.5/178.2/26.6% for Agile 4; 20.6/35.8/38.5% for FIB-4; 53.1/45.7/40.6% for LiverPRO; 83.0/104.8/100.9% for CORE; 11.8% for LiverRisk score (cohort I), and 12.3% for ELF (cohort II).
Conclusion: Despite strong agreement across NITs, their MDC - both absolute and relative - varies significantly with disease severity and clinical context. This underscores the critical need to account for specific settings and background disease populations when interpreting disease dynamics over time, as universal rules for NIT interpretation are not applicable. In screening settings, thresholds for meaningful changes may exceed >6 kPa (>70%) for VCTE, >0.2 (>35%) for FIB-4, and >0.65 (>12%) for ELF.

WED-510
Repeated transient elastography measurements for the assessment of liver fibrosis

Niv Zmora[1], Sharon Levy[1], Liane Rabinowich[1], Oren Shibolet[1], Helena Katchman[1]. *[1]Tel Aviv Sourasky Medical Center, Tel Aviv, Israel*
Email: nivz@tlvmc.gov.il

Background and aims: The advent of non-invasive tools to evaluate liver fibrosis has dramatically reduced the need for liver biopsies. Apart from the obvious benefit of being a non-invasive procedure, transient elastography is aimed at reducing sampling error attributed to liver biopsy, owing to the ability to evaluate a significantly larger area of liver tissue. Correspondingly, most liver diseases feature well established spatial heterogenicity, pointing to a potential benefit for multiple areas of evaluation by transient elastography. While the Baveno VI Consensus recommended performing two measurements on different days to avoid false-positive results, this issue has not been specifically addressed in the succeeding Baveno VII workshop, and currently only one liver stiffness measurement (LSM) is performed during an examination in most centers. We sought to evaluate, whether simultaneous transient elastography measurements in duplicates or triplicates may result in clinically significant discrepancies in the evaluation of liver fibrosis, which can be overlooked using a single measurement.
Method: FibroScan tests reports have been retrospectively retrieved from the Tel-Aviv Sourasky Medical Center repository between the years 2006–2020. Patients whose diagnoses were not specified, or tests in which only one measurement was performed, were excluded from analysis.
Results: Within the study period 16,000 FibroScan tests were performed, of which 8,438 were eligible for analysis. LSM was performed in duplicates in 2,695 (31.94%) and in triplicates in 5,743 (68.06%) of the examinations. 3,901 (46.2%) examinations were performed on female patients and the mean age was 60.53 (±13.87). Etiologies shifted in proportions throughout the study period: between 2006–2012 HCV constituted 75.31% of the examinations and MASH only 9.16%, while between 2013–2020 HCV proportions dropped to 46.30% and MASH increased to 36.00%. Discordance between liver stiffness measurements, which resulted in assignment into different fibrosis grades was observed in 2,205 (26.13%) tests, of which 1,831 (83.04%) exhibited a gap of one category, 331 (15.01%) exhibited a gap of two categories and 43 (1.95%) exhibited a gap of three categories. Most cases of discrepancies were observed in results within the spectrum of F1–2 (44.85%), however in 37.55% of cases discrepant results spanned between mild (F1–2) to advanced (F3–4) fibrosis. The proportions of discordant measurements were etiology-dependent, and ranged from 9% for alcoholic liver disease to 35% for autoimmune hepatitis.
Conclusion: Evaluation of multiple liver areas, rather than a single measurement, in liver transient elastography can potentially detect cases of clinically significant misclassification in fibrosis grade. Means to technically optimize measurements and reconcile discrepancies warrant further studies.

WED-511
FIB-4 for identifying chronic liver disease patients requiring HCC surveillance

Jan Embacher[1,2], Georg Semmler, Mathias Jachs, Lorenz Balcar, Paul Thöne[1,2], Christian Sebesta[1,2], Nina Dominik[1,2], Georg Kramer[1,2], Benedikt Hofer[1,2], Lukas Hartl[1,2], Benedikt Simbrunner[1,2], Bernhard Scheiner[1,2], Matthias Pinter[1], Michael Trauner, Thomas Reiberger, Mattias Mandorfer. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria*
Email: jan.embacher@meduniwien.ac.at

Background and aims: The fibrosis-4 (FIB-4) score is a non-invasive tool developed to estimate the risk for liver fibrosis. Patients with compensated advanced chronic liver disease (cACLD), as defined by a liver stiffness measurement (LSM) ≥10 kPa, are at increased risk for clinically significant portal hypertension (CSPH) and hepatocellular carcinoma (HCC). A FIB-4 score ≥1.75 has been shown to be the equivalent of the LSM cACLD cut-off in tertiary care settings. However, the utility of FIB4 ≥1.75 for identifying those requiring HCC surveillance remains uncertain. This study aims to investigate whether the FIB-4 score is similarly predictive of *de-novo* HCC as compared to LSM, and explore possible thresholds for HCC surveillance.

Method: We retrospectively analyzed 6,143 patients with (suspected) chronic liver disease (CLD) who underwent both FIB-4 and LSM assessments at a tertiary care center. The baseline was defined as the first FIB-4 and LSM assessment. Patients were stratified into two groups: FIB-4 <1.75 (~LSM<10 kPa; n = 4404) and FIB-4 ≥1.75 (~LSM≥10 kPa, n = 1739) as well as FIB-4 <2.67 (~LSM<15 kPa; n = 5245) and FIB-4 ≥2.67 (~LSM≥15 kPa, n = 898).
Results: Patients with FIB-4 ≥1.75 were significantly older (mean age: 57.4 years vs. 44.6 years, p < 0.001) and were more commonly male (62.0% vs. 53.0%, p < 0.001). Viral hepatitis (60.9% vs. 47.8%, p < 0.001) and alcohol-related liver disease (11.0% vs. 3.7%, p < 0.001) were more frequent in the FIB-4 ≥1.75 group, while metabolic dysfunction-associated steatotic liver disease was more common in the FIB-4 <1.75 group (34.4% vs. 15.9%, p < 0.001). The median follow-up duration was 55.4 months, with 91 individuals developing HCC, 41 undergoing liver transplantation, and 526 deaths. Time-dependent ROC analysis showed that FIB-4 is an accurate predictor of de-novo HCC within one (AUC: 0.79, 95%CI: 0.65–0.94), two (AUC: 0.85, 95%CI: 0.76–0.94), and three years (AUC: 0.87, 95%CI: 0.81–0.92), which was similar to LSM (at year 1: AUC: 0.78, 95%CI: 0.62–0.93; year 2: AUC: 0.86, 95%CI: 0.76–0.96; year 3: AUC: 0.85, 95%CI: 0.80–0.91). The 3-year cumulative incidence rates were 0.13% vs. 2.28% (0.05 vs. 0.75/100 person-years) and 0.29% vs. 3.34% (0.09 vs. 1.13/100 person-years) for those with FIB-4 <1.75 vs. ≥1.75 and FIB-4 <2.67 vs. ≥2.67, respectively. A higher incidence of HCC within 3 years was observed in the FIB-4 ≥1.75 group (SHR: 15.8 for HCC, 95% CI: 6.2–40.6) and for the FIB-4 ≥2.67 group (SHR: 11.8 for HCC, 95% CI: 5.9–23.5).
Conclusion: In patients with CLD, the FIB-4 score is similarly predictive of *de-novo* HCC, as compared to LSM, indicating that LSM for staging fibrosis is not needed to identify those at-risk/in whom HCC screening is indicated. Thresholds of FIB-4 ≥1.75 (equivalent to ≥10 kPa) and ≥2.67 (equivalent to ≥15 kPa) may identify the target population for HCC surveillance, depending on health care systems' pay policies and cost-effectiveness considerations.

Email: joan.genesca@vallhebron.cat

Background and aims: In people with compensated advanced chronic liver disease (cACLD), clinically significant portal hypertension (CSPH) may be screened by using non-invasive criteria (Baveno VII). However, these rules leave a substantial proportion of unclassified individuals, especially those with obesity and metabolic dysfunction-associated steatohepatitis (MASH). The ANTICIPATE models (ANTICIPATE and ANTICIPATE-NASH) can predict the risk of CSPH and could improve the screening of CSPH. Our objective was to validate Baveno VII criteria and refine them by using the ANTICIPATE models.
Method: We conducted a systematic review of studies designed to validate Baveno VII criteria of CSPH in Medline, WoS, Google Scholar and Embase. The search strategy was "CSPH" (AND) "Baveno VII," reaching from the Baveno VII consensus till December 2023. We performed a meta-analysis of Baveno VII criteria (rule-in: LSM (liver stiffness measurement) ≥25 kPa and rule-out: LSM ≤15 kPa and platelets ≥150×10^9/L). We further used individual patient data to assess performance by etiology. We also explored the use of different values of risk of CSPH of the ANTICIPATE models for a positive (PPV) and negative (NPV) predictive value of ≥90%.
Results: We identified 566 reports, with a final selection of 5 studies accounting for 1433 cACLD patients (prevalence of CSPH 34% to 62%) with different etiologies, including hepatitis C, hepatitis B, alcohol-related liver disease, MASH, and a heterogeneous group of mixed etiologies, MetALD and cholestatic diseases. LSM ≥25 kPa had an excellent PPV (92%) pooled by studies and in all etiologies, except in MASH individuals with obesity. We identified a value of ≥75% risk of CSPH by the ANTICIPATE models as the most adequate threshold for ruling-in, with a pooled PPV of 94%, improving prediction in MASH-obesity (from 0.67 to 0.83; p < 0.001), with a parallel increase in patients classified as having CSPH from 40% to 45% and a 5% reduction of unclassified patients. The pooled NPV for the rule-out criteria (LSM ≤15 kPa and platelets ≥150×10^9/L) was of 99%, without differences across different etiologies.
Conclusion: Baveno VII criteria for CSPH adequately classify all patients, except patients with obesity and MASH. Using a ≥75% risk threshold by ANTICIPATE models to detect CSPH improves the global diagnostic performance, especially in obese MASH patients, supporting its implementation.

WED-513
Role of liver and spleen stiffness in predicting hepatic decompensation following transarterial chemoembolization in patients with hepatocellular carcinoma

Chidkamon Pattarawongpaiboon[1], Panarat Thaimai[2], Nipaporn Siripon[2], Salisa Wejnaruemarn[2], Prooksa Ananchuensook[2], Sombat Treeprasertsuk[1], Piyawat Komolmit[2], Kessarin Thanapirom[2]. *[1]Division of Gastroenterology, Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [2]Division of Gastroenterology, Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Center of Excellence in Liver Fibrosis and*

Cirrhosis, Chulalongkorn University, Excellence Center in Liver Diseases, King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand
Email: kessarin.t@chula.ac.th

Background and aims: Transarterial chemoembolization (TACE) may influence portal pressure in patients with hepatocellular carcinoma (HCC). Liver and spleen stiffness measurements (LSM and SSM) have emerged as promising tools for assessing portal hypertension. However, limited data exist regarding the effects of TACE on LSM and SSM. This study aims to evaluate the impact of TACE on LSM and SSM and to assess the association between LSM and SSM values and the development of hepatic decompensation within six months following TACE.
Method: This study prospectively enrolled consecutive patients with HCC who underwent TACE. All patients were assessed for LSM and SSM using two-dimensional shear wave elastography (Supersonic Imaging) at baseline, 10 days, and 30 days after TACE. Hepatic decompensation was defined as a composite endpoint, including ascites, variceal bleeding, and overt hepatic encephalopathy.
Results: A total of 93 patients with HCC were included: 28 (30.1%) had Barcelona-Clinic Liver Cancer (BCLC) stage A, 58 (62.4%) had BCLC stage B, and 7 (7.5%) had BCLC stage C. The mean LSM remained unchanged from baseline to day 10 and day 30 after TACE, with values of 26.4 ± 17.0, 26.2 ± 16.6, and 25.4 ± 16.8 kilopascals (kPa), respectively ($p \geq 0.05$). Similarly, mean SSM did not show a significant change from baseline (39.8 ± 17.4 kPa) to day 10 (37.3 ± 15.6 kPa) or day 30 (42.2 ± 16.7 kPa). Significant increases in LSM and SSM (≥10% from baseline) were observed in 30.1% (n = 28) and 25.8% (n = 24) of patients on day 10, and 32.3% (n = 30) and 47.3% (n = 44) on day 30. During the six-month follow-up, 14 (15.1%) patients developed hepatic decompensation. Patients who experienced decompensation had significantly higher baseline LSM (41.0 ± 18.7 vs. 23.8 ± 15.4 kPa, $p < 0.001$) and SSM (55.0 ± 19.3 vs. 37.1 ± 15.7 kPa, $p < 0.001$) compared to those without decompensation. Multivariate analysis identified HCV infection [adjusted Odds Ratio (aOR) = 7.92, 95% CI: 1.04–60.50, p = 0.03], Child-Pugh score (aOR = 2.69, 95% CI: 1.34–5.43, p = 0.006), and baseline SSM (OR = 1.06, 95% CI: 1.01–1.10, p = 0.01) as independent predictors of hepatic decompensation following TACE. Baseline SSM demonstrated good predictive accuracy for liver decompensation, with an area under the receiver operating characteristic curve (AUROC) of 0.76 (95% CI: 0.60–0.91, $p < 0.001$). A baseline SSM > 60 kPa yielded 89.2% accuracy, with 57.1% sensitivity, 94.9% specificity, a 66.7% positive predictive value, and a 92.6% negative predictive value for predicting hepatic decompensation within six months of TACE. Baseline LSM or SSM were not associated with post-TACE syndrome.
Conclusion: TACE did not affect LSM and SSM. Baseline SSM was identified as an independent predictor of hepatic decompensation following TACE, particularly in patients with SSM > 60 kPa. These findings highlight the potential role of SSM for risk stratification for HCC patients undergoing TACE.

WED-514
Prediction of esophageal varices in fontan associated liver disease (FALD)

Victoria Kusztos[1], Mayank Sharma[2], Blake Kassmeyer[2], Ryan Lennon[2], Sudhakar Venkatesh[3], Meng Yin[3], Alexander Egbe[4], Patrick S. Kamath[2], Moira Hilscher[2], Douglas Simonetto[2].
[1]*Department of Internal Medicine, Mayo Clinic, Rochester, United States;* [2]*Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, United States;* [3]*Department of Radiology, Mayo Clinic, Rochester, United States;* [4]*Division of Cardiology, Mayo Clinic, Rochester, United States*
Email: simonetto.douglas@mayo.edu

Background and aims: Though up to half of patients with Fontan-associated liver disease develop esophageal varices, guidance on endoscopic surveillance is lacking. This study aimed to identify clinical features associated with presence of esophageal varices to aid in tailored surveillance for high-risk patients.
Method: We performed a retrospective cohort study using the Mayo Clinic Fontan Outcomes in Liver Disease database, which includes consecutive patients with Fontan physiology from 1984 to 2020. Patients were included if an esophagogastroduodenoscopy (EGD) was performed from January 1984 to July 2024. Laboratory values, imaging findings and hepatic hemodynamics within one year of EGD were analyzed. Odds ratios (OR) and 95% confidence intervals (CI) were calculated using logistic regression and a repeated measures model was used to account for patients with multiple EGDs. Multivariate analysis was performed with predictive variables.
Results: Among 113 patients meeting inclusion criteria, 211 EGDs were performed, 97 with varices detected and 114 without. There was no difference in type of heart defect (most common tricuspid atresia), sex, or median age at Fontan between the two groups. Majority of patients had portosystemic collaterals (96.1% of patients with varices and 94% without). In patients with varices, 18.6% were large and 81.4% were small. Two of 50 patients with varices developed variceal bleeding (4%). Alkaline phosphatase (ALP) level (OR 1.01, 95% CI 1–1.02, p = 0.005), total bilirubin (TB) (OR 1.05, 95% CI 1.04–1.05, $p < 0.001$), mean spleen size (14.9 cm vs. 13.7 cm, p = 0.023) and time from Fontan to EGD (OR 1.04, 95% CI 1–1.07, p = 0.031) were associated with presence of esophageal varices. A multivariate model combining these 4 variables showed a C-statistic of 0.88. No significant difference was found in hepatic venous pressure gradient (HVPG) (median 2.0 mmHg), Fontan pressure and platelet count.
Conclusion: Our findings identify a potential model leveraging noninvasive markers to identify patients with Fontan at risk for esophageal varices. While our model has demonstrated excellent performance, external validation is required. If validated, this tool may be used to tailor endoscopic surveillance in this at-risk population.

WED-515
Phase angle by BIA is useful for screening for malnutrition in patients with cirrhosis

Masafumi Haraguchi[1], Yasuhiko Nakao[1], Masanori Fukushima[1], Ryu Sasaki[1], Satoshi Miuma[1], Hisamitsu Miyaaki[1]. [1]*Department of Gastroenterology and Hepatology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan*
Email: mharaguchi@nagasaki-u.ac.jp

Background and aims: Malnutrition and sarcopenia are critical predictors of poor prognosis in patients with liver cirrhosis. Phase angle (PhA), derived from bioelectrical impedance analysis (BIA), is a non-invasive and simple parameter that reflects cellular membrane integrity and nutritional status. This study aimed to evaluate the utility of the PhA in screening for malnutrition and sarcopenia in patients with liver cirrhosis.
Method: This retrospective observational study included 224 patients with liver cirrhosis who were treated at our hospital between April 2019 and April 2023. Nutritional status was assessed using body mass index (BMI), serum albumin, zinc levels, and the presence of sarcopenia (based on the EWGSOP2 criteria). Malnutrition was defined by using the Geriatric Nutritional Risk Index (GNRI). Patients were randomly divided into training (n = 112) and validation (n = 112) sets. Correlations between PhA and nutritional indicators were analysed in the training set, and decision tree analysis was performed to identify the optimal PhA cut-off values for malnutrition screening. These cut-offs were validated using the validation datasets.
Results: In the training set, the median PhA was 4.6 in males and 4.2 in females. PhA was positively correlated with all nutritional indicators in males and with BMI and albumin levels in females. Multivariate analysis identified PhA and Child-Pugh classification as independent factors associated with malnutrition. Decision tree analysis determined PhA cut-offs of 4.3 for males and 4.1 for females.

Malnutrition was observed in 51 patients (45.5%) in the validation set. Using the PhA cut-off values, the screening performance showed a sensitivity of 0.54, specificity of 0.75, positive predictive value (PPV) of 0.58, and negative predictive value (NPV) of 0.72.
Conclusion: PhA-based screening may be a useful tool for detecting malnutrition in patients with liver cirrhosis. PhA offers a simple and non-invasive approach to assess nutritional status, contributing to early intervention and management. Further studies with larger cohorts are required to validate these findings.

WED-516
Bile acids drive fibroblast activation, fibrogenesis, interstitial matrix fibrosis and outcomes in PSC
Morten Karsdal[1], Tom Hemming Karlsen[2], Mette Vesterhus[2,3], Andressa de Zawadzki[1], Lei Ling[4], Cory Kostrub[5], Pamela Vig[5], Diana Julie Leeming[1]. *[1]Nordic Bioscience, Herlev, Denmark; [2]Oslo University Hospital Rikshospitalet, Oslo, Norway; [3]University of Bergen, Bergen, Norway; [4]NGM Biopharmaceuticals, San Francisco, United States; [5]Mirum Pharmaceuticals, Foster City, United States*
Email: mk@nordicbio.com

Background and aims: Fibrosis often originates from an insult that damages epithelial and endothelial cells and activates chronic pro-inflammatory processes that impair the regular course of tissue repair. Fibrosis initial stages exhibit extensive remodeling of the basement membrane to allow immune cell recruitment and initiate a pro-inflammatory response that propagates to the interstitial layer of the extracellular matrix (ECM). In this process, fibroblast activation induces an excessive production of type I, III and VI collagens leading to fibrogenesis. Several drivers of fibroblast activation including TGF-beta have been reported. Bile acids have previously demonstrated to correlate with fibroblast activation marker PRO-C3 in biliary diseases, however, their role in fibrogenesis remains unclear. We aimed to investigate the relationship between bile acids and ECM formation and degradation markers during anti-fibrotic therapy (FGF-19) and related prognostic ability of fibroblast activities in PSC.
Method: Markers of fibroblast activation (nordicPRO-C3 from type III and nordicPRO-C6 from type VI collagen), fibrosis resolution (nordicCTX-III from MMP degraded crosslinked type III collagen), ECM remodeling (type VIII, XVI and XVIII collagen), the ELF score and bile acids were measured in serum from 62 patients with primary sclerosing cholangitis (PSC) at baseline (BL) and after 12 weeks treatment with Aldafermin (FGF-19))(NCT02704364), and in 167 PSC patients with 4 years transplant free survival. Spearman correlation coefficients (r) were obtained between bile acids and collagen biomarkers at BL, and between delta values reflecting the difference in levels of individual bile acids and PRO-C3 from BL to 12 weeks. Odds ratios for transplant free survival of PRO-C3 in tertiles were calculated.
Results: Aldafermin reduced the levels of hydrophobic bile acids, PRO-C3 and PRO-C6 after treatment, but not other collagen markers. Strong correlations ($r = 0.5$) were observed between bile acids and fibroblast activation marker PRO-C3, ECM degradation by CTX-III and the ELF score at BL. The correlation, post FGF19 therapy between PRO-C3 and bile acids, was borderline significant $r = 0.24$, $P = 0.08$. The correlation of conjugated bile acids, in particular glycine conjugated bile acids (cGCA), at baseline was very strong, (GCA, $r =$ of 0.62, $P < 0.0001$; GCDCA, $r = 0.55$, $P < 0.0001$) and notably, between delta cGCA and PRO-C3 was 0.33, $P > 0.0001$, as previous published. PRO-C3 was highly prognostic for outcome in PSC, with an odds ratio of 8.5 in the upper tertile ($P < 0.001$).
Conclusion: Fibroblast activation and collagen formation is important for outcomes in PSC. These data suggest that bile acids activate fibroblast driving fibrogenesis, and that lowering of bile acids attenuate the fibrotic drive. Lowering fibroblast activity may have positive effects on liver related outcomes in PSC.

WED-517
Weight dependent, weight independent and non-pharmacological effects on fibroblast activity in metabolic dysfunction associated steatotic liver disease (MASLD)
Kim Henriksen[1], Anne Christine Bay-Jensen[1], Diana Julie Leeming[1], Morten Karsdal[1]. *[1]Nordic Bioscience A/S, Herlev, Denmark*
Email: mk@nordicbio.com

Background and aims: Fibroblasts are activated by metabolic dysfunction and are a central component of liver function decline. Fibroblast activities, both type III and type VI collagen formation, have been shown to be highly prognostic for outcome of liver, heart and kidney related events in MAFLD populations. Fibroblast activity, may both be inhibited by weight dependent and independent mechanisms, which allows finding optimal combination treatments. Recent data showing that pharmacological interventions leading to a substantial weight loss can significantly improve MAFLD, and fibroblast activity, at least halting MASH progression. In similar context, weight independent mechanisms such as Resmiterom and FGF-19/21 mediated mechanisms also provide strong deactivation of fibroblasts. Weight loss has also been indicated to have negative impact on bone and muscle, and we need to investigate and understand the patient centric most optimal approach for detecting fibroblasts. To shed light on the effect of weight loss on other organs, we analyzed data from elderly subjects and investigated the relationship between weight loss and bone loss using the biomarker of bone resorption CTX-I. Additionally, we used recently published data on the liver fibrosis biomarker PRO-C3 and the cardiovascular marker PRO-C6, from both weight loss studies, and pharmacological interventions by Resmiterom, GLP-1 receptor agonists, and Survodutide.
Method: 806 subjects were included in the analyses. Their baseline age was 64 years, and the baseline BMI was 29 kg/m^2. The were categorized by baseline BMI (lean, overweight, obese) and two-year weight change (gain/loss ≥5%), and the changes in biomarkers were monitored and related to changes in CTX-1. A weight loss study using VLCD, and data from pharmacological interventions with Resmetirom, GLP1RA and Survodutide previously analyzed for changes in either PRO-C3 and PRO-C6.
Results: Non-pharmacological intervention led to a 30% decreased in PRO-C3, with no reduction in PRO-C6. Weight dependent pharmacological interventions lead to significant reductions in PRO-C3. Weight independent mechanisms such as FGF-21/19 led to large reductions in PRO-C3 and smaller reductions in PRO-C6. The bone resorption biomarker CTX-I increased 1.58-fold [95% CI 1.39, 1.81], 1.37-fold [1.28, 1.47] and 1.11-fold [0.95, 1.28] in the weight loss, stable and weight gain groups.
Conclusion: Pharmacological and non-pharmacological induction of weight loss results in different deactivation of fibroblasts activities, which may have divergent efficacy on heart and liver related outcomes. Furthermore, weight dependent and independent mechanisms of deactivation fibroblasts may result in additional effects on bone and muscle. This understanding may be needed when designing the optimal intervention strategy, including possible combination regimens, for the individual MAFLD patient.

WED-518
Comparing ultrasound and magnetic resonance imaging for hepatocellular carcinoma screening in high-risk populations: a systematic review and meta-analysis of prospective cohorts
Pedro Passos[1], Valbert Costa Filho[2], Mariana Noronha[2], Michael Pavlides[3], Rodrigo Motta[4]. *[1]Centre of Research and Drug Development, Federal University of Ceara, Fortaleza, Brazil; [2]Biomedical Research Centre, Federal University of Ceara, Fortaleza, Brazil; [3]Translational Gastroenterology and Liver Unit, University of Oxford, Radcliffe Department of Medicine, University of Oxford, Oxford NIHR Biomedical Research Centre, University of Oxford, Oxford, United Kingdom; [4]Translational Gastroenterology and Liver Unit, University of*

Oxford, Oxford, United Kingdom
Email: pedropassos@alu.ufc.br

Background and aims: Magnetic resonance imaging (MRI) is known for its higher accuracy in detecting hepatocellular carcinoma (HCC) compared to ultrasound (US). Despite this, guidelines recommend biannual HCC screening with US in cirrhosis patients due to its cost-effectiveness, availability, and non-invasiveness. Our meta-analysis aims to clarify the implications of choosing one modality over the other in routine HCC surveillance.
Method: We searched online databases for prospective cohorts in which the same participants were submitted to both US and MRI as screening for HCC. Per-patient sensitivity and specificity were calculated for each modality. To synthesize the test accuracy across studies, we employed a Bayesian bivariate random-effects model. Expected and predicted diagnostic metrics, as well as their 95% credible intervals (CrI), were then used for comparisons. A decision curve analysis (DCA) was performed to assess the clinical utility of each screening modality with the predicted diagnostic parameters, utilizing a simulated cohort of 1000 participants with a 5% prevalence of HCC.
Results: Four studies, with a total of 823 participants who prospectively underwent both US and MRI, were included. For MRI, the expected sensitivity was 77% (95% CrI: 34%–95%), with a predictive sensitivity of 73% (95% CrI: 1%–100%). The expected specificity for MRI was 92% (95% CrI: 61%–98%), and the predictive specificity was 88% (95% CrI: 13%–100%). For US, the expected sensitivity was 50% (95% CrI: 10%–92%), with a predictive sensitivity of 50% (95% CrI: 0%–100%). The expected specificity for US was 86% (95% CrI: 35%–98%), and the predictive specificity was 81% (95% CrI: 1%–99%). In DCA, MRI demonstrated a higher net benefit than US across all threshold probabilities. The net benefit for US screening dropped to zero at a 12% threshold, while MRI maintained a non-zero net benefit up to a 24% threshold. Based on the predictive accuracy, we estimated that for each 100 screenings in a high-risk (5%) population, 18 individuals without HCC are misclassified as having HCC by US, and 11 by MRI. Additionally, 3 HCC-bearing individuals are misclassified as negative by US, and 1 by MRI. The predictive positive predictive value for MRI in a high-risk population (5%) was 24% (95% CrI: 0%–95%), and for US, it was 12% (95% CrI: 0%–100%). The negative predictive value for MRI was 98% (95% CrI: 71%–100%), while for US, it was 97% (95% CrI: 9%–100%).
Conclusion: This meta-analysis demonstrates that MRI offers superior accuracy compared to US for HCC screening. MRI was more effective in ruling-in HCC and had lower false-positives, which may prove to be cost-effective when applied to populations with high incidence. US displayed considerable variability in its performance, highlighting its potential limitations for HCC screening.

WED-520
Prognostic utility of serum ammonia in cirrhosis: a systematic review and meta-analysis

Yevedzo Ntuli[1], Christopher Harlow[2], Thomas Tranah[2], Ellis Paintsil[1], Victoria Kronsten[2], Alexandra Frolkis[2], Chiara Mangini[3], Debbie L. Shawcross[1]. *[1]King's College London, London, United Kingdom; [2]King's College Hospital, London, United Kingdom; [3]University of Padova, Padova, Italy*
Email: yevedzontuli@gmail.com

Background and aims: There is conflicting evidence regarding the prognostic utility of serum ammonia in patients with cirrhosis. This systematic review and meta-analysis evaluate its ability to predict mortality as a primary outcome in patients with stable cirrhosis, acutely decompensated cirrhosis and acute-on-chronic-liver-failure (ACLF). Secondary outcomes included all cause decompensation and progression to ACLF.
Method: The protocol was registered on PROSPERO (CRD42024567671). Comprehensive searches of Medline, Embase, Scopus, Web of Science and Pubmed were performed with no limits on publishing period on 02/05/2023 and updated on 10/07/2024. Two reviewers independently screened studies from abstract to full text, that included adult patients with cirrhosis of any aetiology. Studies involving acute liver failure, liver transplantation or single decompensation events as a secondary outcome were excluded. Data extraction was conducted using the Checklist for Critical Appraisal and Data Extraction for Systematic Reviews of Prediction Factor Studies (CHARMS-PF) and a risk of bias assessment was made using the Quality in Prognostic Factor Studies (QUIPS) checklist.
Results: Forty-three studies were included in the final review, of which 31 provided useable data for meta-analysis of hazard ratios (HR) using a random effects model. The pooled HR for all stages of cirrhosis (n = 8480) was 1.12 (95% CI 1.04–1.21), with significant heterogeneity. (I^2 = 92.2% (95% CI 90.0–93.9). Subgroup analysis using a fixed effects model showed no significant difference in effect estimate among the three cirrhosis groups. However, ammonia predicted a significantly higher risk of mortality in studies including participants with a Model for End Stage Liver Disease score less than 16, compared to those with a higher score (p = 0.0405). Multiple meta regression revealed that cirrhosis category, study size, survival outcome definition and ammonia handling in statistical models accounted for 51% of the heterogeneity (p = 0.0017).
Conclusion: Serum ammonia is a modest, yet significant biomarker for predicting mortality in cirrhosis, and this may have greater utility in patients with less severe disease at baseline. Future studies should standardize survival definitions and statistical models to reduce heterogeneity and improve comparability.

Health-related quality of life, events of decompensation and mortality – effectiveness of the quality liver nursing care model

Maria Hjorth[1,2], Daniel Sjöberg[1], Anncarin Svanberg[3], Elenor Kaminsky[2], Riccardo LoMartire[1,4], Fredrik Rorsman[3]. *[1]Centre for Clinical Research in Dalarna, Uppsala University, Falun, Sweden; [2]Department of Public Health and Caring Sciences, Uppsala University, Uppsala, Sweden; [3]Department of Medical Sciences, Uppsala University, Uppsala, Sweden; [4]School of Health and Welfare, Dalarna University, Falun, Sweden*
Email: maria.hjorth@regiondalarna.se

Background and aims: Patients with cirrhosis report difficulties in understanding how to cope with their disease. Registered nurse involvement has potential to improve the quality of outpatient cirrhosis care. The benefit of nursing care on health-related quality of life (HRQoL), incidence of decompensation and mortality is scarcely studied. The primary aim of this study was to compare HRQoL in patients receiving either standard medical outpatient care or adjunctive registered nurse-based Quality Liver Nursing Care Model (QLiNCaM) intervention. Secondary aims were to compare decompensation events and mortality.
Method: A pragmatic, multicentre randomised controlled study (www.clinicaltrials.gov NCT02957253) involving six Swedish hepatology outpatient clinics in Sweden. One hundred and sixty-seven participants were allocated to either standard medical care or adjunctive registered nurse-based intervention (QLiNCaM), which was based on person-centred care and Orem's self-care theory of nursing. HRQoL was measured with RAND-36, of which the physical and mental component scores were compared between the study groups in a linear mixed-effects model for repeated measures. Primary and secondary outcomes were assessed after 12 and 24 months.

Results: Differences of the physical and mental component scores of RAND-36 after 24 months were non-significant between the groups (−1.1, p = 0.53; and −0.7, p = 0.67, respectively). There was also no difference in numbers of decompensation events (p ≥ 0.05), but, the intervention reduced the time for identification of a decompensation event with 112 days. After 24 months, mortality was three times higher in the control group compared to the intervention group (12 *vs* 4, p = <0.05).
Conclusion: Adjunctive nurse-led care was not superior to standard medical outpatient care concerning HRQoL, malnutrition or decompensation. Nevertheless, RN involvement reduced the time for identification of decompensation and mortality.

Allied health professionals are essential for facilitating initial evaluation and optimisation of patients for liver transplantation

Katie McCollum[1], Nuala Ryan[1], Rachel Westbrook[1], Sujit Mukherjee[1], Stephanie Mansell[1], Liz Shepherd[1], Deirdre Sexton[1], Abigail Greenwell[2]. *[1]Royal Free Hospital, London, United Kingdom; [2]Royal Free NHS Hospital, London, United Kingdom*
Email: abigailgreenwell@nhs.net

Background and aims: Assessment for Liver Transplantation (LT) involves a multi-disciplinary approach where allied health professionals (AHP) undertake evidence-based approaches to assess risk and suitability for LT and give individualised advice to allow optimisation of their candidacy.
Method: A multidisciplinary assessment clinic (MAC) at our centre (physiotherapist, dietician, specialist nurse in drug and alcohol misuse, hepatologist and anaesthetist) provides evaluation of patients referred for consideration of LT where concerns around frailty, fitness and alcohol history are raised. Data were collected on sequential patients seen in the MAC between June 2022 and May 2023, to include evaluation (hand grip strength (HGS), Liver frailty Index (LFI), alcohol relapse risk), outcome and where appropriate subsequent listing outcome.
Results: Seventy-six patients were seen (50-male), median age 58-years. Aetiology was alcohol (54%), MASLD (16%), Autoimmune (16%), viral (6%) and other (8%). Indications for assessment were decompensated cirrhosis (82%), HCC (5%), variant syndromes (13%). Of the patients seen in the MAC, 26/76 (29%) did not see an AHP. Reasons included no indication, absolute contraindication or advanced palliative stage of disease. These 26 patients did not proceed on a LT pathway. Fifty patients thus underwent full evaluation by AHP's in the MAC following which 22/50 (44%) were booked directly for LT workup of which 19/22 (86%) proceeded to be listed for LT. Between initial MAC and LT workup, LFI and HGS improved significantly, with mean improvement of −0.43 (p < 0.05) and 8.8 KG (p < 0.05) respectively. Twenty-eight patients were deemed to be either too frail or too high risk from an alcohol perspective to proceed to LT work up. After a median time of 17-weeks (range 5–46 weeks), 36% (n = 10/28) improved sufficiently to proceed to LT workup, of which 7/10 were subsequently listed. LFI and HGS improved significantly over this period with mean improvement of −0.45 (p < 0.05) and HGS 9.8KG (p < 0.05) respectively, and subjective alcohol relapse risk reduced.
Conclusion: This data highlights that a MAC approach allows optimisation and identification of patient for LT as evidenced by, identification and optimisation of those patients suitable for immediate LT work up result in high listing proportion (86%); optimisation to facilitate listing of patients deemed initially to be too frail for work-up (35%) and finally aid identification of those patients in which a full LT work-up would be futile (29%). The clinic thus ensures timely and appropriate management plans, intensive optimisation where appropriate and cost saves on futile LT work up. Our centre feels this should be considered as the gold standard for candidacy for LT work up.

THU-497
The challenge of adherence in Wilson disease: a prospective study

Anna Miralpeix[1], Montserrat Rodríguez[2], Núria Fabrellas[3], Mercè Torra[4], Anna Pocurull[5], Xavier Forns[6], Zoe Mariño[7]. *[1]Liver Unit, Hospital Clínic, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer, Facultat d'Infermeria, Escola de Doctorat, Universitat de Barcelona, Barcelona, Spain; [2]Pharmacy Service, Hospital Clínic, Barcelona, Spain; [3]Facultat d'Infermeria, Escola de Doctorat, Universitat de Barcelona, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer, Centro de Investigación Biomédica en Red, Enfermedades hepáticas y digestivas (CIBERehd), Barcelona, Spain; [4]Biochemistry and Molecular Genetics Service, Hospital Clínic, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer, Barcelona, Spain; [5]Liver Unit, Hospital Clínic, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer, Barcelona, Spain; [6]Liver Unit, Hospital Clínic, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer. Centro de Investigación Biomédica en Red, Enfermedades hepáticas y digestivas (CIBERehd), Facultat de Medicina i Ciències de la Salut, Universitat de Barcelona, Barcelona, Spain; [7]Liver Unit, Hospital Clínic, Institut d'Investigacions Biomèdiques Agustí Pi i Sunyer. Centro de Investigación Biomédica en Red, Enfermedades hepáticas y digestivas (CIBERehd), Facultat de Medicina i Ciències de la Salut, Universitat de Barcelona. European Reference Network on Rare Liver Disorders (ERN-RARE Liver), Barcelona, Spain*
Email: amiralpeix@recerca.clinic.cat

Background and aims: Wilson disease (WD) is a rare genetic disorder that promotes copper accumulation in the body, which can lead to hepatic and neurological symptoms and heterogeneous phenotypes. Despite the availability of effective drugs for copper control, which must be taken daily and lifelong, some studies have shown decreased compliance in a significant proportion of WD patients, being this fact related to worse clinical outcomes. Our aim was to assess pharmacological compliance among WD patients in our setting and aid in designing individualized educational interventions.
Method: Prospective, single-center study, including patients with confirmed WD followed at the Liver Unit, Hospital Clínic (Barcelona) and a signed informed consent form. Specific nursing visits were scheduled to assess self-reported adherence (by means of the validated ARMS-e questionnaire) and develop an individualized educational intervention according to the score. Objective adherence data were also obtained from the Pharmacy Service dispensing records at a blinded manner. Low adherence was defined as ARMS-e score ≥16 or medication uptake ≤80%.
Results: 50 WD patients were included: 52% female, median age 38 (IQR 29–47) years, median time since diagnosis 19 (IQR 13–28) years, 70% with hepatic phenotypes. 50% of patients received treatment with chelators and 50% with zinc, with a median current treatment duration of 12 (IQR 2–20) years. According to the ARMS-e questionnaire, 21 patients (42%) reported low adherence mainly associated to medication intake; treatment collection was not reported as a major concern. We observed no statistical differences on adherence according to type/ duration of treatment, phenotype or educational level. Low adherence was associated with higher levels of ALT (p = 0.015) and exchangeable copper (p = 0.058), suggesting poorer metabolic control. According to pharmacy records, 14 patients (31%) were objectively classified as low compliant (≤80% registered collection). No concordance was detected between the two adherence assessments (ARMS-e vs pharmacy records, p = 0.197).
Conclusion: At least one third of our WD patients show low adherence to medication and this seem to be related with worse copper control. No concordance was detected between the two prospective adherence assessments, outlining the limitations of both strategies. These results support the need to design educational tools among these patients, which we have implemented in the nursing practice.

THU-498-YI

Demonstration of the success of a nurse led service surveying for hepatocellular carcinoma and other cirrhosis associated complications

Amy Thatcher[1], Vijay Grover[1], Jennifer Finn[1]. [1]*The Hillingdon Hospital, London, United Kingdom*
Email: amy.thatcher@nhs.net

Background and aims: Hillingdon Hospital hepatology service is predominantly nurse led, comprising one consultant hepatologist, three Clinical Nurse Specialists (CNS) and one Hepatology Assistant Practitioner (HAP). >5000 patients are managed in the Hepatology department annually. Of those, approximately 30% require six monthly Hepatocellular Carcinoma (HCC) surveillance due to the increased risk of HCC with their underlying liver condition. We assessed whether HCC surveillance intervals were being met within National Institute for Clinical Excellence (NICE) guidelines across the CNS, consultant and registrar (SPR) out-patient Hepatology Clinic. We also reviewed requesting rates for gastroscopies for variceal surveillance and bone health (DEXA).
Method: May–August 2024 data for: Clinic date, aetiology, clinician, whether HCC surveillance was required and whether ultrasound (USS), gastroscopy and DEXA had been requested/performed. USS 'did not attend' (DNA) data sourced by radiology to compare against Hepatology figures. HCC diagnoses between this time sourced from the cancer team.
Results: Of 1197 patients reviewed in a three-month period, 30% (362) required HCC surveillance. 86% (311) of those requiring surveillance were seen by the CNS, 8% (29) by SPR and 6% (20) by consultant. In the SPR clinic 68% had an USS requested prior to the planned due date, 83% in the consultant clinic and 98% in the CNS clinic (results for 86% were available in planned clinic review). Six HCC's were detected during this period, four during clinic surveillance, two on inpatients (66% were surveillance detected). The Hepatology USS DNA rate over a five-month period was 27%, versus a total out-patient USS DNA rate across the hospital of just 3%. Of the patients who required and consented to a gastroscopy: 99% requesting rate by CNS, consultant 100% and SPR 77%. 275 patients required a DEXA, only 55% were requested. Out of 97 completed DEXA's, 57% had low bone density. Thus, a 'wash-up' clinic established: HAP filtered through the clinicians' clinics to ensure the appropriate tests have been requested after each clinic. Where gaps were identified, the CNS has since requested all appropriate tests to ensure patient safety.
Conclusion: >30% of patients in the SPR clinic had a delay in their HCC surveillance and 22% a delay in variceal surveillance. HCC surveillance and other cirrhosis related investigations are more likely to be requested from the nurse-led clinic, in line with NICE guidelines. The USS DNA rate is significantly higher for Hepatology compared to all hospital requests, which can lead to further delays in surveillance, thus USS DNA rates will be addressed locally to improve adherence. The overall requesting rate for DEXA was suboptimal within the department, thus the wash-up clinic will ensure a 100% requesting rate moving forward.

THU-499

Health-related quality of life in patients with chronic hepatitis D receiving bulevirtide and pegylated interferon: interim results from the SEE-D clinical trial

Annika Olsson[1], Susanne Cederberg[1], Karin Lindahl[1], Soo Aleman[1]. [1]*Karolinska University Hospital, Stockholm, Sweden*
Email: susanne.cederberg@regionstockholm.se

Background and aims: At the outpatient clinic of Infectious Diseases at Karolinska University Hospital, Sweden, approximately 150 patients with hepatitis D are under care. This study is part of the clinical trial SEE-D (EU 2023-504414-29-00), evaluating the treatment of hepatitis D with bulevirtide (BLV), pegylated interferon (peg-IFN), and nucleos(t)ide analogues. BLV and peg-IFN are administered as daily and weekly subcutaneous injections, respectively. Peg-IFN treatment is associated with frequent side-effects. We aimed to evaluate health-related quality of life (HRQOL) in patients receiving BLV and peg-IFN combination therapy.
Method: HRQOL was assessed using the Hepatitis Quality of Life Questionnaire (HBQOL) with 7 domains, RAND-36 with 8 domains, and the Fatigue Severity Scale (FSS). A total of 19 patients with advanced fibrosis or cirrhosis completed these questionnaires at baseline (BL) and treatment week 24 (w24). Interim data at w24 are presented. HRQOL scores are expressed as mean (±SD) values, and comparisons between BL and w24 were conducted using the Wilcoxon signed rank test. Subgroup analyses were performed for men and women.
Results: Baseline characteristics included a mean (±SD) age of 42.6 (6.7) years, with 60% men and 40% women, and a mean body mass index (±SD) of 25 (3.4) kg/m^2. Median (IQR) liver elasticity was 12.1 (8.6) kpa. Median HDV RNA level (log10) was 5.4 (5.5) IU/ml at BL, with 21.1% of patients achieving undetectable HDV RNA at w24. No statistically significant changes were observed in psychological well-being, anticipation anxiety, transmission concerns, vulnerability or viral response. However, vitality (HBQOL) significantly worsened, with scores increasing from 42.1 (22.8) at BL 48.4 (28.1) at w24 ($p = 0.048$). Stigma scores did not change significantly in the whole group, but men showed a significant improvement, decreasing from 36.5 (16.9) at BL to 27.4 (18.3) at w24 ($p = 0.046$). In RAND-36, significant improvements were noted in role limitations due to physical health, pain, social functioning and vitality (all $p < 0.05$), while physical functioning worsened significantly ($p = 0.02$). Improvements in vitality and pain were particularly pronounced in men. A borderline significant improvement in role limitations due to emotional problems was seen, with scores improving from 68.7 (46.3) at BL to 41.3 (44.9) at w24 ($p = 0.058$). Physical function (RAND-36) declined significantly, with more pronounced changes in women ($p = 0.02$). Significant worsening of fatigue could be shown in FSS, with worsening of mean 3.7 (1.9) to 4.3 ($p = 0.008$), driven primarily by significant worsening in women ($p = 0.03$).
Conclusion: Combination therapy with BLV and peg-IFN shows varying effects on HRQOL, with improvements in several domains, but worsening fatigue and physical functioning, particularly in women. More data are needed to guide targeted support during treatment.

THU-500

Community liver health checks are a valuable tool to support early diagnosis of liver disease

Bethia Featherstone[1], Amy Hicks[1], Faye Coite[1], Lynsey Corless[1]. [1]*Hull University Teaching Hospitals, Hull Royal Infirmary, Anlaby Road, Hull, United Kingdom*
Email: bethia.featherstone@nhs.net

Background and aims: A Community Liver Health Check (CLHC) pilot is being delivered in England via the National Health Service (NHS) Cancer Programme to address the rising incidence of liver cancer. Early detection of chronic liver disease and referral onto surveillance pathways is vital to diagnose liver cancer at an earlier, potentially treatable stage. 18 pilot sites across England were commissioned, with approaches individualised locally. We discuss our novel service using a Community Liver Specialist Nurse.
Method: The CLHC pilot offers a FibroScan to people considered 'at risk' of liver disease in various community settings (long-term excess alcohol intake; diabetes/obesity; previous exposure to viral hepatitis B/C). Our team consists of a Community Liver Nurse Specialist, a Community Liaison Officer and Consultant Hepatologist. All attenders are given liver health guidance and education. Anyone with a FibroScan reading ≥11.5 kPa is offered a second validatory scan within a 2–4 week period. Those with a repeat result of ≥11.5 kPa are referred into liver clinics to consider appropriate follow-up, including cancer surveillance. Further assessment, including liver screen blood tests

and ultrasound are arranged by the nurse specialist so the results are available at the time of Consultant review. Those with FibroScan result 8.5–11.4 kPa are offered a repeat scan in 12 months.
Results: Since April 2023, 2760 people underwent FibroScan. 8.1% (n = 223) had an elevated result; 4.5% (n = 125) were ≥11.5 kPa. After validation scan, 61/125 had confirmed cirrhosis (2.2% overall cohort), 19/125 (0.7%) improved to moderate fibrosis, 29/125 (1.0%) had a normal result and were discharged, and 16/125 (0.6%) await review. In addition to identification of undiagnosed cirrhosis, we identified one case of treatable hepatocellular carcinoma at initial ultrasound, one treatable renal cell carcinoma idenitified during surveillance, and cases of Hepatitis B and Primary Biliary Cholangitis via liver screen tests. 98 patients with moderate fibrosis have had a 12-month repeat scan. Of these, 2 (0.1% overall cohort) progressed to advanced fibrosis, and 30 (1.1%) had a normal result and were discharged.
Conclusion: The nurse-led service offers a unique approach to early identification of liver disease, aiming to improve outcomes, provide tailored, specialist-led education, and ensure smooth referral directly into secondary care. We found that a confirmatory scan is vital, to reduce the risk of unnecessary commitment to long-term surveillance. The prevalence of advanced fibrosis identified through the pilot suggests that thousands of people across the UK are likely to be living with undiagnosed liver disease, and we recommend ongoing expansion of the scheme, which should be accompanied by access to appropriate interventions to limit progression of liver disease.

THU-501-YI
Malnutrition, sarcopenia and inadequate dietary intake before liver transplant: a time for action
Brooke Chapman[1]. [1]*Austin Health, Melbourne, Australia*
Email: Brooke.chapman@austin.org.au

Background and aims: Malnutrition and reduced muscle strength are important prognostic indicators in liver transplantation (LT) leading to adverse waiting list and post-transplant outcomes. The period awaiting LT offers a crucial period for intervention for those requiring optimization. We aimed to describe nutritional parameters, dietary intake and functional muscle strength in a cohort of patients with decompensated cirrhosis referred for LT.
Method: Consecutive patients referred to our centre for LT in 2022–2023 were assessed by a specialist dietitian. Nutritional status (via subjective global assessment), handgrip strength (HGS), dietary energy (kcal) and protein intake were measured and compared to established nutritional targets.
Results: One hundred patients (54% male) with median age 55 years (IQR 45.5, 61.25) and MELD 24 (18, 26) were included. Seventy-four per cent of patients were malnourished (60% moderately malnourished, 14% severely malnourished) with median HGS 18.1 kg (14.4, 23.2) and 31.1 kg (26.4, 34.9) for females and males, respectively. Only 14% of patients had a HGS above their gender and age-matched normative value. Median dietary intake was 22.8kcal/kg (18.1, 26.6) for energy and 0.9 g/kg (0.7, 1.1) for protein; well below the recommended 35kcal/kg and 1.2–1.5 g/kg for this patient population. Only 17% of patients were meeting the lower end of protein requirements (>1.2 g/kg), whilst only 1 patient had a dietary protein intake greater than 1.5 g/kg.
Conclusion: Patients with decompensated cirrhosis referred for LT have a high prevalence of malnutrition and reduced functional muscle strength, contributing to sarcopenia and frailty in this population. Inadequate dietary intake appears to be universal. Aggressive nutritional prehabilitation in the period awaiting LT should be undertaken for all patients with decompensated cirrhosis referred for LT, with specific oral and enteral nutrition interventions aiming to bridge the significant gap between baseline dietary intake and elevated energy and protein targets.

THU-502
Non-weight-based ribavirin dosing for hepatitis E in immunosuppressed patients: a single-centre experience
Fatema Jessa[1], Naveenta Kumar[2], Douglas Macdonald[2]. [1]*Pharmacy Department, Royal Free London NHS Foundation Trust, London, United Kingdom;* [2]*Hepatology Department, Royal Free London NHS Foundation Trust, London, United Kingdom*
Email: fatema.jessa@nhs.net

Background and aims: Hepatitis E virus (HEV) can progress to chronic infection in immunosuppressed patients, causing morbidity and mortality. Whilst ribavirin (RBV) is not licensed for HEV treatment, it is used off-label in this context. Licensed dosing for RBV in hepatitis C (HCV) typically follows a weight-based approach, but optimal dosing for HEV patients remains unclear. This single-centre retrospective analysis evaluates the use of virologically and symptomatically guided RBV dosing in immunosuppressed patients focusing on dosing, duration, tolerability, and outcomes.
Method: Dispensing data from April 2017 to October 2024 were analysed to identify immunosuppressed patients treated with RBV for HEV. Clinical documentation and biochemistry were reviewed to assess RBV dosing, duration, tolerability, and virological response.
Results: 11 patients (mean age: 44.5 years, 55% male) received RBV for HEV. Of these, 73% (8/11) were transplant recipients on a median of 2.5 immunosuppressive agents; renal transplants accounted for 75% (6/8). There were 2 cases of donor derived HEV. 27% (3/11) were on/had recent immunosuppression for non-transplant indications. At treatment initiation, median ALT, AST, and bilirubin were 80 U/L (20–1477), 41 U/L (13–707), and 10 μmol/L (4–180) respectively. RBV was initiated at a median daily dose of 400 mg (100–1000) or 5.5 mg/kg (1.4–13.9). Dose was reduced if not tolerated and increased if there was a lack of response in HEV titres. Side effects included fatigue/tiredness (60%), anaemia/low Hb (50%), headache (40%), GI symptoms (30%) and insomnia or mood disorders (20%). Dose adjustments guided by virological and symptomatic responses were required in 70% of patients with 3 patients on a lower dose at completion. Median dose at completion was 400 mg (100–1000). 100% (10/10, 1 patient currently on treatment) of patients achieved viral clearance. Median treatment duration was 80 days (29–538). There was no significant correlation between median daily dose on initiation and treatment duration ($r = 0.49$, $p = 0.15$).
Conclusion: This tertiary centre experience demonstrates that reducing RBV dosage in the context of side effects and a virological response does not lead to breakthrough or relapse. HEV clearance can be achieved at doses much lower than those used in weight-based HCV therapy. Additionally, proactive symptom and response-guided RBV dose adjustments can achieve better tolerability without compromising outcomes.

THU-503
Internal consistency and diagnostic validity of SARC-F questionnaire in chronic liver disease patients with sarcopenia on liver transplant wait list
Ganesh Sankarrajan[1]. [1]*Memorial Hermann-Texas Medical Center, 6411 Fanin street, Houston, Texas, United States*
Email: ganeshsankarrajan@aol.com

Background and aims: The study investigated the utility of Sarcopenia-Functional (SARC-F) questionnaire, a subjective 5-item questionnaire to screen and rapidly diagnose sarcopenia in patients with chronic liver disease on liver transplant wait list. Internal consistency and reliability of the tool was examined based on the hypothesis that patients classified as frail, prefrail and robust using Liver Frailty Index (LFI) will score high, median and low on SARC-F tool. Diagnostic validity of the tool was examined using performance-oriented measures like Short Physical Performance Battery(SPPB) and LFI derived from balance score of SPPB, hand grip strength, and 5 rep sit to stand (5STS)test. The study also examined the association between frailty and frequency of hospitalization.

Method: 60 subjects (24 females, 36 males with avg Body mass Index 28.10, 31.89 and mean age 60, and 54 respectively) 54% alcoholic cirrhosis, 27% NASH cirrhosis and 19% (other) on wait list for liver transplant were part the study. After consent, subjects answered the 5-item questionnaire, and underwent hand grip measurements using JAMAR hydraulic dynamo-meter, physical performance measures using Short Physical Performance Battery.
Results: SARC-F questionnaire exhibited good internal-consistency reliability, with Cronbach's alpha of 0.82. Correlation between SARC-F and Liver frailty Index was statistically significant, with a positive Pearson co-relation (56) = 0.89, p = <0.001.Mean dominant HG(d) strength, 4 m gait speed test, 5 STS score were all low for Frail subjects 19.31 kg, 6.8 s, 42.62 s. prefrail and robust subjects had mean value of 28.60 kg, 5.6 s,13.59 s and 42.09 kg, 3.5 s, 9.7 s, respectively. The frequency of hospitalization (>3 times) was higher in frail subjects, as compared to prefrail and robust subjects.
Conclusion: SARC-F is a valuable tool in rapidly diagnosing sarcopenia exhibiting both internal consistency and diagnostic validity in these population. SARC-F score ≥4 indicated subjects were either Prefrail and Frail, in our study. The mean SARC-F score in Frail subjects in our study was ≥7. MELD score when combined with SARC-F score can assist transplant surgeons and transplant-hepatology team to make decisions to prioritize the transplant wait-list, with improved post-operative outcomes.

THU-504-YI
Negative consequences of screening for steatotic liver disease

Email: helle.lindholm.hansen@rsyd.dk

Background and aims: Steatotic liver disease is a major public health concern, making screening and early detection essential to prevent severe disease. While screening may promote positive lifestyle changes, it may also cause negative consequences of screening (COS): anxiety, shame and depression as seen in cancer screening. We aimed to describe whether screening for liver disease can inflict negative COS in the short- and long term. Further, we explored the impact of disease severity on negative COS.
Method: We screened individuals from the general population and a high-risk population using controlled attenuation parameter (CAP) and transient elastography (TE). Participants with TE ≥8 kPa were invited for a liver biopsy visit within 3 months. We used a modified version of COS used for lung cancer screening (COS-LC), sent to participants 7 days and 6 months post-screening. We used 7 themes: self-blame, symptoms, introvert, sleep, harm of behaviour, anxiety, and sense of dejection. We focused on "Self-blame" (blame, guilt, disappointment, and anger), using a four-point Likert scale (not at all, slightly, moderate, a lot). Frequency analysis and multinominal logistic regression were used to assess the association between TE and response categories.
Results: We screened 6,453 participants with a median age of 57 (IQR 52–63), 52% female. In total, 6.2% had TE ≥8 kPa. Response rates from baseline to day 7 and 6 months were 78–80% and 81–84% respectively. Overall the theme of self-blame faded over time. Moderate and high levels of "Blame" declined from 3.5% to 2.7%. High levels of anger persisted the most (2.9% at day 7 vs. 2.8% at 6 months). Most themes showed a reduction in negative COS over time, but moderate and high levels of "Harm of behaviour" and "Sense of dejection" increased at 6 months. When adjusting for age and gender, the odds of answering "a lot" in "Blame" is 3.6 higher for those with TE 6–8 kPa and 15.4 higher for those with TE ≥8 kPa compared to those with TE ≤6 kPa. At 6 months the odds are 2.4 and 7.4 respectively. This tendency is found for each of the themes on day 7 and persists at lower odds at 6 months.
Conclusion: Our findings reveal that while some negative COS diminish, others persist or even increase over time, particularly in individuals with higher TE. This underscores the need for targeted support to mitigate the psychological burden associated with those with advanced disease stages.

THU-509-YI
Improving clinical efficiency of Hepatology clinics by optimising patient adherence with blood test monitoring
Jennifer Finn[1], Vijay Grover[1], Amy Thatcher[1]. *[1]The Hillingdon Hospital NHS Foundation Trust, London, United Kingdom*
Email: jennifer.finn@nhs.net

Background and aims: Hillingdon Hospital's Hepatology service consists one consultant hepatologist, three clinical nurse specialists (CNS) and one hepatology assistant practitioner (HAP). The service has approximately 5,000 patients on the caseload, and through evolution is now predominantly a nurse-led service managing 87% of total reviews. Blood tests are a critical requirement for chronic liver diseases and timely bloods pave the way for effective patient management, guiding treatment decisions and identifying deterioration of their condition. Having identified low adherence with blood test monitoring for Hepatology outpatients we aimed to assess and improve this.
Method: Data collected between May–August 2024, inclusive of all clinic types – face to face (F2F), paper and telephone across four clinicians – hepatologist, CNS, HAP and registrar. Aetiology, ethnicity, attendance at F2F review and blood test completion, when required, were recorded. Data analysis focused on adherence to blood tests and whether this improved after two separate interventions, as well as evaluating local DNA (did not attend) rates across aetiology and ethnicities. Baseline data collected, first intervention (reminder letter), second intervention (reminder letter and text), each a one-month period.
Results: 1496 encounters analysed May–August 2024. 52% F2F (777) and 48% (719) virtual/telephone. CNS and HAP 87% of total reviews (639 F2F, 248 telephone and 423 paper). Hepatologist reviewed 7% (103) and registrar 6% (56). Virtual clinics: 91% (652) required bloods before review; 32% adhered at baseline. First intervention increased compliance to 43%, whilst second intervention increased compliance to 50% (chi square test for either intervention versus baseline $p < 0.05$). No statistical difference in uptake of blood tests between a paper and or paper/text reminder ($p > 0.05$). Over the three-month period compliance by ethnicity: Indian, Pakistani and Bangladeshi Asians 41%, Asian Chinese 61%, Asian other 37%, black African 31%, White British 48%, white other 40%, unknown 54%. Hepatology F2F clinics overall DNA rate 20%. 82% (382) attendance for new

appointments, 77% (242) for follow up appointments. Overall DNA rate by ethnicity: Indian, Pakistani, Bangladeshi Asian 22% (60), White British 15% (42), black African 27% (23), white other 17% (14), Asian other 20% (8), unknown 38% (5) and Asian Chinese 10% (1). 16% (125) of total F2F DNAs were for CNS/HAP clinic, 2% (16) registrar and 1.5% (12) Hepatologist.
Conclusion: Our data has highlighted poor blood test adherence within Hepatology clinic attendees, with an 18% improvement with letter or text reminder. Improved clinic attendance and blood test adherence could be facilitated with configuration of electronic notification systems tailored to patient requirements, to promote effective patient care, improve clinician productivity and use of resource.

THU-510
Impact of hepatitis delta infection on quality of life: results from the Nora-hepatitis B study
Judit Romero-Vico[1], Anna Feliu[1], Elena Vargas-Accarino[1], Ester Sánchez-Gavilán[2], Marc Ribó[2], Adriana Palom[1], Juan Carlos Ruiz-Cobo[2], Núria Fabrellas[3], Mar Riveiro Barciela, Maria Buti[2]. *[1]Vall Hebron Research Institute, Barcelona, Spain; [2]Vall d'Hebron University Hospital, Barcelona, Spain; [3]University of Barcelona, Barcelona, Spain*
Email: judviro1630@gmail.com

Background and aims: Hepatitis D (HDV) is an RNA virus that only affects individuals with hepatitis B virus (HBV) infection. Chronic hepatitis D (CHD) is associated with a worse prognosis than HBV mono-infection, with a higher risk of progression to cirrhosis and liver cancer. The aim of this study was to assess the quality of life using health questionnaires in individuals with HDV and compare it to subjects with chronic hepatitis B (CHB).
Method: Prospective study based on the administration of the CLDQ, FACIT-F, and EQ-5D questionnaires using a mobile application (Nora-Hepatitis B) to a cohort of patients with CHD and CHB followed in a hepatology outpatient clinic between February 2022 and April 2024.
Results: A total of 85 individuals, 62 with CHB and 23 with CHD, participated in the questionnaires. Seventy-four percent were men, with an average age of 51.9 years old (±12.5), 72% were Caucasian, and 95% were receiving nucleo(t)ide analogues. Individuals with CHD showed worse results on the CLDQ questionnaire in all dimensions, particularly in abdominal symptoms ($p = 0.001$) and concern regarding their disease ($p = 0.003$). On the FACIT-F questionnaire, only emotional well-being was significantly worse in individuals with CHD ($p = 0.042$), while the total score was similar between both groups. On the EQ-5D questionnaire, although no significant differences were observed in overall health assessment, individuals with CHB had significantly lower levels of anxiety and depression compared to those with CHD ($p = 0.007$).
Conclusion: These results indicate that, overall, patients with CHD have a worse quality of life compared to patients with CHB, particularly in terms of well-being and emotional status. Nora-Hepatitis B is a useful application for evaluating patient-reported outcomes.

THU-511
Evaluation of the utility of the Nora-hepatitis B mobile application: a comparative study between chronic infection and HBeAg-negative chronic hepatitis
Judit Romero-Vico[1], Anna Feliu[1], Elena Vargas-Accarino[2], Ester Sánchez-Gavilán[3], Marc Ribó[3], Adriana Palom[1], Juan Carlos Ruiz-Cobo[3], Núria Fabrellas[4], Mar Riveiro[3], Maria Buti[3]. *[1]Vall Hebron Research Institute, Barcelona, Spain; [2]Vall Hebron Research Institute, Barcelona, Spain; [3]Vall d'Hebron University Hospital, Barcelona, Spain; [4]University of Barcelona, Barcelona, Spain*
Email: judviro1630@gmail.com

Background and aims: Mobile apps are being implemented in the management of some chronic diseases, improving follow-up and treatment adherence. In viral hepatitis, their evaluation has been limited. The aim of this study was to assess the utility of the Nora-Hepatitis B app in individuals with HBeAg-negative chronic hepatitis B infection vs those with chronic hepatitis (CHB), and to determine if the need for treatment has an influence on its use.
Method: The prospective Nora-Hepatitis B study consisted in the distribution of an app (Nora-Hepatitis B) to adults with chronic hepatitis B virus (HBV) infection who attended an outpatient consultation at an academic hospital. Patients needed to have a mobile device, internet access, and were proficient in Spanish. The app provided a chat feature for communication with healthcare staff, allowed users to complete quality of life and knowledge questionnaires, and sent medication reminders. The study was conducted between February 2022 and April 2024 and only results for HBeAg negative population were analysed.
Results: A total of 301 patients accepted to participate; of these, 250 (83%) were HBeAg negative, 147 had chronic infection, and 103 had CHB, with an average age of 50 years, 64% male, and 47% born in Spain. Participants with CHB used the chat feature significantly more frequently (51.4% vs. 34.7%, $p = 0.008$) and had a higher rate of participation in completing questionnaires (39.4% vs. 26.9%, $p = 0.036$) compared to those with chronic infection. No differences were found in patient-reported outcome results between the two groups. However, knowledge about the disease was higher in individuals with CHB (8.46 vs. 7.55, $p = 0.001$).
Conclusion: People with CHB used the chat feature and completed quality of life questionnaires more frequently, suggesting a greater need for contact with healthcare services compared to those with chronic infection. However, both groups reported similar quality of life results, indicating a comparable disease burden in terms of overall well-being.

THU-512
Long-term real-world outcomes of obeticholic acid treatment for primary biliary cholangitis: insights from a pharmacy-led single-centre study
Kate Greener[1], Georgina Tucker[1], Sital Shah[1]. *[1]King's College NHS Foundation Trust, London, United Kingdom*
Email: kate.greener1@nhs.net

Background and aims: First line therapy for the management of Primary Biliary Cholangitis (PBC) is with ursodeoxycholic acid (UDCA). Non-responders or those intolerant to UDCA are entitled to second line therapy with obeticholic acid (OCA) which requires approval via a pharmacy-led regional multidisciplinary team meeting (MDM). Patients are commenced on OCA in a virtual pharmacy-led clinic. Repeat prescribing following subsequent virtual reviews take place in this clinic by a pharmacist and pharmacy technician. Our aim was to retrospectively evaluate the efficacy of OCA in our existing cohort of PBC patients, and to identify who would be eligible for alternative second-line therapies.
Method: Data collected retrospectively identified a total of 196 patients referred to the PBC MDM between November 2017 and November 2022 from 12 different centres. Data was collected for the OCA cohort which included; liver function tests at baseline and 6 monthly intervals up to 2 years, fibroscan, fib-4 & APRI scores at baseline and one year, dose changes and adverse reactions.
Results: A total of 107 (55%) were advised to commence treatment with OCA, 48 (24%) with bezafibrate, and 41 (21%) had another outcome, such as referral for clinical trial. Only 88 patients remained under our care for OCA prescribing which we analysed until at least 24 months of follow-up. Seventy-six patients (86%) were female with a median age of 56 years. A total of 22 (25%) had cirrhosis. Of the 107 patients, 77 (88%) received UDCA at a median dose of 14 mg/kg. At 24 months, 55 patients (63%) remained on OCA. A statistically significant reduction in ALP:ULN (−39.8%) and ALT:ULN (−47.8%) was observed. Response rates were 60% according to POISE criteria and 9% by normal range criteria. There was no change in bilirubin. Of the 33

patients (37%) who prematurely stopped OCA, 25 stopped due to side effects (most commonly treatment-induced pruritus), 2 stopped due to liver decompensation and 6 stopped due to no clinical response. Six patients went on to start bezafibrate. No patients were lost to follow up. Average doses of OCA increased from an average of 4.2 mg/day at baseline to 8.2 mg/day at 24 months. Month 6 saw the most significant change in dose; 48 patients increased in line with national guidance.

Conclusion: The results confirm the effectiveness and safety of OCA, with the response rate mirroring that which was reported in the POISE trial. Access to second-line treatment with OCA is widely available across our region, aided by our pharmacy-led regional MDM and virtual clinic that allow patients to remain with their local clinicians, ensuring continuity of care. Overall, virtual monitoring of response after starting OCA can be challenging as this is dependent on referring clinicians sending timely follow-up data. For those who do not respond adequately to OCA, alternative second-line treatments such as bezafibrate and elafibranor should be explored.

THU-513-YI

Should all patients referred for liver transplantation undergo a review in a dedicated multidisciplinary assessment clinic prior to formal liver transplant work up?

Abigail Greenwell[1], Nuala Ryan[1], Sujit Mukherjee[1], Rachel Westbrook[1], Xenia Mylona[1], Liz Shepherd[1], Katie McCollum[1].
[1]*Royal Free Hospital, London, United Kingdom*
Email: katie.mccollum@nhs.net

Background and aims: Formally evaluating a patient for liver transplantation (LT) involves multiple investigations, specialist input and MDT discussion to determine candidacy. Correctly identifying suitable candidates allows efficient and cost-effective use of LT work up resources. Allied health professional assessments provide objective and validated measures to assess LT risk and help inform candidacy.

Method: In our centre, all potential LT candidates are discussed in principle (DIP) in the LT MDT. Those felt to be higher risk are pre-screened in a multidisciplinary assessment clinic (MAC) with access to dietetic, physiotherapy and alcohol nurse input, to identify those suitable to proceed to work up whereas those perceived after DIP to be more favourable proceed direct to LT work up.

We reviewed all patients who underwent a LT work up (excluding ALF and ACLF) over a 12-month period (June 2022–May 2023) comparing those who have been evaluated/optimised in the MAC prior to LT work up and those proceeding direct to LT work up.

Results: 144 patients underwent a formal LT work up. Median age was 56-years (range 27–71) and 50/144 (34%) were female. The indications for LT work up were decompensated chronic liver disease (74%), HCC (13%) and variant syndrome (13%). Of the 144 LT work ups, 40 (28%) were seen in the MAC prior to LT work up, the remaining 104 patients came direct to LT work up. Alcohol aetiology was higher in those patients seen in the MAC compared to direct LT work up (23/40 (58%) vs 23/104 (22%) $p < 0.01$), whereas the presence of clinical decompensation (32/40 (80%) vs 75/104 (72%) $p = 0.3$), UKELD score (55 vs. 55, p = ns) and age (57 vs 55, p = ns) were similar. Following LT work up 33/40 patients (83%) from the MAC were ultimately listed with 26/40 (65%) listed within a month of work up. The remaining 8 were listed with a median delay of 2 months (range 2–8 months). Conversely of those brought direct in for work up 67/104 (64%) were ultimately listed, with 52/104 (50%) listed within a month. The remining 16 patients were listed with a median delay of 2 months (range 2–8 months). Patients were statistically more likely to be listed if seen in the MAC prior to formal assessment (33/40 vs 67/104, $p = 0.04$) despite being identified at DIP as less favourable candidates. Of the 44 patients that underwent formal work up and were never listed, 16% (7/44) came from the MAC compared to 84% (37/44) from direct work up with common themes for decline being frailty, alcohol risk and medical contraindication.

Conclusion: These data highlight that LT work up slots are used most efficiently by patients who have been evaluated in a MAC, with a significantly higher proportion of patients listed in a timely manner compared to patients coming directly for LT work up. Pre-screening patients in a MAC can thus help avoid costly futile LT work ups. Despite this, in the direct work up group, 64% of patients were listed indicating that there is a subset of patients that can proceed direct to LT work up, although this data failed to identify any predictive markers to guide selection.

THU-514

Patient-perceived quality of care – effectiveness of the quality liver nursing care model

Maria Hjorth[1,2], Anncarin Svanberg[3], Elenor Kaminsky[4], Riccardo LoMartire[5], Fredrik Rorsman[6]. [1]*Department of Public Health and Caring Sciences, Cerntre for Clinical Research in Dalarna, Uppsala, Sweden;* [2]*Centre for Clinical Research in Dalarna, Uppsala University, Falun, Sweden;* [3]*Department of Medical science, Uppsala University, Uppsala, Sweden;* [4]*Department of Public Health and Caring Sciences, Uppsala, Sweden;* [5]*School of Health and Welfare, Centre for Clinical Research in Dalarna, Falun, Sweden;* [6]*Department of Medical Sciences, Uppsala university, Uppsala, Sweden*
Email: maria.hjorth@regiondalarna.se

Background and aims: Liver cirrhosis is a growing health problem due to obesity and excessive alcohol consumption. The disease significantly impacts the person's physical and mental health. Patients with liver cirrhosis express insufficient support from healthcare providers, which may harm patient-satisfaction with healthcare, their psychological well-being, and commitment to manage the disease. In contrast to other chronic diseases, structured registered nurse-based liver cirrhosis outpatient care programmes has not yet been widely established. The aim was to study patient-perceived quality of liver cirrhosis outpatient care after implementing a 24-month adjunctive registered nurse-based intervention, named the Quality Liver Nursing Care Model (QLiNCaM).

Method: A pragmatic, randomised controlled multicentre study (www.clinicaltrials.gov NCT02957253) involving six hepatology outpatient clinics in Sweden. One hundred and sixty-seven participants were allocated to either standard medical care or adjunctive registered nurse-based intervention (QLiNCaM), which was based on person-centred care and Orem's self-care theory of nursing. The questionnaire 'Quality of care from the patient's perspective' (22 items) was used to study patient-perceived quality of care. The response scale of each item was dichotomised into 'lacking quality' or 'good quality'. Complete case analysis with Firth's penalised logistic regression compared 'lacking quality' between the two study groups, at 12 and 24 months respectively. Study results were reported in odds ratio (OR) with 95% confidence intervals (CI).

Results: After 12 months, the registered nurse-based QLiNCaM intervention revealed an improvement in 7 of 22 perspectives of patient-perceived quality of care. The improvements applied: participation in decision-making regarding their care (OR 0.3, CI 0.1–0.8); access to the outpatient clinic (OR 0.1, CI 0.0–0.5); receiving written information (OR 0.3, CI 0.1–0.9); feeling understood (OR 0.1, CI 0.0–1.0); and having influence over their received care (OR 0.1, CI 0.0–0.9). However, these improvements were not sustained after 24 months.

Conclusion: Structured registered nurse-based outpatient care may encourage patient involvement and facilitate patients' accessibility to care, thus being a complement to physician-based care with a more person-centred approach, continuity and care coordination.

THU-515-YI

Impact of consensus guidelines on hepatitis B reactivation risk assessment and management in immunosuppressive therapy

Naz Kanani Alviri[1], Paul Trembling[1,2], Douglas Macdonald[1]. [1]*Royal Free London NHS Foundation Trust, London, United Kingdom;* [2]*East and North Hertfordshire NHS Trust, Stevenage, United Kingdom*
Email: naz.kanani@nhs.net

Background and aims: Hepatitis B virus reactivation (HBVr) can result in fatal liver failure in the setting of immunosuppressive therapy (IST). International guidelines differ in their recommendations on the use of monitoring and/or prophylaxis by class of IST. A systematic review of the available literature on HBVr risk for individual IST agents was conducted by the specialist hepatology pharmacist followed by consultant hepatologist Delphi Consensus process incorporating existing, AASLD, EASL and UK Chemotherapy Board guidelines. Guidelines were reviewed and ratified by clinical leads from key IST prescribing services before publication (rheumatology, dermatology, haematology, oncology, nephrology, gastroenterology, neurology, immunology). In January 2024, a consensus guideline was published which devolves the majority of screening, decision-making and prophylaxis prescribing in those with past HBV infection (pHBV) to the clinicians prescribing IST. The guideline, which categorises IST into risk category groups with associated advice on monitoring and/or antiviral prophylaxis, has the explicit goal of improving rates of both screening and appropriate management whilst minimizing the number of clinical services with which patients needs to engage.
Method: To assess the impact of the guidance, we reviewed referrals to the viral hepatitis multidisciplinary team for HBVr risk assessment queries pre- and post-guideline implementation (prGI and poGI, respectively).
Results: A total of 106 referrals were received between February 2022 and January 2024 and 29 between January and November 2024 indicating a decline of 2 referrals per month (on average). 78% (83/106) and 65% (19/29) of referrals were for patients with pHBV prGI and poGI. 21% (23/106) and 31% (9/29) of referrals were for patients with active infection prGI and poGI. 71% (75/106) and 76% (22/29) of referrals had a full HBV screen at baseline prGI and poGI. All IST prescribing services in our organization have adopted screening, monitoring and prophylaxis prescribing for those with past HBV infection.
Conclusion: Implementation of HBVr guidance reduces overall referrals of patients with pHBV to the viral hepatitis service, increases referrals of those with active infection, and increases proportion of patients with full HBV baseline screen; indicating more efficient use of clinical resources and improved patient experience. The proportions of those being screened, monitored and given appropriate prophylaxis needs to be assessed within IST-prescribing services. Specialist pharmacists are ideally placed to do this during clinical screening of IST.

THU-516-YI

Nurse-led clinic for patients with decompensated liver cirrhosis

Elsebeth Kelstrup[1], Sara Andersen[1], Tine Christensen[1], Karen Thomsen[1,2], Konstantin Kazankov[1,2], Palle Bager[1,2]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark;* [2]*Aarhus University, Department of Clinical Medicine, Aarhus, Denmark*
Email: pallbage@rm.dk

Background and aims: Patients with decompensated liver cirrhosis has a mortality of around 50% within five years of diagnosis. The risk of mortality may be influenced by the management focusing on reducing risk of cirrhosis-related complications. Many individuals with liver cirrhosis have limited health literacy, highlighting a need for tailored information and guidance. Unstructured follow-up has been associated with frequent liver-related readmissions, with structured care potentially preventing up to one-third of these readmissions.
Method: A quasi-experimental, investigator-led single-centre study was conducted from January 2022 to May 2024. The intervention involved a nurse-led clinic designed to meet the special needs of patients with decompensated liver cirrhosis. The primary aims were to reduce liver-related hospital admissions and to identify patients who would benefit the most from the intervention. Monthly data from a hospital database ($N \approx 400$) were analysed across three study periods: before, during, and after the intervention. Demographic and disease-related data were continuously collected.
Results: 55 participants were enrolled in the intervention (45% female, mean age 61 ± 11 years, 78% with alcohol-related cirrhosis, mean MELD score of 16 ± 7, mean Child-Pugh score of 9 ± 2, with 65% living alone). The median duration of affiliation with the clinic was 142 (IQR 43–224) days, and the median number of contacts was 7 (IQR 3–11). Telephone contact was the primary form of communication. Among participants, 55% were discharged from the clinic upon achieving self-management ability, 20% were deemed non-compliant, 16% died, 5% were lost to follow-up, and 4% underwent a liver transplantation. Participants who were evaluated to have achieved self-management ($n = 30$) differed significantly from those who did not ($n = 25$), with lower mean baseline MELD scores (14 ± 1 vs. 19 ± 2, $p = 0.01$), lower mean baseline Child-Pugh scores (8.2 ± 0.3 vs. 9.6 ± 0.4, $p = 0.01$), and a higher proportion had alcohol-related cirrhosis (90% vs. 64%, $p = 0.02$). Hospital data indicated a decrease in mean monthly admission rates among the wider population of cirrhosis patients from 13.6 in 2022 to 9.3 in 2023 ($p = 0.02$), with stable outpatient clinic contact rates. The results may be influenced by the Covid-19 lockdown prior to the intervention.
Conclusion: Establishing a nurse-led clinic for patients with decompensated liver cirrhosis was feasible. Patients who benefited from the clinic were characterised by lower baseline MELD and Child-Pugh scores and a higher prevalence of alcohol-related cirrhosis. The study provided valuable insights into strengthening multidisciplinary team collaboration and streamlining patient pathways within the department.

iCARE: Insights on competency advancement and recommendations for nurses managing HBV/HDV with bulevirtide – findings from a european advisory board

Patrizia Künzler-Heule[1,2], Judit Romero-Vico[3], Mélanie Simoes[4], Martina Fellinghauer[5], Gemma Botterill[6], Samantha Readhead[7]. [1]*Cantonal Hospital St.Gallen, Departement of Gastroenterology and Hepatology and Departement of Nursing, St. Gallen, Switzerland;* [2]*University of Basel, Institute of Nursing Science, Basel, Switzerland;* [3]*Vall Hebron Research Institute (VHIR), Liver Diseases Research Group, Barcelona, Spain;* [4]*Hopital Henri Mondor, Service Hépatologie, Creteil, France;* [5]*Vienna General Hospital, Division of Gastroenterology and Hepatology, Departement of Medicine III, Vienna, Austria;* [6]*University Hospitals Birmingham NHS Foundation Trust (UHB), Birmingham, United Kingdom;* [7]*Brighton and Sussex University Hospitals NHS Trust, Department of Gastroenterology and Hepatology, Brighton, United Kingdom*
Email: patrizia.kuenzler-heule@kssg.ch

Background and aims: Bulevirtide (BLV), a novel treatment for hepatitis D (HDV), offers a promising option to manage liver disease progression in patients (pt) co-infected with chronic hepatitis B. However, the requirement for long-term daily subcutaneous administration presents challenges in pt self-management. Nursing expertise may improve treatment outcomes, safety and pt adherence, requiring specialized knowledge and skills to deliver high-quality, evidence-based HDV care. iCARE was developed to address these challenges by gathering insights from experienced nurses to share best practice, and to develop training to enhance nursing skills supporting long term care.

Method: Nurses managing pt with HBV/HDV completed a written survey detailing their professional background, care settings, BLV experiences, and training needs. A descriptive analysis was conducted, followed by an online European HDV Nurse Advisory Board in September 2024, focused on the pt journey. Key findings were shared with participants.
Results: Six nurses participated, all working in specialized liver units. They had years of experience in caring for HBV/HDV pt and also managing pt on BLV. The survey revealed differences in care priorities arising from local settings and internal pathways, influencing how nurses became involved in care. Despite variations, all emphasized their role as pt advocates, focused on shared decision-making, and empowering pt to manage their disease. Nurses agreed on the importance of clear communication, logistical support and holistic assessments including evaluating social resources to ensure coordinated care. Key responsibilities include: Establishing a trusting relationship with pt, providing emotional support, evaluating treatment readiness and involving family in care. In addition, nurses support pt on BLV by teaching practical skills, such as self-injection. Written and visual materials, along with practice tools, were considered valuable for enhancing pt capabilities. Nurses have a fundamental role in follow-up care and serve as accessible points of contact across settings, facilitated by digital tools.
They require specialized HBV/HDV and BLV knowledge for management of treatment and adverse events. Equally important are skills in building therapeutic relationships-, person-centered communication, and chronic care management, focusing on adherence and motivation.
Conclusion: Liver care nurses across Europe agreed on essential skills required to manage HDV, with local differences having minimal impact on care delivery. They viewed themselves as close partners, comparable to co-pilots, guiding pt and families through their treatment journey. iCARE highlights the vital role of nurses in empowering pt to manage BLV therapy and supports the development of adaptable educational programs across diverse healthcare settings and countries.

THU-518
Multi-displinary team initiation of GLP-1/GIP agonist Tirzepatide in patients with metabolic-dysfunction associated steatotic liver disease (MASLD): single-centre UK study

Rachel Halley[1,2], Callum Riley[1], Jill Johnson[1], Maria Round[1], Julian Yeh[1], Sheeba Khan[1], Alexander Boyd[1], Geoffrey Haydon[1], Samiul Mostafa[1,2], Philip Newsome[1,3], Matthew Armstrong[1]. *[1]Queen Elizabeth Hospital, The Liver Unit, Birmingham, United Kingdom; [2]Queen Elizabeth Hospital, Department of Diabetes, Birmingham, United Kingdom; [3]Roger Williams Institute of Hepatology, Kings College London, London, United Kingdom*
Email: rachel.halley@uhb.nhs.uk

Background and aims: Tirzepatide, a dual GLP-1/GIP agonist, has shown efficacy in type 2 diabetes mellitus (T2DM) and obesity, with promising phase II trials in metabolic dysfunction-associated steatotic liver disease (MASLD). No real-world data exists in MASLD. This study evaluates tirzepatide's efficacy in patients with MASLD and T2DM in secondary care, comparing those with liver multidisciplinary team (MDT) input (inc. diabetes specialist nurse) to those managed in a general diabetes clinic.
Method: Adult patients with T2DM and MASLD prescribed tirzepatide between Jan–Nov 2024 were included. Pre and ≥3 months post initiation data of weight, BMI, HbA1c, liver function tests and liver stiffness measurement (LSM; kPa)/controlled attenuation parameter (CAP) were recorded, in parallel to (dose) changes in other T2DM medications. Statistical tests included 2-sample t-tests (parametric), Wilcoxon rank-sum tests (non-parametric), chi-square tests (binary).
Results: Of 67 patients with MASLD at baseline 32 (47.8%) were male; weight (median (IQR)) was 106.8 Kg (94.1–120.1); BMI 37.2 kg/m² (34.8–40.5); HbA1c 61 mmol/mol (49–73.5), LSM 16.1 KpA (10.7–21.3) and CAP 333.5 dB/m (313–368). 35 (57%) patients had liver MDT input. 47 (70.1%) were on only oral-hypoglycaemics and 20 (29.9%) on insulin ± oral-hypoglycaemics. After 3 months, the median change in weight was −3.9 kg (IQR −3.9; −7.1: p = 0.290), BMI −1.5 kg/m^2 (−0.1;-2.6: p = 0.242), HbA1c −10 mmol/L (−1; −18: p = 0.001), ALT −9.5 IU/L (−3.0; −19.8: p = 0.044), AST −19.5 IU/L (−10.5; −26.3: p = 0.088), LSM −10.4 kPa (−5.9; −13.5: p = 0.408), and CAP −31 dB/m (−11; −57: p = 0.047). 38.6% and 11.4% had at least 5% and 10% weight loss, respectively. 40.3% (25/62) decreased their dose or number of T2DM medications (inc. insulin). There were no safety issues reported. Patients with MDT follow-up had greater, though non-significant, weight loss (−4.9 ± 5.6 vs −3.1 ± 6.6 kg) and changes in BMI (−1.53 ± 2.20 vs −0.38 ± 8.03 kg/m²). Improvements in HbA1c (−11.1 ± 14.2 vs −11.1 ± 16.9 umol/mol) were similar between the groups, however those under liver MDT follow-up were more likely to have successful dose reduction of other T2DM medications, including insulin (56.3% vs 23.3%; p = 0.008).
Conclusion: Tirzepatide is safe and significantly improves liver enzymes, steatosis and glycaemic control in patients with MASLD after only 3 months. Those under liver MDT care significantly reduced the burden of other T2DM medications, whilst maintaining safe improvements in glycaemic control and weight.

THU-519-YI
Prescribing for pain and symptom management in hospital patients with advanced liver disease: a single centre, retrospective clinical audit

Sarah Phillips[1,2], Savitri Chandrasekaran[2], Malaika Gupta[2], Yun Jung Kim[1,2], Kathryn L. Nash[2], Mark Wright[2], Anita K. Omasta-Martin[2,3]. *[1]Pharmacy Department, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; [2]Hepatology Department, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; [3]Supportive and Palliative Care Team, University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom*
Email: sarahphillips2997@gmail.com

Background and aims: Advanced chronic liver disease patients, particularly in their last year of life require adjustments to dose and choice of medication as per the British Association for the Study of the Liver (BASL) guidelines. Most hospital patients should be referred to supportive and palliative care team (SPCT) during their stay to ensure appropriate symptom control is in place. In this study, we assessed whether prescribing adhered to BASL guidelines and if this changed following intervention by SPCT.
Method: Prescribing data were collected retrospectively from the electronic prescribing system at a UK tertiary liver centre over 5 months (April–August 2024). Eligible patients had a Child Pugh score of B or C and were referred to SPCT. Data were reviewed against BASL guidelines to determine if meeting standards prior to and after SPCT review and assessed using t-tests.
Results: 30 patients (50% male) were included with a median age of 64.5 (interquartile range 57–72.5) and mixed aetiologies (53.4% alcohol-related, 20% metabolic dysfunction-associated steatotic liver disease and 26.6% other). Results were grouped by drug and route. Although paracetamol is the first-line analgesic, only 70% of patients sampled (n = 21) had oral paracetamol prescribed, of which 43% met the BASL standard (2–3 g daily) with a mean daily dose (MDD) of 3500 mg. SPCT intervention was statistically significant, reducing MDD to 2476 mg (p < 0.05). For oral morphine (n = 12) patients meeting recommendations (2.5 mg 4–6 hourly) increased from 18% to 36%, with MDD increasing by 25% post referral (p = 0.37). With subcutaneous morphine (n = 10) 80% of patients met standards (1.25–5 mg hourly) and MDD decreased from 36.2 mg to 26.2 mg after SPCT review (p = 0.14). 12 patients were prescribed oral oxycodone with an increase in standards adherence (1.25 mg 6–8 hourly) after intervention from 8.3% to 33.3% and reduction in MDD of 4.6 mg (p = 0.15). 3 patients were prescribed dihydrocodeine and all prescriptions were

stopped following SPCT review ($p < 0.05$). Metoclopramide was prescribed in 6 patients, and none met BASL standards (5 mg 8 hourly) prior to referral but 50% of patients adhered after. MDD reduced from 48.3 mg to 20.8 mg ($p = 0.12$). All prescriptions of intravenous and oral ondansetron ($n = 7$) were higher than recommended BASL doses (8 mg daily) however, no prescription was changed following review.
Conclusion: Adherence to standards varies greatly between drug and route but overall shows a lack of adjustment accounting for liver disease severity, both before and after SPCT review, with trends of improvement post review. Although first-line, safe analgesia at reduced dose, paracetamol is not prescribed for all patients. A small population limited the statistical power of this dataset. Initial findings indicate the development of local prescribing resources would improve patient safety and compliance with BASL guidelines.

THU-520
Improving the outcomes of patients with cirrhosis in a community clinic through the utilization of advanced practice providers and standardized tailored management protocol
Julian Diaz-Moreno[1], Ahmed Atalla[1], Usman Gul[1], Ayisha Aziz[1], Fatma Barakat[2], James Johnson[1], Anna Marie Hefner[1], Deanna Oliver[1], Tarek Hassanein[1]. *[1]Southern California Liver Centers, Coronado, United States; [2]SCTI Research Foundation, Coronado, United States*
Email: julian@livercenters.com

Background and aims: Cirrhosis continues to pose a public health burden worldwide, contributing to substantial morbidity and economic strain on healthcare resources. This is expected to increase exponentially with the current trends in rising liver disease incidence. Modifying long-term liver care is needed to meet evolving demands. The aim of this analysis is to describe the outcomes of managing patients (pts) with cirrhosis through a collaborative physician/allied health including advanced practice providers multi-level healthcare model using standardized protocols tailored to the severity of liver disease.
Method: Between January 2011 and December 2023, 5201 pts with cirrhosis were seen at a community-based single liver center serving suburban and urban communities. Pts were managed by a team of healthcare providers consisting of physicians and allied health professionals including nurse practitioners, physician assistants, nutritionists. Management was according to standardized protocols tailored to each pt's disease severity. Information from the Electronic Medical Records system was analyzed.
Results: 53.7% males. Mean age was 63.8 ± 10.1 years. 47.8% Hispanics and 83.6% whites. Preliminary analysis on 1126 pts showed: underlying etiology was primarily history of HCV (31.3%), 24.2% alcohol-related liver disease (ALD), and 19.3% steatotic liver disease (SLD). 67% were compensated at initial visit. Median follow-up: 54 months (1–144). Median number of outpatient visits: 34 visits (1–141). 10.9% required paracentesis or TIPS. 91% had no or grade 1 varices. 12.4% experienced sepsis. 8% developed Hepatocellular carcinoma. Almost 40% required hospitalization due to liver disease decompensation. Mean total number of hospitalizations was 3. Outcomes: >80% alive. <6% referred to Hospice and 4% received a liver transplant.
Conclusion: Over a 12-year follow-up period of cirrhotic pts at a community-based liver center, the prevalence of underlying etiology of HCV significantly decreased, SLD continued to increase, and ALD remained stable. Pts were managed by a dedicated team of 2 Hepatologists and 3 allied health professionals according to standardized protocols tailored to the pt's disease severity. It utilized the applicable provider's model of care. The joint effort and comprehensive approach led by a Hepatologist: 1) alleviated the reliance on them, 2) enabled early detection and diagnosis of cirrhosis complications and 3) swift management and expanded access to various specialized models of care. This had a major impact on lowering the number of decompensations and led to fewer hospitalizations, procedural interventions and decreased the need for hospice care and transplantation. It significantly improved complications-free survival and outcomes of pts. Management protocols need to be constantly updated with the evolving new therapies and guidelines.

Email: luisdiazpiga@gmail.com

Background and aims: Although metabolic dysfunction-associated steatotic liver disease (MASLD) is intrinsically associated with cardiometabolic risk factors, evidence assessing the potential impact of MASLD-related public health policies (PHP) on reducing the burden of MASLD remains unknown. We aimed to determine the relationship between establishing MASLD-related PHP over time and the burden of MASLD worldwide.
Method: We conducted a multinational ecological study. Data on policies were obtained from the World Health Organization between

2013–2021, while age-standardized disability-adjusted life years (DALYs) due to MASLD were obtained from the Global Burden of Disease study between 2017–2021. We classified PHP into two categories: 1. Countries with the policies established by 2013 and 2. Countries with PHP after 2013 (or no policies). We estimated an incidence rate ratio (IRR) using multilevel generalized linear models with a Poisson family distribution adjusted by population structure, healthcare access and quality index, human development index, alcohol use per capita, smoking, body mass index, and physical activity.

Results: A total of 110 countries were included. The median age-standardized MASLD-related DALYs were 47.8 [IQR:33–74.3] per 100,000 inhabitants. Fifty-three percent of countries had national policies on diabetes by 2013, while 46.4% had cardiovascular disease (CVD) policies, 60.9% had nutritional policies, and 57.3% had policies on physical activity. In adjusted models, the establishment of PHP in diabetes by 2013 was associated with a significant reduction in MASLD-related DALYs (IRR 0.49, 95%CI:0.27–0.90, p = 0.021). Similar associations were observed in the establishment of national policies on nutrition (IRR 0.46, 95%CI:0.23–0.94, p = 0.034) and policies on CVD (IRR 0.43, 95%CI:0.21–0.88, p = 0.020) by 2013. However, the PHPs on physical inactivity were not significantly associated with lower MASLD-related DALYs (IRR 0.60, 95% CI:0.29–1.25, p = 0.177). A comparable effect size was observed among these public health policies in decreasing the incidence of hepatocellular carcinoma and deaths due to MASLD cirrhosis. In all the multivariable models, higher alcohol use was significantly associated with an increase in MASLD-related DALYs.

Conclusion: Establishing national PHP targeting diabetes, CVD, and nutrition may significantly reduce the burden of MASLD. Additionally, alcohol use remains a critical modifiable risk factor contributing to the global burden of MASLD, underscoring the need for integrated approaches in public health strategies and better methods to quantify alcohol use in clinical practice.

TOP-018

Examining the causal link between alcohol consumption and fatty liver disease using Mendelian randomization

Yun-Chen Wu[1,2], Chih-Jen Huang[2], Mei-Hung Pan[2], Ding-Lian Wang[2], Hwai-I Yang[2]. *[1]College of Public Health, Kaohsiung Medical University, Kaohsiung, Taiwan; [2]Genomics Research Center, Academia Sinica, Taipei, Taiwan*
Email: yunchenaaliyah@gmail.com

Background and aims: The prevalence of fatty liver has risen significantly in Asian countries, from 25.3% (1999–2005) to 33.9% (2012–2017). According to the WHO's 2018 Global Report on Alcohol and Health, alcohol consumption causes 3 million deaths annually, with 47.9% related to cirrhosis. Alcohol is metabolized in the liver by ADH and ALDH2 enzymes. Although alcohol consumption has been associated with fatty liver development, the causal relationship remains unclear, especially in humans. Animal studies suggest alcohol leads to liver fat accumulation, but conclusive evidence in humans is lacking. Mendelian randomization (MR) provides a powerful method to assess causality by using genetic variations as instrumental variables. This study aimed to investigate the causal link between alcohol consumption and fatty liver in the Taiwanese population.

Method: The study analyzed data from 120,143 Taiwanese adults (aged 37–60) in the Taiwan Biobank. Fatty liver was determined using the Fatty Liver Index (FLI), with scores ≥20 indicating fatty liver disease (FLD). Participants with viral hepatitis or missing data were excluded, yielding 104,802 individuals. Genetic variants in ADH1A, ADH1B, ADH1C, and ALDH2 associated with alcohol drinking ($P < 5 \times 10^{-8}$) were selected as instrumental variables. To ensure validity, MR assumptions were tested: reliable association with alcohol drinking, no link to confounders, and an effect on fatty liver solely through alcohol. Logistic regression assessed compliance, and MR analysis was conducted using a two-stage residual inclusion method.

Results: Four significant genetic variants were identified: ADH1B rs1229984, ALDH2 rs75162023, ALDH2 rs671, and ALDH2 rs6489793. Logistic regression showed that ALDH2 rs671 and rs6489793 were associated with confounders like smoking, physical activity, and income, and also directly linked to fatty liver, violating MR assumptions. Conversely, ADH1B rs1229984 and ALDH2 rs75162023 satisfied all criteria, qualifying as valid instrumental variables. MR analysis using these valid variants showed no significant causal relationship between alcohol consumption and fatty liver (rs75162023: OR = 1.6, 95% CI = 0.11–23.28; rs1229984: OR = 0.97, 95% CI = 0.11–8.83). Comparatively, analyses with invalid variants (rs671 and rs6489793) showed misleading associations, emphasizing the importance of valid instrumental variables in MR studies.

Conclusion: This study provides no evidence of a causal relationship between alcohol consumption and fatty liver disease in the Taiwanese population. These findings differ from prior observational studies suggesting an association, indicating that fatty liver risk may be influenced by lifestyle factors beyond alcohol, such as unhealthy diets. Future research should address these confounders, and genome-wide association studies (GWAS) could further clarify the complex relationship between alcohol consumption and fatty liver.

TOP-032

Prevalence of the spectrum of steatotic liver disease and associated fibrosis and cirrhosis among adults in the United States

James M. Paik[1,2], Kathryn Hobbs[2,3], Amolika Gupta[2,3], Rand Alkalbani[2,3], Manuel Reyes[2,3], Zobair Younossi[1,2,4]. *[1]The Global NASH/MASH Council, Washington, DC, United States; [2]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, United States; [3]Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, United States; [4]Center for Outcomes Research in Liver Disease, Washington, DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: Spectrum of steatotic liver diseases (SLD), including metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic alcohol-related liver disease (MetALD), and alcohol-related liver disease (ALD), pose a significant public health challenge in the U.S. This study aimed to estimate the age-standardized prevalence of fibrosis stages and cirrhosis across SLD subtypes in U.S. adults.

Method: Data from the National Health and Nutrition Examination Survey (NHANES, 2017–2023) were analyzed. SLD was identified using a Controlled Attenuation Parameter (CAP) threshold of ≥280 dB/m. Subtypes (MASLD, MetALD, ALD) were classified per updated nomenclature. Fibrosis stages were assessed using liver stiffness measurements (LSM): significant fibrosis (LSM > 8 kPa) and advanced fibrosis (LSM > 12 kPa). We defined cirrhosis by LSM according to 2 criteria: Cirrhosis 1 (LSM > 15 kPa) and Cirrhosis 2 (LSM > 20 kPa).

Results: In 2021–2023, the age-standardized prevalence of SLD was 36.88%, including MASLD (32.99%), MetALD (1.86%), and ALD (1.16%). Prevalence was higher in men compared to women for SLD (41.92% vs. 31.72%), MASLD (36.76% vs. 29.54%), MetALD (2.54% vs. 1.15%), and ALD (1.93% vs. 0.33%) (p < 0.03). From 2017–2020 to 2021–2023, the prevalence of SLD and MASLD remained stable; however, the prevalence of significant and advanced fibrosis rose from 17.38% and 5.75% to 22.25% and 8.24% in SLD and from 17.55% and 5.72% to 21.44% and 7.79% in MASLD, respectively. The prevalence of cirrhosis, defined by two different criteria, also increased (Cirrhosis 1 increased from 3.84% to 5.59% in SLD and from 3.83% to 5.55% in MASLD, while Cirrhosis 2 increased modestly from 2.39% to 2.86% in SLD and from

2.47% to 2.85% in MASLD). Similar trends were observed in the MetALD and ALD subgroups. Logistic regression adjusted for metabolic and sociodemographic factors showed severe obesity (BMI ≥40 kg/m²) as the strongest predictor of significant fibrosis (OR = 9.96, 95% CI: 5.95–16.67) and advanced fibrosis (OR = 18.17, 95% CI: 7.83–42.15). Other predictors of significant fibrosis included obesity (OR = 2.81, 95% CI: 1.85–4.26), type 2 diabetes (T2D; OR = 2.58, 95% CI: 1.92–3.48), and hypertension (OR = 1.80, 95% CI: 1.34–2.42). These metabolic risk factors more pronounced predictors of cirrhosis.
Conclusion: While the prevalence of SLD and MASLD remained stable over time in the United States, there is a consistent increase in the prevalence of patients with high-risk disease (advanced fibrosis and cirrhosis). This underscores the need for targeted policies in the United States to avert adverse outcomes.

One-stop shop: a bespoke single-point-of-referral clinic enhances linkage to care for ultrasound surveillance of hepatoma in patients diagnosed with advanced fibrosis and cirrhosis via targeted community screening

Basil Ahmad[1], Helen Boothman[1], Fergus Daly[1], Laura Letham[1], Sally Thomas[1], James Attridge-Smith[1], Michael Tolentino[1], Hassanain Abdulla[1], Daniel Forton[1,2]. *[1]St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [2]St George's, University of London, London, United Kingdom*
Email: daniel.forton@nhs.net

Background and aims: We established a pilot project to identify advanced fibrosis/cirrhosis in patients in community settings using liver stiffness measurements (LSM) by Fibroscan. The aim is to increase ultrasound surveillance (USS) and the diagnosis of early hepatoma, in populations currently unlinked to care. Outreach teams delivered LSM in a mobile clinic van and other community locations. Patients were referred to their local hospital clinic for USS and clinical assessment but linkage to care (LTC) remained a challenge. To address this, we started a bespoke, single-point-of-referral specialist clinic in November 2023. Patients, supported by people with lived experience (peers) if potential engagement risks were identified, underwent a repeat fasted LSM, USS, and complete clinical evaluation in one visit. We aimed to evaluate the effectiveness of 1. community LSM screening to identify subjects for USS for hepatoma and 2. attendance at our bespoke clinic over 12 months compared to prior standard of care.
Method: We extracted data from our program database covering LSMs from October 2022 to September 2024 targeting groups in local drug and alcohol services, community diabetic retinopathy services, hostels, prisons and other community locations in SW London. LSM ≥11.5 kPa was used as a cut-off for advanced fibrosis and referral. We examined attendance rates over 12 months at our bespoke clinic and for USS and/or standard assessment in one hospital in the 12 months prior to the clinic set-up.
Results: In the second period, 1448 persons received community LSMs (915 male : 533 female), and 103 (7.1%) had LSM ≥11.5 kPa and were referred to our clinic, with heavy alcohol consumption in 83%, type II diabetes in 11%, and known metabolic dysfunction-associated steatotic liver disease (MASLD) in 6%. With a mean wait time of 14 days, 97/103 (94%) subjects attended their appointments compared to 28/43 (65%) in the 12 months prior to the dedicated clinic. 24% received peer support. 95/97 (98%) had repeat LSM and USS on the same visit with 54/95 (57%) revealing radiological evidence of cirrhosis. 67/95 (71%) had a concordant repeat LSM (median LSM 22 kPa). 74/85 (87%) patients with heavy alcohol consumption received a brief alcohol intervention. 78/97 (80%) were referred for ongoing USS and 19/97 (20%) were discharged. One was diagnosed with hepatoma. 30/36 (83%) attended their second 6-monthly USS appointment on time.
Conclusion: Targeted community fibroscan is successful at detecting advanced fibrosis and cirrhosis in populations that would not otherwise access liver services. The establishment of a dedicated one-stop point-of-referral service, supported by peers, can deliver excellent attendance and LTC for ongoing USS. It is however a resource intensive undertaking.

THU-004

Hospital-based and individual disparities in liver transplantation access in France: a national health data system analysis

José Ursic Bedoya[1], Charlotte De Choudens[2], Margaux Delhomme[1], Astrid Herrero[3], Stéphanie Faure[4], Lucy Meunier[4], Magdalena Meszaros[4], Georges-Philippe Pageaux[1], Claire Duflos[5]. *[1]Department of Hepatogastroenterology, Hepatology and Liver Transplantation Unit, Saint Eloi Hospital, CHU Montpellier, University of Montpellier, Montpellier, France, Montpellier, France; [2]Clinical Research and Epidemiology Unit, CHU Montpellier, Université de Montpellier, Montpellier, France; CEPEL, Université de Montpellier, CNRS, Montpellier, France, Montpellier, France; [3]Department of General and Liver Transplant Surgery, University Hospital Montpellier, Hôpital Saint Eloi, University of Montpellier, Montpellier, France, Montpellier, France; [4]Department of Hepatogastroenterology, Hepatology and Liver Transplantation Unit, Saint Eloi Hospital, CHU Montpellier, University of Montpellier, Montpellier, France, Montpellier, France; [5]Clinical Research and Epidemiology Unit, CHU Montpellier, Université de Montpellier, Montpellier, France; CEPEL, Université de Montpellier, CNRS, Montpellier, France, Montpellier, France*
Email: jose.ursicbedoya@chu-montpellier.fr

Background and aims: Several studies have shown that non-medical factors can determine access to liver transplantation (LT). Most of this data comes from North America, where the healthcare system has specific features that are difficult to transpose to Europe. We aimed to investigate the factors associated with access to LT in patients admitted to hospital for a first episode of decompensated cirrhosis in France and to determine whether there are treatment gaps in certain centres due to the aetiology of the underlying liver disease.
Method: In this analytical retrospective cohort, we used data from the French national health data system to extract patients between 18–70 years hospitalized for a first decompensation of cirrhosis between 2015–2022, followed until December 2023. We built a frailty model to search for factors associated with access to LT and to quantify inter-centre variability. Then, using a method derived from indirect standardization, we described the differences between the expected and observed incidence of transplantation in patients with an alcohol-related background, between hospital centres.
Results: We identified 65,771 patients, with a mean follow-up time of 36 months and 195,270 person-year. Of these patients, 73.5% were men and 82.3% had an alcohol-related cirrhosis. By December 31st, 2023, 3,596 (5.5%) had been transplanted and 35,660 (54.2%) had died. Patients with an alcohol-related liver disease (ALD) were less likely to be transplanted (HR = 0.75, CI95% = [0.69–0.81]), as were women (HR = 0.75, CI95% = [0.69–0.81]), patients with solidarity-based complementary health insurance (HR = 0.82, CI95% = [0.74–0.90]) and more socially deprived patients (HR = 0.97, CI95% = [0.94–0.99]). The poorer access to LT for ALD patients was evenly distributed between centres.
Conclusion: Our study highlights several factors contributing to unequal access to LT in France. The lower access for ALD patients suggests the presence of structural stigma. Modification of national-based policies could lead to a more equitable access to LT.

THU-005

The largest, exhaustive in-depth analysis and concerning report on 386 complementary and alternative medicinal products belonging to the Indian-systems of medicine (AYUSH) retrieved from patients that caused liver-related harm at the consumer level

Cyriac Philips[1,2], Arif Theruvath[3], Resmi Ravindran[4], Rizwan Ahamed[5], Tharun Oommen[6], Ajit Tharakan, Philip Augustine[5]. *[1]Department of Clinical and Translational Hepatology, The Liver Institute, Rajagiri Hospital, Kochi, India; [2]Department of Clinical Research in Hepatology, Division of Complementary and Alternative Medicine and the Liver, The Liver Institute, Rajagiri Hospital, Kochi, India; [3]Department of Clinical Research in Hepatology, Division of Complementary and Alternative Medicine (Homeopathy) and the Liver, The Liver Institute, Rajagiri Hospital, Kochi, India; [4]Department of Clinical Research in Hepatology, Division of Complementary and Alternative Medicine and the Liver (Ayurveda), The Liver Institute, Rajagiri Hospital, Kochi, India; [5]Department of Gastroenterology and Advanced GI Endoscopy, Center of Excellence in GI Sciences, Rajagiri Hospital, Kochi, India; [6]Department of Gastroenterology and Hepatology, Center of Excellence in GI Sciences, Rajagiri Hospital, Kochi, India*
Email: abbyphilips@theliverinst.in

Background and aims: Complementary and alternative medicines (CAMs) are integrated into the national healthcare system in India and widely exported globally, including Europe and US. The Indian CAM system is officially known as Ayush [Ayurveda, Yoga and Naturopathy, Unani, Siddha, Sowa Riggpa (Tibetan Medicine) and Homeopathy]. Since last decade, large series of Ayush-related liver injuries were increasingly reported in medical literature from India and the West. We aimed to perform pragmatic analysis on vast numbers of Ayush-related CAMs retrieved from patients, that caused consumer-level harm in the context of hepatotoxicity.
Method: CAM products retrieved from patients underwent inductively coupled plasma mass spectrometry and triple quadrupole gas chromatography-mass spectrometry for identification of heavy metals, steroids and prescription drug adulteration and contamination along with detailed evaluation of labels for presence of hepatotoxic ingredients.
Results: From May 2021 to December 2023, we retrieved 386 CAM products consumed by 91 patients belonging to classical, proprietary, and unlabeled ayurvedic (N = 111, 99, 77 respectively); homeopathic (15, 4, 24); Siddha (7, 5, 4); unlabeled Unani (4); Tibetan medicine (5), folk medicine (6) formulations and herbal and dietary supplements (7). Males predominated (N = 69, 75.8%) with median age 49 years. Median number of products consumed per patient was 3 (minimum 1, maximum 18). Acute-on-chronic liver failure was notable in more than one-third (N = 36). We identified a total of 2387 unique compounds in 386 CAMs. After applying criteria of match-factor cut-off >70% with presence in minimum 5 products, (except for prescription drugs), a total of 391 compounds were identified. The most common botanical metabolite was stigmasterol, precursor of naturally occurring anabolic–androgenic steroid in 123 CAMs (32%). Prescription drugs including non-steroidal anti-inflammatory medications, corticosteroids, anti-microbials, cardiac drugs, narcotics, and chemotherapeutic agents were identified in 53 (14%) CAMs. Lead beyond safe limit (0.1 mg/kg) was notable in 259 (67%, highest 67616.3 mg/kg), arsenic (>1 mg/kg) in 121 (31.3%, 11262.4 mg/kg) and mercury (>0.5 mg/kg) in 149 (38.6%, 383663.4 mg/kg). Well-documented hepatotoxic botanicals giloy, turmeric, and ashwagandha were labeled in 60 (16%), 28 (7%), and 23 (5.9%) CAMs respectively, without adequate safety warnings.
Conclusion: A significant proportion of CAMs causing liver injury contain known hepatotoxic botanicals without labeled warnings, extreme levels of heavy metal contamination, adulteration with a variety of prescription drugs and potentially toxic plant metabolites. Public education and patient awareness on avoidable liver injury from non-beneficial CAMs should be normalized in routine physician-driven outpatient and inpatient discussions.

THU-006

Bridging the gap between primary care physicians and hepatology with electronic consultations

Aviel Hankin[1], Avivit Golan-Cohen[1,2], Ilan Green[1,2], Shlomo Vinker[1,2], Ran Tur-Kaspa[1,2,3]. *[1]Leumit Health Services, Tel Aviv, Israel; [2]Department of Family Medicine, Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; [3]Liver Institute, Rabin Medical Center, Petah Tikva, Israel*
Email: ahankin@leumit.co.il

Background and aims: Electronic consultations (e-consults) in primary care enhance communication between primary care physicians (PCPs) and specialists, offering an important tool for managing a range of medical conditions. The advantages of e-consults include reducing the amount of specialist referrals, keeping care within the community, empowering PCPs with improved knowledge, and enabling patients to remain under the care of their usual physician. This study aimed to map the needs of PCPs managing liver conditions, and to analyse their use of hepatology e-consults in the fourth-largest Health Maintenance Organization (HMO) in a small, high-income country.
Method: A random sample of 30% of all hepatology e-consults within an HMO requested by PCPs between January 1, 2023, and July 31, 2024, were categorized according to medical condition addressed, PCP query, and hepatologist response. All responses to hepatology e-consults within the HMO were provided by a single senior hepatologist.
Results: A total of 1,373 hepatology e-consults were recorded during the study period. The most common topics included imaging findings (29%), elevated liver enzyme levels (20%), and combinations of imaging and laboratory findings (12%). Diagnoses discussed in the e-consults included mostly viral hepatitis and metabolic-associated steatotic liver disease. PCPs primarily sought guidance regarding further evaluation (44% of queries), with fewer inquiries about treatment (8%) and follow-up (4%). 15% of queries regarded medication use, procedure clearance, and administrative issues. The hepatologist's responses often included recommendations for imaging (45%) and laboratory tests (35%), while fewer responses (23%) involved treatment recommendations. Only 10% of cases required referral to a hepatology clinic.
Conclusion: This analysis highlights the wide range of liver-related challenges faced by PCPs, with 62% of queries addressing the pre-diagnosis stage of management, while 26% pertain to managing diagnosed liver conditions. Since its introduction in 2019, usage of the hepatology e-consult service by PCPs has increased by 60% annually, underscoring its potential to bridge the gap between primary care and hepatology. The finding that only 10% of cases required referral to a hepatology clinic – significantly lower than figures reported in previous studies – emphasizes the service's effectiveness in reducing the need for specialist consultations. Further studies will identify knowledge gaps among PCPs, inform targeted training programs, reduce the burden on specialist clinics, and further enhance the effectiveness of e-consult services in primary care.

THU-007

Real-world experience using serial transient elastography by FibroScan in a community outreach service for the earlier detection of liver disease

Ann Archer[1,2], Zin Oo[1], Alexandra Kondratiuk[1], Robbie Adamson[1], Sally Tilden[1], Rosemary King'ori[1], James Hawken[1], Fiona Gordon[1], Kushala Abeysekera[1,2]. *[1]University Hospitals Bristol & Weston NHS Trust, Bristol, United Kingdom; [2]Bristol Medical School, University of Bristol, Bristol, United Kingdom*
Email: ann.archer@uhbw.nhs.uk

Background and aims: The *Alright My Liver?* service delivers community screening for advanced liver fibrosis in people at risk from alcohol, viral hepatitis and metabolic syndrome in the South West of England. The service targets the highest risk populations for liver disease (many who rarely access healthcare) using transient elastography (TE) by FibroScan as the initial screening modality. A personalised brief intervention is delivered alongside TE. Of 6100 people screened, 292 had initial TE indicative of suspected advanced fibrosis (LSM > 11.5 kPa). 104 of these patients have undergone repeat TE within 2 years. Here we analyse this subgroup to understand the indications and outcomes of repeated TE in this setting.
Method: Routinely collected data was analysed retrospectively from 104 patients identified over a 26 month period between August 2022 and October 2024. Data was collated on indication for repeat TE; interval change in: liver stiffness measurement (LSM), interquartile range/median value (IQR/M), controlled attenuation parameter (CAP) and alcohol intake. Interval time between TE was recorded, as was the clinical conclusion drawn from TE results alongside other investigations. Data was initially collected for 104 patients, but 27 were removed due to opportunistic rather than planned interval repeat.
Results: 77 patients (67.5% male; mean age 54, SD 13.9) were included. Mean BMI was 29.1 kg/m^2 (SD 6.9). Median interval between scans was 11 months (IQR 7). Aetiology of suspected liver disease was ALD (57.1%), MetALD (16.9%), MASLD (16.9%) and viral hepatitis (9.1%). Median LSM at first TE was 10.8 kPa (IQR 6.3) and at second TE was 7.3 kPa (IQR 5). Median IQR/M values were 21% (IQR 12) and 15% (IQR 5) respectively. The commonest indication was scheduled interval repeat post clinician assessment (n = 57/77); this was largely due to an initial assessment indicating fibrosis or possible cirrhosis with a behaviour change intervention. Other indications included clinical suspicion of inaccuracy due to discordancy of tests (n = 5/77), high IQR/M >25% (n = 12/77) or non-fasted scan (n = 3/77). The median change in LSM between TE was −3.7 kPa (IQR 5.5), median IQR/M change was −6% (IQR 19) and CAP change −10 dB/m (IQR 57). Of the 19 patients with suspected MetALD or ALD and accurate alcohol documentation, the median alcohol intake change was −44.6 units per week (IQR 140). A limitation of this analysis is the alcohol change estimate is subject to reporting bias. Clinical conclusions drawn were fibrosis regression 36.4% (n = 28/77), spurious index TE 31.2% (n = 24/77), fibrosis progression 16.9% (n = 13/77) and no clinically significant change in fibrosis 15.6% (n = 12/77).
Conclusion: We have identified a substantial reduction in the LSM and alcohol use following initial intervention with TE alongside brief intervention in these patients. Only 1.3% (n = 77/6100) of patients required repeat LSM in 2 years of a large regional pilot. Of the total dataset of 6100 people screened, only 0.4% (n = 24/6100) were discarded as spurious.

THU-008
The placebo project - comprehensive analysis of 134 commonly prescribed homeopathic remedies in India uncovers potential for severe hepatotoxicity

Arif Theruvath[1], Resmi Ravindran[1], Cyriac Philips[1,2]. [1]*Department of Clinical Research, Division of Complementary and Alternative Medicine and the Liver, The Liver Institute, Rajagiri Hospital, Kochi, India;* [2]*Department of Clinical and Translational Hepatology, The Liver Institute, Rajagiri Hospital, Kochi, India*
Email: abbyphilips@theliverinst.in

Background and aims: Homeopathy is a popular alternative medical practice globally. However, homeopathic formulations can cause allergies, anaphylaxis, fatal cardiovascular events, kidney injury, and death due to their direct and indirect toxicities. Recently Homeopathic remedies were implicated in severe liver injury, liver failure and death. Despite the growing recognition of potential risks, a comprehensive analysis of commonly prescribed and over-the-counter homeopathic products is notably absent from the medical literature. This study pragmatically analyzed the toxicology of commonly prescribed homeopathic formulations from three categories: classical dilutions, mother tinctures, and proprietary products.
Method: This cross-sectional study assessed the quality and safety of popular over-the-counter homeopathic formulations. Each remedy underwent standardized and complete organic and inorganic content profiling, including heavy metal detection, alcohol quantification, and steroid detection.
Results: We analyzed 134 homeopathic remedies and found labelled evidence of insect and animal parts in alcohol, extremely high alcohol levels, and toxic heavy metals. Mislabeling discrepancies were evident, with some formulations containing higher alcohol content than disclosed. Classical formulations had the highest alcohol content (median: 91.02% v/v). Surprisingly, highly diluted formulations of arsenic and mercury had detectable lead levels. Analysis of proprietary homeopathic formulations revealed various industrial-grade solvents, and pharmaceutical intermediates, raising consumer-level toxicity concerns. Additionally, various plant-based toxic components were also identified, which included monoterpenes and sesquiterpenes such as limonene, terpinene, and phellandrene and anthraquinones and phenolic compounds that were documented to have hepatotoxicity in published literature.
Conclusion: Our findings reveal concerning levels of ethanol, detectable heavy metals, diverse bioactive plant chemicals, industrial-grade solvents, and pharmaceutical processing residues in large number of Homeopathic formulations. Furthermore, the undisclosed nature of many compounds and discrepancies in alcohol content labeling raise significant concerns regarding product transparency and consumer safety. The presence of unregulated and untested proprietary Homeopathic remedies containing irrational combinations of ingredients, including industrial-grade chemicals and animal parts, underscores the need for stringent regulatory oversight to safeguard public health, particularly in the absence of robust clinical evidence supporting their efficacy and safety. Consumers should be aware that the testimonials and anecdotal claims of homeopathic benefits lack scientific validation and can mask potentially harmful effects.

THU-009
Gender biasing and disparities in living donor liver transplant setup from a tertiary care liver transplant centre

Arvind Tomar[1], Ashok Choudhury[2], Guresh Kumar[3], Debajyoti Bhattacharyya[4]. [1]*Pulmonary Medicine, Institute of liver and biliary sciences, New Delhi, India;* [2]*Hepatology, New Delhi, India;* [3]*Epidemiology and clinical research, Institute of liver and biliary sciences, New Delhi, India;* [4]*Pulmonary Medicine, ILBS, New Delhi, India*
Email: arvindtomar.doc@gmail.com

Background and aims: Gender disparities in accessing medical care are global issues. This multifaceted bias experienced by women has also negatively impacted them in the setting of living donor liver transplant, and more so in developing countries. To further emphasize and establish the gender inequities in living donor liver transplantation in India, we have analysed the medical records of cirrhosis patients including that of liver transplantations performed at our liver tertiary care center for gender distribution.
Method: In this retrospective study at ILBS, we analysed for gender distribution and frequency, the medical records of cirrhosis patients including that of liver transplantations performed at our tertiary care, a government apex liver care and transplant centre between Jan 2013 to Jan 2021.
Results: A total of 1523 chronic liver disease (CLD) study subjects were analysed. Of the total CLD patients who were being evaluated for liver transplant workup (n = 1117) only 147 (13.20%) were females and 970 (86.80%) were males ($p < 0.0001$). Similarly, for the CLD patients those who were getting non- transplant standard of care management (n = 406) females and male were representing 98

(24.10%) and 308 (75.90%) ($p < 0.001$) of subjects again representing overwhelming male preponderance. On the other hand, a reverse proportion but again with a negative health and social inequity was observed in living donor for liver transplant population. Of the total donor subjects (n = 627) been evaluated for donor workup only 245 (39.10%) were males while 382 (60.90%) were females.
Conclusion: The present retrospective study confirms and reestablish the overwhelming inequities and gender disparities in access to standard of liver care and lifesaving liver transplant options as evident by overwhelming preponderance of male patients, reflecting gender bias and overall, very low prevalence of habitual drinking in females in India. Similarly, females are disproportionately overrepresented in living donor for liver transplant population again reflecting a negative gender bias and altruistic behaviour of females. There is yet unrealised and unmet need for gender parity in access to liver care and liver transplant that has to be addressed in most ethical, humane and timely manner.

THU-010
Leave no one behind: an examination of how the hepatitis C elimination programme in England is reducing healthcare inequalities

Beatrice Emmanouil[1,2,3], Ashley Brown[3], Graham R Foster[1,2], Specioza Nabiteeko[3], Aneesha Noonan[3], Georgia Threadgold[3], Mark Gillyon-Powell[3]. *[1]Blizard Institute, Faculty of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom; [2]Hepatology, Barts Health NHS Trust, London, United Kingdom; [3]NHS England, Specialised Commissioning, London, United Kingdom*
Email: b.emmanouil@nhs.net

Background and aims: Hepatitis C virus (HCV) infection poses a significant public health challenge, particularly among marginalized and excluded populations. Disparities in access to diagnosis, treatment, and care can contribute to ongoing transmission and preventable morbidity and mortality. The HCV Elimination Programme in England was established as a unique co-production between NHS England, Operational Delivery Networks, people with lived experience, UK Health Security Agency, mobile outreach teams, addiction services, prison healthcare providers, GP champions, Emergency Departments, community pharmacies, needle exchanges and pharma partners. This collaborative works to eliminate HCV as a public health threat by ensuring that care reaches all individuals affected by the virus, wherever they are and regardless of their proactively accessing 'a service'. By integrating services across multiple sectors and fostering partnerships, the programme strives to deliver equitable healthcare at the patient's' convenience and setting, ensuring that no one is left behind in the fight against HCV.
Method: Retrospective review of the impact of various elimination initiatives and healthcare innovations rolled-out by the HCV elimination programme in England alongside its partners. Anonymised data collected routinely were used to assess the programmatic work's impact on healthcare inequalities. Records were matched to Indices of Multiple Deprivation (Office of National Statistics, 2019).
Results: In England, patients living in the 20% most deprived areas received 50% of all HCV treatments since 2015, and 83% of all treatments were given to the most deprived half of the country's population. One in four patients with a recorded nationality (26%) was born outside of United Kingdom. Almost half (47%) of total treatments with a recorded ethnicity, were given to minority ethnicities in England (defined by the government as not White – British). The majority of treatments were given to male patients (72.43%), 0.03% to Transgender patients and 0.001% to patients recoded as nonbinary. Information about injecting risk was recorded in 78% of cases: 76% of patients treated had injected drugs in their lifetime. Four percent of patients treated were HIV positive.
Conclusion: Through its unique co-production and scalable innovations that integrate primary, secondary and community care with partnerships with people with lived experience, addiction services, prisons and pharma, the HCV elimination programme in England provides inclusive and equitable access to healthcare and reduces health inequalities by breaking down stigma barriers, targeting the most deprived and treating (often in non-traditional settings) people at high risk such as those injecting drugs and people born in countries with higher HCV prevalence (e.g. minority white and South Asian ethnicity populations of England).

THU-011
Incidence-based mortality trends of primary liver cancer (hepatocellular carcinoma and intrahepatic cholangiocarcinoma) in Scotland between 2000 and 2021

Berkay Yanik[1,2], Karin Oien[1,3], Greig Stanners[2], Callum Rintoul[2], Anya Adair, Euan Dickson[4,5], David Morrison[2,6]. *[1]School of Cancer Sciences, College of Medical, Veterinary, and Life Sciences, University of Glasgow, Glasgow, United Kingdom; [2]Public Health Scotland, Edinburgh, United Kingdom; [3]Queen Elizabeth University Hospital, Glasgow, United Kingdom; [4]West of Scotland HPB Unit, Glasgow Royal Infirmary, Glasgow, United Kingdom; [5]On behalf of the Scottish HPB cancer Network, Edinburgh, United Kingdom; [6]School of Health & Wellbeing, College of Medical, Veterinary, and Life Sciences, University of Glasgow, Glasgow, United Kingdom*
Email: b.yanik.1@research.gla.ac.uk

Background and aims: Primary liver cancer (PLC) incidence and mortality have been increasing in European countries in recent decades. It is important to distinguish between the two main PLC subtypes, are hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCCA), because aetiology, management and outcomes differ. This study aimed to use an incidence-based mortality approach, which can distinguish PLC subtypes, unlike conventional death certificate-based mortality, to describe PLC mortality in Scotland up to 2021.
Method: PLC death certificates (n = 9673) were accessed from the National Records of Scotland in 2000–2021 and matched with individual-level incidence records, accessed from the Scottish Cancer Registry (SCR) (n = 9358) and any not recorded as PLC incidence were excluded (n = 315, 3% of death certificates). SCR is a nationwide and population-based registry. PLC patients were defined as ICD-O-3 C22 with all morphological codes. HCC patients were defined as ICD-O-3 C22 with 8170–8175 and 8180 morphological codes and ICD-O-3 C22.0 with 8010, 8140 morphological codes. iCCA patients were defined as ICD-O-3 C22 with 8160, 8161 morphological codes and ICD-O-3 C22.1 with 8010, 8140 morphological codes. European Age-Standardised Mortality Rate (EASMR) was annually calculated. Joinpoint regression analysis was applied to examine any change in the mortality trend. 95% lower and upper confidence limits were calculated by normal distribution.
Results: There were 9358 deaths from PLC from 2000 to 2021. PLC, HCC, and iCCA increased from 2000, followed by a more recent plateau. Temporal trends in PLC mortality changed for PLC and iCCA in 2016, and for HCC in 2015. PLC mortality increased between 2000 [n = 250, EASMR = 5.9 (5.2, 6.6) per 100 000] and 2016 [n = 574, EASMR = 11.1 (10.2, 12.0) per 100 000]. PLC mortality plateaued between 2016 and 2021 [n = 650, EASMR = 11.7 (10.8, 12.6) per 100 000]. HCC mortality increased between 2000 [n = 113, EASMR = 2.7 (2.2, 3.2) per 100 000] and 2015 [n = 351, EASMR = 6.9 (6.1, 7.6) per 100 000]. HCC mortality plateaued between 2015 and 2021 [n = 382, EASMR = 6.8 (6.1, 7.5) per 100 000]. iCCA mortality increased between 2000 [n = 97, EASMR = 2.3 (1.8, 2.8) per 100 000] and 2016 [n = 216, EASMR = 4.2 (3.6, 4.8) per 100 000]. iCCA mortality plateaued between 2016 and 2021 [n = 220, EASMR = 4.0 (3.5, 4.5) per 100 000].
Conclusion: PLC, HCC, and iCCA mortality increased from 2000 followed by plateaus from the mid-2010s in Scotland. These trends might be cautiously welcomed, but further research is needed to understand whether they are driven by changes in incidence, survival, or a mixture of the two.

THU-012

Circulating metabolites, gallstones, and gallbladder cancer

Felix Boekstegers[1,2], Vivian Viallon[1], Anastasia Chrysovalantou Chatziioannou[1], Pekka Keski-Rahkonen[1], Dominique Scherer[2], Mazda Jenab[1], Justo Lorenzo Bermejo[2,3].
[1]*International Agency for Research on Cancer (IARC), World Health Organization, Lyon, France;* [2]*Statistical Genetics Group, Institute of Medical Biometry, University of Heidelberg, Heidelberg, Germany;* [3]*Laboratory of Biostatistics for Precision Oncology, Institut de Cancérologie Strasbourg Europe, Strasbourg, France, Strasbourg, France*
Email: boekstegersf@iarc.who.int

Background and aims: Gallbladder cancer (GBC) is an aggressive disease with limited treatment options but high prevention potential. Gallstone disease has been causally linked to GBC, with an estimated latency period of 15–25 years, a time frame that harbors the potential for primary prevention of GBC through gallbladder removal in gallstone patients at high risk for GBC. An efficient prevention strategy requires accurate assessment of GBC risk, and the identification of risk biomarkers is critical. However, studies aimed at identifying GBC biomarkers have generally been challenged by their small sample size, and the robustness of their results is questionable. To overcome this limitation, we capitalized on the link between gallstones and GBC and hypothesized that some metabolites associated with gallstone disease could serve as GBC risk biomarkers.
Method: A two-stage prospective study design was applied to UK Biobank targeted metabolite data using bootstrapping for robust metabolite selection. At the first stage, the association between circulating metabolites and the onset of gallstone-related clinical conditions (gallstone detection, cholecystitis, cholecystectomy) was investigated using regularized Cox regression. At the second stage, the direct association between metabolites selected in the first stage and GBC onset was examined, adjusting for gallstone onset as a time-dependent covariate.
Results: At the first stage, seventeen metabolites, selected by bootstrapping to at least 90%, were considered robustly associated with gallstone-related clinical conditions. At the second stage, four out of these seventeen metabolites were found to be directly associated with GBC. Among these, free cholesterol in small high-density lipoprotein (HDL) was linked to a reduced risk of GBC, while triglycerides in large HDL, glutamine and acetone were associated with an elevated risk of GBC.
Conclusion: Risk assessment, a critical component of disease prevention, would highly benefit from risk biomarkers. For rare diseases such as GBC, the time and cost associated to biomarker identification and measurement limit the clinical utility of biomarker-guided personalised prevention. Our research introduces a novel approach to find risk biomarkers for a rare disease capitalizing on a well-established, strong risk factor. The metabolites identified demonstrate the potential of this approach. Next, we plan to validate our findings in independent prospective cohorts and compare the high-risk-profiles in different populations. Taken together, our work may help refine current prevention strategies by prioritizing gallbladder removal in high-risk patients.

THU-013

First nations australians with cirrhosis have higher and premature mortality and multiple cofactors

Catherine Brown, (First Nation Australian[1], Vikas Bhasker[2,3], Jessica Fong[4], Paul Clark[3,5], Gunter Hartel[1], Richard Skoien[6], James O'Beirne[7], Elizabeth E. Powell[1,3,4], Patricia Valery[1,4]. [1]*QIMR Berghofer Medical Research Institute, Brisbane, Australia;* [2]*QIMR Berghofer Medical Research Institute, Princess Alexandra Hospital, Brisbane, Australia;* [3]*Princess Alexandra Hospital, Brisbane, Australia;* [4]*University of Queensland, Brisbane, Australia;* [5]*Mater Hospital, Brisbane, Australia;* [6]*Royal Brisbane and Women's Hospital, Brisbane, Australia;* [7]*Sunshine Coast University Hospital, Sunshine Coast, Australia*
Email: patricia.valery@qimrberghofer.edu.au

Background and aims: Liver disease is an important contributor to the mortality gap between First Nations (FN) and non-Indigenous (NI) Australian adults. We described cause-specific mortality by indigenous status in people with cirrhosis in Queensland, a large state in the north-east of Australia with a population of over 5 million.
Method: A retrospective analysis of all adults hospitalized with cirrhosis during 2007–2022 was performed using state-wide hospital admissions and mortality data. We identified admissions with cirrhosis, aetiology, and underlying cause of death based on validated algorithms. 1,909 (8.5%) FN and 20,584 (91.5%) NI patients were followed from the first admission with cirrhosis until death, liver transplant, or December-2022, whichever came first. Multivariable Cox regression assessed factors associated with mortality.
Results: Compared to NI patients, FN patients were 8.3 years younger (53.6 years, SD = 11.9 vs 61.9 years, SD = 12.8; $p < 0.01$), a higher proportion resided in most disadvantaged (46.9% vs 26.0%; $p < 0.01$) and remote areas (19.3% vs 1.5%, $p < 0.01$), had diabetes (49.5% vs 37.6%, $p < 0.01$), and cirrhosis decompensation or hepatic failure (43.8% vs 39.9%; $p < 0.01$). Alcohol was an aetiological factor in 74.1% of FN and 58.2% of NI patients ($p < 0.01$). Multiple cofactors was more common in FN patients (70.2% vs 57.8%; $p < 0.01$), alcohol/diabetes was present in 32.6% of FN patients (vs 17.5%; $p < 0.01$), and alcohol/viral hepatitis in 25.0% (vs 14.2%; $p = 0.01$). During a median follow-up of 6.9 years (IQR 3.5–11.1), 52.1% of FN and 55.2% of NI patients died. At death, 40.2% of FN patients were ≥60 years vs 70.0% of NI patients ($p < 0.01$), with a similar pattern of premature mortality due to liver ($p < 0.01$) and cardiovascular disease ($p < 0.01$), but not due to extrahepatic cancer ($p = 0.10$). The 10-year all-cause mortality was 66.8% (95%CI 63.8–70.0) and 68.5% (95%CI 67.6–69.3), respectively. Adjusting for age, sex, socioeconomic status, remoteness of residence, aetiology, decompensation, and diabetes, all-cause mortality was 10% higher in FN vs NI patients (adjusted hazard ratio (aHR) = 1.10, 95%CI 1.02–1.19, $p = 0.01$), and mortality due to cardiovascular was 68% higher (aHR = 1.68, 95%CI 1.34–2.09; $p < 0.01$), with no difference in mortality due to liver disease ($p = 0.76$) and extrahepatic cancer ($p = 0.46$).
Conclusion: FN Australians with cirrhosis have higher mortality and die at a younger age than NI Australians. The presence of multiple liver disease cofactors is a likely driver of earlier disease onset and poorer survival in FN Australians with cirrhosis and highlights the importance of early identification of chronic liver disease and rapid linkage to specialist liver care. The higher prevalence of diabetes and higher mortality due to major cardiovascular event in FN Australians reinforces the need for a holistic approach to management of metabolic comorbidities.

THU-014

Chronic liver diseases are often diagnosed at an advanced stage despite identification of risk factors: insights from a french national study

Laure Tron[1,2], Frederic Balusson[3], Aurore Baron[2], Thomas Decaens[1,2], Emmanuel Oger[3], Charlotte Costentin[1,2]. [1]*CHU Grenoble Alpes, Grenoble, France;* [2]*Institute for Advanced Biosciences, CNRS UMR 5309-INSERM U1209, Grenoble, France;* [3]*Pharmacovigilance et Pharmaco-epidemiologie, CHU Rennes, Rennes, France; Univ Rennes, CHU Rennes, Inserm, EHESP, Irset - UMR_S 1085, Rennes, France*
Email: ccostentin@chu-grenoble.fr

Background and aims: Chronic liver diseases have been reported to be frequently diagnosed at an advanced stage in various country settings. However, descriptive data on chronic liver disease (CLD) in France remain scarce. Such data are essential for designing and implementing effective corrective actions. This study aims to describe the diagnostic modalities, stages at diagnosis, and health trajectories of CLD before the occurrence of complications in France.
Method: Data were collected from the National Health Data Hub covering the National Health Data System (SNDS). Patients with at least one CLD specific ICD-10 code, procedure, or drug and/or an ICD-

10 code for primary liver cancer (PLC) between 2015–2021, were extracted from the 2% SNDS sample. Socio-demographics, etiologies, risk factors, comorbidities, and severity at diagnosis were recorded.
Results: We identified 26,388 patients, including 7,016 prevalent cases in 2015 and 19,372 incident cases between 2015 and 2021. The population of incident cases comprised 57.2% males, average age 60.3 ± 18.2 years, with 43.4% experiencing social deprivation. Etiologies included alcohol (30.6%), metabolic factors (26.6%), viral infections (10.8%), rare diseases (3.7%), and etiology was undetermined in 28.3% of the cases. At diagnosis, 55.7% had non-cirrhotic CLD, 35.2% cirrhosis (of which 91% where diagnosed during an hospitalisation stay), 7.1% liver cancer, 0.1% were identified at the time of liver transplantation and 1.8% at the time of death. Risk factors for CLD (e.g., alcohol, diabetes, obesity) were identified before CLD diagnosis in 43% of patients, with 45.7% presenting severe CLD at diagnosis (e.g., decompensated cirrhosis, liver cancer). During follow-up, nearly 50% of the cohort were diagnosed with cirrhosis or decompensations. Almost 95% of patients diagnosed with cirrhosis were hospitalized at least once during follow-up. Cirrhosis complications included a majority of hepatic encephalopathy, portal hypertension, and ascites, and to a lesser extent alcoholic hepatitis. Hepatorenal syndrome and spontaneous bacterial peritonitis were observed in few patients. About 10% of patients were diagnosed with PLC during follow-up, two-thirds being hepatocellular carcinoma. Fewer than 20% of incident CPF cases were eligible for curative treatment at diagnosis.
Conclusion: This study, utilizing data from the French National Health Data System, demonstrates that nearly half of CLD cases are diagnosed at an advanced stage, despite prior identification of risk factors. These results emphasize the urgent need for enhanced prevention and early detection strategies for CLD.

THU-019

Gaps in palliative care for liver cirrhosis in Singapore: an analysis on disease burden, timing and utilization of palliative services

Charlene Yeo Li Xin[1], Lionel See Kee Yon[2,3], Grace Yang[3], Charlene Tan Hui Min[1,2], Su Qiqi[2,4], Tay Pei Yoke[2,5], Aiden Lin Yuda[2,6], Jolyn Tan Yi Ling[2,7], Koh Guan Hong[2,7], Loh Soak Yee[2,8], Lim Qian Hui[2,9], Marianne DeRoza[1,2]. [1]*Department of Gastroenterology and Hepatology, Sengkang General Hospital, Singapore, Singapore;* [2]*Palliate End Stage and Advanced Cirrhotics Early (PEACE) Multidisciplinary Group, Singapore, Singapore;* [3]*Palliative Medicine Service, Sengkang General Hospital, Singapore, Singapore;* [4]*Advanced Specialty Nursing, Gastroenterology and Hepatology, Sengkang General Hospital, Singapore, Singapore;* [5]*Community Nursing, Singhealth, Singapore, Singapore;* [6]*Department of Physiotherapy, Sengkang General Hospital, Singapore, Singapore;* [7]*Medical Social Services, Sengkang General Hospital, Singapore, Singapore;* [8]*Department of Pharmacy, Sengkang General Hospital, Singapore, Singapore;* [9]*Department of Occupational Therapy, Sengkang General Hospital, Singapore, Singapore*
Email: marianne.anastasia.d.r@singhealth.com.sg

Background and aims: Liver disease afflicts millions worldwide with many of these patients dying or suffering from its associated complications. In 2022, hepatocellular carcinoma (HCC) was the fifth most common cancer and third most common cancer death in Singapore. Despite this, palliative care utilization amongst cirrhotic patients remains low. We aimed to evaluate morbidity burden and palliative care utilization for end stage liver disease (ESLD) patients in our population.
Method: A single centre retrospective observational cohort study included patients with known liver cirrhosis and mortality from 1/1/2018 to 31/5/2024. Patient demographics, hospitalization lengths and palliative care utilization data were collected.
Results: 209 patients were included. Mean age was 71 years old with 68.9% males. 53.11% of patients had a Model for End-Stage Liver Disease (MELD) score between 10–19 and 26.32% had a MELD score <10. 13.4% of patients' MELD was 20–29 and 1.44% had a MELD of >30. 12 patients had missing data that precluded a complete MELD score. On average, each patient was hospitalised 6.56 times. The average length of a hospitalization was 9.59 days. Average total hospitalization days per patient from date of inclusion was 54.50 days. Majority of admissions occurred in the patient's last year of life, with an average of 4.12 admissions during the last year, compared to 1.21 admissions in the second last year of life. Cause of death (COD) was known for 113 patients. Of these, 77 (68.14%) died of liver cirrhosis and its associated complications. The top COD was HCC with 36 (31.86%) patients. 56 (26.79%) patients were referred to specialist palliative care prior to their death. Of these, 19 (33.93%) were made within 7 days of death and a further 18 (32.14%) were made within a month of death. 39 (18.66%) accessed community palliative care and 21 (10.05%) patients were admitted to an inpatient hospice. Only 21 patients (10.05%) completed advanced care planning (ACP).
Conclusion: Despite liver cirrhosis conferring a significant mortality and morbidity burden on patients, palliative care utilization remains low. Even amongst the few who had access to palliative services, these services were provided late in the disease with majority receiving it only in the last month of life. More efforts need to be made to improve access to palliative services earlier in the disease course.

THU-020-YI

Assessing awareness of fatty liver disease among people in Scotland: a cross-sectional survey study (ADIPOSE)

Damien Leith[1], Paul Brennan[1], Ruairi Lynch[1], John F Dillon[1], Christopher Byrne[2]. [1]*Ninewells Hospital and Medical School, Dundee, United Kingdom;* [2]*Ninewells Hospital and Medical School, University of Dundee, Dundee, United Kingdom*
Email: damienleith86@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease [MASLD], which replaced non-alcoholic fatty liver disease [NAFLD], is the commonest liver disease globally, existing within the wider metabolic syndrome. However, awareness of NAFLD/MASLD is low in both general and at-risk groups and no such awareness data exists for large UK populations. We conducted the 1st national survey assessing awareness and knowledge of "fatty liver disease" [FLD] (NAFLD/MASLD), among adults with low and high risk of MASLD in Scotland.
Method: Adults living in Scotland, registered with Scottish Health Research Register, were invited by email to complete an online survey on their awareness of liver disease. Participants self-reported demographic and health information and their knowledge of NAFLD/MASLD and related conditions. Participants were considered "at risk" for MASLD [AR] if they had ≥1 self-reported risk factor (T2D/CVD/BMI ≥25). Individuals with no risk factors were considered low risk [LR]. Analysis utilised descriptive statistics and chi-squared tests.
Results: From 01/07–23/09/24 19,763 people were invited to complete the survey. 2,114 people (11%), from all Scottish Health Boards, completed the survey (1227 [58%] female, 1178 [56%] aged 60–79). 1,586 (75%) were AR (466 [22%] T2D; 474 [22%] CVD; 1325 [63%] BMI ≥25) and 528 (25%) were LR. 217 (10%) reported a diagnosis of "FLD, NAFLD or MASLD" - 200 [13%] AR, 17 [3%] LR ($p < 0.001$).
1,495 (71%) knew of "fatty liver disease," 810 (38%) of NAFLD and 99 (5%) of MASLD. Those AR were not significantly more likely to know of these conditions relative to LR respondents ($p = 0.354$; 0.349; 0.755, respectively). Significantly more women than men were likely to know of FLD (965 [79%], $p = <0.001$) and NAFLD (588 [48%], $p = <0.001$). 86% of respondents were aware of alcohol related liver disease, 75% of viral hepatitis and >90% of other metabolic syndrome features (T2D, hypertension, obesity). After receiving information about the lack of pharmacotherapy for NAFLD/MASLD, 2,073 (98%) stated that if they had the condition, they would wish to know.
Conclusion: This national survey gives the first population-level insight into the awareness of NAFLD/MASLD in the UK. While many people report awareness of "fatty liver disease," less than half are aware of NAFLD and only 5% of MASLD. Those individuals at highest

risk are not more likely to know of these conditions compared to those at lower risk. However, significantly more of the at-risk group report a diagnosis of NAFLD/MASLD. This low NAFLD/MASLD awareness contrasts with a much higher awareness of other liver disease aetiologies and features of the metabolic syndrome. Almost all survey respondents stated that if they had MASLD they would want to be made aware of the diagnosis, even after it was explained that current management is largely lifestyle based. This study clearly demonstrates the outstanding efforts that are necessary to increase population awareness of MASLD, one of the largest public health threats of the coming decades.

THU-021

Advanced care planning (ACP) for liver cirrhosis patients in Singapore: barriers to ACP and influence of hepatocellular carcinoma diagnosis on ACP preferences

Danelle Lai[1], Marianne De Roza[2]. [1]*Lee Kong Chian school of medicine, Singapore, Singapore;* [2]*Sengkang general hospital, Singapore, Singapore*
Email: danellelai7@gmail.com

Background and aims: The unpredictable clinical course of liver cirrhosis necessitates early advanced care planning (ACP) initiation for liver cirrhosis patients to uphold their wishes and quality of life. This study aims to investigate barriers to ACP and the influence of Hepatocellular Carcinoma (HCC) diagnosis on ACP preferences in liver cirrhosis patients.
Method: We reviewed all electronic ACP discussion records from January 2018 to December 2023 at our institution, a public tertiary hospital in Singapore. Those with diagnosis of liver cirrhosis and at least 1 hospital admission in the same period were identified. Patient data on ACP completion rate, reasons for rejection, and ACP preferences on preferred place of death (PPOD), preferred place of care (PPOC), medical intervention and CPR were reviewed in detail.
Results: In total, 53 liver cirrhosis patients with ACP discussion records were included for analysis of which 22 had HCC and 31 non-HCC. Median age was 68 of which 33 were male. 51 were of Asian ethnicity (41 Chinese, 5 Malay, 5 Indian). 50.9% (27/53) of patients rejected or did not complete ACP. Overarching themes and reasons for rejection include: death before completion, lack of readiness to discuss end-of-life (EOL)/ACP, patient denial or avoidance (perception that ACP is unnecessary, preference to discuss when situation arises), family centredness (preference to leave decision to family, family excluding patient in decision-making, family does not want to let patient know his diagnosis), and patient conditions impairing ACP discussion (dementia or encephalopathy). The most frequent reason was death before ACP completion (n = 8). The second most frequent reason was the lack of readiness to discuss EOL/ACP (n = 5). For PPOD, majority chose their own home (34.6%), followed by hospital (23.1%), and long-term care facilities such as nursing home and inpatient hospice (3.8%). An equal proportion of HCC and non-HCC patients selected the hospital (23.1%). Compared to non-HCC patients, a higher proportion of HCC patients selected own home (38.5% vs 30.8%) and long-term care facilities (7.7% vs 0%), although the difference was not statistically significant (p = 0.878). With regards to PPOC, non-HCC patients were much more likely to select the hospital compared to those with HCC (84.6% vs 15.4%, OR30.3, [3.59–254.73]; p = 0.0015). In terms of preferred medical intervention, all patients who completed ACP opted not to attempt cardiopulmonary resuscitation with majority choosing only limited intervention (HCC 84.6% and non-HCC 100%).
Conclusion: Death before ACP completion and patient lack of readiness for ACP discussion are the most significant barriers to ACP. The higher certainty of poor prognosis for liver cirrhosis patients with HCC may influence decisions on place of care, with HCC patients preferring to stay out of hospital compared to non-HCC cirrhotics preferring hospitalisation.

THU-023

Health behaviors significantly modify the sex-specific alcohol-attributable liver-related mortality in the United States. A population-based study

Eduardo Vilar Gomez[1], Lauren Nephew[1], Samer Gawrieh[1], Raj Vuppalanchi[1], Francis Pike[1], Carla Kettler[1], Tu Wanzhu[2], Niharika Samala[1], Suthat Liangpunsakul[1], Naga Chalasani. [1]*Indiana University School of Medicine, Indianapolis, United States;* [2]*Indiana University School of Medicine, Indianapolis, United States*
Email: evilar@iu.edu

Background and aims: The impact of diet quality (DQ) and physical activity (PA) on alcohol-related liver mortality is not well-studied at the population level. This study aims to explore how DQ and PA influence the relationship between alcohol consumption patterns and liver-related mortality.
Method: The study analyzed data from 60,334 adults in the National Health and Nutrition Examination Surveys (1984–2018), linked to the National Death Index through December 31, 2019. Liver-related deaths were identified using ICD-10 codes. Alcohol intake was measured as the average number of drinks per day over the past 12 months. The NIAAA guidelines classified alcohol consumption by sex: for women, light/moderate drinking was 1–3 drinks per day, and heavy drinking was more than 3 drinks per day; for men, light/moderate drinking was 2–4 drinks per day, and heavy drinking was more than 4 drinks per day. Binge drinking was defined as 4 or more drinks for women, or 5 or more drinks for men, on a single occasion within two hours. Diet quality was assessed using the Healthy Eating Index (2010), based on 24-hour dietary recalls. Physical activity levels were evaluated using the Global PA Questionnaire, classifying participants as physically active if they reported at least 150 minutes of moderate-intensity PA, 75 minutes of vigorous-intensity PA, or a combination per week. Cox regression models examined associations between these factors and liver mortality, adjusting for age, sex, race/ethnicity, smoking, BMI, diabetes mellitus, educational attainment, poverty levels, calorie intake, and the Fib-4 index.
Results: During a mean follow-up of 12.2 years, 252 liver-specific deaths were recorded. Covariate-adjusted analyses showed that any daily alcohol intake increased the risk of liver-specific mortality (adjusted Hazard ratio (aHR)-men: 1.25, 95% CI: 1.03–1.54; women: 1.88, 95% CI: 1.25–2.83) compared to abstainers. Binge drinking also increased liver-specific mortality risk (aHR-men: 1.35, 95% CI: 1.02–2.12; women: 2.56, 95% CI: 1.34–4.93) compared to non-binge drinking. Higher diet quality (DQ) levels (HEI top quartile) were linked to lower liver mortality risk among light/moderate (aHR: 0.32, 95% CI: 0.14–0.72), heavy (aHR: 0.10, 95% CI: 0.03–0.39), and binge (aHR: 0.14, 95% CI: 0.05–0.41) drinkers compared to lower DQ levels (HEI first quartile). Physically active participants had a lower risk of liver mortality among light/moderate (aHR: 0.72, 95% CI: 0.40–0.96), heavy (aHR: 0.82, 95% CI: 0.29–0.99), and binge (aHR: 0.51, 95% CI: 0.20–0.95) drinkers compared to inactive individuals. These relationships remained consistent after excluding former drinkers from the non-drinkers and those who died within the first year of follow-up.
Conclusion: Physical activity and healthy eating significantly lower the risk of alcohol-attributable liver mortality in the US population.

THU-024

Angiotensin receptor blockers and drug-induced liver injury: a cohort study using electronic-health records-based common data model database

Jun Kyu Lee[1]. [1]*Dongguk University Ilsan Hospital, Goyang, Korea, Rep. of South*
Email: gerome@dumc.or.kr

Background and aims: Angiotensin receptor blockers (ARBs) are one of the most commonly used anti-hypertensives in South Korea. In 2021, a need for national compensation was acknowledged by the Korea Ministry of Food and Drug Safety for a drug-induced liver injury

(DILI) after azilsartan use, the youngest drug among ARBs. Not much has been known about the association between ARBs and DILI.
Method: To further investigate ARB-induced liver injuries, we executed a retrospective new-user cohort study using electronic-health-records-based common data model database (2017–2021). In this study, patients were designated to treatment groups according to the ARB prescribed at cohort entry, i.e., azilsartan, eprosartan, telmisartan, fimasartan, valsartan, olmesartan, losartan, irbesartan, or candesartan. DILI was operationally defined by adapting the definition from the International DILI Expert Working Group. We conducted cox regression analyses to derive hazard ratios (HRs) and applied propensity score-based inverse probability of treatment weighting.
Results: A total of 229,881 ARB users from 20 university hospitals were included. The crude incidence of DILI ranged from 15.6 to 82.8 by treatment groups. In all treatment groups, the most common type of DILI was the cholestatic type and the majority were of mild severity. In overall, the risk was significantly lower in olmesartan users compared to valsartan users (HR: 0.73 [95% confidence interval (CI): 0.55–0.96]). In patients receiving monotherapy, the risk was significantly higher in azilsartan users compared to valsartan users (HR: 6.55 [95% CI: 5.28–8.12]).
Conclusion: Our findings provide insights to the methods for detecting DILI using real-world data and enhance understanding of the variations in risk of DILI among individuals using different ARBs.

THU-025-YI
Prevalence of and outcomes related to metabolic dysfunction-associated steatotic liver disease (MASLD) in a nationwide cohort: insights from over 23 million individuals in Taiwan's national health insurance research database
Huei-Tyng Huang[1], Liang-Yu Lin[2,3,4], Chuan-Pin Lee[5], Michael Hewitt[1], Catriona Chaplin[1], Yao-Hsu Yang[5,6,7], William Alazawi[1]. *[1]Barts liver centre, blizard institute, queen Mary university of London, London, United Kingdom; [2]Institute of environmental and occupational health sciences, college of public health, national taiwan university, Taipei, Taiwan; [3]Global health program, college of public health, national taiwan university, Taipei, Taiwan; [4]Department of environmental and occupational medicine, national taiwan university hospital, Taipei, Taiwan; [5]Health information and Epidemiology Laboratory, chang gung memorial hospital, Chiayi, Taiwan; [6]Department of traditional chinese medicine, chang gung memorial hospital, Chiayi, Taiwan; [7]School of traditional chinese medicine, college of medicine, chang gung university, Taoyuan, Taiwan*
Email: h.t.huang@qmul.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is associated with increased risk of cirrhosis, hepatocellular carcinoma (HCC) and metabolic endpoints: cardiovascular disease (CVD) and chronic kidney disease (CKD). MASLD affects 15–30% of individuals globally, with most data from Western cohorts. However, its prevalence, progression, and associated outcomes remain underexplored in unselected general populations, particularly in East Asia, where the rates of metabolic diseases are rising. Electronic Health Record data offer very wide population coverage and real-world evidence based on clinical coding. This study leverages Taiwan's National Health Insurance Research Database (NHIRD), representing over 99% of the population, to bridge these knowledge gaps.
Method: This population-based retrospective cohort study extracted NHIRD data from 1 January 2001 to 31 December 2022. Individuals were excluded if they had < 1 year follow-up post-registration, were < 18 years old, or had pre-existing conditions including alcohol abuse, alcoholic liver disease, cirrhosis, HCC, stroke, CVD, or CKD prior to MASLD diagnosis. In the absence of MASLD codes in ICD-9/10, we used NAFLD codes; shown to overlap almost completely with MASLD.
Results: In Taiwan's 23,319,977 insured individuals in 2022, 1,569,912 (6.73%) had recorded MASLD, a significant rise ($p < 0.001$) from 4.13% (N = 965,225) in 2013. The median age of patients was 49 years (IQR: 38–60), with a slight male predominance of 53.2%. Median follow-up duration ranged from 9.6 to 10.4 years for multiple metabolic endpoints analysis. Among MASLD cases, 3.6% (N = 56,394) developed cirrhosis, and 2.3% (N = 36,287) progressed to HCC. New diagnostic codes for extrahepatic outcomes were acquired during follow up: myocardial infarction (2.3%, N = 36,397), stroke (7.2%, N = 112,530), and CKD (12.1%, N = 189,750).
Conclusion: This pilot is the first MASLD study using whole population data of NHIRD, offering a near-complete depiction of MASLD codes in an East Asian population. Although there has been a marked increase in prevalence over the past decade, substantial under-diagnosis and under-recording persists compared to expected. Progression to both hepatic and extrahepatic endpoints indicates MASLD's systemic impact. The population-wide NHIRD database can advance understanding of MASLD and guide tailored public health strategies in East Asia.

THU-026
Population study of hepatocellular carcinoma survival in northest region of Spain
Isabel Serra[1], Aina Romaguera[2], Ariadna Clos[3], María Valenzuela[1], Berta Bartrolí[1], Gemma Espin[1], Carmen López Núñez[3], Raquel Guardeño[4], Jan Trallero[2], Montse Puigdemont[1], Arantza Sanvisens[2], Margarita Sala[1], Rafael Marcos-Gragera[2]. *[1]Department of Hepatology. Universitary Hospital Doctor Josep Trueta, Girona, Spain; [2]Epidemiology and Cancer Registry Unit of Girona, Catalan Institute of Oncology – Oncology Master Plan. Biomedical Research Institute Dr. Josep Trueta, Girona, Spain; [3]Universitary Hospital Doctor Josep Trueta, Girona, Spain; [4]Department of Medical Oncology, Catalan Institute of Oncology, Universitary Hospital Dr. Josep Trueta, Girona, Spain*
Email: iserramatamala@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is the most common primary liver tumor and is considered to have a poor prognosis. At the population level, there are few studies describing the survival of this pathology, and there are no data specific to Spain. Recently, the III Spanish HCC Registry of the Spanish Association for the Study of the Liver has been published at the hospital level, describing a mortality rate of 67%. The aim is to describe the observed survival (OS) of HCC at the population level in the province of Girona (2010–2020), by sex, age, and diagnostic period.
Method: A population-based study was conducted, including all cases of HCC diagnosed from 2010 to 2020 in the province of Girona, as recorded by the Girona Cancer Registry. Cases were coded using the International Classification of Diseases for Oncology, 3rd edition (histological codes 8170–8180). Follow-up of cases continued until December 31, 2021. OS at 1, 3, and 5 years was estimated using Kaplan-Meier curves by sex, age (<50, 50–64, 65–79, and ≥80 years), and diagnostic period (2010–2013, 2014–2017, and 2018–2020).
Results: A total of 679 cases were collected, with 79.6% being male. The median age at diagnosis was 67 years [interquartile range (IQR): 59–75]. The majority of cases (62.6%) were diagnosed through imaging tests, while the rest had a microscopically confirmed diagnosis; 4 cases (0.6%) were diagnosed with combined HCC and cholangiocarcinoma. At the end of the follow-up period, 507 patients (74.6%) had died, with a median follow-up of 1.2 years (IQR: 0.2–3.4). OS at 1, 3, and 5 years was 55%, 33%, and 22% respectively, with no statistically significant differences by sex and diagnostic period. By age group, OS varied considerably after 3 years, with 5-year OS being 41% in the <50 years group and 8.9% in the ≥80 years group.
Conclusion: Population survival of HCC remains low, although age is a determining factor in medium-term prognosis. No improvement in survival has been observed in the last decade, reflecting the need for more resources to address this pathology.

THU-027

Vibration-controlled transient elastography dynamics in the general population: longitudinal results from the LiverScreen consortium

Jesse Pustjens[1], Katrine Bech[2], Guillem Pera[3], Helle Schnefeld[4], Laurens A. van Kleef[1], Robert J. de Knegt[1], Peter Andersen[4], Johanne Kragh Hansen[4], Llorenç Caballeria[3], Carla Chacon[3], Pere Torán[3], Sarwa Darwish Murad[1], Anita Arslanow[5], Harry L.A. Janssen[1], Aleksander Krag, Isabel Graupera[6,7], Maja Thiele, Willem Pieter Brouwer[1]. *[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Centre, Rotterdam, Netherlands; [2]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, 3. Email: j.pustjens@erasmusmc.nl

Background and aims: Chronic liver disease is a growing global health concern driven by the rising prevalence of steatotic liver disease. Liver stiffness measurement (LSM) via vibration-controlled transient elastography (VCTE) is a recommended screening tool for liver fibrosis. However, incidence and risk factors for significant LSM changes in the general population remain poorly understood. This study examines LSM dynamics within a general population cohort and identifies risk factors for significant increases.
Method: This multicenter, prospective cohort study analyzed two population-based cohorts (Barcelona and Rotterdam) and one focused on a population with ongoing or prior moderate-to-high alcohol consumption (Odense). Participants underwent baseline and follow-up VCTE screenings over an approximate four-year interval, alongside questionnaires, anthropometric and laboratory assessments. Clinically significant LSM change was defined as a ≥30% increase or decrease from baseline, and crossing the 8 kPa threshold. Logistic regression models were used to identify risk factors for significant LSM increase, adjusting for age, sex, baseline LSM, cohort and length of follow-up.
Results: A total of 5,584 participants underwent baseline VCTE screening, of which 3,308 participants were reassessed (participation rate 75% of those eligible). At baseline, 49% were male, median age was 63 years [53–69], median baseline LSM 4.6 kPa [3.6–5.6] and 215 (6.5%) had a baseline LSM≥8 kPa. 81% had at least one metabolic risk factor. After a median follow-up of 4.2 years (3.8–4.4; 12,634 person-years), 614 (19%) experienced an LSM change of ≥30%. Among participants with baseline LSM <8 kPa (n = 3093), 2.7% (n = 82) experienced a clinically significant LSM increase, of which 14 (17%) progressed to ≥12 kPa. Independent baseline predictors of clinically significant LSM increase included obesity (aOR 3.69; 95% CI 1.66–8.17), elevated ALT (aOR 2.94; 1.72–5.04), metabolic syndrome (aOR 2.60; 1.62–4.16) and diabetes (aOR 2.44; 1.44–4.14). Of those that screened ≥8 kPa at baseline (n = 215), 87 (40%) experienced a clinically significant decrease.
Conclusion: We found a 4-year incidence of liver fibrosis close to 3%, as assessed by VCTE in this European population, suggesting that this interval is suitable for monitoring liver fibrosis development. Baseline metabolic dysfunction or elevated ALT predicted significant LSM increases, supporting current clinical practice guidelines to screen for fibrosis in at-risk populations.

THU-028

Hospital wide approach to limiting and treating alcohol use disorder

Janis Fernandes[1,2], James O'Beirne[1,2,3], Mikaela Daniells[1], Craig Allen[1], Rohit Gupta[1]. *[1]Sunshine Coast University Hospital, Sunshine Coast, Australia; [2]Griffith University, Sunshine Coast, Australia; [3]University of the Sunshine Coast, Sunshine Coast, Australia*
Email: Janis.fernandes@health.qld.gov.au

Background and aims: Alcohol related liver disease (ARLD) is a major public health challenge and addressing alcohol use disorder (AUD) remains the cornerstone of prevention. The inpatient setting provides an ideal and underutilised opportunity to capture risky alcohol behaviours and provide brief intervention as required. Patients with AUD have double the length of stay (5.7 vs 2.3 days), are at risk for various comorbidities in their lifetime and have a significantly higher all-cause mortality. Consequently, there are obvious health, social and monetary benefits in developing a systematic approach to assessing alcohol use in the inpatient setting for the purpose of providing brief intervention to those identified as having AUD.
Method: The hospital wide approach to limiting and treating alcohol use disorder (HALT-AUD) initiative aims to address AUD with early detection and treatment. To facilitate this approach a pilot study was conducted prior to the implementation of a hospital-wide protocol using the AUDIT-C questionnaire on a medical ward. Nursing staff administered the survey upon patient admission, with results linked to a traffic light management plan. Green (< 4): No intervention required. Yellow (4–7): Brief intervention provided, including AUD resources and motivational interviewing. Red (≥ 8): Referral to the Consultation Liaison Psychiatry Alcohol Service (CLPAS) for inpatient review and further outpatient contact. The primary goal of the study was to use a quality improvement framework to evaluate the identification and management of patients at risk of alcohol-related harm. Following a 2-month period of data collection, an additional 2-month period utilised quality improvement strategies dedicated to staff assessment, education, patient feedback and workflow management. Monthly rates of compliance were collated throughout the study. The secondary measured outcomes were prevalence of significant alcohol intake (AUDIT-C ≥4), patient and staff satisfaction.
Results: 608 patients were admitted throughout the study period with 353 patients (58%) completing the AUDIT-C. Of those who completed the AUDIT C, 28% had a score ≥ 4. In the initial observation stage, the compliance in the 1st month was 51% and the 2nd month was 46%. Staff feedback, education and workflow initiatives were implemented leading to improvement to 60% and 74% compliance in the subsequent two months. Patients found the questionnaire to be comfortable and straightforward (90% agree and strongly agree), whilst after education and training 90% of nursing staff felt confident in discussing alcohol intake with patients.
Conclusion: Utilising AUDIT-C through a hospital wide approach is a simple, fast and effective tool to address AUD through a public health lens. Automation, education and focus on workflow practices improve compliance and effectiveness of AUD pathways.

Awareness of metabolic dysfunction-associated steatotic liver disease (MASLD) in four cities in the United States, including among people with diabetes and primary care providers

Trenton M White[1,2], Scott Isaacs[3], Norah Terrault[4], Mary E. Rinella[5], Alina M Allen[6], Naim Alkhouri[7], Meena Bansal[8], Michael Charlton[5], Ira Jacobson[9], Sonal Kumar[10], Mazen Noureddin[11], Silvana Pannain[5], Ayman El-Mohandes[1], Jeffrey Lazarus[1,2]. *[1]City University of New York Graduate School of Public Health & Health Policy (CUNY SPH), New York City, United States; [2]Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [3]Atlanta Endocrine Associates, Atlanta, United States; [4]University of Southern California (USC), Los Angeles, United States; [5]University of Chicago, Pritzker School of Medicine, Chicago, United*

States; [6]Mayo Clinic, Rochester, United States; [7]Arizona Liver Health, Phoenix, United States; [8]Icahn School of Medicine at Mount Sinai, New York City, United States; [9]NYU Langone Health, New York City, United States; [10]Weill Cornell Medicine, New York City, United States; [11]Houston Research Institute, Houston, United States
Email: Jeffrey.Lazarus@isglobal.org

Background and aims: Despite an estimated metabolic dysfunction-associated steatotic liver disease (MASLD) prevalence of 38.2% (33.72–42.89) in the global population aged above 20 years and an estimated prevalence of 7–14% among children, public awareness remains low. This study evaluates MASLD awareness among adults in the general population, a leading at-risk population (people with diabetes), and primary care providers (PCPs) in the four most populous cities in the United States.
Method: An online survey was conducted 5–13 September 2024 in New York City, Los Angeles, Chicago, and Houston. Respondents included a sample of 5,408 adults, including 1,000 adults self-reporting having diabetes and 800 PCPs, weighted to n = 4,000 (1,000 per city) reflective of the cities' populations in terms of age, gender, ethnicity, and educational background. Awareness of MASLD was assessed with the item "Have you ever heard of metabolic dysfunction-associated steatotic liver disease (MASLD)?," reported as descriptive statistics evaluated with Chi-square tests. A regression model assessed awareness of MASLD with age, gender, ethnicity, education and health utilization factors (reporting ever had a blood test to assess liver enzymes and annual primary care visits). Odds ratios were reported with 95% confidence intervals (CI) at alpha = 0.05.
Results: Among the general population, 18.7% had heard of MASLD, ranging from 16.2% in Houston to 20.2% in Chicago. Among adults with diabetes, 37.8% were aware of MASLD. Of PCPs 54.7% reported having heard of MASLD. Age was negatively associated with MASLD awareness, with only 9.7% of those aged ≥60 aware. Individuals with higher education levels were significantly more likely to have heard of MASLD, with 45.7% of those holding post-graduate degrees reporting awareness ($p < 0.001$). Those who had ever had a blood test to assess liver enzymes were 4.4 [CI: 3.39–5.65] times more likely, and those who reported annual primary care visits were 2.0 [CI: 1.26–3.03] times more likely to have heard of MASLD ($p < 0.005$). Ethnicity and city of residency were not significant factors for awareness.
Conclusion: In the four U.S. cities studied, awareness of MASLD was low overall as well as among people with diabetes and PCPs, highlighting the need for targeted health literacy initiatives, including at the city level, to raise MASLD awareness and prevention efforts. Focused initiatives can support individuals in making informed health decisions, reinforcing the importance of prevention among at-risk populations and their caregivers.

THU-030

Risk factor awareness for liver disease in four United States cities

Trenton M White[1,2], Scott Isaacs[3], Norah Terrault[4], Mary E. Rinella[5], Alina M Allen[6], Naim Alkhouri[7], Meena Bansal[8], Michael Charlton[5], Ira Jacobson[9], Sonal Kumar[10], Mazen Noureddin[11], Silvana Pannain[5], Ayman El-Mohandes[1], Jeffrey Lazarus[1,2]. *[1]City University of New York Graduate School of Public Health & Health Policy (CUNY SPH), New York City, United States; [2]Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [3]Atlanta Endocrine Associates, Atlanta, United States; [4]University of Southern California (USC), Los Angeles, United States; [5]University of Chicago, Pritzker School of Medicine, Chicago, United States; [6]Mayo Clinic, Rochester, United States; [7]Arizona Liver Health, Phoenix, United States; [8]Icahn School of Medicine at Mount Sinai, New York City, United States; [9]NYU Langone Health, New York City, United States; [10]Weill Cornell Medicine, New York City, United States; [11]Houston Research Institute, Houston, United States*
Email: Jeffrey.Lazarus@isglobal.org

Background and aims: Liver diseases pose a significant public health burden, yet awareness of their risk factors remains limited. This study evaluates awareness of key risk factors for liver disease among the general population in the four most populous U.S. cities.
Method: An online survey was conducted 5–13 September 2024 in New York City, Los Angeles, Chicago, and Houston to assess knowledge of liver disease risk factors in a sample of 5,408 adults, including 1,000 individuals with self-reported diabetes and 800 PCPs, weighted to 4,000 adults (1,000 per city) reflective of the cities' populations in terms of age, gender, ethnicity, and educational background. A risk factor awareness index was created based on responses to questions about the association of five specific dietary and lifestyle factors (high-calorie diets, high-cholesterol foods, ultra-processed foods, sedentary lifestyle, and alcohol consumption) with liver disease. Each factor was assigned a score of 1 if the respondent was aware of the association, resulting in a total score ranging from 0 to 5, which was then transformed to a 0 to 100 scale. Ordered logistic regression analysis was performed on the index with age, education, ethnicity, diabetes status, and primary care provider status.
Results: Chicago had the highest awareness of risk factors score (47.0), followed by Houston (43.9), Los Angeles (43.3), and New York City (42.0). Primary care providers were over twice (odds ratio (OR) = 2.09, $p < 0.001$) as likely to demonstrate higher awareness of the five risk factors. Higher educational attainment strongly correlated with increased awareness (OR = 1.50, $p < 0.001$). A significant positive association was observed between age and awareness (OR = 1.07, p = 0.026), with older respondents demonstrating greater awareness.
Conclusion: This study highlights an overall low awareness of risk factors for liver disease in major U.S. cities, underscoring the importance of raising awareness to support preventive health measures. Age and education were key determinants of awareness, with older and more educated individuals demonstrating greater knowledge of liver disease risk factors. These findings emphasize the need for targeted educational interventions to increase awareness, particularly among younger and less-educated populations.

Gastroenterology and Hepatology, Maastricht, Netherlands*
Email: leen.heyens@uhasselt.be

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a prevalent cause of chronic liver disease.

Data on quality of life (QoL), work productivity, and absenteeism in early-stage steatotic MASLD are scarce. This study aimed to investigate the influence of steatosis on general and mental health, as well as productivity among patients in primary care and a diabetic population with low fibrosis prevalence.
Method: The study comprised three prospective cohort studies conducted from 2019 to 2023 across primary care centers in Belgium and the Netherlands and a hospital endocrinology department in Belgium. Fibrosis (liver stiffness) was defined by a cutoff value of above 12 kPa, and steatosis by a cutoff value of >275 dB/m, both measured using the Transient Elastography and Controlled Attenuation Parameter (CAP) with FibroScan® (Echosens, France). Participants completed questionnaires measuring anxiety (General Anxiety Disorder (GAD)-7), depression (Patient Health Questionnaire (PHQ)-9), work productivity, absenteeism, and presenteeism (Workers Productivity and Activity Impairment (WPAI), and general health (Short-Health Form (SF-36)). Data were analysed using Mann-Whitney U-test and Spearman correlation.
Results: Out of 870 screened participants, 619 (71.1%) were eligible, with 311 (69.2%) completing the questionnaires. Steatosis and advanced fibrosis were present in 142 (45.7%) and 15 (4.7%) of participants, respectively. Steatotic individuals had a significantly higher median BMI (30.5 kg/m² vs. 25.5 kg/m², $p < 0.001$) and increased liver stiffness (5.7 kPa vs. 4.6 kPa, $p < 0.001$) compared to those without. No significant differences were found between steatotic and non-steatotic individuals for depression (PHQ-9, $p = 0.955$) or anxiety (GAD-7, $p = 0.557$). However, absenteeism was more prevalent in the steatosis group (WPAI, $p = 0.016$). People with steatosis had significantly lower general health scores (SF-36, $p < 0.001$) and physical functioning (SF-36, $p = 0.024$) compared to those without. Correlation analysis revealed that higher CAP values were negatively associated with physical functioning ($r = -0.193$, $p < 0.001$), energy/fatigue (SF-36, $r = -0.112$, $p = 0.049$), and general health ($r = -0.235$, $p < 0.001$) in the total cohort but not in the steatotic and non-steatotic groups.
Conclusion: Steatosis negatively impacts general health and work productivity but does not appear to affect anxiety or depression in this cohort study.

THU-033
The "Traffic Light System" – a radiology-led pathway for hepatocellular carcinoma surveillance in patients with liver cirrhosis
Lusyan Dayalan[1], Robert Miller[1], Caragh Mathew[1], Christina Owen[1], Thomas Johnston[1], Timothy Jobson[1], Rudiger Matull[1]. [1]*Somerset NHS Foundation Trust, Taunton, United Kingdom*
Email: lusyan7@gmail.com

Background and aims: Patients with liver cirrhosis are at increased risk of developing hepatocellular carcinoma (HCC). An effective HCC surveillance program enhances early diagnosis but there is currently no framework for implementation in the United Kingdom. Six-monthly ultrasound scans (USS) are recommended but the processes of interpreting reports and re-booking scans can be time-consuming and risks patients being lost to follow-up. We developed a radiology-led pathway using our "Traffic Light System" (TLS), aimed at creating a safe and effective process that minimises clinician involvement and improves patient experience. We aimed to a) assess the safety of the TLS by identifying patients where no follow-up USS occurred without a decision to stop surveillance; b) determine the number of patients diagnosed with HCC through the TLS; and c) evaluate the effectiveness of the diagnostic imaging pathway once an alert was issued.
Method: A protocol and USS report templates were developed following consultations among sonographers, radiologists, and hepatologists. The TLS defines criteria for green, amber and red pathways (we added grey for non-diagnostic). 'Green' indicates no changes on USS, prompting the sonographer to inform the patient about the good news and agree on the next date in six months (radiology staff requesting USS). 'Red' indicates concern for possible cancer (e.g. new focal liver lesion): the sonographer completes an MRI safety questionnaire with the patient and requests an MRI liver (within 14 days) and notifies the 'cancer co-ordinator' and hepatologist. If the MRI supports HCC, the radiology team requests the staging CT scan (within 14 days). 'Amber' indicates 'something has changed', e.g. evidence of liver disease progression, or other incidental finding, and the hepatologist is notified urgently. 'Grey' indicates 'non-diagnostic USS', e.g. limited views of the liver; sonographer notifies the hepatology team. We included all patients with liver cirrhosis enrolled in the HCC surveillance program at our hospital from 01/03/2021 to 28/02/2022. Booked USS appointments were tracked until 01/03/2024.
Results: 220 patients were included. 3 patients (1.4%) were lost to follow-up: one due to radiology process error and two due to hepatology not restarting the TLS after an amber warning. Focal liver lesions were identified in 18 patients (8.1%), all of whom progressed to MRI scan. HCC was diagnosed in 9 patients (4.0%), with a median time between USS and MRI of 11 days. During the 3-year period, 16 patients (7.3%) died, with 9 (56%) deaths attributed to end-stage liver disease.
Conclusion: We developed a safe and efficient method for managing 6-monthly USS liver surveillance (HCC screening), with enhanced patient experience and reduced process steps (time). We believe the TLS has the potential for wider adoption within the National Health System (NHS) and further afield.

Changing prevalence and risk factors of metabolic dysfunction associated steatotic liver disease in Taiwan
Ming-Lun Yeh[1,2,3], Pei-Chien Tsai[1,3], Chung-Feng Huang[1,3], Jee-Fu Huang[1,3], Chia-Yen Dai[1,3], Wan-Long Chuang[1,3], Ming-Lung Yu[1,3]. [1]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, Kaohsiung, Taiwan;* [2]*School of Medicine and Doctoral Program of Clinical and Experimental Medicine, College of Medicine and Centre of Excellence for Metabolic Associated Fatty Liver Disease, National Sun Yat-sen University, Kaohsiung, Taiwan, Kaohsiung, Taiwan;* [3]*Hepatitis Research Centre, School of Medicine and Centre for Liquid Biopsy and Cohort Research, Kaohsiung Medical University, Kaohsiung, Taiwan, Kaohsiung, Taiwan*
Email: minglunyeh@gmail.com

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD) is the most growing etiology of liver disease worldwide. MASLD is currently the leading cause of hepatocellular carcinoma and liver transplantation in many countries. Herein, we aim to investigate the changing prevalence and risk factors of MASLD in Taiwan.
Method: This study utilized data from two large cohorts in Taiwan including the Taiwan Biobank (TWB) and the MJ Health Management Institution cohort (MJ cohort) from 1996 to 2022. The diagnosis of steatotic liver disease (SLD) was made by abdominal ultrasound or hepatic steatosis index >36 or fatty liver index >30. MASLD was defined as SLD with at least one of the 5 cardiometabolic risk factors, excluding hepatitis C viral infection and alcoholism. Personal data including regions of residence, income and biochemistry data were analyzed as their association with MASLD.
Results: A total of 729,061 participants (including 149,687 from TWB and 579,374 from MJ cohort) were enrolled. The mean age was 42.2 ± 13.5 years old and 45.5% of the participants were male. The proportions of hepatitis B, C viral infection and alcoholism were 12.4%, 0.8%, and 3.8%. The prevalences of SLD, MASLD were 34.2%, and 31.2%. The Eastern and central region of Taiwan had the highest and lowest prevalence of MASLD. We found the risk factors of developing

MASLD were old age, male gender, high or no working income, and living in the Southern and Eastern regions of Taiwan. Meanwhile, we found the increased prevalence of MASLD over time, particularly among participants of younger age, and male gender. And there were also increasing prevalence of having cardiometabolic risk factors over time, especially in the overweight and pre-diabetes/type 2 diabetes.
Conclusion: We identified the changing prevalence and risk factors of MASLD in Taiwan which will further help making the national strategies in the prevention and managements of MASLD.

FRI-004

Association between metabolic syndrome and hepatocellular carcinoma in Mongolia: Prevalence and risk factors across different populations

Munguntsetseg Batkhuu[1], Nomuunaa Bayarbat[1], Barkhas Batkhuu[2], Khandmaa Narantsetseg[2], Tuvshinjargal Ulziibadrakh[1], Ganbolor Jargalsaikhan[1], Oyungerel Lkhagva-Ochir[1], Baigal Narantuya[1], Orkhonselenge Davaadamdain[2], Bekhbold Dashtseren[1], Purevjargal Bat-Ulzii[1], Uurtsaikh Baatarsuren[2], Zolzaya Doljoo[1], Sumiya Byambabaatar[1], Enkhnomin Ochirbat[1], Byambasuren Ochirsum[1], Sharawdorj Gur[1], Erdenechuluun Sainbayar[1], Enkhtuvshin Khorolgarav[2], Munkhzaya Munkhbaatar[1], Naranjargal Dashdorj[2], Badamsuren Mend-Amar[1], Anujin Batkholboo[1]. *[1]The Liver Center, Ulaanbaatar, Mongolia; [2]Onom Foundation, Ulaanbaatar, Mongolia*
Email: mtsb@livercenter.mn

Background and aims: Metabolic Syndrome (MetS) is a cluster of risk factors increasing the likelihood of cardiovascular diseases and type 2 diabetes. Hepatocellular carcinoma (HCC), the most prevalent form of liver cancer, is a leading cause of cancer-related mortality in Mongolia, with viral hepatitis being a key factor. The high prevalence of both MetS and HCC in Mongolia represents a significant public health issue. This study aims to assess the prevalence of MetS in a high-risk HCC population in Mongolia and investigate the potential association between MetS and HCC.
Method: This analysis used data from 940 subjects enrolled in the DETECT-HCC study between September 15, 2023, and September 23, 2024. HCC diagnosis was confirmed by contrast-enhanced MRI (CE-MRI). MetS was assessed using the Asian-modified National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) criteria. Hepatitis infection status was evaluated using qHBsAg and qAnti-HCV tests on a HISCL5000 analyzer, while HBV-DNA and HCV-RNA loads were measured with Cepheid GeneXpert. Cirrhosis was assessed using Fibrocan 630 (Echosens) and CTP score. Statistical analysis was conducted using R software.
Results: The prevalence of MetS in the HCC group (n = 366) was 28.7%, compared to 20.4% in the non-HCC group (n = 574), with a significant association between MetS and cohort status ($X^2 = 3.93$, $p = 0.047$). In the HCC cohort, 210 were male (mean age 59.6) and 156 were female (mean age 64.47). Among them, 174 had HBV/HDV co-infection, 25 had HBV mono-infection, 62 had active HCV infection, 66 had undetected HCV, and 35 had non-viral hepatitis. The highest prevalence of MetS was observed in the non-viral hepatitis group (48.6%), followed by the undetected HCV group (39.4%), detected HCV group (35.4%), mono-HBV group (24%), and HBV/HDV superinfection group (18.9%). After excluding subjects with alcohol abuse and liver cirrhosis, the adjusted prevalence rates were 25.7%, 29.2%, 30.6%, 15.5%, and 12.5%, respectively. Additionally, subjects from Ulaanbaatar's Ger District and Nomads showed higher glucose levels (8.5 mmol/L and 8.7 mmol/L, respectively) compared to those living in apartments (6.8 mmol/L). This trend was consistent across all five MetS risk factors, suggesting a higher overall risk for MetS in these groups.
Conclusion: This study highlights a significant association between MetS and HCC, with a higher prevalence of MetS in the HCC cohort. These findings suggest that MetS may contribute to the risk of HCC, underscoring the need for targeted prevention strategies. Additionally, subjects in Ulaanbaatar's Ger District and Nomads appear to face a higher risk for MetS, likely due to lifestyle, socioeconomic, and environmental factors. Further research is needed to explore the mechanisms linking MetS and HCC and to refine prevention strategies.

FRI-005

Metabolic dysfunction-associated steatotic liver disease as the leading cause of hepatocellular carcinoma in mexican cirrhotic patients: a perspective consistent with trends observed in europe

Nahum Méndez-Sánchez[1], Mariana Ramírez-Mejía[2], Carlos Cortez-Hernández[3], Elianee Tovar-Bojorquez[3], Raul Contreras[4], Juan Monsiváis Morales[5], Jacqueline Cordova-Gallardo[6], Mauricio Castillo[7], Nubia Guzmán-Rodriguez[7], Maria Sarai González-Huezo[8], Adrián Sández Araiza[8], Eira Cerda Reyes[9], Beatriz Barranco-Fragoso[10], Ana Cano-Contreras[11], José Remes-Troche[11], Fatima Higuera-de-la-Tijera[12], José Luis Pérez-Hernández[12], Norberto Chávez-Tapia[13], Francisco Valentin-Cortez[13], Iaarah Montalvo[14], Ruben R Lozano-Salazar[15], Montserrat Sabanes[16], Itziar Borbolla-Schega[16], Heriberto Rodriguez-Hernández[17]. *[1]Liver Research Unit, Medica Sur Clinic & Foundation, Mexico City, Mexico; [2]Plan of Combined Studies in Medicine (PECEM-MD/PhD), Faculty of Medicine, National Autonomous University of Mexico, Mexico City, Mexico; [3]Gastroenterology Service, Department of Internal Medicine, Faculty of Medicine, Hospital Universitario "Dr. José E. Email: nmendez@medicasur.org.mx

Background and aims: Hepatocellular carcinoma (HCC) is the most common primary liver cancer and a leading cause of cancer-related mortality, often linked to chronic liver diseases such as hepatitis B (HBV) and C (HCV) infections, alcohol-related liver disease (ALD) and metabolic dysfunction-associated steatotic liver disease (MASLD). Although cirrhosis is a major precursor of HCC, it can also develop in non-cirrhotic livers, particularly in MASLD and HBV cases. The increasing prevalence of obesity and metabolic disorders has changed the etiology of HCC, especially in Western countries. In Mexico, HCC reflects a complex mix of traditional and emerging risk factors, including viral hepatitis and MASLD. This study evaluates the prevalence and etiologies of HCC, focusing on key risk factors in Mexican patients with liver cirrhosis.
Method: A multicenter retrospective study was conducted across 13 health centers in Mexico from 2018 to June 2024. Clinical records of adults with liver cirrhosis were reviewed to identify cases of HCC, assessing prevalence, etiologies, and clinical characteristics. Sociodemographic, clinical, imaging, and biochemical data were analyzed, with a focus on regional variations.

Results: The study included a total of 2,182 patients diagnosed with liver cirrhosis, with a mean age of 61 ± 12 years. Of these, 53.8% (n = 1,175) were female and 46.1% (n = 1,007) were male. Of the 2,182 patients, 8.8% (n = 194) developed HCC. The prevalence of HCC was higher in women (55.1%, n = 107) and in older age groups. Patients aged 60 years or older accounted for 78.3% (n = 152) of all HCC cases. Among women, the majority of HCC cases were observed between the ages of 70 and 79 years (39.2%, n = 42), while in men, the peak prevalence was observed between the ages of 60 and 69 years (39%, n = 34). Geographic analysis revealed notable variations in the prevalence of HCC in the different regions of Mexico. Central region showed the highest prevalence of HCC (10.4%), while southern region had a prevalence of 4.1%, and southern region had the lowest prevalence at 3.8% ($p < 0.001$). The overall distribution of HCC etiologies showed that the main cause was MASLD, with 39.1% (n = 76) of cases, followed by HCV infection, with 33% (n = 64), and ALD, with 18.6% (n = 36), while less common etiologies such as autoimmune hepatitis, primary biliary cholangitis, and VHB together accounted for 7.2% (n = 14) of cases.
Conclusion: This study highlights the significant burden of HCC in patients with liver cirrhosis in Mexico, with notable demographic and regional variations. The findings demonstrate a higher prevalence of HCC in women and older age groups. These results are consistent with changes observed worldwide, especially in European countries, where MASLD has become a predominant cause of HCC, in particular among women. The parallels between Mexico and Europe emphasize the growing impact of metabolic disorders in HCC and underscore the importance of global strategies to address this changing etiological landscape.

FRI-006

Reference blood-based biomarkers SteatoTest-2 (ST2) and NashTest-2 (NT2) permit assessment of the prevalence of steatosis and MASH in large general population of UK-Biobank (UKB), stratified by cardiometabolic risk factors (CRF) and alcohol consumption (AC)

Olivier Deckmyn[1], Thierry Poynard[2]. [1]*BioPredictive, Paris, France;* [2]*Sorbonne University, BioPredictive, Paris, France*
Email: olivier@biopredictive.com

Background and aims: There are no widely validated biomarkers of liver steatosis and MASH inflammation available in the UKB. MRI-PDFF is only available in a 10-percent-subset. Available UKB blood biomarkers do not allow direct calculation of ST2 nor NT2. The aim was to construct proxies with very high correlation to allow assessment of the stratified prevalence of these diseases in general population.
Method: Using the princeps cohort with CRN-7-tier biopsies (n = 1,081), ST2-proxy and NT2-proxy were built using the markers available in the UKB (Bilirubin, GGT, ALT, AST, Apo-A1, Triglycerides (TG), Total-Cholesterol(TC)), both adjusted by age and gender. Performance was estimated with Pearson-correlation and difference of AUCs. ST2-proxy and NT2-proxy were then applied into the UKB (n = 343,064), pre-determined cut-offs were applied to estimate steatosis (S0: <5%, S1: 5–33%, S2S3: >33%) and MASH inflammation; and prevalence were assessed stratified by CRF (BMI, Diabetes, Hypertension, high TG and low HDL) and AC.
Results: NT2-proxy and ST2-proxy had high correlations ($R^2 = 0.99$ and 0.91, respectively) in the princeps cohort and AUCs were not different (0.79[%95CI = 0.77–0.82] vs. 0.79[0.77–0.82] p-difference = 0.66 and 0.76[0.70–0.81] vs. 0.77[0.72–0.83] p-difference = 0.24, respectively). When applied in the UKB, significant steatosis prevalence was 14.1% overall, from 0.3–0.5% for subjects with 0 CRF, 1.6–1.8% for 1 CRF, 6.4–7.9% for 2 CRF, 18.4–25.3% for 3 CRF and 47.2–57.3% for 4–5 CRF. MASH prevalence was 24% overall, from 1.7–2% for subjects with 0 CRF, 5.8–6.5% for 1 CRF, 15.5–20.9% for 2 CRF, 32.3–48% for 3 CRF and 56.7–72.7% for 4–5 CRF. For both, the more severe AC had the highest prevalence.
Conclusion: Presence of validated biomarkers ST2 and NT2 in the UKB permit assessment of steatosis and MASH in large population like UKB, allowing other applications.

FRI-007

An algorithm based on the liver risk score to identify subjects at-risk for advanced liver disease in the general population

Patrick Ingiliz[1], Henri Tran[2], Cecile Fargeat[3], Anne-Laure Mazalivoua[1], Odile Rousselet[3], Adrien Ko[4], Stefano Caruso[1], Vincent Leroy[1]. [1]*APHP Hôpital Henri-Mondor, Créteil, France;* [2]*APHP Hôpital Henri-Mondor, Creteil, France;* [3]*Cerba Healthcare, Paris, France;* [4]*Biokortex, Paris, France*
Email: patrick.ingiliz@aphp.fr

Background and aims: Screening for advanced hepatic fibrosis in the general population may help to identify patients at risk for negative hepatic outcomes. However, the ideal non-invasive marker in terms of accessibility and accuracy is yet to be developed. Current guidelines (EASL 2021) recommend using the low exclusion threshold of the FIB-4 score (< 1.3) as a primary screening tool in patients at risk for metabolic-dysfunction associated steatotic liver disease (MASLD), but the low specificity may result in a large number of potentially false-positive results requiring specialist referral and costs. Recently, the liver risk score (LRS) has been suggested to more accurately identify patients at-risk. The aim of this study was to evaluate the prevalence of individuals at-risk for advanced liver fibrosis in the general population of the Paris region according to FIB-4 and LRS.
Method: "Cerbafib" was a prospective cohort derived from a collaboration with laboratories throughout the Paris region to evaluate the prevalence of advanced liver disease in the general population.
Results: Between January and April 2023, 179 865 patients were included in the cohort. The mean age was 52 years and 45% were men. FIB-4 identified 55 376 (31%) patients requiring specialist referral (> = 1.3) and 4 002 patients (2.2%) with suspected advanced fibrosis. LRS identified 38 175 (21%) patients with estimated liver stiffness > = 6 kPa, 1 933 patients (1%) > = 10 kPa and 35 (0.02%) patients > = 15 kPa. There was a significant but poor correlation between the two tests ($r = 0.45$, $p < 0.01$). Among patients with a FIB-4 score above 1.3, 61% have an LRS corresponding to a minimal risk of liver fibrosis. In return, 24% of the minimal risk patients according to LRS have a FIB-4 score above 1.3.
Conclusion: The Liver Risk Score is a practical tool to identify a population in need of further hepatologic evaluation. Its use as a mass screening test in the general population at risk for MASLD may help to more accurately identify those at risk for advanced liver disease. The well-established FIB-4 test only partially identifies this subgroup and may generate more false positives and increase the need for confirmatory resources and costs. We suggest an adapted new screening algorithm using the LRS.

FRI-008

Prevalence of steatotic liver disease and steatohepatitis in a population of healthy workers

Pietro Guerra[1], Javier Lopez Perez[2], Silvia Cagnin[1], Paula Iruzubieta[3], Patrizia Pontisso[1], María Luz Martínez-Chantar[4], Andrea Martini[5].
[1]*Department of Medicine, University of Padova, Padova, Italy;* [2]*Bridgestone Hispania Manufacturing S.L, Bilbao, Spain;* [3]*Gastroenterology and Hepatology Department, Marqués de Valdecilla University Hospital, Clinical and Translational Digestive Research Group, IDIVAL, Santander, Spain;* [4]*Liver Disease and Liver Metabolism Laboratory, CIC bioGUNE-BRTA (Basque Research & Technology Alliance), Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Derio, Spain;* [5]*Department of Medicine, Azienda Ospedale-Università di Padova, Padova, Italy*
Email: andrea.martini@aopd.veneto.it

Background and aims: Steatotic Liver Disease (SLD) may silently evolve into Steatohepatitis (SH). In clinical practice, elevation of liver enzymes (LE) is used as a surrogate marker of liver inflammation.

Screening of liver disease is gaining attention and novel strategies need to be found. We aimed to study the prevalence and associated factors of SLD and SH in a population of healthy workers.
Method: 780 healthy workers were prospectively enrolled during yearly health checkups (from January to September 2024) at Bridgestone factory (Bilbao, Spain). Ultrasound, anthropometric and biochemical data were collected. 335 patients with all available data were further analysed. Patients were divided into the following groups: no steatosis and normal LE (Healthy), steatosis and normal LE (SLD), steatosis and elevated LE (SH), no steatosis and elevated LE (Hepatitis).
Results: The Healthy Group accounted for half of the patients (57%), while the remaining patients were divided into the other three groups (SLD 20%; SH 11%; Hepatitis 12%). The analysis of variance showed differences in age, BMI, HDL, triglycerides, glucose and haemoglobin. At post-hoc analysis only BMI increased significantly between Healthy (25.10 [23.15, 27.16]), SLD (26.87 [24.97, 30.05]) and SH Groups (30.38 [27.59, 33.18]). Multivariate logistic regression for risk factors for SLD showed: BMI (aOR 1.21 [1.11, 1.31], $p < 0.001$), and hypertension (aOR 2.19 [1.10, 4.37], $p = 0.026$). The only significant risk factor for SH after adjustment was BMI (aOR 1.31 [1.18, 1.48], $p < 0.001$).
Conclusion: The inclusion of liver ultrasound and transaminases in healthy workers' checkups can be effective in identifying patients with metabolic liver disease.

FRI-009

External validation of Dallas steatosis index (DSI) in the diagnosis of steatotic liver disease (SLD) in thai population

Thareerat Ananchaisarp[1], Apichat Kaewdech[2], Supinya Sono[1], Naichaya Chamroonkul[2], Pimsiri Sripongpun[2]. *[1]Division of Family Medicine and Preventive Medicine, Faculty of Medicine, Prince of Songkla University, Hat Yai, Thailand; [2]Division of Internal Medicine, Faculty of Medicine, Prince of Songkla University, Hat Yai, Thailand*
Email: pimsiri.s@psu.ac.th

Background and aims: Steatotic liver disease (SLD) is a global health concern, associated with long-term liver and extrahepatic complications. The Fatty Liver Index (FLI) is the most widely accepted scoring system for identifying patients with SLD at the population level. However, FLI includes waist circumference and gamma-glutamyl transferase (GGT), which are not routinely measured in clinical practice. The Dallas Steatosis Index (DSI), which incorporates more routinely available variables, has recently been developed to detect SLD in the U.S. population. This study aims to validate the DSI for diagnosing SLD in Thai population.
Method: A cross-sectional study was conducted from 2019 to 2023 at a tertiary care hospital in Southern Thailand. The study included individuals aged ≥18 years old who participated in health check-up programs that involved abdominal ultrasound (USG) and blood tests. SLD was diagnosed when liver steatosis was identified on the USG report. The exclusion criteria were those with positive HBsAg and/or HCV Ab, missing data on variables for calculating DSI (Age, Sex, ALT, Triglycerides [TG], BMI, fasting blood sugar [FBS], Diabetes, and Hypertension status). For ethnicity, which is one of the variables in DSI, all participants were categorized as Asian. The performance of DSI in diagnosing SLD was evaluated using areas under the receiver operating characteristics curve (AUROC), and sensitivity and specificity at the given cutoff were evaluated.
Results: A total of 5987 individuals were eligible and included in the study. The prevalence of SLD diagnosed by ultrasound was 45.2% in the entire cohort. As expected, individuals with SLD were more likely to be older, predominantly male, and had higher waist circumference, BMI, TG, FBS, LDL, AST, ALT, and platelet levels compared to those without SLD. Additionally, they had a significantly higher proportion of concomitant diabetes, hypertension, dyslipidemia, and cardiovascular disease. DSI was calculated using the published formula (https://dsi.wustl.edu/) and presented as predictive probabilities. DSI showed a very good performance in diagnosing SLD with an AUROC of 0.830 (95%CI: 0.820–0.841). At the given cutoff of 0.2 and 0.5 as the low and high cutoffs for the diagnosis of SLD, DSI <0.2 showed a sensitivity of 86% and NPV of 84.4% for ruling out SLD, and at the DSI >0.5, the specificity and PPV were 92.5% and 83.97% to ascertain SLD status, respectively.
Conclusion: This is the first external validation of DSI in Asian population. The DSI demonstrated satisfactory performance in the diagnosis of SLD with an AUROC of 0.83 and may be considered as an alternative to FLI for the diagnosis of SLD at the population level particularly in settings where ultrasonography, transient elastography, or other imaging modalities are not feasible. Nonetheless, further studies comparing the diagnostic accuracy of DSI and FLI are still needed.

FRI-010

Economic evaluation of biomarker-base surveillance for hepatocellular carcinoma in thai patients with compensated liver cirrhosis

Nutcha Pinjaroen[1], Wirichada Pan-ngum[2], Kittiyod Poovorawan[3], David Wastlund[4], Peng Lu[4], Pisit Tangkijvanich[5]. *[1]Department of Radiology, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; [2]Department of Tropical Hygiene, Mahidol University Faculty of Tropical Medicine, Bangkok, Thailand; [3]Department of Clinical Tropical Medicine, Mahidol University Faculty of Tropical Medicine, Bangkok, Thailand; [4]Vista Health Ltd Pty, Singapore, Singapore; [5]Center of Excellence in Hepatitis and Liver Cancer, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand*
Email: pisittkvn@yahoo.com

Background and aims: Hepatocellular carcinoma (HCC) is the leading cause of cancer-related death in Thailand. However, most Thai patients at high risk of HCC lack access to routine surveillance programs. This study used ultrasound- or biomarker-based screening approaches to assess the cost-utility analysis of routine HCC surveillance in patients with compensated liver cirrhosis (CLC).
Method: The model utilized a Markov-style microsimulation framework to simulate outcomes from alternative HCC surveillance methods for Thai patients. The model was designed to represent Thai patients and healthcare as accurately as possible, and novel Thai patient data was used to estimate treatment and survival associated with screening. Outcomes included diagnostic performance, total costs, and overall health expressed as quality-adjusted life years (QALYs). The incremental cost-effectiveness ratio (ICER) was assessed according to the Thai willingness-to-pay threshold (฿160,000 = USD 4,660).
Results: Results suggest that routine HCC surveillance is likely cost-effective in Thai patients with CLC. Among the biomarker-based approaches, GAAD score, which combined gender, age, alpha-fetoprotein (AFP), and des-gamma carboxyprothrombin (DCP), was the most cost-effective due to its high detection of HCC while resulting in relatively few false positive diagnoses. Compared to no routine surveillance, GAAD surveillance was cost-effective (ICER: ฿154,372). Compared to ultrasound plus AFP – the recommended standard of care – GAAD was dominant, resulting in better overall health at a lower cost.
Conclusion: Bi-annual routine HCC surveillance is cost-effective for the Thai healthcare system when used for patients with CLC. Among biomarker-based approaches, GAAD appears to be the most cost-effective and could maximize the benefits of HCC surveillance in high-risk patients.

FRI-011

What is known about the relationship between food insecurity and metabolic dysfunction-associated steatotic liver disease? A systematic review

Patricia Treseder-Griffin[1], Ryan M Buchanan[2], Kate Glyn-Owen[1].
[1]*University of Southampton, Southampton, United Kingdom;* [2]*University of Southampton, University Hospital Southampton Hepatology, Southampton, United Kingdom*
Email: ptg1n20@soton.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has risen in prevalence in parallel with obesity over the past decade reaching epidemic proportions. With limited pharmacological options, a prudent diet is the first line of treatment to mitigate an unfavourable prognosis leading potentially to cirrhosis and irreparable liver damage. Little is known on the relationship between limited or uncertain access to nutritious food as is experienced during food insecurity and liver health. This review aimed to summarise and synthesise quantitative data on the relationship between food insecurity and MASLD.
Method: A systematic review was conducted across four databases: MEDLINE (Ovid platform), Embase, Web of Science and CINAHL, up to 9th April 2024. Any design of observational study whose participants were adults or children over 2 years of age, with food security status assessed via a validated tool, and MASLD defined by clinical diagnosis or estimated by robust diagnostic criteria were included. All studies were quality assessed using Joanna Briggs Institute tools. Narrative synthesis was conducted as the clinical heterogeneity of the studies precluded meta-analysis.
Results: Thirteen full text studies and nine abstracts were included. All data on food insecurity and MASLD were cross-sectional regardless of study design. Seven of the ten studies with relevant data reported that food insecure individuals had an increased odds of MASLD compared to those who were food secure, reported increases ranged from 38% to 237% ($p < 0.05$). Studies reported a prevalence of food insecurity in those with MASLD ranging from 9%–57%. In all but one small study this was consistently higher than comparable reported levels of food insecurity amongst the general population. Prevalence of MASLD amongst food insecure participants varied from 17%–54%, with higher rates seen in studies comprised of Hispanic participants.
Conclusion: These results indicate that public health programmes to facilitate food and nutrition security in communities in need, coupled with screening for food insecurity in clinical settings are critical to ensure health equity and prevent unnecessary disease progression in MASLD patients. The review highlights the paucity of data examining food insecurity and its relationship with hepatic health in the context of cardiometabolic disease, indicating that further cross-speciality prospective longitudinal research is warranted in this area.

FRI-012

Unveiling the burden of cirrhosis among Ontario, Canada's refugee population

Saloni Aggarwal[1], Maya Djerboua[2], Jennifer Flemming[3]. [1]*Queen's University, Kingston, Canada;* [2]*ICES - Queen's University, Kingston, Canada;* [3]*Queen's University, ICES - Queen's University, Kingston, Canada*
Email: saggarwal@qmed.ca

Background and aims: Liver disease is on the rise, contributing to high mortality and healthcare costs. Refugees face additional barriers to healthcare, leading to delayed diagnoses of conditions like cirrhosis, which can arise from chronic diseases like HBV, HCV, and ALD. Despite this, little is known about cirrhosis in refugee populations. This study investigates the incidence and etiology of cirrhosis among refugees in Ontario compared to other immigrant populations. Previous research has identified the growing burden of cirrhosis worldwide, and a recent paper by our research group has defined the incidence of cirrhosis among recent immigrants and refugees to Ontario, however, this project is the first to specifically identify the unique health burdens of refugee populations. Understanding these factors can help inform targeted screening, prevention, and treatment efforts, ultimately reducing the impact on the healthcare system and improving outcomes for vulnerable populations.
Method: This population-based cohort study made use of routinely collected healthcare data housed in various ICES databases. Using a validated algorithm, individuals with cirrhosis were identified, stratified by etiology, and linked to other datasets using unique encoded identifiers. These data were separated by immigration status to compare recent immigrants and refugees to one another. Frequencies and proportions were used to describe categorical variables, and medians and IQRs were used to describe continuous variables. Rate ratios were calculated using a Poisson regression, at a significance of $p < 0.05$.
Results: From 2000 to 2017, 22,469 immigrants with incident cirrhosis were identified (4,403 refugees, 18,066 non-refugee immigrants). Within the refugee population, 35% were female with a median age at cirrhosis diagnosis of 49 years (IQR 40–58), and 73% lived in neighborhoods of the lowest/second lowest income quintiles. Within the non-refugee immigrants, 43% were female, with a median age of diagnosis of 50 years old (IQR 40–63), and 56% live in neighborhoods of the lowest/second lowest income quintiles. Incidence rates of cirrhosis increased over time, both between the two groups (RR 1.342 (CI 1.298–1.387); $p < 0.001$) and also when examining year over year increase within each group (RR 1.034 (CI 1.031–1.037, non-immigrant refugees); RR 1.040 (CI 1.034–1.046, refugees); $p < 0.001$). Non-refugee immigrants exhibited a lower incidence rate of cirrhosis. MASLD-cirrhosis had the highest increase in incidence rate over time.
Conclusion: This study is the first to examine cirrhosis among refugees in Ontario, revealing a 1.37-fold higher rate among refugees compared to immigrants, along with an overall increase in the incidence of cirrhosis for both populations. Continued research will refine our understanding of cirrhosis epidemiology and contribute to improved public health outcomes.

FRI-013

Age-related trends in FIB-4 scores among MASLD risk groups: insights from primary care data

Hiroko Setoyama[1], Takehisa Watanabe[1], Toshinori Toyota[1], Kentaro Tanaka[1], Koki Inada[1], Satoshi Narahara[1], Takayuki Tokunaga[1], Etsuko Iio[1], Katsuya Nagaoka[1], Yoko Yoshimaru[1], Yasuhito Tanaka[1].
[1]*Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan*
Email: setoyama.h@me.com

Background and aims: The Fibrosis-4 index (FIB-4) is a valuable screening tool for fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD). Guidelines emphasize its use in identifying high-risk MASLD patients who may benefit from treatment. Given the prevalence of diabetes, dyslipidemia, or hypertension—common MASLD risk factors—among middle-aged and elderly individuals visiting family doctors, we examined the distribution and characteristics of FIB-4 among this demographic.
Method: We analyzed FIB-4 score from clinical tests ordered by family doctors at the Kumamoto City Medical Association Inspection Center from August to October 2024. Key variables—FIB-4 score, aspartate aminotransferase (AST) levels, alanine aminotransferase (ALT) levels, and platelet counts—were stratified by age group. High-risk cases of advanced fibrosis were defined as FIB-4 > 2.67, and the relationship between high-risk judgement and the components of the FIB-4 formula was analyzed.
Results: Among 63,728 cases, the largest age group was the 70 s (21.0%), with 57.3% aged 60 or older. FIB-4 scores increased with age and platelet counts decreased ($P < 0.05$). ALT levels decreased after the 40 s ($P < 0.05$). High-risk judged patients accounted for 12.5%,

with age-specific rates of 0.6% (40 s), 1.6% (50 s), 4.4% (60 s), 14.2% (70 s), 34.6% (80 s), and 54.0% (90+). For those in their 80 s, the rates of high-risk judgment, platelet count ≤150,000, and ALT > 30 were 14.6% and 6.9%, respectively. ROC analysis showed platelet count had the highest AUROC for identifying high-risk cases across all ages (0.906), and the AUROC for age decreased in the elderly (all ages: 0.870, 80 years and over: 0.631). For 80 and older, AUROC was highest for 1/platelet count (0.888) and AST/$\sqrt{}$ALT (0.785).
Conclusion: The age group that most frequently undergoes blood tests at their family doctor corresponds to the peak age of first occurrence of metabolism-associated liver cancer in our data, suggesting that screening methods for liver fibrosis at family doctors is an important issue. The significant rise in high-risk judgment in patients aged 80+ suggests aging and declining platelet counts and ALT levels may increase false positives. Of the factors involved in calculating FIB-4, platelet count had the greatest impact on screening for cases suspected of having severe fibrosis in all age groups. When using FIB-4 for screening, age-specific adjustments, including the incorporation of platelet count, may reduce over-diagnosis in elderly patients.

FRI-014
Impact of COVID-19 pandemic on racial/ethnic disparities in liver transplant waitlist outcomes among U.S. adults with end-stage liver disease
Shyam Patel[1], Wei Zhang[2], Ashwani K. Singal[3], Ramsey C. Cheung[4,5], Robert Wong[6]. [1]*Department of Medicine, California Pacific Medical Center, San Francisco, CA, United States;* [2]*Gastroenterology Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States;* [3]*Division of Gastroenterology, Hepatology and Nutrition, University of Louisville School of Medicine; Transplant Hepatology, UofL Health Jewish Hospital and Trager Transplant Center; Rob Rexley VA Medical Center, Louisville, KY, United States;* [4]*Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University, Palo Alto, CA, United States;* [5]*Gastroenterology Section, Veterans Affairs Palo Alto Healthcare System, Palo Alto, CA, United States;* [6]*Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University, Gastroenterology Section, Veterans Affairs Palo Alto Healthcare System, Palo Alto, CA, United States*
Email: shyampatel7543@gmail.com

Background and aims: In the U.S., end-stage liver disease (ESLD) disproportionately affects vulnerable populations, including racial/ethnic minorities. Existing racial/ethnic disparities in access to liver transplantation (LT) may have been exacerbated by the COVID-19 pandemic. Whether these pandemic-related disparities persist 4 years following the COVID-19 pandemic is not clear. We aim to evaluate racial/ethnic disparities in receipt of LT and LT waitlist mortality among U.S. adults with ESLD before, during, and following onset of the COVID-19 pandemic.
Method: Adults (≥18 years old) with ESLD without hepatocellular carcinoma who were listed for LT from 3/1/2018–2/29/2024 were evaluated using the United Network for Organ Sharing registry data. Probabilities of receiving LT and waitlist removal (death or too sick) within 1 year of listing were evaluated using competing-risks adjusted Cox proportional hazards models across three periods: Era 1 (3/1/2018–2/29/2020), Era 2 (3/1/2020–2/28/2022), and Era 3 (3/1/2022–2/29/2024).
Results: We identified 49,949 adults with ESLD awaiting LT from 2018–2024. During Era 1, significantly lower probability of LT within 1 year was observed among Hispanics (vs. non-Hispanic whites [NHW]) (55% vs. 59%; aHR 0.88, 95% CI 0.79–0.98). The disparity in LT receipt among Hispanics (vs. NHW) worsened in Era 2 (54% vs. 63%; aHR 0.77, 95% CI 0.70–0.85). While this inequity improved in Era 3, lower probability of LT among Hispanics (vs. NHW) remained (65% vs. 69%; aHR 0.90, 95% CI 0.82–0.97). Although Hispanics (vs. NHW) were more likely to be removed from the LT waitlist due to death or sickness within 1 year, the risk of removal did not significantly change during the pandemic (Era 1: aHR 1.30, 95% CI 1.02–1.65; Era 2: aHR 1.25, 95% CI 1.03–1.52). While there was no significant difference in LT waitlist removal among Asians (vs. NHW) in Era 1 or 2, Asians were significantly more likely to be removed from the waitlist in Era 3 (aHR 1.53, 95% CI 1.04–2.25, all $p < 0.05$).
Conclusion: Racial/ethnic disparities in LT waitlist outcomes were exacerbated during the COVID-19 pandemic, especially for Hispanics who had greater risk of waitlist removal and lower probability of LT. Asians also had disproportionately greater risk of waitlist removal compared to NHW. Better understanding and addressing modifiable barriers to equitable LT care is needed to address the persisting disparities that remain following the COVID-19 pandemic.

FRI-019
Patient safety, cross-sectoral quality of care, cost efficiency, and interprofessional competence: a comparison of the interprofessional training wards A-STAR with conventional hepatology-focused wards at Regensburg university hospital
Schlosser Sophie[1], Jonas Dörr[1], Elisabeth Aichner[1], Marcus Meier[1], Sheila Albaladejo-Fuertes[1], Kirstin Ruttmann[1], Johannes Heine[1], Paul Hermes[1], Philipp Dobsch[1], Stephan Schmid[1], Martina Müller-Schilling[1]. [1]*University Hospital Regensburg, Clinic and Polyclinic for Internal Medicine I, Gastroenterology, Hepatology, Endocrinology, Rheumatology and Infectious Diseases, Regensburg, Germany*
Email: sophie.schlosser@ukr.de

Background and aims: Effective interprofessional collaboration is crucial in modern medical practice. Since the establishment of interprofessional training wards (IPSTAs) in 1996, these wards have been designed to improve teamwork and communication across different professional boundaries. This study conducted at Regensburg University Hospital examines and compares patient outcomes, cost-effectiveness, quality of cross-sectoral care, and satisfaction levels among patients, families, and caregivers between the interprofessional training ward A-STAR in Regensburg and traditional hospital wards.
Method: The study was conducted from October 2019 to October 2024. Anonymized and standardized questionnaires were utilized to evaluate patient outcomes, cost efficiency, and satisfaction. This included the Collaboration and Satisfaction About Care Decisions (CSACD) and the Family Satisfaction in the Intensive Care Unit (FS-ICU) assessments. Both general practitioners and patients were surveyed regarding the quality of trans-sectoral transfers.
Results: The analysis included data from 1,514 patients treated on the A-STAR ward and 5,847 patients from conventional wards. The clinical outcomes, such as discharges against medical advice, complication-related readmissions, and mortality rates, showed no significant differences between the two groups. However, the A-STAR ward demonstrated greater cost efficiency, characterized by lower material costs and higher DRG revenue per case. Patient, family, and caregiver satisfaction was notably high in the interprofessional wards. Patients in the A-STAR ward required significantly fewer medication adjustments by follow-up physicians (0% compared to 12.63%; $p = 0.035$). They also reported more frequent health improvements and experienced significantly fewer new symptoms after discharge (3.03% compared to 22.45%; $p = 0.011$).
Conclusion: IPSTAs, such as A-STAR, provide patient care that is comparable to conventional wards while improving the training quality for healthcare professionals. The findings indicate that these wards are cost-effective and have a positive impact on patient and family satisfaction, as well as on the overall quality of care across different sectors. Incorporating these training wards into medical education could enhance patient safety and promote stronger collaboration among healthcare teams.

FRI-021

Differential liver-related mortality among native hawaiian/pacific islander (NHPI) and asian subpopulations: a national cohort study

Tiange Zhang[1], Jennifer Dodge[1], Brian Lee[1]. [1]*University of Southern California Keck School of Medicine, Los Angeles, United States*
Email: tiange.zhang@med.usc.edu

Background and aims: Globally, over 30 million Asians live in North America and Europe, encompassing over 20 origin groups. Asians are often aggregated in health surveillance registries, which can mask health differences among subpopulations. In the United States (US), a recent modification to race categories on death certificates enables the disaggregation of Native Hawaiian/Pacific Islanders (NHPIs) from Asians. This study compares liver-related mortality between NHPI and Asian adults.
Method: We analysed mortality data among adults aged ≥25 years from the US National Vital Statistics System between 2018–2022. Following established definitions, NHPI was defined as individuals with NHPI listed as their race on death certificates, whether as a single race or in combination with other race groups. Similarly, Asians included individuals with single or multi-race listings. Validated international classification of diseases 10th revision (ICD-10) codes for the underlying cause of death were used to categorize deaths as attributable to liver disease. Age-standardized mortality rates per 100,000 and rate ratios were used to compare NHPI and Asian adults.
Results: From 2018 to 2022, there were 699 and 8,592 liver-related deaths among NHPI and Asian adults, respectively. A higher proportion of liver-related deaths occurred among NHPI adults under the age of 65 compared to Asian adults (NHPI: 62.9% vs. Asian: 46.0%). The liver disease-related age-standardized mortality rate for NHPI adults was 15.8 (95% CI: 14.6–17.0) deaths per 100,000 adults, which was 1.4 (95% CI: 1.4–1.5) times higher than that of Asian adults (11.7 deaths per 100,000; 95% CI: 11.4–11.9). The liver disease-related age-standardized mortality rate for Black and White adults was 18.3 (95% CI: 18.1–18.6) and 25.5 (95% CI: 25.4–25.6) deaths per 100,000 adults, respectively. In terms of etiology, alcohol-related liver disease had an age-standardized mortality rate of 5.0 (95% CI: 4.4–5.7) deaths per 100,000 adults for NHPI adults compared to 2.9 (95% CI: 2.7–3.0) deaths per 100,000 adults for Asian adults, and non-alcohol-related liver disease had an age-standardized mortality rate of 10.7 (95% CI: 9.7–11.7) deaths per 100,000 adults for NHPI adults compared to 8.8 (95% CI: 8.6–9.0) deaths per 100,000 adults for Asian adults.
Conclusion: NHPIs have higher mortality rates from liver diseases compared to Asians, especially among younger adults and for alcohol-related liver disease, a disparity previously masked by aggregation of NHPI within Asian populations for mortality surveillance. This national study underscores the importance of carefully considering how Asian populations are categorized in national health surveillance registries to better inform targeted global public health strategies across the world.

FRI-022

Ultra-processed foods significantly increase liver and metabolic injury among younger adults, lessons from the liver screening program SIRIUS

Tomas Koller[1], Daniel Jan Havaj[2], Svetlana Adamcova Selcanova[2], Daniela Žilinčanová[2], Natalia Kubanek[2], Karolina Sulejova[2], Martin Janičko[3], Sylvia Dražilová[3], Maria Szantova[4], Marek Rac[5], Lubomir Skladany[2]. [1]*Comenius University Faculty of Medicine in Bratislava, Bratislava, Slovakia;* [2]*Department of Hepatology, Gastroenterology and Transplantation (HEGITO), FD Roosevelt Faculty Hospital, Banska Bystrica, Slovakia;* [3]*2nd Department of Internal Medicine, PJ Safarik Faculty of Medicine, Kosice, Slovakia;* [4]*Comenius University Faculty of Medicine, Bratislava, Slovakia;* [5]*Department of Internal Medicine, Faculty Hospital, Nitra, Slovakia*
Email: tomas.koller@fmed.uniba.sk

Background and aims: Ultra-processed foods (UPF) have been linked to a plethora of diseases, including metabolic syndrome and metabolic dysfunction-associated steatotic liver disease. However, the link may be biased since metabolic burden increases with age while UPF consumption tends to decrease. We explored data from the liver screening program SIRIUS for age-dependent links between UPFs, liver injury and its excess burden.
Method: The point-of-care SIRIUS project operated in Slovakia since 2022 and visited more than 30 sites. Free-of-charge screening for liver disease is offered to local community-dwelling adults. Inclusion criteria were age >18 y, excluded were cases with a history of chronic liver disease or incapacitating severe systemic diseases. The screening procedure included questionnaires on medical history, AUDIT-C, quality of life, basic anthropometric measurements, blood drop analysis for aminotransferases and blood lipids, and liver stiffness and CAP (Fibroscan by Echosense). The consumption of UPFs was evaluated using the 24-hour dietary recall questionnaire.
Results: 4319 cases were included in the analysis with a median age of 53.2, 40.8% of males, 75.3% with abdominal obesity, 6.6% with a history of diabetes, 9.5% with ALT > 1.5 times the upper limit of normal, 47.7 and 47.3% with liver steatosis based on FLI > 60 or CAP > 248, and 5.2% of liver stiffness >10 kPa. The median quantity of UPFs consumed was 2 (range 0–20). In participants younger than 46 years comprising the lower three age deciles, individuals consuming UPF quantities in the 5th quintile (median 6.2 items) had significantly ($p < 0.05$) higher fatty liver index (+27.7%), CAP value (+5,3%), ALT (+41.4%), and waist circumference (+4.8%) compared to the 1st quintile (median 0.7 items). The difference has not been observed for liver stiffness and in older participants.
Conclusion: Evidence from the liver screening program SIRIUS shows that younger individuals are more susceptible to the adverse effects of ultra-processed foods having a 5 to 40% excess burden on the liver and metabolic health.

FRI-023

Prevalence of MASLD and its association with the consumption of sugar sweetened beverages among a non-communicable disease cohort in the rural district of Iringa, Tanzania

Valentin Calvez[1], Francesca Schiavello[1], Rehema Itambu[2], Paolo Belardi[2], Emmanuel Ndile[2], Noemi Bazzanini[2], Bruno Ndunguru[3], Antonio Liguori[4], Benjamin Mfaume[2], Antonio Gasbarrini[1], Giovanni Putoto[5], Luca Miele[1]. [1]*Fondazione Policlinico Universitario "A. Gemelli" IRCCS, Catholic University of Rome, Department of Translational Medicine and Surgery, Rome, Italy;* [2]*Tosamaganga Designated District Hospital, Iringa, Tanzania;* [3]*Iringa District Council, Iringa, Tanzania;* [4]*Fondazione Policlinico Universitario "A. Gemelli" IRCCS, Catholic University of Rome, Department of Translational Medicine and Surgery, Rome, Tanzania;* [5]*CUAMM - Medici con l'Africa, Padua, Italy*
Email: valentino.calvez@gmail.com

Background and aims: The global health community has increasingly shifted its focus toward non-communicable diseases (NCDs), recognizing them as a critical public health emergency, particularly pronounced in low and lower middle-income countries. The prevalence, associated factors, and consequences of MASLD in the African continent, particularly in Sub-Saharan Africa (SSA), remain poorly understood. Indeed, no SSA studies were included in the latest major literature review and meta-analysis on the global epidemiology of MASLD. Tanzania, like many other SSA countries, is undergoing a demographic and epidemiological transition, leading to a marked increase in the burden of NCDs. The primary aim of this study was to estimate the prevalence of MASLD among an NCDs population in rural Tanzania. The secondary objective was to investigate whether the consumption of sugar sweetened beverages (SSB) is associated with MASLD.
Method: This study entailed a retrospective analysis of a prospectively collected cohort of consecutive patients attending the NCDs

outpatient clinic of Tosamaganga Hospital, from August 2022 to March 2023. Detailed sociodemographic, clinical, laboratory, and abdominal ultrasound data were collected for all participants. The Beverage Intake Questionnaire (BEVQ-15) was administered to evaluate their everyday drinking behaviors; and for each item, the average daily intake in fluid ounces (fl-oz), and calories (kcal) were calculated.

Results: Of 183 patients enrolled in the cohort, 128/183 (70%) were female. The mean age was 58 ± 13.7 years and mean BMI was 28 ± 6.67 Kg/m^2. Hypertension affected 141 individuals (77.0%), diabetes affected 77 (42.1%), and both conditions co-occurred in 35 patients (19.1%). SLD was found in 88/183 (48%) patients; with 39/88 (44.3%) of moderate or severe steatosis. MASLD was identified in all steatotic patients. Overall, on average the participants drank a mean of 12.6 fl-oz of SSB (throght sodas). MASLD patients drank an average of 22.4 fl-oz of SSB per day. Multivariable analysis revealed that BMI and daily SSB consumption (fl-oz) exhibited significant associations with MASLD, with respective OR of 1.16 (95% CI: 1.06–1.28, p = 0.002) and 1.19 (95% CI: 1.12–1.27, p < 0.001).

Conclusion: This study unveils a considerable prevalence of MASLD among the rural Tanzanian NCDs population, affecting nearly half (48%) of all patients studied. Timely identification of MASLD, facilitated by straightforward diagnostic means, holds pivotal importance for patient management and the dissemination of vital lifestyle modification guidance. Furthermore, our study, one of the pioneering efforts to demonstrate a significant association between SSB consumption and MASLD in an African context, underscores the imperative to heighten awareness regarding the risks posed by SSB consumption among NCDs patients and potentially the wider population.

FRI-024

Living with liver disease: patient and carer experiences in the United Kingdom

Vanessa Hebditch[1], Natasha North[1], Stephen Ryder[2], Ahmed M Elsharkawy[3], Richard Parker[4,5]. *[1]British Liver Trust, Winchester, United Kingdom; [2]NIHR Nottingham Biomedical Research Centre, Nottingham, United Kingdom; [3]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom; [4]Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom; [5]University of Leeds, Leeds, United Kingdom*
Email: richardparker@nhs.net

Background and aims: To understand and assess differences in patient experience and satisfaction with liver care, insights were gathered from patients across the UK. These insights provide a foundation for improving patient outcomes and standardising care practices across the UK and provide a framework for similar projects in other countries.

Method: An online survey was distributed through multiple channels, including the British Liver Trust's newsletter, support networks and social media. Clinicians assisted shared the survey with patients at appointments or through email. The survey was conducted twice, in 2019 and 2024. Survey respondents' satisfaction with their care was graded on a scale from 0 to 100 where 100 indicated complete satisfaction. Data were analysed in R.

Results: 1465 responses were received in 2019 and 2425 responses in 2024. People with liver disease made up the majority of responses (3209, 82.5%), and 645 respondents described themselves as carers or family members of people with liver disease. Most people experienced symptoms prior to their diagnosis of liver disease. The most common symptom was abdominal pain or swelling (59%). Itching was common (24%) especially amongst people with PBC (49%). Approximately one third felt their disease was diagnosed at an early stage (34%), and another third felt their disease was diagnosed at a late stage (30%). Late diagnoses were most common in people with cholangiocarcinoma (50%), hepatitis C (43%) and ArLD (37%). Respondents' experience of the initial identification of possible liver disease was mixed: 48% were referred or admitted to hospital and 22% were offered further testing, but 24% felt their condition was dismissed. Nearly one in five respondents waited for more than 12 months for specialist referral, and 10% reported not being referred at all. A majority of respondents felt their condition had been explained properly (43%) but the information given was usually inadequate: 53% were given too little information and 22% were given no information at all. Most people (91%) sought further information mainly from online sources. In the 2024 survey 22.5% of respondents felt that there was stigma associated with a diagnosis of liver disease. Over the two iterations of the survey in 2019 and 2024, satisfaction with care fell from a median of 63 to 52 out of 100. In addition, there were small reductions in the number of people whose condition was diagnosed early (29% to 26%) and an increase in those diagnosed late (21% to 24%).

Conclusion: Timely diagnosis, referral and providing patients with a good understanding of their disease are all critical for effective management. However, many patients are experiencing delays and are not receiving the information or support that they require once diagnosed. The perception of the quality of care received has fallen over the last five years. The voice of patients and carers is essential to improve liver services.

FRI-025

Readily available indices of liver fibrosis and insulin resistance associated with cancer and cardiovascular disease outcomes

Longgang Zhao[1], Xinyuan Zhang[2], Diego Martínez-Urbistondo[3], Miguel Martínez-González[4], Frank Hu[5], Xuehong Zhang[1]. *[1]Yale School of Nursing, Orange, United States; [2]Brigham and Women's Hospital and Harvard Medical School, Boston, United States; [3]Clínica Universidad de Navarra, Madrid, Spain; [4]University of Navarra, Pamplona, Spain; [5]Harvard T.H. Chan School of Public Health, Boston, United States*
Email: longgang.zhao@yale.edu

Background and aims: Liver fibrosis and insulin resistance are known drivers of cancer and cardiovascular disease (CVD) outcomes through metabolic dysfunction and inflammation. However, gold standard measurements, e.g., imaging and hyperinsulinemic-euglycemic clamp test, are often costly and impractical in large population-based studies or resource-constrained settings, making surrogate markers appealing alternatives. We aimed to evaluate the prospective associations of commonly used liver fibrosis (Fibrosis-4, FIB-4) and insulin resistance measurement (triglyceride glucose index, TyG) with cancer and CVD risk.

Method: We developed a prospective cohort based on data from the Harvard Mass General Brigham Biobank. We excluded those with cancer or CVD diagnosis at baseline and without biomarker data and integrated data on demographics and lifestyles (analysis sample: N = 66,015 for cancer and 62,747 for CVD). FIB-4 was derived using age, aspartate aminotransferase, alanine aminotransferase, and platelet count, with a cutoff of 1.3. TyG was derived using fasting blood glucose and triglyceride, with a cutoff of 8.8. Health outcomes were collected via electric medical records. We used Cox models to estimate hazard ratios (HRs) [95% confidence intervals (CIs)] for disease outcomes adjusting for potential confounding factors including demographics and lifestyles factors.

Results: With a median follow-up of 14.6 y for cancer and 6.5 y for CVD analyses, we identified 25,407 cancer and 46,488 CVD outcomes. A higher FIB-4 index was associated with elevated risk of digestive cancers (1.13 [1.04–1.22]), liver cancer (2.34 [1.94–2.82]), hepatocellular carcinoma (3.92 [3.10–4.95]), intrahepatic cholangiocarcinoma (1.64 [1.12–2.39]), leukemia (1.90 [1.67–2.17]), and non-Hodgkin lymphoma (1.37 [1.23–1.53]). TyG index was positively associated with pancreatic cancer (1.19 [1.02–1.39]), lung cancer (1.14 [1.04–1.24]), kidney cancer (1.35 [1.20–1.53]), bladder cancer (1.20 [1.07–1.36]), leukemia (1.22 [1.09–1.37]), and non-Hodgkin lymphoma (1.16 [1.06–1.27]). For CVD, higher FIB-4 index was associated with all types of CVD outcomes except for the hypertension with a HR ranged

from 1.11 [1.04–1.19] for ischemic stroke to 1.36 [1.24–1.49] for hemorrhagic stroke. Similarly, TyG index was associated with higher risk of all types of CVD outcomes with a HR ranged from 1.06 [1.02–1.10] for atrial fibrillation to 1.51 [1.43–1.59] for myocardial infarction. Those associations remained essentially unchanged in sensitivity analyses including excluding cases that occurred in the first two years of follow-up.
Conclusion: Liver fibrosis and insulin resistance, as assessed by readily available measures such as the FIB-4 and TyG index, are associated with elevated risks of specific cancers and most CVD outcomes. Further studies in other populations are needed to confirm our findings.

FRI-026
Metabolic dysfunction-associated steatohepatitis (MASH) prevalence in germany – results from a claims analysis
Yestle Kim[1], Thomas Ramezani[1], Jennifer Haas[2], Peter Rydqvist[1].
[1]Madrigal Pharmaceuticals Inc., Conshohocken, United States; [2]Xcenda GmbH, part of Cencora Inc., Hannover, Germany
Email: ykim@madrigalpharma.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a progressive form of metabolic dysfunction-associated steatotic liver disease (MASLD) that can lead to severe complications, including liver cirrhosis and hepatocellular carcinoma. These conditions impose a significant burden on both patients and healthcare systems. An estimated 4% of the German population is affected by MASH as of 2016 with an increasing global prevalence of the disease. Despite its rising prevalence, MASH often remains underdiagnosed due to patients being asymptomatic and the invasive nature of liver biopsy which is required for the confirmatory diagnosis. This results in a lack of appropriate follow-up and management for many patients. This study aimed to estimate the administrative incidence and prevalence of MASH in Germany, as well as to characterize these patients in terms of age and gender.
Method: A retrospective analysis was conducted using statutory health insurance claims data from the InGef research database. The study period spanned from January 1st, 2020, to December 31st, 2022. Prevalence and incidence figures were analyzed for the year 2022, identifying MASH patients by International Statistical Classification of Diseases and Related Health Problems, 10th Revision, German Modification (ICD-10-GM) diagnosis code K75.8 "Other specified inflammatory liver diseases [Nonalcoholic steatohepatitis NASH]." For inclusion, this diagnosis had to be recorded at least once in the inpatient sector (as primary or secondary discharge diagnosis) or at least twice in different quarters in the outpatient setting. Incident patients were defined as those with a diagnosis-free period of two years. Patients with evidence of alcohol use disorder or alcohol-associated liver disease were excluded.
Results: In 2022, 3,719 prevalent MASH patients in the InGef research database were identified, which corresponds to an administrative one-year-prevalence rate of 103.03 patients per 100,000 individuals, or 0.10%. The incidence rate was 15.71 patients per 100,000 individuals, equivalent to 0.02%. The average age of prevalent patients was 59.9 years, with 49.3% being female, while incident patients were slightly younger, averaging 55.7 years of age.
Conclusion: The results of this study suggest that significant underdiagnosis of MASH exists within the German healthcare system.

FRI-027
Metabolic dysfunction-associated steatohepatitis as a risk factor for hepatocellular carcinoma mortality
Yestle Kim[1], Samantha Clark[2], Arushi Chadha[2], Eric Zuk[2], Robert G. Gish[3]. *[1]Madrigal Pharmaceuticals, Inc., West Conshohocken, United States; [2]Medicus Economics, LLC, Milton, United States; [3]Robert G Gish Consultants LLC, La Jolla, United States*
Email: ykim@madrigalpharma.com

Background and aims: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related deaths worldwide. Metabolic dysfunction-associated steatohepatitis (MASH), the progressive form of metabolic dysfunction-associated steatotic liver disease (MASLD), has become one of the fastest growing risk factors of HCC in the US. While studies suggest that individuals with MASLD are at a higher risk of HCC mortality, evidence regarding the relationship between MASH and HCC mortality death is limited. In this analysis, we aim to add to the existing evidence base by assessing the differential risk of HCC-related death among MASH and non-MASH patients within a competing events framework.
Method: A retrospective cohort study including HCC patients diagnosed from 2015–2020 was conducted using SEER-Medicare data. The 12-month period prior to HCC diagnosis date (index date) was used for sample selection, covariate measurement, and to determine MASH status using the K75.81 diagnosis code. Patients presenting with MASH and other liver diseases (e.g., viral hepatitis) were excluded due to an inability to identify proximate HCC cause. The study period consisted of the time from a patient's index date through first of the following events: HCC death, non-HCC death, a censoring event, or loss to follow-up. Cause-specific (CS) hazard models were fitted to evaluate the relationship between MASH, HCC death, and the competing risk of non-HCC death. Results from a separate Fine-Gray (FG) subdistribution hazard model were used to assess the extent to which differential non-HCC death rates may be driving these results. All models adjusted for year of HCC diagnosis, age at HCC diagnosis, sex, race/ethnicity, cirrhosis status, HCC stage at diagnosis, and Charlson Comorbidity Index. Model assumptions were tested via residual analysis.
Results: Of the 6,301 HCC patients included in the final sample, 313 (5%) had a prior MASH diagnosis and 5,988 (95%) did not. The majority of patients (68.1%) died within 5 years of their HCC diagnosis, with 76% of these deaths attributable to HCC. CS model results indicate that the risk of HCC mortality was 23% higher in MASH patients over the follow-up period (adjusted CS hazard ratio [HR]: 1.23, 95% confidence interval (CI): 1.05–1.44). The minimal difference between HRs from the CS model for HCC death and FG model (adjusted FG HR: 1.17, 95% CI: 1.00–1.38) indicate that the impact of non-HCC death as a competing event is small.
Conclusion: In this analysis, clinically rich SEER-Medicare data were combined with competing risks survival analysis to generate additional insight into the relationship between MASH and HCC death. Results suggesting that MASH patients are at a higher risk of HCC death highlight the importance of expanded surveillance and effective treatment in reducing HCC mortality in this population.

FRI-028
Shortfalls and obstacles in sexual function assessment by healthcare providers in patients with liver disease and liver transplantation
Yooyun Chung[1], Deepak Joshi[1], Niloufar Safinia[1], Michael Heneghan[1].
[1]King's College London, London, United Kingdom
Email: yooyun.chung@nhs.net

Background and aims: Sexual function (SF) is an important patient reported outcome which is often neglected in patients with liver disease (LD) and liver transplantation (LT). The aim of this study was to identify potential barriers to SF assessment by healthcare providers (HCP).
Method: A 24-item online questionnaire was sent to all HCP who are members of the British Association for the Study of the Liver (BASL), United Kingdom.
Results: A total of 149 responses out of 1,100 potential participants were received (response rate 14%). One participant did not review patients with LD/LT and was excluded. There were more women (57%) compared to men (40%) and other gender groups (3%). The majority were consultant Hepatologists (31%), trainees (22%) and specialist nurses (30%). There were a similar proportion from transplant centres

(44%) and teaching hospitals (43%) with less from district general hospitals (13%). 58% had 1–10 years' experience in managing LD/LT patients and 36% had over 10 years' experience. Almost 40% of HCP were unsure what percentage of their LD patients were experiencing sexual dysfunction (SD) and this increased to 50% when asked about LT recipients. Over half of the HCP reported never or hardly ever discussing SD with their patients despite 61% disagreeing with the statement that "it was not their duty" to discuss SD and 43% felt that all specialists should manage SD. Obstacles for SF assessment included time constraints (65%), lack of knowledge about SD (60%) and having more important clinical priorities than SD (51%). Overall, 29% felt uncomfortable discussing SF with their patients and this increased to 51% when involving patients under 18 years of age. Over 90% disagreed or strongly disagreed that they had received sufficient training about managing SD and would prefer online resources (84%) or medical conferences (53%) to learn about SD. Only 1% reported lack of interest in learning about SD. On multivariate analysis, having knowledge about SF predicted the likelihood of asking about SF (CI −2.79–−0.68, p = 0.001) whereas gender, years of experience, place of work, training received and feeling uncomfortable was not statistically significant.

Conclusion: There is interest and a need to increase resources on SD in patients with LD/LT for HCP with a focus on LT recipients and younger patients. This will ultimately move towards improving quality of life measures in patients with LD/LT.

FRI-029

The global prevalence and mortality of metabolic dysfunction associated steatotic liver disease-related cirrhosis

James M. Paik[1,2,3], Soroor Owrangi[2], Pegah Golabi[1,2,3], Leyla Deavila[1,2], Ryuuki Hashida[2], Ariana Nader[2], Annette Paik[1,2], Linda Henry[1,2,3], Zobair Younossi[1,2,3]. [1]*The Global NASH/MASH Council, Washington, DC, United States;* [2]*Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, United States;* [3]*Center for Outcomes Research in Liver Disease, Washington, DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: Despite its increasing global burden, the prevalence and mortality of MASLD-related cirrhosis among the general population remains incompletely characterized. Our aim was to provide updated estimates of the global prevalence and outcomes of MASLD-related cirrhosis.

Method: A systematic review was conducted by searching PubMed, Ovid MEDLINE, EMBASE, Web of Science, and SCOPUS databases through June 2024, followed by a meta-analysis of the extracted data. Eligible studies focused on MASLD and cirrhosis, with populations categorized into general practice settings (outpatient) and high-risk settings (inpatient or referred for liver biopsy due to clinical indications). Data extraction and quality assessment adhered to PRISMA guidelines. Random-effects models were used to pool prevalence and outcome measures, accounting for between-study heterogeneity.

Results: From 7,924 screened studies, 35 articles encompassing 513,742 MASLD patients met inclusion criteria. The pooled prevalence of cirrhosis was 3.26% (95% CI: 2.47–4.31%) in the general practice and 14.51% (95% CI: 11.22–18.57%) in the high-risk settings. Global regional differences in prevalence among high-risk populations were noted, with North America and Australia showing the highest rates (18.38%; 95% CI: 9.06–33.75%), followed by Europe (10.16%; 95% CI: 5.71–17.44%) and Asia (9.12%; 95% CI: 6.11–13.40%) (p = 0.007). Notably, ICD-based cirrhosis diagnoses yielded higher prevalence estimates (27.43%) as compared to biopsy-confirmed cases (13.24%; p < 0.001).

The pooled all-cause mortality rate among MASLD-cirrhosis patients was 7.91 per 100 person-years (PY) (95% CI: 4.44–13.71). Stratification by severity of cirrhosis revealed mortality rates of 4.85 per 100 PY (95% CI: 3.43–6.80) for MASLD-related compensated cirrhosis and 12.47 per 100 PY (95% CI: 4.44–30.37) for MASLD-related decompensated cirrhosis. Incidence of hepatic decompensation among patients with compensated MASLD-cirrhosis was 7.17 per 100 PY (95% CI: 2.33–12.10). Additionally, in all patients with MASLD-cirrhosis, the incidence of hepatocellular carcinoma incidence was 4.45 per 100 PY (95% CI: 0.55–8.35), and liver transplantation was 1.84 per 100 PY (95% CI: 0.84–2.84).

Conclusion: This systematic review reveals a significant burden of MASLD-related cirrhosis across the globe with some geographic and diagnostic variability.

Email: zobair.younossi@cldq.org

Background and aims: Metabolic dysfunctional-associated steatotic liver disease (MASLD) patients have impaired health-related quality of life and other patient-reported outcomes (PROs) which can be exacerbated by comorbidities, including sleep disorders. Our aim was to assess the prevalence of sleep disturbance and its association with PROs in MASLD.
Method: Patients with MASLD were prospectively enrolled into the Global NAFLD/MASLD Registry™ (GNR). Clinical and PROs (FACIT-F, CLDQ-MASH, and WPAI) data were analyzed by the presence of sleep disturbance (defined as CLDQ-MASH Sleep score of ≤4 on a 1–7 scale).
Results: 5342 MASLD patients from 17 countries in the GNR were included: mean (SD) age 53 (13) years, 48% male and 60% obese, 41% had type 2 diabetes (T2D), 46% hypertension, 43% hyperlipidemia, 15% with advanced fibrosis (by biopsy or FIB-4 or transient elastography), 20% depression, 52% clinically overt fatigue, 32% abdominal pain, and 20% sleep apnea. Prevalence of sleep disturbance among MASLD was 34%. MASLD patients and sleep disturbance were more commonly female (63% vs. 46%), with more components of metabolic syndrome (obesity 65% vs. 57%, T2D 47% vs. 37%, hypertension 54% vs. 42%, hyperlipidemia 51% vs. 39%), non-hepatic comorbidities (anxiety 52% vs. 24%, depression 31% vs. 13%, clinically overt fatigue 60% vs. 48%) and sleep apnea (26% vs. 16%) than those without sleep disturbance (all $p < 0.01$). In logistic regression model, presence of sleep disturbance in MASLD was associated with older age, female sex, history of anxiety, depression, clinically overt fatigue, abdominal pain, smoking, lack of regular exercise, and presence of significant pruritus (all $p < 0.01$). In MASLD patients with sleep disturbance, PRO scores in all domains of CLDQ-MASH and FACIT-F were lower (up to −25% of a score range size), and work productivity impairment was higher (mean [SD] 0.30 [0.33] vs. 0.11 [0.23]) (all $p < 0.0001$). In particular, the presence of sleep disturbance was strongly associated with lower fatigue scores of CLDQ-MASH and FACIT-F (more fatigue) and with lower pruritus scores (more pruritus) of CLDQ-MASH (effect size −17% to −23%, all $p < 0.0001$). In multiple regression analysis, sleep disturbance was independently associated with lower PRO scores in all domains of CLDQ-MASH, FACIT-F, and WPAI (beta up to −15%). Other independent predictors of lower PRO scores in MASLD included age, female sex, comorbidities (metabolic syndrome components, psychiatric disorders, clinically overt fatigue, and sleep apnea), advanced fibrosis, smoking, and lack of regular exercise ($p < 0.05$).
Conclusion: Sleep disturbance is highly prevalent in patients with MASLD. It is associated with fatigue and pruritus, non-hepatic comorbidities, lifestyle factors, and substantial impairment in HRQL and work productivity. Patients with MASLD should be assessed for sleep disturbances and advised accordingly.

FRI-031

Performance of chronic liver disease questionnaire – metabolic dysfunction-associated steatohepatitis (CLDQ-MASH) against non-invasive tests

Email: zobair.younossi@cldq.org

Background and aims: Patients with more advanced histologic fibrosis due to metabolic dysfunction-associated steatotic liver disease (MASLD) can experience health-related quality of life (HRQL) impairment. Most HRQL instruments that have been validated in MASLD were evaluated against liver biopsy. However, non-invasive tests (NITs) are increasingly being used in clinical practice and clinical research. Our aim was to assess correlations of NIT scores with HRQL scores using a newly validated HRQL instrument for MASH (Chronic Liver Disease Questionnaire – Metabolic Dysfunction-Associated Steatohepatitis, CLDQ-MASH).
Method: The data from MASLD/MASH patients enrolled in the Global NASH/MASH Registry were used, including NIT scores (FIB-4, Enhanced Liver Function or ELF, liver stiffness measurement (LSM) by transient elastography) and HRQL assessed by the CLDQ-MASH (7 domains) instrument. The NIT cutoff values with the strongest association (the greatest effect size) with the total CLDQ-MASH score were identified.
Results: There were 8504 MASLD patients with NIT and HRQL data included: mean (SD) age 54 (12) years, 45% male, 62% obesity (BMI > 30), 50% type 2 diabetes, FIB-4 score 1.59 (1.25), ELF score 10.0 (1.0), LSM 12.4 (10.2) kPa. All studied NITs were significantly negatively correlated with Activity (correlation coefficient (r) −0.04 to −0.12), Fatigue (r = −0.04 to −0.06), Sleep (r = −0.04 to −0.05), and Systemic symptoms (r = −0.06 to −0.11) domains of CLDQ-MASH; FIB-4 and LSM were additionally correlated with Worry (r = −0.08 to −0.13), and LSM with Digestive symptoms (r = −0.07) domain scores (all $p < 0.01$). For FIB-4, the cutoff with the strongest association with HRQL was 1.60 (34% of the sample met the cutoff); as a result, patients with FIB-4 ≥1.60 had significantly lower HRQL scores in 5/7 domains of CLDQ-MASH including Activity, Fatigue, Sleep, Systemic symptoms, and Worry (mean score impairment up to −0.23 on a 1–7 scale, $p < 0.0001$) while the domains of Digestive symptoms and

Emotional health were not associated with FIB-4 at any cutoff (all p > 0.05). For ELF, the cutoff for the strongest association with HRQL was 10.8 (met by 22%): MASLD patients who met the cutoff had lower scores in all 7 domains of CLDQ-MASH (score impairment up to –0.37, all p < 0.01). For LSM, the cutoff with the greatest effect size for association with HRQL was 26.5 kPa (met by 7%): in patients who met the cutoff, all CLDQ-MASH scores were significantly lower by up to –0.57 (all p < 0.01).
Conclusion: NIT scores in MASLD correlate negatively with HRQL as assessed by CLDQ-MASH. This indicates that higher NIT scores consistent with higher disease severity correlate with more HRQL impairment. The NIT cutoffs commonly used for the diagnosis of advanced fibrosis return the strongest association with HRQL impairment in MASLD. This suggests that CLDQ-MASH can be used in conjunction with NITs in clinical research in MASH/MASLD.

Public Health – Viral Hepatitis

Background and aims: Migrants and refugees from countries with intermediate or high incidence and prevalence of hepatitis B and C virus (HBV and HCV) are at higher risk of acquiring these infections. This study aimed to increase HBV and HCV testing, HBV vaccination, and linkage-to-care among migrants and refugees living in Europe and report the latest epidemiological data.
Method: From 11/2022–11/2024, the VH-COMSAVAC study was implemented in Greece, Italy and Spain. Decentralised screening for HBV and HCV was offered in community and faith-based spaces, non-governmental organisations, and prisons. Simplified diagnostic tools, including HBsAg and anti-HCV rapid diagnostic tests were used, and expedited referral pathways were established to refer positive participants to collaborating tertiary hospitals. Intercultural mediators and community health workers supported recruitment and screening interventions to enable language and cultural appropriateness.
Results: Among 1,704 participants screened across the three countries, overall HBsAg and anti-HCV prevalence were both 3.4%. The highest HBsAg prevalence was observed in Spain (6.1%), which was higher than in Greece (2.2%) and Italy (2.1%). Anti-HCV prevalence was highest in Greece (5.9%) followed by Italy (2.3%). Participants were mostly male (74.2%), with a median age of 38 years (IQR = 30–48), and 51.9% were recently arrived migrants (≤5 years in country). 28.3% of participants were from sub-Saharan Africa, followed by Eastern Europe (17.8%), and Central and South America (13.9%). Most HBsAg+ participants (71.4%) were sub-Saharan African, mainly from Ghana and Senegal. 48.3% of anti-HCV+ participants were from Eastern Europe. Georgia, Pakistan and Egypt contributed to the highest HCV burden with an anti-HCV prevalence of 51.4%, 13.8%, and 7.0%, respectively. Among positive participants, 63.6% were successfully linked to care in Spain (N = 21/33), 47.5% in Greece (N = 29/61), and 12.5% in Italy (N = 2/14). Most of those not yet linked are facing legal barriers to access care.
Conclusion: The migrants and refugees in this study had high levels of viral hepatitis. Decentralized and simplified screening for viral hepatitis can successfully enhance diagnosis of HBV and HCV among migrants and refugees across Europe when provided in a culturally and linguistically appropriate manner. Legal barriers hindering individuals from accessing healthcare services must be addressed to ensure access throughout the cascade of care.

Disparities in hepatocellular carcinoma screening and in its detection rates in individuals with hepatitis B or C and cirrhosis in Canada
Jean Damascene Makuza[1], Stanley Wong[2], Dahn Jeong[3], Richard Morrow[3], Sofia Bartlett[4], Héctor Alexander Velásquez García[3], Prince Adu[2], Amanda Yu[2], Maria Alvarez[2], Alnoor Ramji[5], Eric Yoshida[5], Mel Krajden[2], Naveed Janjua[6]. *[1]University of British Columbia, School of Population and Public Health, BC Centre for Disease Control, BC Centre for Excellence in HIV/AIDS, Vancouver, Canada; [2]BC Centre for Disease Control, Vancouver, Canada; [3]University of British Columbia, School of Population and Public Health, BC Centre for Disease Control, Vancouver, Canada; [4]BC Centre for Disease Control, University of British Columbia, School of Population and Public Health, Vancouver, Canada; [5]University of British Columbia, Division of Gastroenterology, Vancouver, Canada; [6]University of British Columbia, School of Population and Public Health, BC Centre for Disease Control, University of British Columbia, Faculty of Medicine, UBC CDC, Vancouver, Canada*
Email: makorofr@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is a major global and Canadian cause of mortality. Regular HCC screening improves early detection and survival, especially among individuals with liver cirrhosis due to chronic hepatitis B (HBV) or C (HCV). Despite the benefits, disparities in HCC screening and their impact on post-diagnosis outcomes are underexplored. We assessed HCC screening disparities and detection among individuals with HBV or HCV in British Columbia, Canada.
Method: Using the BC Hepatitis Testers Cohort, we included individuals with HBV or HCV diagnosed with cirrhosis from 1990–2020. Screening was defined as >1 liver or abdominal ultrasound; HCC diagnosis required matching topography and histology codes. Logistic regression identified factors associated with screening and HCC detection.
Results: Among 117,524 individuals with chronic HBV (n = 42,259), HCV (n = 69,117), or HBV/HCV co-infection (n = 6,148), 13,995 had cirrhosis (HCV: 10,246; HBV: 2,221; HBV/HCV: 1,528). Median age at cirrhosis diagnosis was 56 years (Q1-Q3: 49–63); 68.1% were male, and 59.7% had decompensated cirrhosis. Over half of the cohort underwent at least one HCC screening, including those with HCV mono- or HBV/HCV co-infection. Overall, 15% were diagnosed with HCC, with the highest prevalence among HBV mono-infected individuals (22.7%). In multivariable models, diabetes was positively associated with screening (adjusted odds ratio [aOR]: 1.49–1.62 across groups). South Asian (aOR: 1.49; 95% CI: 1.13–1.95) and other

ethnicities (aOR: 1.75; 95% CI: 1.54–1.99) were more likely to be screened compared to East Asians. Conversely, males, individuals aged ≥45, those with injection drug use history, and decompensated cirrhosis were less likely to be screened. HCC detection was more likely in older individuals (45–54 years), males, and those with decompensated cirrhosis, while injection drug use and non-East Asian ethnicity were associated with lower odds of detection.
Conclusion: Significant disparities in HCC screening and detection exist by age, sex, injection drug use, ethnicity, and liver disease severity among individuals with cirrhosis due to HBV and HCV. Targeted interventions are needed to address these disparities, particularly for middle-aged males and those with advanced liver disease. Future research should explore barriers to screening in high-risk groups and evaluate strategies to improve surveillance and outcomes.

Emergency department opt out testing for HBV and HCV in London with integrated linkage to care: an effective initiative to diagnose hepatitis or work in progress?

Rachel Hill-Tout[1], Graham R Foster[2], Ashley Brown[3], Douglas Macdonald[4], Dan Forton[5,6], Patrick Kennedy[2], Matthew Foxton[7], Paul Trembling[4], Upkar Gill[2,8], Meera Kirby[8,9], Thendral Mangala[10], Gabriel Willis[11], Laura Blackmore[12], Julian Surey[13,14], Stuart Smith[15], Pamela Healy[16], Supa Chantschool[17], Joy Ko[18], Emma Susannah Young[8], Oliver Mizzi[19], Laura Hunter[20], Kevin Fenton[21], Mark Gillyon-Powell[22], Ian Jackson[1], Stephen Hindle[1], Georgia Threadgold[22], Beatrice Emmanouil[1], Peter Sandwith[8], Kosh Agarwal[23]. *[1]NHS England, London, United Kingdom; [2]Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [3]Imperial College Healthcare NHS Foundation Trust, London, United Kingdom; [4]Royal Free London NHS Foundation Trust, London, United Kingdom; [5]St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [6]St George's University of London, London, United Kingdom; [7]Chelsea and Westminster Hospital NHS Foundation Trust, London, United Kingdom; [8]Barts Health NHS Trust, London, United Kingdom; [9]Barking, Havering and Redbridge University Hospitals NHS Trust, London, United Kingdom; [10]North Middlesex University Hospital, London, United Kingdom; [11]London North West University Healthcare NHS Trust, London, United Kingdom; [12]Lewisham and Greenwich NHS Trust, London, United Kingdom; [13]Find and Treat, University College London Hospitals NHS Foundation Trust, London, United Kingdom; [14]Institute of Global Health, University College London, London, United Kingdom; [15]The Hepatitis C Trust, London, United Kingdom; [16]British Liver Trust, London, United Kingdom; [17]HepB Companion, London, United Kingdom; [18]Central and North West London NHS Foundation Trust, London, United Kingdom; [19]Kings College Hospital NHS Foundation Trust, London, United Kingdom; [20]Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; [21]Office for Health Improvement and Disparities (OHID), Department of Health and Social Care, London, United Kingdom; [22]NHS England, Leeds, United Kingdom; [23]Institute of Liver Studies, King's College Hospital, London, United Kingdom*
Email: r.hill-tout@nhs.net

Background and aims: Widespread opportunistic screening is critical to eliminating HBV and HCV. From April 2022, in areas of high (>5/1000) HIV prevalence, NHS England launched 'opt-out' testing for HIV, HBV and HCV in 34 emergency departments (EDs) with integrated linkage to care. We report on the first 2 years, focusing on 28 EDs in London, an urban metropolis with a diverse population of 9.7 million with over 40% of residents born outside of the UK.
Method: Adults attending ED who were having blood tests were offered opt-out screening for HBV and HCV (HBV surface antigen (HBsAg) and HCV antibody (HCV Ab), with reflex RNA if Ab positive). Information was displayed using posters in EDs and BBV screening performed unless the individual opted out. Results management was directed through hepatitis services with engagement and contact to individuals with a new or unlinked positive result. Linkage to care (LTC) was recorded if there was ≥1 attendance at hepatitis services. Aggregated, anonymised data was reported monthly by sites; LTC is underestimated as it does not take into account clinical exclusions, attendance at a service other than the notifying one, or that individuals may have been tested in more than one ED.
Results: By 2 years, triple BBV testing in London was live in 28 EDs. Screening for HBV and HCV was undertaken for a median of 18 months. There were 3.3 million ED attendances with 1.9 million having blood tests. 1,157,321 HBsAg and 1,171,253 HCV Ab tests were performed; testing uptake was 68% [IQR 48–77% between sites] for HBV and 69% [IQR 51–81%] for HCV. HBV: There were 9115 positive HBsAg tests: HBsAg positivity was 0.77% [IQR 0.57–0.94%]). Care status of screen positive cases, after excluding duplicates, was: 2866/7971 (48%) new diagnoses, 586 (10%) previously diagnosed but not in care and 2538 (42%) in care. LTC was 57% [IQR 31–75%]. HCV: There were 11831 positive HCV Ab tests: HCV Ab positivity was 0.98% [IQR 0.76–1.26%]. In those with current or past infection (HCV Ab+) only 13% [IQR 9–20%] of RNA tests were positive. Among RNA+ cases: 874/1289 (76% [IQR 59–87%]) were new diagnoses, 164 (9% [IQR 2–15%]) were previously diagnosed but not in care and 274 (8% [IQR 6–27%]) were in care. LTC was 68% [IQR 49–83%] for new diagnoses and 29% [IQR 2–69%] for people lost to care. Sites reported that 18% [IQR 10–26%] and 15% [IQR 0–26%] of new/ unlinked HBV and HCV RNA+ cases were 'uncontactable'. When this occurred, inclusion health partners (community peers, outreach and primary care providers) were engaged.
Conclusion: Opt-out ED BBV testing in London, a capital city with an ethnically diverse population, is effective and acceptable in diagnosing people living with HBV and HCV, with large cohorts of infected individuals identified. Low RNA+ rates in HCV exposed people indicates significant progress towards elimination. LTC was variable. Capacity building to deliver responsive clinical pathways, peer support and specialist management is critical to ensure optimal outcomes at an individual and population health level.

Genetic determinants of hepatitis B surface antibody disappearance in Taiwan's vaccinated generations: a genome-wide association study

Chun-Yi Chang[1,2], Chih-Jen Huang[2], Mei-Hung Pan[3], Ding-Lian Wang[2], Hwai-I Yang[2]. *[1]Department of Public Heath, Chung Shan Medical University, Taichung, Taiwan; [2]Genomic Research Center, Academia Sinica, Taipei, Taiwan; [3]Genomic Research Center, Academia Sinic, Taipei, Taiwan*
Email: smilekey16@gmail.com

Background and aims: Hepatitis B (HB), caused by HBV, affects 257 million people globally and causes 1.1 million deaths annually due to complications like cirrhosis and HCC. Chronic hepatitis B (CHB), defined as persistent HBsAg for over six months, remains a key public health concern. Taiwan's universal HBV vaccination program for newborns, launched in 1986, reduced the HBsAg positivity rate from 9.8% pre-vaccination to 0.64% after 35 years, significantly lowering HBV carrier rates and HCC incidence. However, studies show 60% of vaccinated individuals have anti-HBs levels below the protective threshold 15–18 years post-vaccination, raising concerns about increased HBV susceptibility. The mechanisms underlying anti-HBs decline remain unclear. This study investigates genetic factors associated with anti-HBs decline to develop risk prediction models and personalized HBV prevention strategies.
Method: The study utilized data from the Taiwan Biobank, including 6,255 participants born after July 1, 1986, under Taiwan's universal

vaccination program. Individuals born before this date or testing positive for anti-HBc were excluded. A genome-wide association study (GWAS) was conducted to explore genetic factors influencing anti-HBs seronegativity. Rigorous quality control (QC) procedures using PLINK software included sex-genotype concordance checks, thresholds for SNP call rates, heterozygosity evaluation, and kinship filtering to exclude related individuals. At the SNP level, QC involved filtering based on minimum allele frequency, SNP call rates, and Hardy-Weinberg equilibrium testing. Significant SNPs identified through GWAS were mapped to gene regions, and logistic regression analysis with Bonferroni correction was applied to control for false positives.

Results: Seventy-five SNPs were significantly associated with anti-HBs seronegativity ($p < 5 \times 10^{-8}$), with 73 SNPs clustered in the HLA-DPB1 region and 2 in COL11A2. Analysis of specific HLA-DPB1 allele combinations, such as HLA-DPB1 05:01/05:01 and HLA-DPB1 02:02/02:02, revealed significant associations. Logistic regression models adjusted for age and sex showed that individuals with the HLA-DPB1 05:01/05:01 allele combination had a higher risk of anti-HBs seronegativity compared to those with other combinations (OR = 1.27, 95% CI = 1.09–1.47, p = 0.002). Conversely, individuals with the HLA-DPB1 05:01/02:02 combination had a reduced risk of anti-HBs seronegativity (OR = 0.73, 95% CI = 0.58–0.92, p = 0.008).

Conclusion: HLA-DPB1 variation significantly influences anti-HBs seronegativity in individuals vaccinated against HBV. The HLA-DPB1 05:01/05:01 allele combination increased the risk of anti-HBs disappearance, while HLA-DPB1 02:02/02:02 was protective. These findings underscore the role of genetic variation in determining long-term immune responses to HBV vaccination and provide a foundation for personalized vaccination strategies and improved HBV prevention.

WED-003

One-pot assay based on CRISPR/Cas13a technology for HEV RNA point-of-care testing

Ling Xu[1], Zihao Fan[2], Xiangying Zhang[2], Yaling Cao[2], feng ren[2].
[1]*Beijing Institute of Hepatology/Beijing Youan Hospital, Capital Medical University, Beijing, China;* [2]*Beijing Institute of Hepatology/Beijin, Beijing, China*
Email: 15764235913@163.com

Background and aims: Hepatitis E virus (HEV) poses a serious threat to both public health and animal food safety, thereby highlighting the demands for rapid, sensitive, and easy-to-use detection. This study aimed to develop a One-Pot assay using CRISPR/Cas13a for detecting HEV RNA, suitable for point-of-care testing (POCT) in resource-limited settings.

Method: CRISPR/Cas13a combined with reverse transcription polymerase chain reaction (RT-PCR) and reverse transcription recombinase-aided amplification (RT-RAA) was applied to a One-Pot assay device. Additionally, a large cohort of HEV-infected patient (154) and animal (104) specimens was utilized for validation.

Results: The RT-PCR/RT-RAA+CRISPR/Cas13a assays for HEV RNA detection (genotypes: HEV-1, HEV-3, and HEV-4) were established, optimized, and validated, achieving a limit of detection (LoD) of 1 copy/μL and 100% specificity. In the application validation for HEV infection, the positive rates of the RT-PCR+CRISPR and RT-RAA +CRISPR assays were 98.6% and 89.6% for patients, and 96.6% and 88.8% for animals, respectively, which were superior to those of RT-qPCR. Furthermore, sample rapid lysis, reagent lyophilization, and the One-Pot device were integrated to construct a One-Pot assay with a LoD of 102 copies/μL. Despite slight decreases in sensitivity, the One-Pot assay significantly reduces the assay time to 35 minutes, making it easy to perform, minimizing contamination, and meeting the requirements for screening.

Conclusion: We developed a One-Pot assay of HEV RNA using the CRISPR/Cas13a which effectively realizes a POCT test and maximizes the impetus for POCT implementation and shows potential as a valuable tool for detecting and monitoring HEV infection.

WED-004

Global burden of liver cancer related to viral hepatitis attributable to high body mass index from 1990 to 2021

Sitao Ye[1], Yingjie Ai[1], Bowei Shen[2], Xiaoquan Huang[1], Shiyao Chen[1].
[1]*Zhongshan Hospital, Fudan University, Shanghai, China;* [2]*University of Shanghai for Science and Technology, Shanghai, China*
Email: 17301050277@fudan.edu.cn

Background and aims: Liver cancer is a prominent contributor to global cancer mortality, with primary etiologies including hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Metabolic risk factors, including high body mass index (BMI), has been associated with an increased risk of liver cancer and is gaining recognition in the context of its global impact. This study aims to estimate the global burden of liver cancer due to hepatitis B or hepatitis C attributable to high BMI.

Method: Data on the number and rate of deaths and disability-adjusted life years (DALYs) of liver cancer due to hepatitis B or C attributable to high BMI were extracted from the Global Burden of Disease (GBD) 2021. Age-standardized rates (ASR) of deaths and disability-adjusted life years (DALYs) were analysed across various demographics, including sex, age groups, and socio-demographic index (SDI) levels. The estimated annual percentage change (EAPC) in deaths and DALYs was calculated to identify trends over time.

Results: The overall ASR of deaths due to hepatitis B has decreased from 2.5 (95% CI 2.154–2.916) in 1990 to 2.089 (95% CI 1.721–2.551) in 2021, with an EAPC of –0.65 (95% CI –0.789–0.511), and for hepatitis C from 1.699 (95% CI 1.466–1.986) to 1.739 (95% CI 1.489–1.994) with an EAPC of –0.084 (95% CI –0.247–0.080). However, the ASR of deaths attributable to high BMI has shown an alarming increase. For hepatitis B, the ASR of deaths rose from 0.081 (95% CI 0.032–0.131) in 1990 to 0.18 (95% CI 0.069–0.309) in 2021, with an EAPC of 2.598 (95% CI 2.506–2.691). For hepatitis C, the ASR of deaths increased from 0.101 (95% CI 0.041–0.169) to 0.2 (95% CI 0.084–0.337), with an EAPC of 2.2 (95% CI 2.091–2.309). Additionally, ASR of DALYs for hepatitis B and C have also increased, with DALYs for hepatitis B rising from 2.639 (95% CI 1.023–4.235) to 5.74 (95% CI 2.204–9.840) and for hepatitis C from 2.346 (95% CI 0.941–3.982) to 4.461 (95% CI 1.860–7.620), both showing EAPCs of 2.489 (95% CI 2.388–2.590) and 2.101 (95% CI 1.986–2.217) respectively. Male exhibits higher EAPC of deaths and DALYs than female. When stratified by age, the crude rate of deaths and DALYs are higher in the 50–69 and 70+ age groups, which are also increasing annually. However, the EAPC is notably higher in the 15–49 age group. In terms of SDI, the ASRs of deaths and DALYs attributable to high BMI is highest in the high-middle SDI group for hepatitis B, and in the high SDI groups for hepatitis C. Nevertheless, the middle SDI group exhibits the highest EAPC for both hepatitis B and C.

Conclusion: Despite the global decline in both mortality and DALYs for liver cancer due to hepatitis B and C, there is a contrasting increase in the burden attributable to high BMI. This upward trend is particularly evident among male, in countries with middle SDI, and within the 15–49 age group.

WED-005

Current hepatitis D virus infection prevalence in persons with human immunodeficiency virus and hepatitis B virus across Europe

Anders Boyd[1], Lutz Thomas[2], Kathrin van Bremen[3], Alessandro Tavelli[4], Antonella d'Arminio Monforte[4], Marc van der Valk[5], Milosz Parczewski[6], Iwona Cielniak[7], Luz Martín-Carbonero[8], Charles Béguelin[9], Gilles Wandeler[9], Kosh Agarwal[10], Sanjay Bhagani[11], Charlotte Lim[11], Juan Berenguer[12], Jürgen Rockstroh[3], Pablo Ryan[13]. Germany; [3]Bonn University Hospital, Bonn, Germany; [4]Icona Foundation, Milan, Italy; [5]Stichting hiv monitoring, Amsterdam, Netherlands; [6]Pomeranian Medical University, Szczecin, Poland; [7]Collegium Medicum Cardinal Stefan Wyszynski University, Warsaw, Poland; [8]Hospital Universitario La Paz, Madrid, Spain; [9]Inselspital, Bern University Hospital, Bern, Switzerland; [10]King's College Hospital, London, United Kingdom; [11]Royal Free London Foundation Trust, London, United Kingdom; [12]Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain; [13]Instituto de Salud Carlos III, Madrid, Spain
Email: a.c.boyd@amsterdamumc.nl

Background and aims: People with human immunodeficiency virus (HIV) and hepatitis B virus (HBV) are at increased risk of also having hepatitis D virus (HDV) infection given the shared transmission pathways. However, much of the current epidemiological literature on HDV in those with HIV/HBV are based on decades-worth of data and there is no clear understanding of the current prevalence of HDV in this patient population. We aimed to determine the HDV screening rate and estimate the prevalence of HDV infection of people with HIV/HBV who are currently in care in Europe.
Method: Data from several clinical cohorts across Europe (i.e., the Netherlands, Germany, Switzerland, Spain, Italy, United Kingdom, and Poland) of people with a confirmed HIV diagnosis were used. We included those who were ever hepatitis B surface antigen positive, aged ≥18 years, and actively in care on December 31, 2023. We assessed HDV testing rates in the total cohort. In addition, we calculated the prevalence of individuals who ever had an anti-HDV positive serology (i.e., past/current infection) and the prevalence of individuals whose last HDV RNA result was positive (i.e., active infection). We also provided prevalences by key population, based on HIV transmission [i.e., men who have sex with men (MSM), heterosexual/other, and people who inject(ed) drugs (PWID)].
Results: Of 3176 persons with HIV/HBV included, anti-HDV antibody results were available in 2027 (63.8%). Of them, 263 had past/current HDV infection (13.0%, 95% CI = 11.5–14.5). This prevalence ranged from 4.5% in the Netherlands to 22.2% in Poland. Among the 263 individuals with an anti-HDV positive result, 174 had been tested for HDV RNA and of them, 88 had active HDV infection (50.6%, 95% CI = 42.9–58.2%). The prevalence of active HDV infection was comparable across countries. The majority of past/current infections were observed in PWID (n = 127/289; 48.3%) followed by heterosexual/other (n = 84/868; 31.9%) and MSM (n = 52/870; 19.8%). Similarly, most of active infections were observed in PWID (n = 38/80; 43.2%) compared to heterosexual/other (n = 28/60; 31.8%) and MSM (n = 22/34; 25.0%).
Conclusion: In Europe, roughly one in eight individuals with HIV/HBV who are actively in care have evidence of past/current HDV infection. A smaller percentage of individuals had active HDV infection, representing 88 individuals likely needing treatment. Nevertheless, these results come from a setting where HDV RNA testing needs to be increased.

WED-006
Liver stiffness and AST-to-platelet ratio index (APRI) predict all-cause mortality in untreated people living with hepatitis B across Africa: a multi-centre cohort analysis in the hepatitis B in Africa collaborative network (HEPSANET)

Email: a.stockdale@liverpool.ac.uk

Background and aims: The African region has the highest global prevalence of hepatitis B, yet longitudinal data for people living with hepatitis B (PLWHB) on the continent are scarce. There is a need for improved data on the prognostic value of liver stiffness measurement (LSM) and low-cost biomarkers such as APRI, which were developed in non-African populations, for making treatment decisions. We aimed to evaluate the relationship between pre-treatment LSM and APRI and overall mortality among untreated PLWHB in HEPSANET, an Africa-wide cohort collaboration.
Method: We included treatment-naïve PLWHB aged ≥12 years who had a pre-therapy evaluation with transient elastography and/or APRI, and longitudinal outcome data. We excluded PLWHB with HIV, hepatitis C or D co-infection and those who developed hepatocellular carcinoma within 180 days of enrolment, and for APRI, those with AST > 200 U/L. For 10 PLWHB with an unknown date of death, we imputed survival time using multiple imputation. We used a Cox proportional hazards model for all-cause mortality with a restricted cubic spline with 5 knots for LSM and APRI. We right-censored patients 180 days after their last visit if designated lost to follow up, or at commencement of HBV treatment.
Results: Across 12 sites in 9 African countries, we included 3,803 treatment-naive PLWHB with a total of 12,629 person-years of follow up (PYFU) with a baseline LSM, and 3,860 PLWHB with 12,613 PYFU with a baseline APRI score. Median age was 33 years [IQR 27, 41] and 60% were male. Pre-therapy LSM was <7, 7–12 and >12 kPa in 79%, 15% and 7%, respectively; APRI was <0.5, 0.5–0.9, 1.0–1.4 and ≥1.5 in 79%, 13%, 3% and 5%, respectively. LSM and APRI were non-linearly associated with mortality, and increasing incidence of mortality was observed when LSM exceeded 7 kPa and APRI exceeded 0.3. Relative to LSM of 4 kPa, hazard ratios for mortality after a median follow up of 2.8 years (IQR 0.7, 5.8) at 7, 10, 15, 20 and 30 kPa were 1.6 [95% CI 1.2–2.2], 9.4 [6.6–13.4], 26.4 [16.3–43.0], 33.4 [21.0–53.2] and 51.5 [33.5–79.2]. Relative to APRI of 0.3, APRI scores of 0.5, 1.0 and 2.0 were associated with hazard ratios for mortality after a median 2.6 years [0.6–5.7] of follow up, of 3.4 [2.9–4.3], 8.2 [5.9–11.5] and 8.5 [6.1–12.0], respectively.
Conclusion: This analysis shows a strong and non-linear association between mortality and both LSM and APRI in PLWHB in Africa. This finding may support the expansion of antiviral therapy for PLWHB with LSM > 7 kPa or APRI > 0.5, as recently recommended by the World Health Organization 2024 guidelines.

Email: mariabutiferret@gmail.com

Background and aims: In Spain, the prevalence of HBsAg is 0.22%, with a 7.7% rate of HDV coinfection. Previous research involving small cohorts has shown that introducing reflex testing for hepatitis D in HBsAg-positive cases leads to an increase in absolute diagnoses. This project aims to establish and implement a reflex screening program for hepatitis D in all HBsAg-positive samples across the public healthcare centers of the Catalan Health Institute (Institut Català de la Salut, ICS). Additionally, a registry of positive cases will be created to evaluate their clinical characteristics and treatment indications.
Method: A multicenter prospective study was conducted, including all HBsAg+ samples analyzed at the seven ICS laboratories (covering more than 95% of the Catalan population). A double reflex testing for anti-HDV and HDV RNA was performed. Demographic, epidemiological, clinical, laboratory data, and patient linkage to care status for all anti-HDV positive patients were recorded on a digital platform.
Results: From 1/Jan to 31/Oct of 2024, 220,242 HBsAg determinations were performed, identifying 5,333 HBsAg+ samples. Anti-HDV antibodies were tested in 4,810 samples (90%), of which 185 (3.8%) were positive after removing duplicates. Of the 185 anti-HDV positive cases, 63 (35%) were also positive for HDV RNA. The program allowed testing for 2,223 HBsAg+ samples (46%) that had not been previously tested for HDV, detecting 56 new anti-HDV+ and 9 new HDV RNA+ subjects. Of the 53 currently registered HDV RNA+ patients, 65% were male, with a median age of 53 years (range 42–59). Thirty-nine percent were Spanish, and 38% reported risk factors. Thirty-eight percent had elevated ALT levels, 51% had liver cirrhosis, 8% had a history of hepatic decompensation, and 6% had hepatocellular carcinoma. A total of 26 patients had previously received treatment with PegIFN without response. Currently, 25 (47%) patients have started treatment with Bulevirtide. Those treated had more advanced fibrosis (≥F3: 84% vs 50%, p = 0.01), a higher frequency of prior PegIFN treatment (80% vs 21%, p < 0.001), and a higher frequency of previously known HDV diagnosis (96% vs 82%, p = 0.195) compared to untreated patients. The reasons for not receiving treatment included refusal due to fibrosis stage <F2 (36%), no prior PegIFN treatment (21%), limitations in drug administration (14%), or other reasons (29%).
Conclusion: This regional program has enabled the testing for hepatitis D in 46% of HBsAg-positive samples for the first time. Half of the patients with hepatitis D are now receiving Bulevirtide, particularly those with advanced fibrosis and those who failed to prior PegIFN treatment. This ongoing screening and monitoring program, integrated into the public healthcare system, will help determine the prevalence, characteristics, and treatment response to Bulevirtide in patients with hepatitis D.

WED-008-YI
Micro-elimination of hepatitis C utilizing hepatitis C virus self-testing in a district prison of northern India: a demonstration project

Ajeet Bhadoria[1], Amrita Mehndiratta[1], Rakesh Gairola[2], Rajesh Somvanshi[3], Muhammad Jamil[4], Niklas Luhmann[5]. [1]*All India Institute of Medical Sciences Rishikesh, Rishikesh, India;* [2]*Haridwar District Jail, Haridwar, India;* [3]*State National Health Mission, Haridwar, India;* [4]*World Health Organization EMRO, Cairo, Egypt;* [5]*World Health Organization, Geneva, Switzerland*
Email: ajeetsinghbhadoria@gmail.com

Background and aims: Incarcerated populations have a high prevalence of Hepatitis C virus (HCV) infection and face significant barriers to testing and treatment. This demonstration project evaluated the feasibility of using Hepatitis C virus self-testing (HCVST) to achieve micro-elimination of HCV in a district prison in Northern India.
Method: A micro-elimination project, was conducted at Haridwar Jail, Uttarakhand, among 1150 inmates (55 female) from August to October 2024. Participants were offered HCVST. Those with reactive results received reflex HCV RNA testing and fibrosis assessment using vibration-controlled transient elastography (VCTE). All those with active HCV infection were linked to on-site care and initiated on direct-acting antiviral (DAA) therapy under national viral hepatitis control program (NVHCP). A total of 111 inmates were enrolled to evaluate the usability and acceptability of HCVST kits.
Results: Participants (n-1150, 55 females) ranged in age from 18 to 90 years (mean age = 34.8 ± 14.4 years), with 43% under 30 years old. Most were literate (74%) and 40% were unmarried. Two-thirds (66.6%) belonged to lower socioeconomic classes. Reported risk behaviors included history of surgery (2.5%), dental procedures (5.9%), razor sharing (68%), tattooing (1.3%), needle sharing (3.1%), intravenous drug use (3.9%), and unsafe sex (26%). Intravenous drug use (odds ratio 37, 95% confidence interval (CI) 17–77), tattooing (odds ratio 6.5, 95% CI 1.7–23.9), and needle sharing (odds ratio 45, 95% CI 20–99) were significantly associated with HCV infection. HCVST identified 72 (6.3%) individuals with anti-HCV antibodies. Of these, 41 (56.9%) had active HCV infection (HCV RNA positive) with a median HCV RNA level of 30,245 IU/ml (range 262–625463). Four of the 41 HCV RNA positive individuals had liver stiffness measurement >12 kPa, indicating significant liver fibrosis. All 41 individuals with active HCV infection initiated DAA treatment. Overall usability of the HCVST kits was 70%, with sample collection being the most challenging step (98% required assistance).
Conclusion: This project demonstrates the feasibility of utilizing HCVST to screen for HCV infection and link inmates to care within a correctional setting. By implementing a comprehensive micro-elimination strategy, including readily accessible testing, treatment, and support services, significant progress can be made towards eliminating HCV in this high-risk population and contributing to national elimination goals.

WED-009
Return to Care (R2C) - the missing link in hepatitis C elimination

John Gibbons[1], Julian Surey[1,2], Mark Leonard[1,3], Martha Veitch[1], James Rock[1], Indrajit Ghosh[4,5], Alistair Story[1,6]. [1]*Find&Treat Team, UCLH NHS Trust, London, United Kingdom;* [2]*Institute of Global Health, UCL, London, United Kingdom;* [3]*Groundswell, London, United Kingdom;* [4]*Find&Treat Team, London, United Kingdom;* [5]*CNWL NHS Trust, London, United Kingdom;* [6]*Collaborative Centre for Inclusion Health, UCL, London, United Kingdom*
Email: john.gibbons@nhs.net

Background and aims: The UK is committed to eliminating the Hepatitis C virus (HCV) by 2030. The landscape of HCV detection and treatment has been transformed by the advent of highly effective and well tolerated oral treatments, but large numbers of people remain infected and not engaged with treatment and care. A previous national HCV re-engagement exercise, led by UKHSA, identified over 50,000 untreated patients in England but had limited success, with 71% of cases remaining unresolved. This presentation describes a new, highly effective peer-led outreach model developed by Find&Treat (a pan-London NHS inclusion health outreach service) to identify, contact, and engage 'lost to follow-up' (LFU) patients.
Method: Return 2 Care (R2C) was established in response to rising LFU referrals, driven by expanded opportunistic bloodborne viral disease testing in prisons and emergency departments, as well as improved surveillance and information systems identifying untreated patients. The programme employs peers who use digital searches, direct collaboration with NHS and allied providers, and intelligence-led street outreach to identify, contact, and engage patients. These efforts facilitate retesting, treatment, and holistic support. This study examines the first 1,000 patients referred to the service.
Results: Of the 1,000 patients referred, 84 (8.4%) had died, 682 (68.2%) were successfully identified, contacted, and engaged (ICE), while 234 (23.4%) remain uncontacted. Of the ICE'd cohort (682), 364 (53.4%) were engaged directly by peers, 257 (37.7%) through NHS and third-sector services, and 61 (8.9%) via prison healthcare. Among these, 404 (59.2%) were confirmed as previously treated, 199 (29.2%) have initiated or completed treatment, 39 (5.7%) are pending assessment for treatment, 35 (5.1%) achieved spontaneous viral clearance, and 5 (0.7%) experienced treatment failure and remain under review. Despite an extremely high level of social complexity (59% were homeless, 10% incarcerated, and 28% actively using heroin and crack cocaine) 72% of those requiring treatment have been treated or cured.
Conclusion: This study highlights the effectiveness of a peer-led model in reengaging untreated HCV-positive patients with care and treatment. This approach represents a critical component of HCV elimination strategies and can be scaled internationally to address both retrospective and future LFU cases.

WED-010
Complex multiple morbidity and social vulnerability among hep C patients with delays accessing care

John Gibbons[1], Julian Surey[1,2], Mark Leonard[1,3], Martha Veitch[1], James Rock[1], Indrajit Ghosh[1,4], Rachel Dowling[1], Ambre Khan-chambers[1], Alistair Story[1]. *[1]Find&Treat Team, UCLH NHS Trust, London, United Kingdom; [2]Institute of Global Health, UCL, London, United Kingdom; [3]Groundswell, London, United Kingdom; [4]CNWL NHS Trust, London, United Kingdom*
Email: john.gibbons@nhs.net

Background and aims: Multiple studies have highlighted an association between chronic Hepatitis C viral (HCV) infection and chronic renal disease, mental illness, and neurological disorders, but evidence on other common long-term chronic diseases, social vulnerability and especially on multiple morbidity is lacking. Understanding the factors that complicate accessing care for HCV patients is essential to better tailor services that can meet their needs. Find&Treat are a peer led pan-London NHS inclusion health outreach service who receive referrals for HCV patients in need of locating and engaging with treatment and care. We characterised the health status of a large cohort (200) of HCV patients who experienced significant challenges and delays accessing Hep C treatment to better understand the burden of complex comorbidity and social vulnerability and inform their ongoing care needs during and post HCV treatment.
Method: We linked a representative sample of 200 HCV patients referred for reengagement with care to the London Care Record, a secure NHS platform that combines data from both primary care practices and hospitals across London. This resource provides a comprehensive health care record for patients that can be viewed by medical practitioners across the capital to speed up communication and improve care. Data on key diagnoses, health care access and social vulnerabilities were collated to characterise the burden of complex comorbidity and multiple morbidity.
Results: The majority were UK born (71%) and male (73%), and the overall mean age was 54 (Range 24–78). 52% had a diagnosis of anxiety/depression, 20% schizophrenia/psychosis, 11% diabetic or pre-diabetic, 17% had a cardiovascular diagnosis and 42% had chronic obstructive respiratory disease. 2% were HIV coinfected, 56% had an ulcer, wound, abscess and/or cellulitis and 23% had a history of serious head injury. 11% of patients had one recorded comorbidity and 38% had over 5 comorbidities. 75% reported ongoing drug and alcohol dependency and 60% were homeless.
Conclusion: This study reveals a substantial burden of comorbidity, complex multimorbidity, and social vulnerability among HCV patients experiencing delays in accessing care in London. These patients have significant unmet healthcare needs at time of engagement with Hep C treatment services and major ongoing care needs. Further research is needed to better understand the care needs of Hep C patients and to develop HCV treatment models that can improve linkage to care for ongoing health needs post HCV treatment.

WED-011
Treatment for chronic hepatitis C infection in Pakistan – in a high prevalence country treatment initiation is sub-optimal and may impact elimination programs

Aliya Hasnain[1], Auj Chaudhry[2], Ambreen Arif[2], Muhammad Asim[3], Saeed Sadiq Hamid[1], Saad Niaz[3], Huma Qureshi[2], Graham R Foster[4], Naheed Choudhry[4], HepFreePak Consortium[4], Asad Chaudhry[5]. *[1]Aga Khan University, Karachi, Pakistan; [2]Doctors Plaza, Karachi, Pakistan; [3]Dow University, Karachi, Pakistan; [4]QMUL, London, United Kingdom; [5]Chaudhry Hospital, Gujranwala, Pakistan*
Email: g.r.foster@qmul.ac.uk

Background and aims: Elimination of HCV requires treatment of most infected people. The prevalence of HCV in Pakistan is among the highest in the world (estimated at 6.8%) and current treatment programs with sofosbuvir/daclatasvir are being rolled out nationwide in an effort to eliminate the infection. In this under educated population with limited access to accurate health information the uptake of antiviral therapy may be suboptimal. Here we assess the uptake of therapy, provided at no cost to the patient, in local programs as part of a preliminary elimination program.
Method: HepFreePak is an observational 25,000 person study of the impact of sofosbuvir/daclatasvir treatment in Pakistan that examines, prevalence, incidence over 12 months in uninfected and successfully treated patients and response to current standard of care (sofosbuvir/daclatasvir for 12 weeks in people with an APRI score of <1.5 or 24 weeks in those with an APRI score of >1.5 or other features of cirrhosis). We examined treatment uptake and attendance for SVR12 testing in three different treatment programs: a 'door-to-door' case finding approach (Malir); an urban clinic and community testing events (Karachi) and a community camp based 'test and treat' strategy (Gujranwala). All treatment associated costs were met by the program along with small cash incentives to attend for treatment/testing.
Results: In a 'door-to-door' test and treat strategy in Malir, Karachi 14,612 people were tested, 167 (1.2%) were antibody positive but RNA negative and 930 (6.36%) were HCV RNA positive. 713 (77%) initiated treatment and 633 (89%) attended for SVR12 assessment of whom 89% achieved an SVR12.
In an urban clinic and community testing program in Karachi 2828 people were tested, 199 (7%) were HCV antibody positive and HCV RNA negative and 242 (8.6%) were HCV RNA positive. 227 (94%) initiated treatment and 157 (69% of treated) attended for SVR12 assessment of whom 96% achieved SVR12. In a community-based test

and treat strategy in Gujranwala (Punjab) 3609 people were tested, 127 (3.8%) were antibody positive and HCV RNA negative and 246 (6.8%) were HCV RNA positive. 178 (72%) initiated treatment and 76 (42% of those treated) attended for SVR12 assessment of whom 95% achieved an SVR.
Conclusion: The prevalence of chronic HCV infection remains very high with rates of 6–8%. Despite the availability of free antiviral treatment and incentives to attend for treatment less than 80% commenced treatment and even fewer were able to complete an SVR12 assessment. Information and awareness programs along with appropriate pictorial literature will be required to assist the elimination program in Pakistan.

WED-012

A comparative analysis of carbon footprints: nucleic acid test vs. rapid antigen test for preventing mother-to-child transmission of hepatitis B in the gambia

Alassane Ndiaye[1], Florian Motyl[2], Sainabou Drammeh[3], Bakary Dibba[3], Alexandra Famiglietti[4], Maya Whittaker[5], Kevin Jean[6], Maud Lemoine[7], Sylvie Boyer[8], Dramane Kania[9], Kris Murray[3], Chistopher Vandi[3], Florence Guivel-Benhassine[1], Helene Da Conceicao[1], Guillaume Pakula[2], Gibril Ndow[10], Yusuke Shimakawa[1]. *[1]Unité d'Epidémiologie des Maladies Emergentes, Institut Pasteur Paris, Paris, France; [2]Celcius group, Marseille, France; [3]MRC Unit The Gambia at LSHTM, Serrekunda, Gambia; [4]Unité d'Epidémiologie des Maladies Emergentes, Institut Pasteur Paris, France, Paris, France; [5]The University of Manchester, UK, Manchester, United Kingdom; [6]Ecole Normale Supérieure PSL, France, Paris, France; [7]Imperial College London, UK, London, United Kingdom; [8]Aix Marseille University, France, Marseille, France; [9]Institut National de Santé Publique, Bobo Dioulasso, Bobo Dioulasso, Burkina Faso; [10]Unité d'Epidémiologie des Maladies Emergentes, Institut Pasteur Paris, Serrekunda, Gambia*
Email: aloundiaye91@yahoo.com

Background and aims: Healthcare systems contribute over 4% of global carbon emissions, underscoring the urgent need for measures to mitigate their environmental impact. When selecting between different healthcare strategies, environmental impact should be considered alongside health outcomes and economic costs to guide decision-making. However, only some studies have conducted life cycle assessments (LCA) to estimate the carbon footprint related to healthcare technologies. To date, there is no study comparing the carbon footprint of alternative rapid tests versus conventional reference tests in resource-limited countries. In this study, we estimated and compared the carbon emissions of three testing strategies used to assess eligibility for antiviral prophylaxis in pregnant women with chronic hepatitis B virus (HBV) infection in The Gambia: i) conventional strategy to quantify serum HBV DNA levels using point-of-care real-time PCR (Xpert HBV Viral Load), ii) the innovative strategy to detect hepatitis B core-related antigen with a rapid diagnostic test (HBcrAg-RDT) using capillary blood, and iii) the HBcrAg-RDT strategy using plasma.
Method: We conducted an LCA with field data collection in four healthcare facilities in The Gambia. The data collection included all products and processes involved in each testing strategy. Our functional unit was defined as a single testing visit to determine eligibility for peripartum antiviral prophylaxis during antenatal care in The Gambia. The carbon emissions, expressed as grams of CO2 equivalent (gCO2e), of each testing strategy were calculated and presented with their respective uncertainties.
Results: Across the four study sites, the average CO2e of the Xpert® HBV Viral Load (1519.7 gCO_2e [95% CI, 1323.0–1716.0]) was significantly higher than that of both HBcrAg-RDT using plasma (392.3 gCO2e [95% CI, 342.3–442.3]) and HBcrAg-RDT using capillary blood (253.5 g CO2e [95% CI, 215.1–291.7]). This trend was consistent across all healthcare facilities. The largest contributors to carbon emissions varied with the testing strategy. For the Xpert® HBV Viral Load, the share of emissions was dominated by energy consumption (57.4%), the test (17.8%), and women's travel (12.2%). The high associated energy consumption for Xpert® HBV Viral Load is mainly attributed to air conditioning required during HBV DNA amplification to maintain optimal operating conditions. Furthermore, the analysis of the carbon footprint of testing strategies across healthcare facilities revealed considerable variations mainly attributable to on-site service organization and women's trajectories.
Conclusion: The carbon emissions associated with HBcrAg-RDTs are approximately four to six times lower than those of conventional molecular assays. This underscores the importance of incorporating alternative rapid tests that do not require machines to promote a more sustainable strategy for eliminating HBV mother-to-child transmission in resource-limited settings.

WED-013

Clearing the road for viral hepatitis microelimination in croatian prisons: the Hepatos project

Tatjana Reic[1], Magda Pletikosa Pavic[2], Diana Nonkovic[2,3], Maja Sremac[4], Iva Košuta[4], Ivona Reic[1], Ana Visic[1], Anna Mrzljak[4,5]. *[1]Croatian Society for the Liver Diseases "Hepatos", Split, Croatia; [2]Teaching Institute for Public Health, Split - Dalmatia County, Split, Croatia; [3]Department of Health Studies, University of Split, Split, Croatia; [4]Department of Gastroenterology and Hepatology, University Hospital Center Zagreb, Zagreb, Croatia; [5]School of Medicine, University of Zagreb, Zagreb, Croatia*
Email: tatjana@hepatos.hr

Background and aims: In Croatian prisons, hepatitis C (HCV) prevalence is notably higher than in the general population. To bridge the gap between diagnosis and treatment, the Croatian Society for Liver Disease - Hepatos launched the Mobile InfoHep Centre (MIHC), a mobile clinic within the prison system. This initiative aimed to demonstrate the feasibility of HCV microelimination through civil society-led linkage-to-care services in collaboration with governmental institutions, public health authorities, and clinical experts.
Method: From June 2021 to April 2024, the project engaged experts from the Croatian Gastroenterological Society and the Public Health Institute, with financial backing from the Ministry of Justice. The Hepatos MIHC provided linkage-to-care services, including on-site liver exams using FibroScan®, consultations, HCV and/or HIV testing, and referrals to specialists.
Results: Hepatos conducted 18 outreach activities across 10 prisons, engaging 537 male and 62 female prisoners, mean age 42.3 ± 11.9 years and delivering 2078 services. The MIHC reached about 5% of the Croatian prison population. Only 8.7% of examined prisoners self-reported previous HCV contact, while 33.7% and 13.7% agreed to HCV and HIV testing, respectively. 41% (83/202) of tested prisoners were anti-HCV positive, and none was HIV positive. All anti-HCV positive prisoners were referred to HCV RNA testing: 19.3% tested negative and 43.4% (36/83) who tested positive were further referred to DAA treatment. For the rest PCR test is pending. 597 prisoners underwent on-site Fibroscan® exam with a median LMS of 5.3 (IQR 2.2, range 1.6.–52.3) kPa, with the following distribution of fibrosis: stage 1) 24.2%, stage 2) 9.7%, stage 3) 4.7% stage 4) 2.5%. A median CAP was 253 (IQR 81, range 100–400) dB/m and 36.9% of prisoners had steatosis with CAP values >276 dB/m. All prisoners with high degrees of fibrosis were referred to specialists. Anti-HCV positive prisoners had significantly higher LMS values (6.2 (IQR 3.8, range 2.8–52.3) kPa) compared to anti-HCV negative prisoners (5.1 (IQR 1.8, range 1.6–27.0) kPa), ($p < 0.001$).
Conclusion: Prisons play a critical role in detecting and treating HCV, particularly for those with limited healthcare access and engaged in risky behaviours. This collaboration among civil society, governmental bodies, and public health agencies showed that Croatia still has a significant HCV burden in prisons, but the joint approach enables to enhance prisoner health literacy and stimulate inmate willingness to undergo testing and treatment. Following governmental recognition

of these efforts, the Ministry of Justice is co-financing continuation of Hepatos program for the following three years (2025–2027) - providing linkage-to-care activities within prisons aiming to get a step closer to microelimination in Croatian prisons.

WED-014

Evaluation of Belgium's progress towards HBV elimination: results from a national serosurvey

Arno Furquim d'Almeida[1,2], Erwin Ho[1], Philippe Beutels[3], Kirsten Maertens[4], Niel Hens[3,5], Pierre Van Damme[4], Thomas Vanwolleghem[1,2]. [1]*Viral Hepatitis Research Group, Laboratory of Experimental Medicine and Pediatrics, University of Antwerp, Antwerp, Belgium;* [2]*Department of Gastroenterology and Hepatology, Antwerp University Hospital, Antwerp, Belgium;* [3]*Centre for Health Economics Research and Modelling of Infectious Diseases (CHERMID), Vaccine & Infectious Disease Institute (VAXINFECTIO), University of Antwerp, Antwerp, Belgium;* [4]*Centre for the Evaluation of Vaccination, Vaccine and Infectious Disease Institute (VAXINFECTIO), University of Antwerp, Antwerp, Belgium;* [5]*Data Science Institute, Interuniversity Institute for Biostatistics and statistical Bioinformatics (I-BioStat), University of Hasselt, Hasselt, Belgium*
Email: arno.furquimdalmeida@uantwerpen.be

Background and aims: The WHO strives to eliminate HBV by 2030 by reducing the hepatitis B surface antigen (HBsAg) prevalence to ≤0.1% in ≤5-year-olds and achieving at least 90% coverage of 3 doses of HBV vaccine (HepB3). In addition, universal infant HBV vaccination is recommended. This has been implemented in Belgium since 1999, with a catch-up at 12-years of age. In 2021, the vaccine coverage in Belgium was estimated to be 97.1% in 18–24-month-old children. We previously showed that HBsAg positivity alone overestimates the HBV prevalence and hepatitis B core antibody (anti-HBc) confirmatory testing should be performed in low-endemic countries. In this nationwide serosurvey, we evaluated Belgium's progress to reach the WHO elimination targets and assessed the impact of the national vaccination strategy by systematically analyzing HBsAg, anti-HBc and hepatitis B surface antibodies (anti-HBs).
Method: A total of 4968 individual residual serum samples were collected from ambulatory patients at 10 private diagnostic laboratories in Belgium – geographically representing the whole country – during Q2/Q3 2020 (outside COVID-19 lockdown). The number of samples in each laboratory was stratified per region, age group (10-year age bands) and sex. HBsAg, anti-HBs and anti-HBc were analyzed on the Abbott Alinity I. The samples were weighted by comparing sample and population frequencies by sex, 10-year age band and province. Quantifiable anti-HBs titers (limit of quantification (LOQ) = 2 IU/L) were evaluated as a proxy for HBV vaccine uptake, therefore not taking into account natural waning of vaccine-induced antibodies and residual HBV immune memory.
Results: HBsAg was detected in 2/89 (2.2%) samples from children aged ≤5 years. Both samples were anti-HBc negative (<1 S/CO), corresponding to the absence of chronic HBV infection. In our study, 2336 of the 4968 (47.0%) samples were HBsAg and anti-HBc double negative and had a quantifiable anti-HBs titer, indicative of prior HBV vaccination. Weighted analysis estimated a vaccination degree, based on anti-HBs >LOQ, of minimum 47.2% (95% CI 45.5%–48.8%) for the Belgian population. This was significantly higher in the younger age groups. More specifically, the weighted proportion with anti-HBs titers >2 IU/L was significantly higher ($p < 0.001$) in the ≤33-year-olds (71.5%, 95% CI 69.1%–73.7%) compared to the >33-year-olds (31.2%, 95% CI 29.2%–33.2%), which is in line with the Belgian vaccination policy implemented in 1999.
Conclusion: In this population-based nationwide serosurvey, none of the samples of ≤5-year-olds were HBsAg and anti-HBc double positive. At least 71.5% (95% CI 69.1%–73.7%) of the age cohort subject to the universal vaccine program had quantifiable anti-HBs titers. These results reinforce that Belgium is on track to reach the 2030 WHO HBV elimination targets.

WED-019

Direct measurement of incidence and prevalence of Hepatitis C infection using the gold-standard of prospective HCV re-testing of people at risk. A national needs assessment of people who inject drugs and of all people who use addiction services in England

Beatrice Emmanouil[1,2,3], Mark Gillyon-Powell[3], Specioza Nabiteeko[3], Peter Sandwith[2], Stuart Smith[4], Georgia Threadgold[3], Graham R Foster[2,5]. [1]*The Blizard Institute, Faculty of Medicine and Dentistry, Queen Mary University of London, 4 Newark Street, E1 2AT, London, United Kingdom;* [2]*Hepatology, Barts Health NHS Trust, London, United Kingdom;* [3]*NHS England, Specialised Commissioning, London, United Kingdom;* [4]*The Hepatitis C Trust, London, United Kingdom;* [5]*Blizard Institute, Faculty of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom*
Email: b.emmanouil@nhs.net

Background and aims: In England, it is recommended that people who inject drugs (PWID) attending addiction services are tested regularly for hepatitis C virus (HCV) infection following an assessment of infection risk. There is divergent practice as to what constitutes 'risk of infection' and testing frequency. Accurate information on the current prevalence in all people attending addiction services is essential for planning future HCV programs. A proportion of PWID do not attend addiction services. We assessed the needs of these populations by direct measurement of incidence and prevalence.
Method: Prospective HCV antibody (AB) and RNA testing & retesting of people at high risk either in addiction services or outside of structured treatment. Additional variables collected included post-code, age, gender, reason attending services, engagement with structured treatment and awareness of infection. Analyses were conducted using SPSSS 28.
Results: In autumn 2022, 11,020 people were tested for both HCV antibodies and RNA in a period of 6–8 weeks in >200 locations in all English regions. Testing took place in over 150 addiction services as well as the community, needle exchanges, soup kitchens, hostels, and the streets, using trained outreach teams of nurses and people with lived experience to identify people not engaged with structured services. Every living person was offered re-testing in 2023–24, even if relocated or incarcerated. In addiction services, prevalence of chronic HCV infection was significantly different between PWID (10.9%, 95% CI [10.0–11.9%]) and other clients (1.8%, 95% CI [1.4–2.2%]), $p < 0.001$. As expected, prevalence was higher in PWID outside structured treatment compared to those who were engaged with a service in the previous 12 months (15.9%, 95% CI [13.6–18.4%]). Prevalence was significantly higher in people who had been tested previously in the last 12 months in all groups and in all settings, $p < 0.001$. The highest prevalence was in a subgroup or people who had not engaged with treatment in the previous year but who had -nonetheless- been tested for HCV in the previous year by an outreach team (25%, 95% CI [19.4–31.3%]). Testing frequency and age were equally distributed in both gender groups. Virus clearance increased with age and was higher amongst women and people attending services. 6,000 people had a valid follow-up HCV test, and the preliminary annual incidence value based on the paired tests is 1.85 per 100 in all PWID.
Conclusion: This is the first direct measurement of incidence amongst at risk groups in England, with a large initial sample and extensive location coverage. Prevalence is higher with testing frequency, highlighting the programme's robust HCV testing structures and the holistic person-centred approached delivered by multidisciplinary teams inside and outside structured treatment. Incidence figures indicate that this World Health Organisation target has already been reached.

WED-020

Mind the gap - addressing inequitable hepatitis D testing in Wales

Bazga Ali[1], Rhys Oakley[2], Donall Forde[3]. [1]*Public Health Wales, Cardiff & Vale, Cardiff, United Kingdom;* [2]*Cardiff & Vale University Health Board, Cardiff, United Kingdom;* [3]*Public Health Wales, Cardiff, United Kingdom*
Email: bazga.ali2@wales.nhs.uk

Background and aims: Hepatitis D (HDV) infection only occurs in those with concurrent Hepatitis B (HBV), as HDV lacks the ability to replicate in the absence of co-infection The true prevalence of hepatitis D infection in Wales is unknown. It is important to identify coinfected patients as treatment is now available targeting HDV. EASL, AASLD & NICE all recommend screening for HDV infection. Wales has a population of 3.2 million of whom approximately 3000 have HBV infection. Clinical care of those living with infectious hepatitis is provided by a variety of specialties in six health boards. However, laboratory diagnostic services are centralised and performed at just two sites by one organization, Public Health Wales (PHW). At present HDV Ab testing must be requested by the reviewing clinician. Samples returning a positive HDV Ab result require an additional request for HDV PCR to ascertain whether there is ongoing infection. These processes introduce potential missed/delayed opportunities for diagnoses. We used the PHW laboratory network to identify those with hepatitis B surface antigen (HBsAg) positivity and ascertain what proportion by health board had HDV Ab testing performed. If poor compliance with hepatitis D testing was shown we planned to instigate reflex testing for HDV infection in all those that are HBsAg positive to improve compliance with guidance and identify more patients who may benefit from treatment.
Method: An all-Wales laboratory integrated management system managed by PHW called Datastore was used to extract all HBsAg positive samples that tested positive from 12/01/2015–06/04/24 and all hepatitis D requests in the same period.
Results: 3000 people over 9 years were identified as HBsAg positive. 35% had at least one HDV Ab test performed, leaving 65% of those identified with HBV infection in Wales, never having had HDV screening. Further interrogation of the data demonstrated wide variation in testing by health board. The best performing health board had tested 45% of all HBsAg positive patients compared with one health board only having tested 23.5%. Furthermore, of those that were identified as HDV Ab positive, 28% had no record of going on to have HDV PCR testing performed at any time.
Conclusion: This piece of work has demonstrated the importance of standardized operating procedures in diagnostics to ensure equitable care irrespective of patient location or clinical team specialism. Through this piece of work we have successfully, as of September 2024 bought in reflex testing of all HBsAg positive samples for HDV Ab on at least one occasion. Additionally, we have gone on to ensure reflex HDV PCR testing in all those samples that test positive for HDV Ab. We plan to review our data one year (Sept 2025) from instating this change in practice. By this time, all those that have had a positive HBsAg living in Wales, who are accessing care will have had reflexive HDV Ab testing and HDV PCR testing, where indicated. The availability of bulveritide, highlights the value of prompt, effective HDV testing.

WED-021

Emergency department screening and linkage to care for undiagnosed hepatitis C infection: an effective initiative to reach elimination targets

Kartikeya Khanna[1], Mia Olsen[2], Nabiha Essaji[1], Susanne Johansen[1], Pinar Eren[2], Teresa Bowyer[2], Abigail Manning[3], Angela Hart[3], Laura Blackmore[3], Kate Childs[2], Kosh Agarwal[2], Bo Wang[1]. [1]*Guy's & St Thomas' NHS Foundation Trust, London, United Kingdom;* [2]*Kings College Hospital NHS Foundation Trust, London, United Kingdom;* [3]*Lewisham & Greenwich NHS Trust, London, United Kingdom*
Email: kartikeya.khanna1@nhs.net

Background and aims: NHS England has set a target to eliminate Hepatitis C (HCV) by 2025. As part of elimination efforts, selected emergency departments (ED) have been implementing opt-out blood-borne virus (BBV) testing including HCV since April 2022. We describe how BBV testing in three Southeast London NHS Trusts has helped identify hard-to-reach patients, initiate them on treatment and achieve sustained virologic response (SVR).
Method: Patients seen in EDs in Southeast London with a reactive HCV antibody result and a positive reflex-tested HCV RNA or HCV core antigen between November 2022 to June 2024 were identified. Telephone contact was attempted with all patients and those accepting were offered follow-up and direct-acting antiviral (DAA) treatment. The clinical data and treatment outcomes were collected.
Results: In the 20-month period, 226,517 hepatitis C antibody tests were performed, and 303 unique patients had a positive diagnosis of HCV. 169 (55.8%) were new diagnoses. The median age was 53 years (IQR 43–64) and 207 were male (68.3%). 28 patients (9.2%) were clinically cirrhotic on presentation, 2 patients subsequently died of decompensated liver disease. 4 patients presented with hepatocellular carcinoma (HCC), and all have subsequently died. In addition, 38 patients have also died from non-liver related causes. Of the 303 patients identified, 164 patients (54.1%) have been initiated on treatment with 107 patients having confirmed SVR at time of writing. A further 39 patients have completed treatment awaiting SVR confirmation. 16 patients with confirmed SVR were diagnosed in ED but subsequently completed treatment in other non-hospital settings. It was established that 52 patients (17.2%) had no fixed abode or were in temporary accommodation, of whom 19 patients achieved SVR following an ED diagnosis.
Conclusion: ED screening effectively identifies new diagnoses of HCV infection; indeed 55.8% of HCV diagnoses here were in patients who had not been tested before. Many of these individuals did not have standard risk factors for infection and would not have been covered by other screening programmes. Overall, of those linked into treatment, a high SVR rate is seen. A significant proportion of those diagnosed in ED were individuals without permanent residence but more than a third of these were still successfully linked into treatment and SVR. Barriers remain to linkage after an ED diagnosis; 45% of patients here were not linked and efforts are ongoing to engage with these patients and understand the barriers. Nonetheless, as we work towards elimination, ED testing has been a successful and powerful initiative to diagnose and cure patients with HCV.

WED-022

Automated universal testing for hepatitis B in the emergency department improves screening and characterises the undiagnosed and untreated cohort in an australian setting

Bonita Gu[1], Julia Di Girolamo[1], Alexander Prudence[1], Joseph Pipicella[1], Sicha Manandhar[1], Melissa Bagatella[1], Krishan Pratap[2], Irena Petrovski[3], Jeremy Lawrence[4], Richard Cracknell[5], Matthew Smith[6], Alex Mackey[7], Michael Maley[8], Hong Foo[8], Nathan Jones[9], Gregory Dore[10], David Prince[1], Miriam Levy[1].
[1]*Liverpool Hospital Gastroenterology Department, Sydney, Australia;* [2]*Bankstown Hospital Gastroenterology Department, Sydney, Australia;* [3]*Campbelltown Hospital Gastroenterology Department, Sydney, Australia;* [4]*Fairfield Hospital Emergency Department, Sydney, Australia;* [5]*Campbelltown Hospital Emergency Department, Sydney, Australia;* [6]*Bankstown Hospital Emergency Department, Sydney, Australia;* [7]*Liverpool Hospital Emergency Department, Sydney, Australia;* [8]*Liverpool Hospital Infectious Diseases Department, Sydney, Australia;* [9]*Liverpool Hospital Aboriginal Health, Sydney, Australia;* [10]*UNSW Kirby Institute, Sydney, Australia*
Email: miriam.levy@health.nsw.gov.au

Background and aims: Untreated chronic hepatitis B (HBV) infection causes cirrhosis and hepatocellular carcinoma (HCC), concerning for those with HBV who remain undiagnosed and/or not linked to care. Migrant populations with higher HBV prevalence may encounter

unique barriers to routine health care. This study aimed to evaluate the utility of an automated, universal HBV screening service in the emergency department (ED) setting. Prevalence and characterisation of unmet needs are reported.

Method: SEARCH-3X (Screening of Emergency Admissions at Risk of Chronic Hepatitis-Extension 3) is a novel pilot clinical service which was feasibility tested across 4 four metropolitan EDs in Sydney, Australia. 5000 patients were tested per site. A computer algorithm automatically triggered HBV surface antigen (HBsAg) testing in all biochemistry blood tubes collected as part of routine care in the ED. Data were collected on patient demographics, HBV prevalence and HBV clinical care. South Western Sydney Local Health District Human Research Ethics Committee approval number is 2022/ETH01158.

Results: A total of 19,607 adult patients were tested, of whom 183 (0.9%) were HBsAg positive. Linkage to care has been successful in 175/183 (95.6%). Over half of the HBsAg positive group were male (54.1%). Median age at time of testing was 58.3 years (IQR 47.5–70.0). HBsAg was more likely to be positive in those ≥40 years old (1.1%) compared to those aged 18–39 (0.2%), $p < 0.00001$. Overseas born (OB) patients were more likely to be HBsAg positive than Australian born patients (1.6% vs 0.2%, $p < 0.00001$). Indigenous Australians were more likely to be HBsAg positive compared to non-Indigenous Australians (0.7% vs 0.1%, $p = 0.009$). Prevalence of HBsAg varied greatly according to country of birth; countries with the highest prevalence were Cambodia (8.8%, 19/215), Tonga (6.8%, 8/117), Vietnam (5.6%, 53/940), Sudan (5.5%, 3/55), Malaysia (4.3%, 3/70), China, (4.1%, 25/608), Myanmar (4.0%, 2/50), Thailand (4.0%, 3/76), Jordan (3.9%, 3/77), Hong Kong (3.6%, 2/55) and Cyprus (3.3%, 3/92). The prevalence of HBV in OB patients ranged from 0.6% in younger patients aged 18–24 up to a maximum of 2.5% in those aged 50–59. A new diagnosis of HBV was made in 23.4% (41/175) of patients. HBV monitoring had been conducted in 67.2% (90/134) of those with known HBV within the past 12 months. 50.9% (55/108) of those with known HBV and an indication for HCC surveillance had undergone surveillance within the preceding 12 months. There were no patient complaints and ED throughput was unaffected.

Conclusion: Automated testing for HBsAg in the ED is easy and effective. Universal testing in EDs with a high migrant population detects significant rates of infection, often in patients who were not aware of their HBV diagnosis or whose care was suboptimal. The OB and/or indigenous Australian cohort has higher HBsAg prevalence and appears to be the one to focus on for universal testing.

WED-023

Three-year evaluation of retention in specialist care among migrants and refugees living with HBV in Catalonia following a community-based intervention

Aina Nicolàs Olivé[1], Marta Arola[1], Sabela Lens[2,3], Xavier Forns[2,3], Maria Buti[2,4], Sergio Rodriguez-Tajes[2,3], Francisco Javier Pamplona Portero[5], Carmen López Núñez[6], Mireia Miquel[2,7,8], Jeffrey Lazarus[1,9], Camila Picchio[1]. *[1]Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [2]CIBER Hepatic and Digestive Diseases (CIBERehd), Instituto Carlos III, Madrid, Spain; [3]Liver Unit, Hospital Clínic, IDIBAPS, University of Barcelona, Barcelona, Spain; [4]Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [5]Department of Digestive Diseases, Hospital de Santa Caterina, Salt, Spain; [6]Department of Digestive Diseases, Hospital Trueta, Girona, Spain; [7]Hepatology Unit, Digestive System Service, Hospital Universitari Parc Taulí, Research and Innovation Institute I3PT, Medicine Department at Universitat Autònoma de Barcelona, Sabadell, Spain; [8]Medicine Department, Universitat de Vic – Universitat Central de Catalunya (UVic-UCC), Vic, Spain; [9]CUNY Graduate School of Public Health and Health Policy (CUNY SPH), New York, United States*
Email: aina.nicolas@isglobal.org

Background and aims: People born in countries with intermediate or high prevalence of HBV are at higher risk of acquiring this infection due, in part, to a scarcity of effective prevention and screening strategies in their countries. Upon migration, these individuals face additional barriers to access and navigate their host health system, delaying their diagnosis and care opportunities, in turn hindering their capacity to be treated and retained in care. This study aims to evaluate the retention in care of migrants and refugees living with HBV, following screening in community-based settings.

Method: From 11/2020 to 12/2023, the HBV-COMSAVA pilot study was implemented in Catalonia, Spain to offer decentralized screening for HBV in 61 screening interventions in community and faith-based spaces. A field team of community workers and nurses used HBsAg rapid diagnostic tests and plasma separation cards (PSCs) to test for HBV. Expedited referral pathways for positive participants to collaborating tertiary hospitals were provided. Data on patient´s baseline, follow-up, and retention in care, including HBV treatment, were collected.

Results: Among 830 people screened; 70 (8.4%) had a HBsAg positive RDT result by rapid point of care test and were referred to a collaborating hospital. Of the 56 (80.0%) participants with a documented first visit with a specialist, 47 had retention in care information available. Of these, seven (14.9%) did not return for additional visits. The majority of HBsAg+ participants were men (85.1%), mean age of 40.9 years and HBeAg negative (95.2%). Most patients were from Ghana (78.7%, N = 37) and Senegal (17.0%, N = 8). The median number of specialist care visits were two (IQR = 2–4), with a mean follow-up time of 14 months. Three (6.4%) people were eligible for antiviral treatment, of which two initiated and adhered to Nucleoside Analogue (NUC) treatment. Median HBV DNA and ALT levels were higher among those with treatment indication than those without, 61,000 UI/mL vs. 287 UI/mL, and 38 U/L vs. 31.5 U/L, respectively. Two (4.3%) participants were identified as false positives for an active HBV infection, and were positive for anti-HBc. Among the remaining, upon finalization of the follow-up period, eleven (23.4%) were still in follow-up care, while 21 (44.7%) were lost to follow-up.

Conclusion: Community-based strategies for screening of viral hepatitis infections were effective in increasing HBV diagnosis among migrants and refugees; however, linkage and retention in care was found to be a major challenge despite expedited referral processes. Additional strategies to enable successful linkage and retention in care must be explored to reduce loss to follow and improve health outcomes.

WED-024

Linking community-based organizations and specialized prescribing pharmacist teams to improve testing and treatment in hard-to-reach hepatitis C-infected groups: the LiveRx experience in Alberta, Canada

Cari Egan[1], Chinedu Diribe[2], Daniyal Khan[2], Klaudia Zabrzenski, [3], Jaanek Grewal[2], Colter Young[2], Irfan Hyder[2], Mark Swain[2]. *[1]Alberta Health Services, Calgary, Canada; [2]University of Calgary, University of Calgary Liver Unit, Calgary, Canada; [3]Mint Health and Drugs, Calgary, Canada*
Email: swain@ucalgary.ca

Background and aims: LiveRx is a research project funded through Alberta Innovates with the goal to develop community-focused approaches to address significant hepatitis C (HCV) testing and treatment gaps in underserved populations who do not/cannot access traditional healthcare models in Alberta, Canada, including people who are Indigenous, houseless, use drugs, or live in rural/remote areas. LiveRx leverages the *Alberta Primary Care HCV Testing/Treatment Pathway* (www.albertahealthservices.ca/assets/about/scn/ahs-scn-dh-pathway-hepatitisc.pdf) to enhance links between community-based pharmacies and community-based organizations (CBOs – including health programs and not-for-profit organizations) to identify, test, treat, retain in care, and ultimately cure HCV-infected individuals in their local communities.

Method: Community pharmacists with medication prescribing authorization and an interest to be trained in treating HCV, who worked in pharmacies recognized as providing safe environments for underserved populations were identified through collaborative discussions with CBOs and individuals with lived experience. LiveRx pharmacists received training through tailored HCV e-modules and in-person workshops co-developed by the International Network on Health and Hepatitis in Substance Users (INSHU) and LiveRx for HCV screening (point of care [POCT], diagnosis, direct acting antiviral [DAA] prescribing, and follow-up care). LiveRx staff, hepatologists, and pharmacy consultants provided support for HCV screening and treatment through pharmacist case-finding, referrals and community/peer outreach.
Results: A total of 20 LiveRx pharmacies screened 700 patients for HCV via POCT and 116 individuals (16.6%) were found to be HCV antibody reactive (Ab +ve). Additionally, 38 HCV Ab +ve patients were identified through pharmacy record case-finding. HCV RNA testing was obtained for 103 of these HCV Ab +ve cases, 44 via Dried Blood Spot Testing (DBS) and 59 via phlebotomy, with 61 HCV RNA +ve cases (59.2%) identified. Notably, 14.8% of identified individuals were previously documented to be HCV Ab +ve and 49.6% HCV RNA +ve but were never successfully linked to treatment. DAA therapy was initiated by LiveRx pharmacists for 58 individuals (95.1%) and 51 (87.9%) completed treatment. 33 treated individuals (64.7%) had post-treatment HCV RNA testing for sustained virologic response (SVR), with a 100% SVR rate. Two deaths occurred during treatment, unrelated to HCV treatment.
Conclusion: Collaborations developed through LiveRx between community-based pharmacies and CBOs facilitated high rates of identification and successful linkage to care/ treatment of HCV-infected individuals within groups that are historically very challenging to treat. Wider implementation of similar pharmacist-CBO HCV care models may enhance achieving HCV elimination goals.

WED-025

Engaging hard-to-reach individuals through community-based holistic care health and wellness fairs linked to HCV testing and treatment in Alberta, Canada

Cari Egan[1], Chinedu Diribe[2], Daniyal Khan[2], Irfan Hyder[2], Klaudia Zabrzenski, [3], Jaanek Grewal[2], Colter Young[2], Ann Toohey[4], Jenny Godley[5], Mark Swain[6]. *[1]Alberta Health Services, Calgary, Canada; [2]University of Calgary, University of Calgary Liver Unit, Calgary, Canada; [3]Mint Health and Drugs, Calgary, Canada; [4]Alberta Health Services, Alberta Health Services Cancer Prevention & Screening Innovation, Calgary, Canada; [5]University of Calgary, Department of Sociology, Calgary, Canada; [6]University of Calgary, University of Calgary Liver Unit, Department of Medicine, Calgary, Canada*
Email: swain@ucalgary.ca

Background and aims: In Alberta, Canada, an implemented primary care hepatitis C (HCV) pathway (www.albertahealthservices.ca/assets/about/scn/ahs-scn-dh-pathway-hepatitisc.pdf) and well-defined screening strategies have increased diagnosis of hepatitis C (HCV). However, linking diagnosed individuals to treatment remains challenging, especially in those with unmet complex healthcare needs related to persistent, social, economic, and systemic structural barriers including lack of connection to traditional healthcare pathways. The LiveRx program was created to address this care gap by exploring alternative ways to better link highly marginalized to HCV testing and treatment.
Method: To do this LiveRx designed/ implemented health and wellness fairs as part of a novel HCV care model co-developed with engaged community-based organizations (CBOs). The goal was to foster connection of attendees to existing but difficult to access support services/programs including housing, addictions, mental health, foot/wound care, diabetes care, cultural support, STI testing/ treatment, vaccination and women's health under one roof, as well as point-of-care (POCT) HCV antibody (Ab) and HCV RNA testing with direct on-site linkage to pharmacist direct acting antiviral (DAA) prescribers for positive cases.
Results: 1591 individuals were engaged through ten health and wellness events conducted in 7 small and large communities across Alberta, Canada between January 2023-October 2024 (9 of 10 occurred in 2024). A total of 224 organizations/ programs were engaged across the 10 events. 1054 (66%) of attendees underwent POCT HCV Ab testing and 139 (13%) were HCV Ab +ve (69 [49%] were previously known to be HCV Ab +ve but had not been linked to treatment); 113 (81%) had HCV RNA testing and 38 (33%) were RNA +ve. Of these 38 individuals 36 were linked to post-test counselling and a pharmacist DAA prescriber at the event. 10 of these 36 (28%) initiated DAA treatment with 6 completing therapy and 2 having a documented SVR to date.
Conclusion: Health and wellness fairs are an effective strategy to engage individuals from underserved populations in an inclusive, non-stigmatizing, and culturally appropriate venue that removes barriers to access to healthcare services, filling an unmet public health need. Bundling HCV testing/ treatment access with other priority health and wellness services led to high HCV testing rates (66%) and identified significant HCV Ab (13%) and RNA (33% of Ab +ve cases) positivity rates. 95% of HCV RNA +ve cases were linked to a DAA prescribing LiveRx pharmacist at the event, and ~30% have started therapy.

WED-026

Development of a predictive model using artificial intelligence (AI) for the detection of hepatitis C based on real-world data from the population health database (BPS) of Andalusia, Spain

Carlos Loucera[1], Carmen Lara-Romero[2], Victor De La Oliva[1], Ana Lucena Valera[2], Raquel Millan[2], Alberto Esteban-Medina[1], Joaquín Dopazo[1], Manuel Romero-Gómez[2]. *[1]Computational Medicine Platform, Progress and Health Foundation, Seville, Seville, Spain; [2]Liver and Digestive Diseases Unit, Virgen del Rocío University Hospital, SeLiver Group,Biomedicine Institute of Seville (HUVR/CSIC/US), Medicine Department, University of Sevilla, CIBEREHD., Sevilla, Spain, Seville, Spain*
Email: carmenlararomero@gmail.com

Background and aims: The 2016–2021 WHO strategy aimed to significantly reduce hepatitis C as a public health threat by achieving a 90% reduction in new infections, a 65% reduction in hepatitis C-related deaths, and treating 80% of detected cases by 2030. Reaching vulnerable populations remains challenging, and age-based screening has been controversial. In the AI era, developing predictive models can aid clinicians in identifying hepatitis C cases, optimizing the effort required for successful screening.
Method: Using real-life data from the Andalusian Health Population Database (BPS), containing electronic medical records of over 15 million patients, we trained a predictive AI model to identify undiagnosed hepatitis C cases. Several machine learning methods were evaluated, with XGBoost (eXtreme Gradient Boosting) proving the most accurate. The model was trained using 6,078 patients diagnosed with hepatitis C from 2017 to 2022, alongside a control group of 121,560 individuals with similar characteristics who tested negative for hepatitis C.
Results: The model successfully identified 84% of all hepatitis C patients with a sensitivity of 0.15, despite class imbalance simulating a real-world scenario. This significantly outperformed the conventional detection strategy, which achieved a sensitivity of only 0.007. The model selected various informative variables for prediction, including different hepatitis C analytical tests and comorbidities, listed in the table. The developed model identified one case for every six individuals selected, whereas the conventional risk group strategy required evaluating 143 people to find one case.
Conclusion: The developed predictor constitutes a cost-effective and highly accurate screening model using already available patient data in the healthcare system, clearly outperforming conventional risk

group-based or age-based screening. This model could aid early detection and potentially boost regional efforts aimed at eliminating hepatitis C.

WED-027-YI

Changes in hepatitis C virus screening and treatment rates in pregnant individuals before and after implementation of universal screening guidelines compared to hepatitis B virus screening during the same time frame

Chandler Shapiro[1], Sheena Gillani[1], Nancy S. Reau[1], Samantha de los Reyes[1]. [1]*Rush University Medical Center, Chicago, United States*
Email: chandler_b_shapiro@rush.edu

Background and aims: Hepatitis C virus (HCV) incidence has doubled since 2013 among individuals of reproductive age. In contrast, Hepatitis B virus (HBV) rates have remained stable. As a result, HCV screening recommendations have changed drastically. In Aug 2017, the Society of Maternal Fetal Medicine (sMFM) recommended HCV screening for high-risk pregnancies, followed by universal screening in March 2020 by the United States Preventive Services Task Force (USPSTF) and the American College of Obstetricians and Gynecologists (ACOG) in May 2021. Universal HCV screening improved detection, but not linkage to care within a year postpartum. HBV screening was recommended by the USPSTF in 1996 and supported in the recent 2023 ACOG guidelines. This study aims to assess adherence to universal HCV and HBV screening during pregnancy and its impact on postpartum treatment.
Method: Retrospective analysis of pregnant adult patients who received their first prenatal visit at two centers within our institution between Jan 1, 2013–Oct 1, 2023. HCV screening was defined as HCV-antibody (Ab) testing, and HBV screening was defined as HBV-surface antigen (HBsAg) testing. HCV-Ab, HBsAg, and HCV/HBV viral loads were extracted from electronic medical records. Patients were grouped into 3 screening phases (SP): SP 1 – before risk screening (Jan 1, 2013–Aug 1, 2017), SP 2 – after sMFM risk screening but before ACOG universal screening (Aug 2, 2017–May 1, 2021), and SP 3 – after ACOG universal screening (May 2, 2021–Oct 1, 2023). For patients with positive HCV-Ab/HCV viral load or HBsAg, charts were reviewed to assess linkage to care and treatment within 1-year postpartum.
Results: Of 31,927 patients, 6,713 (21%) had HCV-Ab testing. 1% (111/11,414) in SP1, 16.6% (2,085/12,594) in SP2, and 57% (4,517/7,919) in SP3. 40 were HCV-Ab positive (0.6%), with 35 (87.5%) undergoing HCV RNA testing; 5 of which were positive. All 5 were linked to an HCV provider, but none received treatment within 1-year postpartum; 1 was treated after that period. For HBV screening, 28,759/31,927 (90.1%) patients had HBsAg ordered. Screening rates were 84% (9,587/11,414) in SP1, 92.7% (11,671/12,594) in SP2, and 94.7% (7,501/7,919) in SP3. Only 60.2% of patients who had testing ordered completed screening. Of those, 49.2% (4,715/9,587) in SP1, 66.9% (7,813/11,671) in SP2, and 63.7% (4,779/7,501) in SP3 were screened. In total, 23 patients tested positive for HBsAg, two of whom had known HBV and were already under hepatology care. Of the remaining 21, 15 were appropriately linked to care.
Conclusion: HCV and HBV screening increased with each screening phase, though both remain suboptimal. While patients with positive HCV viral loads were linked to care, treatment initiation was rare. In contrast, HBV screening recommendations were high, but many patients did not complete testing, and nearly 30% of those with positive HBV results were not linked to care.

WED-028

Hepatitis B surface antigen clearance rate achieved with pegylated interferon-alpha therapy in different chronic hepatitis B virus infection populations: a systematic review and meta-analysis

Chengrun Song[1], Yujing Li[1], Yalin Yin[2], Jingwen Feng[1], Min He[1], Yonghong Wang[1], Menglan Wang[1], Yachao Tao[1], Taoyou Zhou[1], Fang He[1], Jiajie Lu[1], Wei Jiang[1], Dongbo Wu[1], Sheyu Li[1], Xuezhong Lei[1], Hong Tang[1], Enqiang Chen[1]. [1]*West China Hospital, Chengdu, China;* [2]*School of Life Sciences, Xiamen University, Xiamen, China, Xiamen, China*
Email: chenenqiang@scu.edu.cn

Background and aims: The clearance or seroconversion of hepatitis B surface antigen (HBsAg) serves as a critical marker of functional cure in patients with chronic hepatitis B (CHB). HBsAg clearance can significantly reduce the risk of CHB progressing to end-stage liver disease. Currently, Pegylated interferon- alpha (PegIFNα)-based therapy is recognized as the most effective approach to enhance HBsAg clearance in CHB patients. HBsAg clearance rates may differernt among different natural course of infection, treatment and special patient populations. This study aims to thoroughly analyze HBsAg clearance and seroconversion rates in different chronic hepatitis B virus (HBV) infection treated with PegIFNα, accounting for multiple influencing factors.
Method: We conducted a systematic review and meta-analysis, searching PubMed, Embase, Web of Science, and the Cochrane Library up to December 6, 2023, for studies on HBsAg clearance or seroconversion in HBV treated with PegIFNα, excluding co-infections. Independent quality assessment, data appraisal, and extraction were performed by trained reviewers. We systematically analyzed and summarized demographic characteristics, HBsAg clearance, and seroconversion rates across chronic HBV populations, exploring heterogeneity through subgroup analyses and meta-regression. This study protocol was registered with PROSPERO, CRD42024604070.
Results: Out Of 4867 screened, 121 studies met the inclusion criteria, with 115 of these included in the meta-analyses. The overall rate of HBsAg clearance following PegIFNα-based therapy in chronic HBV infection was 16% (95% CI 13%–20%). Notably, there were differences in the efficacy among different HBV infected populations. The HBsAg clearance rate at the end of PegIFNα-based treatment in treatment-naive CHB patients, Nucleos(t)ide analogues (NAs)-treated CHB patients, inactive HBsAg carriers and children with CHB were 5% (95% CI 4%–7%), 21% (95% CI 16%–26%), 57% (95% CI 48%–65%), and 22% (95% CI 10%–37%), respectively. Subgroup and meta-regression analysis identified that the year of publication, study design, sample size, HBeAg status, treatment strategy, treatment duration, and follow-up duration were key factors influencing HBsAg loss and seroconversion.
Conclusion: Different populations with chronic HBV infection exhibit varying potentials for HBsAg clearance following PegIFNα treatment. These notable differences underscore the complexity of managing chronic HBV infection and the need for personalized treatment strategies tailored to each group's unique characteristics and circumstances.

M. and A. Migliavacca" Center for Liver Disease, University of Milan, Milan, Italy
Email: chong.kim9@gilead.com

Background and aims: Chronic hepatitis delta (CHD), the most severe form of viral hepatitis, leads to worse patient physical and psychologic quality of life compared with chronic hepatitis B. Patients with CHD who received 48 weeks (W) of bulevirtide (BLV) 2 mg monotherapy reported greater improvements in their perceived health status compared with patients who received no treatment. This study reports an exploratory analysis of EQ-5D visual analogue scale (EQ VAS) outcomes at 144W of BLV 2 mg treatment among patients with CHD in an ongoing clinical investigation.
Method: Patients in this study (n = 150) were enrolled in MYR301 (NCT03852719), a Phase 3, randomised (1:1:1), multicentre, open-label, parallel-group trial. Treatment groups received either BLV 2 mg once daily (QD; n = 49) or BLV 10 mg QD (n = 50) for 144W, or delayed treatment for 48W followed by BLV 10 mg QD for 96W. This study focuses on BLV 2 mg, which is approved by the European Medicines Agency (and other agencies in non-European countries). Patients completed the EQ VAS on their own at key time points, including baseline (BL), 24W, 48W, 96W, and 144W. High scores on the EQ VAS (range, 0–100) reflect the patients' best perceived imaginable health state. Mean (95% confidence interval [CI]) scores and least squares mean (LSM) changes from BL are reported; changes from BL where the 95% CI included 0 were considered not statistically significant. Subgroup analyses of patients by cirrhosis status at BL are also reported.
Results: Patient characteristics and mean EQ VAS scores (range, 72.0–73.9) were similar between treatment groups at BL. By 144W, 12 patients dropped out of the study, with no discontinuations due to study treatment. For patients who received BLV 2 mg (n = 44 at W144), the mean (95% CI) EQ VAS score at W144 was 85.5 (81.14–89.91); LSM (95% CI) score improvement from BL to W144 was 12.1 (7.32–16.87) and was considered statistically significant. LSM (95% CI) EQ VAS score improvement from BL reported at W144 of BLV 2 mg treatment was greater than the LSM improvement from BL to W48 and W96. Among patients with cirrhosis, LSM (95% CI) EQ VAS score improvement from BL to W144 (12.5 [5.32–19.61]; n = 21) was considered significant and was greater than the LSM improvement from BL to W48 and W96. Likewise, for patients without cirrhosis, LSM (95% CI) EQ VAS score improvement from BL to W144 (11.8 [5.20–18.39]; n = 23) was considered significant and was greater than corresponding scores at W48 and W96.
Conclusion: Patients with CHD with and without cirrhosis who were treated with BLV 2 mg for up to 144W reported improvements in their perceived health state compared with BL. These improvements were greater than perceptions reported at both 48W and 96W of treatment, demonstrating the long-term benefits of BLV monotherapy.

WED-030

Trends in the effect of direct acting antivirals on mortality in people diagnosed with hepatitis C in England using routine surveillance data

David Etoori[1], Ruth Simmons[2], Monica Desai[2], Annabel Powell[2], Paul Trembling[3], caroline sabin[1], William Rosenberg[1]. [1]NIHR Health Protection Research Unit (HPRU) in Blood-borne and Sexually Transmitted Infections at UCL, University College London, London, United Kingdom; [2]Blood Safety, Hepatitis, STIs and HIV Division, UK Health Security Agency, London, United Kingdom; [3]Royal Free Trust, National Health Services (NHS), London, United Kingdom
Email: d.etoori@ucl.ac.uk

Background and aims: With fewer side-effects and higher cure rates, direct acting antivirals (DAAs) transformed the clinical management and epidemiology of hepatitis C virus (HCV) infection. We aimed to compare mortality between treated and untreated individuals diagnosed with HCV and to describe trends in adult life expectancy (LE) between these populations.
Method: Data come from routine surveillance of HCV in England, and cause of death information from the UK Office for National Statistics. Individuals contributed person-time to the analyses from their fifteenth birthday or their earliest HCV diagnosis date, whichever was later. Individuals were classified as treated six months after their most recent treatment date. Estimates of adult LE were computed using continuous-time survival analysis as the area under the Kaplan-Meier survival curve. The analysis was split into two four-year periods (2015–18 and 2019–22). 2015–2018 represents the early DAA era when treatment prioritized advanced liver disease. The four-year period reduced the influence of mortality changes in any single year and combined sufficient data to stratify analyses, allowing us to decompose total LE difference due to treatment into contributions from mortality differences in five-year age groups. Age group contributions were calculated using the Arriaga method. Using cause-specific mortality fractions, we estimated the cause contributions to treatment differences in adult LE for each age group. Analyses were performed separately for each period.
Results: Between 2015 and 2022, 93,024 adults diagnosed with HCV were included in the analyses. They contributed 322,397.8 untreated and 200,564.1 treated person-years of observation. In 2015–18, there were 5,812 deaths resulting in a crude death rate of 22.4 (21.2–23.6) per 1000 person-years among untreated females, 27.5 (26.7–28.4) among untreated males, 16.7 (14.3–19.4) among treated females and 24.3 (22.4–26.4) among treated males. In 2019–22, there were 7,486 deaths resulting in a crude death rate of 25.6 (24.1–27.2) among untreated females, 30.0 (28.9–31.2) among untreated males, 17.9 (16.7–19.1) among treated females and 24.9 (24.1–25.9) among treated males. These differences translated into 8.5 years LE advantage for treated females and 8.9 years for treated males in 2015–18. This contracted in 2019–22 for both sexes to 6.7 and 5.2, respectively. This contraction was explained by a reduction in mortality rates between 25–65 years for the untreated population and reduced differences in mortality from liver related causes between the treated and untreated.
Conclusion: LE was higher for treated compared to untreated individuals. The effects of treatment on mortality shrunk between the two periods studied, but LE remained significantly higher for the treated. We hypothesize that the early prioritization of individuals with advanced cirrhosis resulted in a relatively healthier untreated population in 2019–2022 compared to 2015–2018.

WED-031

Healthcare resource use (HCRU) and cost impact of potential drug-drug interactions (DDIs) among HCV patients receiving Direct-Acting Antivirals (DAAs) concomitantly with antipsychotic drugs in the US

Dilip Makhija[1], Xiu Chen[2], Thomas Debray[3], Candido Hernández[4]. [1]Gilead LifeSciences, Parsippany, United States; [2]Gilead Lifesciences, Pars, United States; [3]Smart Data analysis and Statistics, Utrecht, Netherlands; [4]Gilead Lifesciences, S.L.U, Madrid, Spain
Email: candido.hernandez@gilead.com

Background and aims: Scarce information exists in the US regarding the use of Direct-Acting Agents (DAA) concomitantly with antipsychotic drugs in HCV patients. We explored the use of antipsychotic drugs in a US claims database concomitantly with the use of any of the two pangenotypic DAAs, sofosbuvir/velpatasvir (SOF/VEL) or glecaprevir/pibrentasvir (GLE/PIB), evaluating the risk of associated

DDIs, quality of the prescriptions based on the DDI risk, and the related healthcare resource use and costs.
Method: A retrospective cohort study was conducted using IQVIA PharMetrics Plus claims database from July 2015 to June 2023 for HCV patients treated with SOF/VEL or GLE/PIB concomitantly with antipsychotic drugs. We assessed the quality of prescriptions by evaluating the risk of DDIs using the Liverpool DDI tracker (https://www.hep-druginteractions.org/) and calculating the proportion of patients prescribed DDI-related comedications (DDIRC) classified as clinically significant. All-cause HCRU and costs (per patient per month (PPPM)) were assessed over a 6-month follow-up period starting from the initiation of DAA therapy. These outcomes were compared between SOF/VEL and GLE/PIB cohorts, created using 1:1 propensity score matching without replacement. Mean costs were analyzed using Generalized Gamma regression.
Results: Patients on antipsychotics represented 3.7% (420/11,324) of the total HCV cohort, 3.9% (267/6,784) treated with SOF/VEL and 3.4% (153/4,540) with GLE/PIB. 95% patients received only one antipsychotic during the DAA therapy, but 5% (23) received >1 (14 in SOF/VEL and 9 in GLE/PIB), indicating multi-DDI risk. Among the 267 SOF/VEL patients, DDI risk was present in 39 patients (14.6%; 1.5% for clinically significant DDIs (CSDDI) and 13.1% for weak DDIs (WDDI). For the 153 GLE/PIB patients, 100% were on DDI risk (83.7% for CSDDI and 19% for WDDI). The matched SOF/VEL and GLE/PIB cohorts concomitantly receiving antipsychotics, each comprised 142 patients. All matched patients incurred HCRU, with the majority attributed to pharmacy visits (242 patients) and outpatient visits (22 SOF/VEL patients and 26 GLE/PIB patients). All-cause costs PPPM were lower for SOF/VEL patients ($39) compared to GLE/PIB patients ($69); however, the difference was not statistically significant (P = 0.07). In contrast, when examining specific components of healthcare costs, patients prescribed SOF/VEL had significantly lower mean all-cause outpatient costs PPPM ($7) compared GLE/PIB ($29).
Conclusion: Despite the extended recognition of the use of the Liverpool HEP DDI tracker by all HCV treatment guidelines, this analysis of the DAAs based on the DDI risk demonstrates importance of safety monitoring of patients and the need for individualized medicine to ensure an appropriate DAA is used in patients with polypharmacy. Additionally, compared to GLE/PIB, SOF/VEL presents lower DDI risk and lower outpatient costs in the HCV patients receiving DAA treatment concomitantly with antipsychotic drugs.

WED-033
Treatment persistence, discontinuation, and health care cost among chronic hepatitis B (CHB) patients initiating antiviral treatment

Dilip Makhija[1], Ben Chastek[2], Mary Grace Johnson[2], Aileen Chi[3], Alice Hsiao[3], Marvin Rock[3]. *[1]Gilead, Foster City, United States; [2]Optum, Eden Prairie, United States; [3]Gilead Sciences, Foster City, United States*
Email: dilip.makhija@gilead.com

Background and aims: Nucleos(t)ide analogues are recommended as first-line monotherapy for patients with CHB. Little is known about treatment pattens and cost in a real world setting. This study describes CHB-related health care cost, persistence, discontinuation, switch, restart in treatment (TX)-naïve patients.
Method: This was a retrospective study using claims from the Optum Research Database for commercial and Medicare Advantage enrollees. TX-naïve CHB patients initiating tenofovir alafenamide fumarate (TAF), entecavir (ETV), or tenofovir disoproxil fumarate (TDF) between 01Nov2016 and 30Nov2022 were identified. Persistence was the time to discontinuation (therapy gap >30 days), switch, or end of follow-up. Adherence was the proportion of days covered (PDC) during the variable length follow-up. CHB-related cost included claims with a diagnosis of CHB and fills for CHB medications. Descriptives, Kaplan-Meier (KM), Cox PH and GLM models adjusting for demographics, clinical characteristics, and baseline cost and utilization were conducted overall and among patients ≥65.
Results: Of CHB patients identified (N = 14,935), 4067 treated adults and had 6 months baseline and follow-up enrollment. A total of 1384 TX-naïve patients met inclusion criteria. On index 338(24%) patients initiated TAF, 477(35%) ETV, and 567(41%) TDF. Age was ≥65 for 89 (26.3%) TAF, 146(30.6%) ETV, and 127(22.4%) TDF patients. From KM analysis, median persistence (months) was longest for TAF (23.3), followed by ETV (11.5) and TDF (9.2). Among patients 65+, median persistence was 38.0 (TAF), 9.0 (ETV) and 6.9 (TDF). Mean PDC was highest for TAF (0.75) followed by ETV (0.62) and TDF (0.54). Persistence was more likely to end due to discontinuation vs. switching; TAF: 49% vs. 7.4%; ETV: 60% vs. 3.6%; TDF: 64% vs. 7.6%. After discontinuation, most patients (56%-60%) restarted the index therapy. Compared to TAF, adjusting for covariates, the rate of discontinuation/switch was higher for ETV (HR = 1.34, p < 0.01) and TDF (HR = 1.62, p < 0.01). CHB-related medical cost were similar between the cohorts with costs 1% greater for ETV (Cost Ratio [CR] = 1.01, p = 0.98) and 28% lower for TDF (CR = 0.72, p = 0.14). Among patients ≥65, medical costs were 10% greater for ETV (CR = 1.10, p = 0.81) and 26% lower for TDF (CR = 0.74, p = 0.43). Pharmacy costs were lower for ETV (CR = 0.21, p < 0.01) and TDF (CR = 0.20, p < 0.01) compared to TAF overall and among patients ≥65 (ETV: CR = 0.13, p < 0.01; TDF CR = 0.17, p < 0.01).
Conclusion: Despite having greater pharmacy costs, TAF was found to have higher adherence, longer persistence, and similar medical cost versus ETV and TDF, especially among patients 65+ years old. These findings have clinical implications for patient engagement, therapy selection, and achieving long-term treatment success and should be considered when formulary decisions and exclusions are implemented as they may impact patient outcomes.

WED-034
Prevalence of HBV and HCV among migrants in EU-27: the impact of the ukrainian refugee crisis

Devin Razavi-Shearer[1], Loreta Kondili[2,3], Samantha Hall[1], Ivane Gamkrelidze[1], Homie Razavi[1]. *[1]Center for Disease Analysis Foundation, Lafayette, United States; [2]Istituto Superiore di Sanita, Rome, Italy; [3]UniCamillus-Saint Camillus International University of Health Sciences, Rome, Italy*
Email: drazavishearer@cdafound.org

Background and aims: In countries with relatively low baseline burdens of hepatitis B and C viruses (HBV, HCV) but high levels of migration, the burden of viral hepatitis can be greatly impacted by migration. The screening and linkage to care of migrants requires different methods and sensitivities than a broad-based program. We aimed to estimate the prevalence of HBV and HCV among migrants in EU-27 countries in 2020. To consider recent trends, the Ukrainian refugee situation was also analyzed. These data can provide policy makers with guidance of which migrant communities are most in need.
Method: Using the United Nations 2020 migrant stock data, we were able to estimate the migrant population for each EU-27 country by five-year age and sex cohorts by country of origin. These five-year age and sex distributions were then cross-multiplied by five-year age and sex prevalence estimates in the country-of-origin models maintained by the Polaris Observatory. The total number of refugees from Ukraine recorded in-country was combined with the age and sex distribution of Ukrainian refugees undergoing health screening. These data were then multiplied the by the age- and sex-specific prevalence in the Ukrainian country models and added to the 2020 totals.
Results: In 2020, we estimate that there were 1.47 million (UI: 887,000–2.2 million) migrants living with HBV and 563,000 (UI: 395,000–879,000) living with viremic HCV in EU-27, corresponding to migrant prevalences of 2.68% (UI: 1.6–4.1%) and 1.02% (UI: 0.7–1.6%) respectively. The highest prevalence of HBV among migrants, 5.5%, was estimated to be in Portugal, but the largest absolute number of migrants living with HBV was in Germany, 399,000. For HCV, the highest prevalence among migrants, 1.98%, was estimated to be in

Lithuania, while the largest absolute number of migrants living with HCV was in Germany, 181,000. There was great heterogeneity in the leading country of origin for HBV and HCV prevalence in EU-27. Four counties had Syria as the country of origin with the most absolute number of migrants living with HBV and four countries had the Russian Federation as the country of origin with the most absolute number of migrants living with HCV. We estimate that the Ukrainian refugee situation resulted in an additional 37,800 people living with HBV and an additional 68,800 people living with HCV in EU-27 compared to the 2020 analysis. While these migrants only represent 3% and 12% increases relative to the 2020 HBV and HCV baseline estimates at the EU-27 level, respectively, they have a large impact on the HCV prevalence in certain countries.
Conclusion: Using the most detailed data — the 2020 UN estimates — and combining it with the impact of the Ukrainian refugee crisis would result in an estimated 1.5 million (UI: 910,800–2.3 million) migrants living with HBV, and 632,000 (UI: 451,000–969,300) migrants living with viremic HCV infection in EU-27.

WED-035

A National web self-testing portal for hepatitis C: an empowering solution with good uptake and linkage to care - preliminary data

Ewan Glassey[1], Maria Guerra Veloz[1], Kosh Agarwal[1], Georgia Threadgold[2], Specioza Nabiteeko[2], Rachel Halford[3], Beatrice Emmanouil[2], Graham R. Foster[4], Mark Gillyon-Powell[2], Ashley Brown[5]. *[1]King's College Hospital, London, United Kingdom; [2]NHS England, London, United Kingdom; [3]Hepatitis C Trust, London, United Kingdom; [4]Queen Mary University of London, London, United Kingdom; [5]Imperial College London, London, United Kingdom*
Email: e.glassey@doctors.org.uk

Background and aims: The advent of direct-acting antivirals (DAA) has changed the landscape of Hepatitis C virus (HCV) management. With curative treatments, the emphasis has changed to identifying the remaining obstacles/gaps in the HCV care cascade to achieve WHO elimination metrics. To deliver these by 2030, and the UK target of 2025, the HCV National Elimination Program in England has introduced a remote diagnostics tool (Preventx), alongside a media campaign, in order 'to bridge the gap' between individuals living with HCV and improve linkage to care. This strategy focuses on self-testing and patient empowerment. We report real world data of HCV of this self-testing tool as a component of the NHS England elimination strategy.
Method: We reviewed data from the national initiative of patient self-referral and self-testing for HCV. Individuals requested testing kits online, fingerpick blood samples were collected at home, returned freepost with results then delivered via text message. Positive results were then automatically linked to Operational Delivery Networks (ODNs). We cross referenced to our local (Southeast London and Kent [SEL+K]) HCV database to identify whether positive HCV test were truly new cases.
Results: Over a period of 16 months 77,791 tests were requested, 52,513 (67.5%) were returned for HCV testing. In the 730 tests (0.94%) which were antibody positive, 93 confirmatory tests were invalid and in the 637 with a confirmatory test only 145 (22.7%) were viraemic. Engagement was lower in London with 84 requests per 100000 population, compared 134 nationally and 117 in SEL+K. However, prevalence of HCV RNA positivity was 0.55% in London, 0.31% nationally, and 0.26% in SEL+K. Within our region of SEL+K there were 37 HCV Ab positive results. 29 patients were HCV RNA negative and 8 HCV RNA positive. Cross-referenced with our local registry showed that only 6 (21.7%) of the HCV RNA negative and only 1 (12.5%) of the HCV RNA positive patients had been previously identified. This suggests that the majority of positive test were new self-diagnoses. The majority of these RNA positive cases were male with median age of 48.1 years. Linkage to care is excellent with all HCV RNA positive individuals in appropriate care and commencing treatment.
Conclusion: Self-testing for HCV via a web portal was an acceptable initiative for testing with impressive test return rates. Initial data supports patient empowerment, and self-testing is key in identifying individuals with HCV and linking to treatment. We also demonstrate that the total numbers of new or previously not identified HCV RNA positive cases was relatively low, reflecting the success of the national HCV elimination program.

WED-036

The impact of cardio-metabolic risk factors on liver-related diseases and mortality after hepatitis C virus eradication: insights from a multi-center taiwanese cohort

Ming-Lung Yu[1], Pei-Chien Tsai[2], Chung-Feng Huang[3], Jee-Fu Huang[3], Chiayen Dai[3], Wan-Long Chuang[3]. *[1]Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Center of Excellence for Metabolic Associated Fatty Liver Disease and School of Medicine, College of Medicine, National Sun Yet-sen University, Kaohsiung, Kaohsiung, Taiwan; [2]Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; [3]Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan*
Email: fish6069@gmail.com

Background and aims: Chronic hepatitis C (CHC) patients frequently present with steatotic liver disease (SLD) and cardiometabolic risk factors (CMRFs). The long-term risk of major liver-related (LR) diseases and mortality following sustained virological response (SVR) remains unclear. This study aimed to evaluate the impact of CMRF grade and CMRF items on LR risks and all-cause mortality in SLD patients post HCV eradication.
Method: This study utilized nationwide multi-center registry cohorts in Taiwan, including an interferon-based cohort (T-COACH) and a direct-acting antivirals cohort (TACR). SLD was identified via ultrasonography and a hepatic steatosis index (HSI) > 36. Metabolic dysfunction-associated steatotic liver disease (MASLD) was defined as SLD with at least one of five CMRFs. Competing risks of death and liver transplant were considered to analyze the LR incidence using Gray's cumulative incidence method and Cox subdistribution hazards. Cox regression was used to analyze the all-cause mortality.
Results: Among 10,589 CHC patients, achieving SVR with SLD, 323 (3.1%) developed major liver-related diseases (HCC or decompensated liver cirrhosis) over a median follow-up of 3.8 years. Overall, MASLD patients did not exhibit a higher LR incidence or all-cause mortality compared than simple SLD patients. After adjusted for age, FIB-4 and eGFR, hazard ratios indicated that having at least three CMRF significantly increased LR risk (aHR = 1.83 for CMRF grade $\geq$3). Hypertension and diabetes was the two major CMRF increasing LR risk (aHR for hypertension = 1.65, P = 0.001; aHR for diabetes = 1.53, P = 0.011; aHR for both = 2.03, P < 0.001). Additionally, having more than three CMRFs, or having hypertension or diabetes significantly increased all-cause mortality with a 2.8-fold higher risk in patients with both hypertension and diabetes compared to these without these risk factors.
Conclusion: Targeted management of liver-related diseases and mortality is crucial for CHC patients with MASLD post-SVR, particularly for those with more than three CMRFs or with combined hypertension and diabetes.

WED-037

Hepatitis C knowledge and perceptions among Singapore's LGBTQ + Individuals: barriers and opportunities for outreach

Garrett Kang[1], Nicholas Cheong[2], Ennaliza Salazar[3], Rajneesh Kumar[3], Chen Seong Wong[4], Rayner Tan[5], Tee Zhuo[6], Kuo Chao Yew[2].
[1]Department of Gastroenterology & Hepatology, Sengkang General Hospital, Singapore, Singapore; [2]Department of Gastroenterology & Hepatology, Tan Tock Seng Hospital, Singapore, Singapore; [3]Department of Gastroenterology and Hepatology, Singapore General Hospital, Singapore, Singapore; [4]National Centre for Infectious Diseases, Singapore, Singapore; [5]Saw Swee Hock School of Public Health, National University of Singapore and National University Health System, Singapore, Singapore; [6]PinkDot SG, Singapore, Singapore
Email: garrett.kang.junhui@singhealth.com.sg

Background and aims: Singapore has a low general population prevalence of chronic Hepatitis C Virus (HCV) at 0.3–0.5%. The lesbian, gay, bisexual, transgender & queer (LGBTQ+) community may face higher HCV infection risks. This study examines the knowledge and perceptions of HCV within the LGBTQ+ community. We hope to use these results to inform and optimise targeted outreach and prevention programs effectively.
Method: Ethical approval (NHG DSRB Ref: 2023/00882) was obtained for this study. Participants were recruited via social media and Pinkdot Pride event on 29 June 2024. An anonymous online questionnaire assessed HCV knowledge and treatment attitudes as well as comparing responses across different LGBTQ+ groups to identify gaps to form targeted interventions.
Results: We recruited 95 participants with an estimated average age of 32.4, most having tertiary education (80%). The majority were male (56.8%), followed by female (29.5%), non-binary (5.3%), transmasculine (3.2%), transfeminine (3.2%), and others (2.1%). Sexual orientations included gay (45.3%), bisexual (17.9%), heterosexual (12.6%), lesbian (9.5%), others (9.5%), and asexual (5.3%). Overall, the awareness of HCV transmission through needles (89.5%) and sex (87.4%) was high but lower for tattoos (57.9%), with misconceptions about transmission via utensils (9.5%) and toilets (5.3%). Most participants would consider HCV testing (87.4%), preferring point-of-care testing over blood draws (64.2% vs. 35.8%). While 84.2% expressed willingness to seek treatment if a cure exists, cost (50.5%) was the top barrier, followed by side effects (40%) and stigma (8.4%). Stigma concerns included those from family and friends (66.3%), workplace (54.7%), public (37.9%), and healthcare workers (32.6%). Among the 47 gay, bisexual men, and transmasculine (GBT) participants, knowledge about HCV was higher compared to the non-GBT group. The GBT group was more likely to have heard of HCV (61.7% vs. 31.3%, $p < 0.05$), recognise it as an infectious disease (78.7% vs. 47.9%, $p < 0.05$), know it is curable (38.3% vs. 16.7%, $p < 0.05$), and identify oral medications as treatment (29.8% vs. 8.3%, $p < 0.05$). However, fewer GBT participants knew HCV could be diagnosed via body fluid investigations (27.7% vs. 54.2%, $p < 0.05$). These findings highlight critical areas for targeted education and intervention.
Conclusion: Among a predominantly LGBTQ+ population, gay, bisexual men, and transmasculine participants demonstrated greater HCV awareness, including its infectious nature and curability. Despite openness to testing and treatment, cost and stigma were significant barriers. These findings highlight the need for tailored outreach programs addressing financial and stigma-related concerns to support Hepatitis C elimination efforts within this community.

WED-038

The impact of COVID-19 outbreak from February to June 2022 on chronic hepatitis B patient management in Shanghai: a cross-sectional study

Simin Guo[1], Qing Xie[2], Shao-wen Jiang[2], Ziqiang Li[2]. *[1]The London School of Hygiene and Tropical Medicine, London, United Kingdom; [2]Shanghai Jiaotong University School of Medicine, Shanghai, China*
Email: aalii@126.com

Background and aims: The COVID-19 pandemic has posed significant challenges for individuals with chronic diseases, particularly those with chronic hepatitis B (CHB). These patients face interruptions in their ongoing antiviral treatment and regular follow-up, which can lead to HBV breakthrough and missed diagnosis of early-stage hepatocellular carcinoma (HCC). Our study highlights the impact of the COVID-19 pandemic on patients with CHB, as well as the responses of these individuals facing the health crisis during the special lockdown period in Shanghai, China, from February 28 to June 1, 2022.
Method: CHB outpatients in the Infectious Diseases Department of Shanghai Ruijin Hospital were invited to complete a structured questionnaire about the continuity of antiviral treatment and HCC surveillance during the pandemic, either online via the WeChat app or through a face-to-face interview. Descriptive statistics and logistic regression analysis were used for statistical analysis.
Results: A total of 487 respondents, receiving nucleos(t)ide analogs (NAs), interferon, or no antiviral treatment, were enrolled in our analysis. Among those taking antivirals, drug interruption occurred in 13.4% (58/434) of those on NAs and 57.8% (26/45) of those on interferon-based treatment. Telemedicine outpatient services of public hospitals (43.5%) was their main source of accessing NAs during the lockdown phase. Logistic regression analysis showed that interferon-based treatment and age were independently associated with drug interruption (OR = 8.346, 95% CI: 4.253–16.377, $p < 0.001$; OR = 0.968, 95% CI: 0.945–0.992, $p = 0.010$). Of all respondents, 71.3% reported delayed medical needs (accessing antivirals and outpatient reviews), with movement restrictions being the primary reason (88.5%) for the delays. After the lockdown was lifted, 3.7% of respondents were found to have developed hepatocellular carcinoma (HCC), 4.1% had abnormal liver function tests, 5.1% experienced HBV-DNA rebound, and 9.2% had not performed any outpatient reviews so far. Additionally, 48.4% of respondents had an interval of more than six months between two liver ultrasounds, with the COVID-19 pandemic being the leading reason (34.7%) for delayed HCC surveillance.
Conclusion: The COVID-19 outbreak negatively impacted the CHB outpatients care during the lockdown. Younger age and interferon-based antiviral treatment were identified as factors influencing the interruption of ongoing treatment, while sex, residential location, and comorbidities showed no significant correlation with treatment disruption. Measures like telemedicine services need to be implemented to meet the medical needs of patients with chronic diseases during future pandemics of emerging infectious diseases.

WED-039

A comparative study on liver disease severity and comorbidity profile in patients with chronic hepatitis B virus infection and hepatitis B virus/hepatitis D virus co-infection: a korean nationwide study

Heejoon Jang[1], Hoyoung Na[2], Hazel Shin[2], Julie Lee[2], Jinhye Cha[2], Bo Ok Kim[3], Helin Han[3], Yun Bin Lee. *[1]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Seoul National University College of Medicine, Seoul Metropolitan Government Boramae Medical Center, Seoul, Republic of Korea, Seoul, Korea, Rep. of South; [2]Medical Affairs, Gilead Sciences Korea Inc., Seoul, Korea, Rep. of South; [3]Cerner Enviza, Seoul, Korea, Rep. of South*
Email: yblee@snu.ac.kr

Background and aims: This study aimed to describe and compare the baseline characteristics, comorbidities, liver disease severity, and antiviral treatment history for chronic hepatitis B virus (HBV) infection in patients with HBV/hepatitis D virus (HDV) co-infection and those with chronic HBV infection in Korea from 2014 to 2018.
Method: This nationwide retrospective cohort study analyzed claims data from the Korea Health Insurance Review and Assessment Service database between 2013 and 2019. Eligible patients were adults (≥18 years) with ≥1 inpatient or outpatient claims related to chronic

hepatitis B (CHB) (ICD-10 code B17.0, B18.0, and B18.1) between 2014 and 2018. Patients with hepatitis C-related claims were excluded. Patients with HBV/HDV co-infection were identified based on ≥1 claim for an HDV antibody test followed by ≥1 HDV-related claim, while patients with chronic HBV infection were identified as having no HDV-related claims, regardless of any HDV antibody test claims. Comorbidities and liver-related diseases were assessed based on claims during the 12 months prior to the index date, defined as the date of the first observed HBV-related claim for patients with chronic HBV infection or HDV-related claim after HDV antibody test for patients with HBV/HDV co-infection during the identification period.
Results: Among 590,102 eligible patients, 589,349 (99.87%) had chronic HBV infection and 753 (0.13%) had HBV/HDV co-infection. The mean (standard deviation) age of patients with chronic HBV infection and HBV/HDV co-infection was 50.0 (13.3) years and 51.2 (11.7) years, respectively. Patients were predominantly aged 51–60 years (28.8% of chronic HBV infection patients and 38.5% of HBV/HDV co-infection patients), males (56.1% and 66.8%) and visited hospitals in Seoul (25.7% and 50.6%). Patients with HBV/HDV co-infection had significantly greater comorbidity burden than patients with chronic HBV infection: 91.6% vs. 74.0% had any Charlson Comorbidity Index (CCI) comorbidity, 63.2% vs. 27.7% had CCI score ≥3, 34.4% vs. 26.8% had hypertension, and 34.0% vs. 17.7% had diabetes (all $p < 0.0001$). Patients with HBV/HDV co-infection had significantly higher rates of liver-related complications than those with chronic HBV infection: compensated cirrhosis (47.0% vs. 11.2%), decompensated cirrhosis (42.0% vs. 3.4%), and hepatocellular carcinoma (36.3% vs. 5.6%) (all $p < 0.0001$). A higher proportion of patients with HBV/HDV co-infection was on antiviral therapy for CHB than patients with chronic HBV infection (63.1% vs. 23.1%, $p < 0.0001$).
Conclusion: Patients with HBV/HDV co-infection had a greater burden of comorbidities and liver-related complications than those with chronic HBV infection. Early identification, accurate diagnosis, and proper management of HBV/HDV co-infection among CHB patients are crucial to prevent liver disease progression.

WED-040

Trends and cross-country inequalities in the global burden of acute hepatitis A, 1990–2021: a population-based study

Deliang Huang[1], Xiangchang Zeng[1], Jun Chen[1]. [1]*The Third People's Hospital of Shenzhen, Shenzhen, China*
Email: drchenjun@163.com

Background and aims: Acute Hepatitis A (AHA) poses a significant global public health challenge and is targeted for elimination by the Sustainable Development Goals 2030. A thorough global analysis is essential for directing effective prevention and control strategies for AHA. This study evaluates the burden at the global, regional, and national levels.
Method: Data from the Global Burden of Disease (GBD) from 1990 to 2021 were leveraged to analyze trends in AHA incidence and disability-adjusted life years (DALYs). A comprehensive assessment was conducted using joint point regression, decomposition, health inequality, and Bayesian forecasting analysis.
Results: The GBD estimates for global AHA incidence and DALYs in 2021 were 160,860,121.69 (95% UIs: 170,430,684.15 to 152,201,084.97) and 1,817,363.17 (95% UIs: 2,792,339.01 to 1,275,384.28), respectively, with age-standardized rates (ASRs) of 2,273.72 (95% UIs: 2,403.76 to 2,150.13) and 24.95 (95% UIs: 39.12 to 17.32) per 100,000. The GBD regional analysis reveals that South Asia had the highest incidence and DALYs cases in 2021, with Eastern sub-Saharan Africa and South Asia exhibiting the highest ASRs. From 1990 to 2021, there was a general decline in global AHA incidence and DALYs, with a more pronounced decrease in DALYs, despite significant disparities across different Socio-demographic Index (SDI) regions, countries, and regions. Decomposition analysis indicates that population growth and epidemiological changes are the primary drivers of the global AHA DALYs burden, with epidemiological control largely offsetting the burden due to population changes. The relative inequality index suggests that countries with lower SDI levels disproportionately bear the AHA burden, although inequalities related to SDI have been narrowing over time. The incidence gap between the highest and lowest SDI countries decreased from −1992 in 1990 to −1242 in 2021, and the DALYs gap reduced from −78 to −15. Projections for 2030 are promising, with a continued downward trend in AHA ASRs and numbers of incidence and DALYs.
Conclusion: This indicates that significant strides have been made in AHA prevention and control over the past three decades through vaccination and health policy implementation, while further comprehensive policies and preventive measures are necessary to effectively achieve the goal of eliminating viral hepatitis.

Email: zobair.younossi@cldq.org

Background and aims: Despite availability of curative treatment, there are disparities in HCV-related outcomes. We assessed global clinical practices related to HCV-fibrosis assessment in clinical practice.
Method: An online 7-item global survey (September-November 2024) developed by the Global Liver Council was developed to assess fibrosis assessment (pre- and post- treatment) and screening for hepatocellular carcinoma (HCC).
Results: Healthcare providers from 48 countries completed 361 surveys [59% male, 33% aged 35–44 years old, 87% MD, 32% ≥20 in practice years; 44% hepatology (Hep), 21% Gastroenterology (GI), 12% infectious disease (ID), 23% primary care providers (PCP); 67% practiced in academic health institution, 79% located in an urban setting, 66% reported <10% of their practice involved individuals with history of injection drug use]. Comparing clinical practices between Hep/GI (n = 236) and ID/PCP (n = 125), Hep/GI were in practice longer (>20 years: 39% vs. 18%); practiced in academic institutions (74% vs. 55%), urban settings (84% vs. 69%) but were less likely to see patients with intravenous drug use (73% vs. 54% see <10%) (all $p < 0.01$). Hep/GI were more likely to self-report "superior" HCV knowledge (52% vs. 18%), comfortable treating HCV patients (88% vs. 42%), treating >200

patients (57% vs 19%), using direct acting antivirals (96% vs. 49%) (all p < 0.01). Hep/GI more frequently followed AASLD (35%) and EASL (25%) guidelines; ID/PCP followed WHO guidelines (20%) or did not know (21%). Across global regions, transient elastography (TE) for fibrosis screening was most commonly used North America providers (69% before treatment, 85% after treatment vs. 49% and 72%, respectively, in other regions). Hep/GI compared to ID/PCP reported more frequently screening for fibrosis or cirrhosis prior to starting HCV treatment (99% vs. 78% at least sometimes, 77% vs. 42% always, p < 0.01) with TE (63% vs. 27%); ID/PCP used imaging or FIB-4 score (28% each) (p < 0.05). Hep/GI more frequently screened for fibrosis and cirrhosis after treatment (95% vs. 70% at least sometimes, 45% vs 23% always), using TE (82%); ID/PCP used TE or imaging (54% each) (p < 0.05). In screening for HCC after achieving SVR, 43% Hep/GI only screened if pre-treatment fibrosis of ≥F3 was present, 19% only with cirrhosis- 38% would screen all patients; 19% and 18% of ID/PCP would screen for HCC for those with ≥F3 and cirrhosis, respectively, while 28% would screen all post-SVR patients. Both groups (≥60% each) reported would not stop screening for HCC among HCV with advanced fibrosis or cirrhosis even for evidence of fibrosis regression after SVR- most commonly would consider stopping screening for HCC at a fibrosis level of F2 (36%).

Conclusion: There are variations in HCV screening and management among practitioners. Educational efforts on HCV treatment and follow-up are warranted and may help address HCV outcome disparities.

SAT-004

Emergency department opt-out testing for hepatitis B: a 2-year multicentre study of outcomes across 7 sites

Jennifer Plunkett[1], Basil Ahmad[2], Amy Teague[1], Tanzina Haque[3], Stephanie Paget[3], Jennifer Hart[3], Maximillian Habibi[4], Jonathan Durban[2], Shiny Jaimes[2], Sally Thomas[2], Helen Boothman[2], Philippa C. Matthews[5], Rachel Hill-Tout[6], Dan Forton[7], Douglas Macdonald[8]. *[1]Hepatology, Royal Free London NHS Trust, London, United Kingdom; [2]Department of Gastroenterology and Hepatology, St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [3]Department of Virology, Royal Free London NHS Trust, London, United Kingdom; [4]Department of Clinical Infection, St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [5]The Francis Crick Institute, London, United Kingdom; [6]NHS England, London, United Kingdom; [7]Department of Gastroenterology and Hepatology, St George's University Hospitals NHS Foundation Trust, Institute of Infection and Immunity, St George's, University of London, London, United Kingdom; [8]Institute of Liver and Digestive Health, UCL, Hepatology, Royal Free London NHS Trust, London, United Kingdom*
Email: douglasmacdonald@nhs.net

Background and aims: Opt-out testing for blood-borne viruses (BBV) in adults attending emergency departments (ED) in London is now being rolled out across England. Single-centre reports have identified large numbers of hepatitis B virus (HBV) infected patients who are not in care. Patient and disease characteristics and rates of engagement have not been studied across a large representative cohort.

Method: We undertook a multicentre retrospective study of HBsAg+ patients across 7 ED testing hospitals from North and South London between April 2022 and April 2024. Recruitment was for a minimum of 12 months with a 6 month follow-up period before censor. Patient and disease characteristics were compared with those referred by standard routes (e.g. primary, secondary and antenatal care – "non-ED").

Results: A total of 339627 HBsAg tests were performed at the study sites representing 29% of all tests performed in the program in this period. A total of 1097 HBsAg+ patients were identified after exclusion of 142 false positives on re-testing. 117 patients were not contactable by phone or post. Of the 980 contacted, 286 were already under follow-up and 694 were not under care. Of these, 544 were new to service and 150 were lost to follow-up. 674/694 (98%) were successfully engaged for a full clinical assessment. In the ED cohort, 12.4% had an LSM > 7.4 kPa, 15.5% had a CAP score >300 and 7.7% had a viral load >20000. 13.9% were commenced on nucleotide therapy. 3 new cases of HCC and 4 new cases of HDV infection were identified. A Cox regression multivariate analysis of time from result notification to assessment was performed. Covariates included age, gender, ethnicity, harmful alcohol use, fibrosis stage, viral load, English-speaking status and diagnosis at an ED in a hospital with a dedicated viral hepatitis service. Only the latter significantly improved time to assessment (HR 1.533, 95% CI 1.281–1.834, p < 0.001). The ED cohort was significantly older than those referred by non-ED routes (mean age = 5 0.3 vs 47, p < 0.001), had lower viral loads (mean = 3.8 M vs 15.8 M, p = 0.004) and higher CAP scores (mean = 245 vs 236, p = 0.019, all two-tailed t-tests). ED testing resulted in a 109% increase in hepatitis B assessments in the study period.

Conclusion: ED testing is more than doubling numbers of patients entering hepatitis B services. Excellent rates of engagement can be achieved and delays are attributable to service differences rather than patient factors. Significant proportions have disease that would benefit from liver cancer surveillance and/or viral suppression. Further resources will be needed so that this rapidly expanding cohort can benefit from longitudinal care without detriment to those already under follow-up.

SAT-005

From screening to treatment: the impact of opportunistic hepatitis screening in emergency departments on hepatitis C prevalence

Juan Carlos Ruiz-Cobo[1,2,3,4], Jordi Llaneras[5], Ariadna Rando-Segura[6], Adriana Palom[3,4], Elena Vargas-Accarino[3,4], Francisco Rodríguez-Frías[6], Mar Riveiro Barciela, Judit Romero-Vico[4,7], Lourdes Ruiz[1,2,4], Rafael Esteban[1], Maria Buti[1,2,3,4]. *[1]Hepatology Department, Vall d'Hebron University Hospital, Barcelona, Spain; [2]Medicine Department, Universitat Autònoma de Barcelona, Barcelona, Spain; [3]Centro De Investigación Biomédica En Red De Enfermedades Hepáticas y Digestivas (CIBERehd), Madrid, Spain; [4]Vall d'hebron Research Institute (VHIR), Barcelona, Spain; [5]Emergency Department, Vall d'Hebron University Hospital, Barcelona, Spain; [6]Microbiology Department, Vall d'Hebron University Hospital, Barcelona, Spain; [7]Nursery Department, Universitat de Barcelona, Barcelona, Spain*
Email: juancarlosrcobo@gmail.com

Background and aims: Most viral hepatitis screening programs in Emergency Departments (ED) have focused on Hepatitis C (HCV), and the reported results are short-term (1–2 years). The aim of this study was to assess the medium-term impact of a systematic and opportunistic viral hepatitis screening program (B, C, and D) in the ED.

Method: A prospective viral hepatitis screening study was conducted from January 2020 to July 2024. HBsAg and anti-HCV antibodies were tested in adults attending the ED who required a blood test. Reflex testing for HBV-DNA and anti-HDV for performed in case of HBsAg + and HCV-RNA in case of anti-HCV+. To maximize cost-effectiveness, after analyzing data from the first three years, an age-based screening strategy was implemented, excluding patients over 80 years old due to the low prevalence of HBV (<0.3%) and the low rate of HCV cases considered suitable for treatment (15%). To assess the effectiveness of the screening, the prevalence of HCV RNA and HBsAg in patients ≤80 years old was compared between the first (Jan/20–Dec/20) and last year (Aug/23–Jul/24) of screening. All patients were individually evaluated by a clinician and referred to outpatient consultations when deemed appropriate.

Results: During the 4.5 years of the program, 35,553 patients were screened. Of these, 200 (0.56%) had detectable HCV RNA, 216 (0.61%) were HBsAg positive, and 8 were anti-HDV positive (3.7% of HBsAg+ cases). 81% of patients with HCV and 57% of patients with HBV were

born in Spain. Only 40% of patients with detectable HCV RNA and 13% of those with HBsAg+ reported risk factors for viral hepatitis. The prevalence of HCV RNA detectable in patients ≤80 years old in 2020 was 0.45% (22/4922) while in the last year, was 0.23% (25/10807) ($p < 0.001$). However, no significant differences were found in the prevalence of HBsAg between the first (0.57%; 28/4922) and last year (0.52%; 56/10807) ($p = 0.6$).

Half of the patients with detectable HCV RNA (n = 98), were considered eligible for linkage, and 88 (90%) were treated and cured. Of the 216 HBV cases, 144 were not linked to care, 119 (83%) were considered candidates for linkage, 103 (87%) attended the outpatient clinics, and 16 started treatment.

Conclusion: Maintaining an opportunistic viral hepatitis screening program in the ED for more than 4 years enabled the detection and linkage to care of a significant number of patients with Hepatitis B and C, most of whom did not report risk factors. This strategy had a significant impact on decreasing the prevalence of Hepatitis C among patients attending the Emergency Department. Screening in emergency settings is an effective tool for the elimination of viral hepatitis as a public health threat.

SAT-006

Emergency department blood-borne virus screening and the revealed burden of hepatitis B-driven liver disease

Kartikeya Khanna[1], Mia Olsen[2], Nabiha Essaji[1], Susanne Johansen[1], Kathryn Oakes[2], Sam Douthwaite[1], Kosh Agarwal[2], Kate Childs[2], Bo Wang[1]. *[1]Guy's & St Thomas' NHS Foundation Trust, London, United Kingdom; [2]Kings College Hospital NHS Foundation Trust, London, United Kingdom*

Email: bo.wang@nhs.net

Background and aims: Opt-out blood-borne virus (BBV) testing for HIV, Hepatitis B (HBV) and Hepatitis C (HCV) infection has been carried out in selected emergency departments (ED) across England since April 2022. Here we describe patients with newly diagnosed chronic HBV from ED testing at two large NHS Trusts in Southeast London in the first 20 months of testing.

Method: Patients with reactive hepatitis B surface antigen (HBsAg) results from ED were contacted and their hospital and GP records were analysed to establish if this was a new or a known diagnosis. Clinical data and details on linkage to care were collected for all new diagnoses made between November 2022 to June 2024.

Results: In the 20-month period, 1188 patients were reactive for HBsAg. Of these, 353 patients had a new HBV diagnosis. 13 patients presented with clinically overt cirrhosis and 3 had hepatocellular carcinoma (HCC) diagnosed during the admission. 254 new patients (71.9%) were subsequently contactable and accepted a first appointment; 202 attended this first appointment, including 169 having transient elastography (Fibroscan) assessment. Of the patients who had a Fibroscan assessment, 19 (11.2%) had liver stiffness measurements (LSM) of 7–11 kPa and 9 (5.3%) had a LSM of >11 kPa. In addition, 61 patients have a calculated APRI score of 0.5–1.0 and 26 patients a score of >1.0.

44 patients have been initiated on nucleos(t)ide analogue treatment since diagnosis. However, based on the World Health Organisation (WHO) 2024 guidance (APRI >0.5 or HBV DNA >2000 IU/mL and ALT above upper limit of normal) 123 (34.8%) of the newly diagnosed patients meet criteria for initiating treatment. Furthermore 138 patients (39.1%) warrant HCC surveillance based on EASL guidelines; a significant proportion of this cohort being Black Afro-Caribbean males over the age of 40.

74 patients seen in one ED with known chronic HBV but lost to specialist follow up (LTFU) were identified and analysed. 53 patients (71.6%) were re-linked to care, 26 patients (35.1%) meet the WHO 2024 treatment criteria, and 32 (43.2%) patients require HCC surveillance.

Conclusion: Patients with Hepatitis B identified through ED testing represent a significant burden of clinical disease. In the first 20 months of ED testing in Southeast London, 34.8% of those newly diagnosed potentially meet treatment criteria and 39.1% require surveillance for HCC. ED testing is also an opportunity to re-engage LTFU patients, with success in one centre as reported here. Resource is now required as a priority to meet this increase in demand on specialist services in a long-term sustainable manner and novel models of care need to be considered.

SAT-007

National hepatitis C virus (HCV) screening pilot using rapid HCV antibody tests in Kazakhstan

Kulpash Kaliaskarova[1], Kulkayeva Gulnara Utepergenovna[1], Alma Aubakirova[2], Samantha Hall[3], Alexis Voeller[3], Shakhlo Sadirova[4], Alan Bijiyev[5], Imdat Efendiyev[6], Tatyana Kassymova[7], Yelena Laryushina[8], Irina Lozinskaya[9], Zhanar Rsaliyeva[10], Lyazat Saduakassova[11], Nazigul Sapargaliyeva[12], Marzhan Zhanasbayeva[5], Homie Razavi[3]. *[1]National Research Oncology Center (NROC), Astana, Kazakhstan; [2]National Research Center for Health Development (NRCHD), Astana, Kazakhstan; [3]Center for Disease Analysis Foundation, Lafayette, United States; [4]Center for Disease Analysis Foundation, Tashkant, Uzbekistan; [5]National Research Oncology Center, Astana, Kazakhstan; [6]Regional Clinical Hospital, Semey Region, Semey, Kazakhstan; [7]Regional Clinical Hospital, Turkestan Region, Turkestan, Kazakhstan; [8]Karaganda Medical University, Karaganda, Kazakhstan; [9]Regional Clinical Hospital, Karaganda Region, Karaganda, Kazakhstan; [10]Shymkent city, City Hospital 2, Shymkent city, Kazakhstan; [11]International Healthcare Best Practice Support Group, Astana, Kazakhstan; [12]East-Kazakhstan Regional Hospital. East-Kazakhstan Region, East-Kazakhstan, Kazakhstan*

Email: kulpash.kaliaskarova@gmail.com

Background and aims: Hepatitis C virus (HCV) infection continues to pose a major public health challenge in Kazakhstan, affecting an estimated 398,000 individuals. Despite the availability of free testing and treatment, fewer than 10% of cases were diagnosed by 2021. Current screening programs target only high-risk groups, such as pregnant women and surgical patients, leaving many undiagnosed. This gap undermines Kazakhstan's progress toward the World Health Organization's (WHO) 2030 elimination target. This pilot evaluated the effectiveness of large-scale general adult population screening in urban and rural polyclinics. The findings aim to inform the development of a national program to improve diagnosis, treatment, and public health outcomes to meet WHO elimination goals.

Method: Convenience sampling was employed to recruit adults attending polyclinics in five regions: East Kazakhstan, Abay, Turkistan, Karaganda, and Shymkent City. A total of 99,200 individuals were screened for anti-HCV antibodies using rapid diagnostic tests, with data recorded in an electronic registry. Prevalence was analyzed by age, sex, birth region, and clinic region. Poisson regression identified factors contributing to variability in HCV prevalence.

Results: Overall HCV prevalence, adjusted for age and sex, was estimated to be 0.59% (95% CI: 0.55–0.65%). Males had higher prevalence (1.22% (1.10–1.34%)) than females (0.30%, (0.26–0.34%)). Prevalence peaked at 0.99% for those aged 45–49. Regionally, Aktobe exhibited the highest prevalence at 4.68% (0.82–14.2%). Among clinic regions, Shymkent had the lowest statistically significant prevalence of 0.43% (0.31–0.61%). Regression analyses found higher HCV rates in individuals born in Aktobe and tested in Turkistan ($p < 0.001$). Younger age groups showed significantly lower rates compare to those aged 35–39 ($p < 0.01$).

Conclusion: This pilot program demonstrated the feasibility of large-scale HCV screening and identified significant variability in prevalence by age, sex, and geography. Males, individuals aged 45–49, and those from the Aktobe region showed elevated prevalence, highlighting the need for targeted interventions. However, expanding the program to populous regions like Almaty, in addition to high-risk groups, is critical for a comprehensive assessment of HCV prevalence.

Development of a national screening strategy will be essential for Kazakhstan to meet WHO elimination targets and reduce the public health burden of HCV.

SAT-008

Population-based hepatitis C screening and elimination program in Lithuania: 26-month results

Limas Kupcinskas[1], Alexis Voeller[2], Egle Ciupkeviciene[3], Gediminas Urbonas[4], Homie Razavi[2], John Ward[5], Juozas Kupcinskas[6], Janina Petkeviciene[3]. *[1]Institute for DIgestive Research, Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Center for Disease Analysis Foundation, Lafayette, Colorado, United States; [3]Health Research Institute, Lithuanian University of Health Sciences, Kaunas, Lithuania; [4]Department of Family Medicine, Lithuanian University of Health Sciences, Kaunas, Lithuania; [5]Coalition for Global Hepatitis Elimination, Decatur, United States; [6]Department of Gastroenterology, Lithuanian University of Health Sciences, Kaunas, Lithuania*
Email: l.kupcinskas@gmail.com

Background and aims: The Lithuanian HCV screening programme started in May 2022. General practitioners (GPs) received special promoting fee for serological HCV antibody testing: 1. For people born between 1945 and 1994 (once in a lifetime) and 2. For people who inject drugs (PWID) or HIV-positive people (annual HCV testing). This initiative is the first in Central and Eastern Europe. The aim of this study was to assess the results of the first 26 months of the programme and the different scenarios for achieving the WHO 2030 targets.
Method: GPs invited people to perform a serum blood test for HCV antibodies. Anti-HCV positive patients were referred to a gastroenterologist or infectologist for HCV RNA testing, and if result was positive, direct-acting antiviral (DAA) therapy was prescribed. Information about patients was obtained from the database of the National Health Insurance Fund. The Markov disease progression model elaborated by the CDA Foundation was used to assess HCV elimination progress. The data from the 2022–2023 screening were used as inputs Three scenarios were developed: the 'Base' scenario - return to pre-screening program level in 2023 and 2 scenarios with different extents of treatment.
Results: At the beginning of 2022, about 1.8 million people born in 1945–1994 lived in Lithuania. Between May 5, 2022 and June 30, 2024 from this population 1264527 people (69.7%) were tested for HCV antibodies. Positive test results were found in 1.25% of cases. In the risk group, 10670 PWID and HIV+ people were screened, of whom 29.6% were seropositive. Seropositive patients were referred to specialists and viremia was detected in 58,6%. During 26-month (May 2022–June 2024) period 3 times more HCV patients were treated with DAA than during the same period (Aug 2020–April 2022) before starting of the program (5881 vs 1921). Treatment delay for 48.9% of HCV patients was related to organizational problems (fibrosis limitations for treatment were canceled only on April, 2024; delay for patients' referral from GP to specialists). The Markov disease progression model to assess HCV elimination progress showed the following scenarios: Scenario 1: if the same number of patients are treated as before the screening, the WHO targets will not be reached. Scenario 2: treating 70% of infected patients will meet most but not all WHO targets. Scenario 3: by treating all infected patients by 2030, the WHO target will be met by saving 150 lives and preventing 90 new cases of decompensated cirrhosis and 120 cases of hepatocellular carcinoma.
Conclusion: Our data show that in European country with moderate HCV seroprevalence, a population-based screening program can be feasible, screening near 70% (more than 1,2 million) of the population born between 1945 and 1994 during the first 26 months of the program. With no restrictions on DAA treatment, we hope that the WHO 2030 targets can be achieved in Lithuania, but it is essential to ensure that all seropositive patients who have been screened by a GP are consulted and treated by specialists.

SAT-009

Risk of advanced liver disease among individuals with hepatitis B virus infection with low-level viremia compared to individuals with no evidence of hepatitis B virus infection

Paul Yien Kwo[1], Laura Telep[2], Lai San Hong[3], Leland J. Yee[2], Sarjita Naik[2], Betty Chiang[2], Catherine (Carrie) Frenette[2], Amanda Singer[2], Anand Chokkalingam[2], Robert Wong[4,5], Camilla Graham[6,7]. *[1]Stanford University School of Medicine, Palo Alto, CA, United States; [2]Gilead Sciences, Inc., Foster City, United States; [3]Gilead Sciences, Inc., Uxbridge, United Kingdom; [4]Stanford University School of Medicine, Division of Gastroenterology and Hepatology, Palo Alto, CA, United States; [5]Veterans Affairs Palo Alto Healthcare System, Gastroenterology and Hepatology Section, Palo Alto, CA, United States; [6]Harvard Medical School, Cambridge, Massachusetts, United States; [7]Beth Israel Deaconess Medical Center, Boston, Massachusetts, United States*
Email: pkwo@stanford.edu

Background and aims: Current medical society treatment guidelines for hepatitis B virus (HBV) infection do not recommend antiviral therapy for individual with low-level viremia (LLV: defined as HBV DNA ≤2,000 IU/mL) unless cirrhosis has been diagnosed; however, the association between LLV and advanced liver disease is unclear. In this study we examine United States (US) administrative claims and laboratory result data to describe the characteristics of individuals with LLV compared to those with no evidence of HBV, and to evaluate the risk of advanced liver disease events (including compensated and decompensated cirrhosis (CC, DC), hepatocellular carcinoma (HCC), liver transplant (LTx) and a composite outcome of any of these events) in these two groups.
Method: Adults (age ≥18 years) with chronic HBV (defined as ≥2 positive HBV surface antigen (HBsAg) or HBV DNA at least 6 months apart) and low-level viremia (LLV, defined as HBV DNA ≤2,000 IU/mL) were identified from October 2016 – June 2024 using the Optum Clinformatics® Data Mart, a large US administrative claims database of individuals covered by commercial and Medicare Advantage insurance. Individuals with evidence of CC, DC, HCC, LTx, HIV, concurrent hepatitis C or D, or those who had <365 dates of continuous enrollment prior to index or had evidence of nucleot(s)ide analogue (NA) treatment in the six months prior to index were excluded. Index date was defined as the date of the first laboratory results for HBV DNA ≤2,000 that met all inclusion criteria. Chronic HBV patients with LLV were matched to adults with no evidence of chronic HBV on age at index, sex, race, and baseline comorbidities, and differences in the risk (per 100 person-years) of CC, DC, HCC, and composite outcome of aforementioned endpoints were compared between propensity score (PS)-matched groups using Cox proportional hazards models.
Results: After 1:1 PS-matching, we identified N = 4,236 individuals for each cohort (HBV LLV and uninfected controls). When compared to individuals with no evidence of HBV, those with HBV LLV had a significant increased risk of all examined outcomes: CC (HR: 14.24 (6.95–29.18)), DC (HR: 1.90 (1.26–2.86)), HCC (HR: 9.79 (3.90–24.57)), and the composite outcome (HR: 4.83 (3.48–6.71)). Similar results were observed for all outcomes in a subgroup analysis that compared uninfected controls to individuals with HBV LLV with no evidence of NA treatment or recorded HBV DNA > 2,000 at any point during the follow up period (73.6% of the original cohort; N = 3,121). Additional analyses examining the risk of HBV DNA > 2,000 IU/mL with evidence of NA treatment vs. HBV DNA ≤2,000 IU/mL with no evidence of treatment were also conducted.
Conclusion: In this analysis of US claims data including Medicare and laboratory results, individuals with HBV DNA ≤2,000 had a significant increased risk of advanced liver disease events relative to those with no evidence of HBV. These results support the conduct of additional

studies to determine whether starting antiviral therapy in people with hepatitis B virus and low-level viremia prevents advanced liver disease.

SAT-010

Peer-led mass testing in prisons to support hepatitis C elimination

Sorcha Daly[1], Sean Cox[1], Leila Reid[1], Georgia Threadgold[2], Beatrice Emmanouil[2], Mark Gillyon-Powell[2], Natasha Gaskin[1], Lee Christensen[1]. *[1]The Hepatitis C Trust, London, United Kingdom; [2]NHS England, London, United Kingdom*
Email: sorcha.daly@hepctrust.org.uk

Background and aims: People in criminal justice systems (CJS) face high rates of hepatitis C as well as high levels of loss to follow up. High Intensity Test and Treat interventions (HITTs) have operated across English prisons since 2019 to screen whole prison populations for hepatitis C (HCV). Delivered collaboratively by NGO The Hepatitis C Trust (HCT), the Prison service, Prison Healthcare, and local community hepatitis C healthcare teams, HITTs enable a prison to 'micro-eliminate' HCV. Funding for additional testing, incentives, clinical and custodial staff time to facilitate the activity was provided by NHS England. HITTs aim to improve understanding of HCV among staff and residents, address stigma, diagnose and rapidly treat HCV within the existing prison population, and increase rates of testing at reception for all new residents. We report early programme evaluation findings.
Method: HCT plan HITTs with prison Governors, conducting site visits and delivering peer-led HCV awareness sessions for prison residents and staff. Taking a wing-based approach and working in teams comprising of a nurse, prison officer, and a peer (someone with lived experience of CJS and HCV testing), teams go cell to cell testing for HCV antibodies (AB). Prisoners testing AB+ access point of care testing using Xpert® HCV Viral Load Fingerstick (Cepheid, CA). Positive cases are referred to the specialist BBV nurse and access a rapid treatment pathway, starting treatment within 2–14 days.
Results: In five years, 54,080 of 58,606 prison residents (92%) were tested through 82 HITTs. HITTs have identified 3,992 people (7.4%) with HCV antibodies, including 49% of residents in one prison. 611 have been referred for treatment, 522 (85%) started treatment, of these 478 (78%) initiating treatment in prison. Ongoing analysis of pre- and post-HITT data in 2024 indicates that reception testing increases by an average of 10% with each HITT. Qualitative feedback indicates high acceptability for prison residents.
Conclusion: HITTs play a key role in raising awareness of HCV in English prisons among prisoners, healthcare professionals and prison staff. This strengthens both the immediate prison-level response to hepatitis C, and ongoing HCV screening and treatment. This is an innovative and consistently effective approach to eliminating hepatitis C among people in prisons.

SAT-011-YI

Survival and inactivation of hepatitis A virus on inanimate surfaces

Lilli Pottkämper[1,2], Michelle Jagst[1], Daniel Todt[1,3], Eike Steinmann[1]. *[1]Ruhr-University Bochum, Bochum, Germany; [2]University of Veterinary Medicine Hannover, Hannover, Germany; [3]European Virus Bioinformatics Center (EVBC), Jena, Germany*
Email: lilli.pottkaemper@rub.de

Background and aims: Hepatitis A virus (HAV) causes an estimated 159 million infections annually with most of them attributed to fecal-oral transmission through contaminated drinking water or food. Limited data regarding its surface stability and sensitivity to chemical disinfectants are available. The aim of the study was to establish an HAV-based carrier assay to evaluate its surface stability and the virucidal activity of various surface disinfectants.
Method: An efficient cell culture system based on the cytopathic HAV strain HAVcyt/HB1.1 and FRhK-4 cells was utilized. Steel-disc carriers were inoculated with HAV particles and incubated at room temperature and the remaining viral titers were assessed over a period of 50 days. Environmental data regarding temperature and humidity were monitored over the course of the experiment. Furthermore, HAV resistance against different disinfection agents with varying concentrations and exposure times was evaluated according to the manufacturer's guidelines.
Results: Infectious virus was recoverable for up to 40 days, with a half-life of 18.63 days, and changes in temperature and humidity throughout the experiment seemed to have minimal impact on its stability. All alcohol-based disinfectants (Bacillol, Antifect and Meliseptol) were found to be ineffective in significantly reducing viral titers. Virucidal effects could also not be observed for peracetic acid-based disinfectants and hydrogen-peroxide. Only two aldehyde-based products were able to inactivate HAV under the detection limit.
Conclusion: Overall, HAV displayed a high degree of stability against a wide range of surface disinfectants. Of the nine surface disinfectants tested, only two demonstrated a reduction in viral titer below the lower limit of detection, which were based on aldehyde. These findings have strong implications for the recommendation of evidence-based hygiene guidelines to reduce HAV transmission.

SAT-012

Evaluating and aiding hepatitis C elimination efforts through natural language processing (Cogstack): analysis of electronic health records including diagnosis, demographics and outcomes

Mahd Siddiqi[1], Mohammad Al-Agil[2], Saima Ajaz[3], Kosh Agarwal[4]. *[1]Institute of Liver Studies, Kings College Hospital, Faculty of Life Sciences & Medicine, Kings College London, London, United Kingdom; [2]Kings College Hospital, London, United Kingdom; [3]Institute of Liver Studies, King's College Hospital, London, United Kingdom; [4]Institute of Liver Studies, Kings College Hospital, London, United Kingdom*
Email: mahd.siddiqi@kcl.ac.uk

Background and aims: Hepatitis C virus (HCV) remains a significant global health challenge, affecting over 50 million individuals worldwide, leading to substantial morbidity and mortality, including cirrhosis and hepatocellular carcinoma (HCC). The WHO aims to eliminate HCV by 2030, emphasising comprehensive screening, early diagnosis, and effective treatment. Despite these goals, barriers to patient identification and treatment access persist. Our aim was to evaluate the clinical impact of current screening and elimination strategies for HCV, leveraging natural language processing (NLP) tools by improving patient identification and assessing survival rate.
Method: This retrospective cohort study analysed electronic health records (EHRs) of HCV-RNA +ve patients between 2014–2023 at King's College Hospital, London. Data extraction and collation were performed using CogStack, an NLP tool for processing clinical text. Data were collected on new HCV diagnoses, including Ab+ve and RNA +ve cases, and patient demographics. Five and 10-year survival rates were assessed. Statistical analyses identified trends and factors influencing HCV incidence and clinical outcomes.
Results: A total of 2,199 HCV RNA-positive patients were identified through the CogStack platform. From these, 61.9% of patients had postcode data available and were from the catchment areas: Lewisham (23.4%), Lambeth (34.7%), Southwark (29.9%), and Bromley (12.0%). The cohort had a male predominance, with 63% male and 37% female patients and a mean age of 49 years (range: 17, 92). Most patients were Caucasian (68.4%), followed by Black (12.1%), with smaller proportions of Unknown (10.7%), Other (4.9%), Asian (3.7%), and Mixed (0.3%) ethnicities. Survival analysis revealed a 5-year survival rate of 76% and a 10-year survival rate of 57%. Social deprivation analysis showed that 69% of patients were in the fifth decile or below for the Index of Multiple Deprivation (IMD), highlighting significant socioeconomic challenges within the cohort. IMD data were available for 838 patients (38% of the total cohort). Among those in the fifth decile or below with liver stiffness measurements (LSM) data, the mean LSM was 10.77 (IQR: 5.23), and

41.1% had high LSM, suggesting significant fibrosis. Treatment data and its impact will be presented.
Conclusion: The use of NLP tools show significant potential in improving the identification of HCV-positive patients and evaluating the impact of screening and elimination strategies. The findings emphasize the need for targeted interventions, especially in socioeconomically deprived populations, to achieve the WHO's 2030 elimination metrics. This study underscores the value of connected advanced data extraction techniques in supporting public health initiatives to eliminate HCV, as well as identify those with risk factors for screening.

SAT-013

Knowledge and perception of chronic hepatitis B infection and attitude towards point-of-care testing among the general population in primary care settings in Hong Kong

Marco Tsun Lee[1], Judy Siu Har Lee[2], Ching Lung Cheung[1], Lung-Yi Mak[1]. [1]*The University of Hong Kong, Hong Kong, Hong Kong;* [2]*The Hong Kong Society for Rehabilitation, Hong Kong, Hong Kong*
Email: marcolt@hku.hk

Background and aims: Chronic hepatitis B (CHB) infection caused by hepatitis B virus (HBV) remains a leading cause of liver disease worldwide. Early detection and linkage to care are essential to mitigate complications. However, universal screening program for CHB is still lacking even in areas with high prevalence. This study aimed to evaluate the feasibility and patient attitude of implementing point-of-care (POC) testing for CHB in a community primary care setting.
Method: A cross-sectional study was conducted to evaluate POC hepatitis B surface antigen (HBsAg) testing in primary care settings. Participants were recruited from the Central and Western District Health Centre Express in Hong Kong from October to November 2024 during member registration and health events, targeting adults aged ≥18 who could provide consent, read and write Chinese, excluding those with known CHB diagnosis, pregnancy, or serious medical conditions. Participants underwent POC testing for HBsAg by Abbott Diagnostics Determine™ HBsAg 2 rapid test kit, which has a lower limit of detection of 0.1 IU/ml, followed by a structured validated questionnaire in Chinese that collected data on demographics, hepatitis B history, knowledge, perceptions, and attitude.
Results: A total of 28 participants were included (mean age of 60.9 years; 71.4% female). Vaccination history against HBV was reported by 39.3%. Knowledge about HBV transmission was variable; 89.3% correctly identified both mother-to-child and blood-borne transmission, but only 53.6% agreed that CHB can be transmitted by sexual contact. 35.7% disagreed with the misconception of HBV transmission through sharing of food utensils. Most participants understood HBV-related complications, with 92.9% aware of its asymptomatic nature. 96.4% and all of participants recognizing its link to cirrhosis and liver cancer respectively. While 100% would test if recommended by their doctor, only 14.3% reported prior discussions about HBV POC testing with their doctor. All participants expressed high satisfaction with the POC testing, rating convenience (mean score 9.4/10) and immediate results to allow timely interaction with healthcare professionals (mean score 9.6/10) as key advantages.
Conclusion: POC testing for HBV in primary care settings is well-received and can improve accessibility and early detection. However, educational interventions are needed to address persistent misconceptions about transmission. Expanding POC testing could enhance hepatitis B screening rates and facilitate timely intervention.

SAT-014

Setting the record straight: utility and outcomes in patients with HCV related HCC

Maria Guerra Veloz[1], Renita George[1], Mia Olsen[1], Sital Shah[1], Sarah Selemani[2], Paul Ross[2], Kosh Agarwal. [1]*Institute of Liver Studies, King's College Hospital, London, United Kingdom;* [2]*Department of Oncology, King's College Hospital NHS Foundation Trust, London, United Kingdom*
Email: maria.guerraveloz@nhs.net

Background and aims: The effectiveness of direct acting antiviral (DAA) therapy in patients with hepatocellular carcinoma (HCC) is poorly defined. Although there is agreement regarding HCV treatment in patients who have received curative HCC treatments, the optimal timing for DAA therapy in those with active HCC or those with advanced stage remains undefined. AASLD and IDSA guidance recommends against HCV treatment in those with advanced HCC and limited life expectancy (less than 12 months). In 2015, DAA therapy was approved in the UK for all viraemic patients (including those with HCC independent of the cancer stage). Preliminary data from the England HCV elimination programme suggests that almost 4% of viraemic patients treated during 2016 and 2023 had documented HCC at the time of DAA therapy. The aim of this retrospective study is to provide a real-life data of HCV treatment in those with HCC since the introduction of DAAs.
Method: Patients with HCV related HCC from the National Hepatitis C registry in South-East England between 2016 and 2023 were retrospectively included. The primary outcome was to assess HCV care cascade (treatment pathway) in patients with HCV related HCC (HCC cohort) in comparison with those without cancer (non-HCC cohort) as well as to assess treatment outcome and overall survival (OS) in patients with varying stages of HCC.
Results: 228/6850 (3.3%) HCV related HCC patients were identified. 71.8% (4755/6622) from the non-HCC cohort and 63.2% (144/228) from the HCC cohort initiated DAA therapy ($p < 0.05$). By ITT, SVR rate in HCC cohort was 85.8% (97/113) vs 89.3% (3643/4081) in the non-HCC cohort ($p = 0.992$). 11% (17) in the HCC cohort and 3.5% (168) in the non-HCC cohort were re-treated ($p < 0.05$). Patients in the HCC cohort were older (67 vs 55 years; $p < 0.05$), had a significant greater degree of fibrosis (moderate fibrosis, 22.6 vs 7.1%, cirrhosis 55.6 vs 18.7%; $p < 0.05$), were infected with genotype 3 (41 vs 27.3%, $p < 0.05$), had higher alcohol intake (31 vs 15%, $p < 0.05$) and required sequential treatment with more than one DAA regimen (11.8 vs 3.5%, $p < 0.05$) in comparison with those without HCC. At the time of DAA therapy 88% had an active HCC and the majority (64%) had early stage cancer (BCLC stage 0 = 4; BCLC stage A = 80). SVR rate was 95%, 56.3% and 78% in BCLC 0/A, B, and C respectively. The death rate during HCV treatment or before SVR was 77% in BCLC stage D, 20% in BCLC stage C, 4.3% in BCLC stage B and 2.4% BCLC 0/A. The median OS after DAA therapy was 105, 32, 18 and 4 months for BCLC 0-A/B/C/D respectively. 80% had a median OS more than 12 months.
Conclusion: More than two thirds of patients with HCV-related HCC initiated and completed DAA therapies in South-East England. This high level of treatment uptake has led to an acceptable cure rate. The majority of patients had an overall survival of more than 12 months and so we believe that HCV treatment needs to be recommended in those with BCLC stages A, B and C.

SAT-019

Knowledge of hepatitis D epidemiology and access to hepatitis D diagnostic testing among healthcare providers in Africa: a multi-country survey

Maria Buti[1], C Wendy Spearman[2], Karin Siebelt[3], Manal El-Sayed[4]. [1]*Liver Unit, Internal Medicine Department, Hospital Universitari Vall d'Hebron, Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain;* [2]*Department of Medicine, Faculty of Health Sciences, University of Cape Town, Cape Town, South Africa;* [3]*Academic Medical Education, Utrecht,*

Netherlands; [4]Ain Shams University, Cairo, Egypt
Email: mariabutiferret@gmail.com

Background and aims: Chronic hepatitis D infection, a disease associated with accelerated progression to liver cirrhosis and hepatocellular carcinoma, is considered the most severe form of viral hepatitis. An estimated 1.6 million people in the WHO Africa region are living with hepatitis D. However, the HDV prevalence data in this region are likely suboptimal due to low awareness and limited access to HDV screening and diagnostic tests. This multi-country survey aimed to assess health care providers' knowledge of HDV prevalence and the availability of hepatitis D screening and confirmatory diagnostic testing across all African countries. Additionally, a literature review was conducted on HDV prevalence and available diagnostic testing in Africa.
Method: A web-based questionnaire created by members of the Society on Liver Disease in Africa (SOLDA) and the European Association for the Study of the Liver (EASL) was distributed to all SOLDA and Project ECHO Viral Hepatitis members through African network channels.
Results: In total, 608 surveys were completed, representing 43 of the total of 54 (80%) countries in Africa. The distribution of respondents was as follows: eastern Africa (266 respondents, 44%), western Africa (217, 36%), southern Africa (50, 8%), northern Africa (37, 6%), and central Africa (38, 6%). Participants from 24 of 43 countries (56%) were aware of their HDV epidemiological data, and 33 (61%) of 54 countries reviewed in the literature had published data. There were no statistical differences between these percentages ($p = 0.598$), Survey participants reported that data on hepatitis D seroprevalence had been assessed in the following populations: HBsAg carriers (77%), blood donors (23%), chronic liver disease (25%), hepatocellular carcinoma (18%), children and adolescents (12%), dialysis patients (16%), and people who inject drugs (13%). Anti-HDV antibody determination was available in 17 of 43 countries (39%), while published data indicated availability in 14 of 54 countries (26%) ($p = 0.153$). Anti-HDV and HDV RNA testing in the context of clinical studies is reimbursed in only 12 countries.
Conclusion: Healthcare providers' knowledge of HDV prevalence varies across African countries. Access to anti-HDV and HDV RNA testing in Africa is limited and seldom reimbursed, and diagnostic tests are not incorporated into routine clinical practice.

SAT-020

Patient perspectives on barriers and enablers to a treatment for all approach for hepatitis B

Marvad Ahad[1,2], Jack Wallace[1,3], Bradley Whitton[4], Susanne Glasgow[4], Dina Moussa[1,5], Alexander Thompson[4,5], Amanda Wade[1], Joseph Doyle[1,2], Jess Howell[1,4,5]. *[1]Burnet Institute, Melbourne, Australia; [2]Monash University, Melbourne, Australia; [3]La Trobe University, Melbourne, Australia; [4]St Vincent's Hospital Melbourne, Melbourne, Australia; [5]The University of Melbourne, Melbourne, Australia*
Email: marvad.ahad@burnet.edu.au

Background and aims: Major gaps exist in diagnosis, linkage to and maintenance in hepatitis B care in Australia and globally. To meet the World Health Organization's (WHO) 2030 viral hepatitis elimination targets, access to and engagement in clinical care needs to be increased. Under current Australian treatment guidelines, not all people with hepatitis B are eligible for antiviral treatment. The recent WHO updated hepatitis B treatment guidelines vastly expanded hepatitis B treatment eligibility, with all people with hepatitis B provided with the opportunity to access treatment, including from the point of diagnosis. This qualitative study explored patient perceptions of hepatitis B treatment and opinions on a "treatment for all approach.".
Method: Twenty-three semi-structured interviews were conducted with patients from a metropolitan gastroenterology clinic in Melbourne, Australia. Of the interviewed participants, 13 were female and 10 were male, and 21 patients were born in countries other than Australia (the most common country of birth being Vietnam) and 2 were born in Australia. Participants were aged between 33 and 69 years. Data from semi-structured interviews were thematically analysed.
Results: Thirteen participants were open to a "treatment for all approach," eight were not, and two were unsure. Five enablers and four barriers were identified from the thematic analysis. Enablers included: 1) perceived seriousness of hepatitis B and its complications, 2) belief in medications, 3) belief in benefits of early intervention, 4) receiving support through the treatment experience, and 5) trust in medical professionals. Barriers included: 1) psychological impact related to long-term medication, 2) perceived culture of overmedicalisation, 3) belief that the medication is unnecessary, and 4) cost and logistics associated with prescription medication.
Conclusion: Perspectives both for and against a "treatment for all" approach were discussed by people with hepatitis B in this study. A key enabler identified was of psychological support for patients throughout treatment decision making. Given that cure for hepatitis B is a future possibility, exploring the acceptability of a treatment for all approach and patient considerations for treatment is crucial preparatory work to determine acceptability of treatment.

SAT-021

Initiation of direct acting viral therapy in prison is associated with a significant loss to follow-up: relevance to WHO elimination metrics?

Peter Sandwith[1], Kosh Agarwal[2], Graham R Foster[3], Beatrice Emmanouil[3,4], Mark Gillyon-Powell[4], Specioza Nabiteeko[4], Georgia Threadgold[4], Julian Surey[5], Rachel Hill-Tout[4,6], Leila Reid[7], Stuart Smith[7], Paul Trembling[8], Douglas Macdonald[8], Dan Forton[9], Upkar Gill[1,10], Ashley Brown[11], Matthew Foxton[12]. *[1]Department of Hepatology, Barts Health, Whitechapel Road, E1 1FR, London, United Kingdom; [2]Institute of Liver Studies, Kings College Hospital, SE5 9RS, London, United Kingdom; [3]Blizard Institute, Faculty of Medicine and Dentistry, Queen Mary University of London, 4 Newark Street, E1 2AT, London, United Kingdom; [4]Specialised commissioning, NHS England, Wellington House, 133-155 Waterloo Rd, SE1 8UG, London, United Kingdom; [5]Find and Treat Team, University College Hospital, 235 Euston Road, NW1 2BU, London, United Kingdom; [6]Bromley-By-Bow Health Centre, St. Leonards Street, Bow, London, Greater London, E3 3BT, LONDON, United Kingdom; [7]Hepatitis C Trust, 72 Weston Street, SE1 3QG, London, United Kingdom; [8]Department of Hepatology, Royal Free Hospital, Pond Street, NW3 2QG, London, United Kingdom; [9]Dept of Gastroenteroloy and Hepatology St George's University Hospital NHS Foundation Trust, Blackshaw Road, SW17 0QT, London, United Kingdom; [10]Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [11]Department of Hepatology, St Marys Hospital, Paddington, London, United Kingdom; [12]Department of Gastroenterology and Hepatology, Chelsea & Westminster Hospital, SW10 9NH, London, United Kingdom*
Email: matthew.foxton@nhs.net

Background and aims: Prisons represent an area of high HCV prevalence. There has been a focus on improving the testing and treatment of incarcerated individuals. The sustained virological response (SVR) rates at 12 weeks, however in patients initiating treatment in detention centres is unclear.
Method: All patients treated with DAA therapy within 18 centres in London from September 2013 -March 2024 were collated on a central registry. Within London, a metropolis of 9.7M with significant diversity, there are 7 prisons where DAA therapy can be initiated, including remand facilities. This data was interrogated for all patients initiated on DAA therapy whilst in prison. The demographics and outcomes were compared with all patients initiating therapy in other treatment settings over the same period. All comparisons are with patients treated outside of prisons.

Results: 687 patients were initiated on therapy whilst in detention and 15,784 treatment initiations in other settings in the same period. Patients treated in prison were almost exclusively male (99.6%) with a significant component who currently inject drugs (PWID) (33.8% vs 11.3%), genotype 1 (48.9% vs 53.3%) or genotype unknown (15.3% vs 4.9%) and of white ethnicity (51.4% vs 60.1%); [ethnicity was not recorded in 28.8% of prisoners (vs 11.2% of non-prisoners)]. The planned treatment duration was 8 weeks in 317; 12 weeks in 360; 16 weeks in 9 and 24 weeks in 1 patient. In those receiving 8 weeks of therapy, 23 (7.3%) received < 8 weeks; in those receiving 12 weeks, 45 (12.5%) received <12 weeks of therapy. Of the patients starting treatment in prison, 274 (39.9%) were lost to follow up or had no outcome recorded. In those, starting treatment in non-prison settings, the lost to follow-up/outcome not recorded rate was 13.7% (2157 patients) ($p < 0.01$).
Conclusion: Patients who initiate DAA therapy whilst incarcerated have excellent outcomes based on per-protocol analysis. However, a significant proportion are LTFU, impacting ITT outcomes. Given that a third are PWID at treatment initiation, this poses a significant public health risk for reinfection and may impact on HCV elimination initiatives.

SAT-022

Screening for risk factors for hepatitis C infection with a large metropolitan primary care population - The size of the problem

Matthew Foxton[1], Benjamin Pierce[2], Gulam Muktadir[2], Lyndsey Williams[3], Ashley Brown[4]. *[1]Department of Gastroenterology and Hepatology, Chelsea and Westminster Hospital, London, SW10 9NH, London, United Kingdom; [2]Imperial College Health Partners, London, United Kingdom; [3]NHS NORTH WEST LONDON ICB, London, United Kingdom; [4]Department of Hepatology, St Marys Hospital, Paddington, London, London, United Kingdom*
Email: matthew.foxton@nhs.net

Background and aims: The Hepatitis C (HCV) elimination programme within England has identified primary care as a priority where a large number of people with unidentified HCV infection may be identified. Outside of universal screening, targeting patients with risk factors for HCV infection, identified through primary care records, may represent the best way to identify these patients. Northwest London (NWL) whole systems integrated care (WSIC) is an integrated care record that stores data on individuals from primary, secondary and community care records. NHS England has developed a case-finding tool for HCV infection that identifies patients with risk factors utilising >1800 SNOMED codes. Our aim was to quantify the number of patients at risk of HCV infection in NWL with the case-finding tool searching Discover-NOW, an integrated database comprising de-identified, linked electronic health records for >2.8 million residents registered with a GP in North West London (NWL).
Method: All patient records between 31/12/1989 and 01/12/2023 were interrogated. Patients were excluded if they were deceased or in palliative care. Six searches were run (1: Hepatitis C positive; 2: Hepatitis C resolved; 3: All patients with exactly 2 risk factors; 4: All patients with 3 or more risk factors; 5: All patients with at least 3 low risk factors or 1 high risk factor; and 6: all patients born within countries with a high prevalence of HCV infection). The searches were stratified by primary care practice and primary care network.
Results: The records of 2,842,509 patients across 337 primary care practices within 44 primary care networks was interrogated. The background prevalence of HCV infection was 0.3%. The range of HCV antibody positivity prevalence varied between 0.1% and 15.3% between practices. The number of patients with 2 risk factors was 479,471 (median 17%, IQR 15–20%). The prevalence of 3 or more risk factors was present in 240,948 patients (median 9% and IQR 7–10%). Search 5, using a combination of 3 or more low risk factors or 1 high risk factor, identified 431,444 patients (median 15%, IQR 12–19%. This study identified 472,112 patients (median 16% and IQR 7–27%) within NWL born within countries with a high prevalence of HCV infection.
Conclusion: The prevalence of risk factors for HCV infection is common in the NWL population with 1 in 6 patients having 2 or more risk factors and 1 in 11 patients having 3 or more risk factors. There was a wide variation between primary care practices. These data can inform strategies to screen for HCV infection based on the prevalence of risk factors within each practice or primary care network.

SAT-023

Treatment of Hepatitis C in the over-80 s in the direct anti-viral therapy era: age is no barrier!

Peter Sandwith[1], Kosh Agarwal[2], Graham R Foster[3], Beatrice Emmanouil[3,4], Mark Gillyon-Powell[4], Specioza Nabiteeko[4], Georgia Threadgold[4], Julian Surey[5], Rachel Hill-Tout[4,6], Leila Reid[7], Stuart Smith[7], Paul Trembling[8], Douglas Macdonald[8], Dan Forton[9], Upkar Gill[1,10], Ashley Brown[11], Matthew Foxton[12]. *[1]Department of Hepatology, Barts Health, Whitechapel Road, E1 1FR, London, United Kingdom; [2]Institute of Liver Studies, Kings College Hospital, Denmark Hill, SE5 9RS, London, United Kingdom; [3]Blizard Institute, Faculty of Medicine and Dentistry, Queen Mary University of London, 4 Newark Street, E1 2AT, London, United Kingdom; [4]Specialised commissioning, NHS England, Wellington House, 133-155 Waterloo Rd, SE1 8UG, London, United Kingdom; [5]Find and Treat Team, University College Hospital 235 Euston Road, NW1 2BU, London, United Kingdom; [6]Bromley-By-Bow Health Centre, St. Leonards Street, Bow, E3 3BT, London, United Kingdom; [7]Hepatitis C Trust, 72 Weston Street, SE1 3QG, London, United Kingdom; [8]Department of Hepatology, Royal Free Hospital, Pond Street, NW3 2QG, London, United Kingdom; [9]Dept of Gastroenterology and Hepatology St George's University Hospital NHS Foundation Trust, Blackshaw Road, SW17 0QT, London, United Kingdom; [10]Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [11]Department of Hepatology, St Marys Hospital, Paddington, London, United Kingdom; [12]Department of Gastroenterology and Hepatology, Chelsea & Westminster Hospital, London SW10 9NH, London, United Kingdom*
Email: matthew.foxton@nhs.net

Background and aims: The use of direct anti-viral (DAA) therapy to treat chronic hepatitis C virus (HCV) infection has expanded access of therapy to populations that would otherwise not have been offered treatment. Previous studies have shown that DAA treatment is well tolerated with comparable outcomes in those aged 75 years, however data in patients aged >80, and of mixed ethnicity remains limited.
Method: All patients treated with DAA therapy within 18 centres in London from September 2013–March 2024 were entered into a central registry. Data was interrogated for all patients initiated on DAA therapy aged 80 and above. The demographics and outcomes were compared with all patients undergoing a single treatment episode.
Results: In total,16,471 patients received treatment of whom 592 were aged ≥80, with a median age of 84 years (range 80–101). More patients were female (56.8% vs 28.9% in under 80 s). The ethnicity of the ≥80 s cohort was documented as Asian in 98 (16.5%); black in 170 (28.7% vs 6.7% in under 80 s, $p < 0.01$); mixed race in 7; white in 193, other in 53, and not recorded in 71 (12.0%). The fibrosis stage was none or mild in 244 (41.2%); moderate in 72 (12.2%) and 244 (41.2%) had cirrhosis. The predominant genotype was 1 (307/592); [Genotype 2 (70/592); Genotype 3 (108/592); genotype 4 (83/592); other genotypes n = 9 and unknown in 15]. Renal failure (eGFR <30 ml/min) was present in 40/592, 9 had co-infection with HIV and 25 had HCC at the time of treatment. The mode of acquisition was unknown in 334 (56%). Only 24 (4%) patients died prior to SVR12 delineation. The mortality rate between treatment initiation and SVR12 was 5.2% in the cirrhotic patients and 3.2% in the non-cirrhotic patients (p = NS). The SVR rate overall was 76.4% as intention to treat with the SVR12 being 72.9% in patients with cirrhosis and 78.8% in those without cirrhosis. The SVR12 rate in the under 80 s was 78.1% (77.9% in those without cirrhosis and 79% in those with cirrhosis).

There was no significant difference in SVR12 rate in between the over vs. under 80 s, regardless of fibrosis stage.
Conclusion: Treatment of chronic HCV infection with DAA therapy in those aged >80 is associated with comparable outcomes to those <80. The significantly higher number of women in this cohort is likely secondary via healthcare acquisition. The higher proportion of individuals of black ethnicity identifies a population that may be under-screened for HCV infection. DAA, treatment, however should be available to all.

SAT-024

Semi-qualitative feedback from individuals living with HBV newly diagnosed in the emergency department ED opt-out testing program – high acceptability but better platforms of advocacy and support required

Mia Olsen[1], Kosh Agarwal[2], Kathryn Oakes[3], Esther Dennis-Nkeki[3], Rachel Hill-Tout[4], Geoffrey Dusheiko[2], Pamela Rice[3], Teresa Bowyer[3], Ivana Carey[3], Rachel Halford[5], Kate Childs[3], Supa Chantschool[6].

Email: mia.olsen@nhs.net

Background and aims: Widespread opportunistic screening is critical to achieving WHO global elimination goals for HBV and HCV. From April 2022, in areas of high (>5/1000) HIV prevalence, NHS England launched 'opt out' testing for HIV, HBV and HCV in London Emergency Departments (EDs) with integrated linkage to clinical care. In the first 18 months of testing a cohort of new HBV diagnoses were found at King's College Hospital, which serves a diverse multi-ethnic population. We collected semi-formalised qualitative patient feedback from those with newly diagnosed HBV who had been linked to care, with the aim to assess their experience with the opt-out screening process, their knowledge of HBV and what holistic support individuals with HBV require.
Method: Between November 2022 and April 2024, a total of 173 patients were found to have a new diagnosis of HBV out of 434477 tests performed. Telephone interviews were conducted with 78/153 (51%) of those patients that had been linked to care. Demographic data and feedback regarding their knowledge of HBV and their experience was collected via F2F or phone discussion.
Results: 78/153 (51%) consented to be interviewed. 7/78 (9%) were in ages ranging from 21–30, 12/78 (15%) 31–40, 19/78 (24%) 41–50, 18/78 (23%) 51–60, 12/78 (15%) 61–70 and 10/78 (13%) over the age of 71. 59/78 (75%) were of Black- African/Caribbean/British ethnicity, 11/78 (14%) White, 6/78 (8%) Asian and 2/78 (3%) of mixed ethnicity. 1/78 (1%) had no formal education, 4/78 (5%) primary education, 29/78 (37%) secondary education, 10/78 (13%) vocational education and 34/78 (44%) had a university degree.19 different languages were reported as first language. 49/78 (63%) live within the bottom 30% most deprived areas in England, calculated by the index of multiple deprivation. 62/78 (79%) reported they had no prior knowledge of hepatitis B and 55/78 (71%) were initially alarmed when they received their diagnosis. However, 66/78 (85%) believed testing of blood borne viruses and receiving a diagnosis through opt-out testing was beneficial. 46/78 (59%) had asked their family members and close contacts to be tested and vaccinated. We found that only 18/78 (23%) were aware of the peer led support group, HepB companion. Rating their knowledge of hepatitis B now on a scale of 1–5, 5/78 (7%) rated their knowledge to be 1 (very poor), 13/78 (17%) 2 (poor), 26/78 (34%) 3 (good), 17/78 (22%) 4 (very good) and 17/78 (22%) 5 (excellent). Only 15/71 (19%) knew about new treatments for HBV.
Conclusion: Feedback from a diverse group of newly diagnosed individuals living with HBV, shows acceptability of the ED opt-out scheme. Linkage to clinical care has improved their knowledge and newly diagnosed individuals feel comfortable discussing HBV with families and close contacts. However, more easily accessible information that reaches out to diverse communities with holistic support and education, allied to opportunities for novel therapy, and provision of a patient advocacy platform is required.

SAT-025

Epidemiological, economic and budgetary implications of expanding screening strategies for hepatitis C virus in Brazil: a modelling study

Everton Macêdo[1,2], Mathieu Castry[1], Clotilde Lepers[1], Nadia Hachicha[1], Anthony Cousien[1,3], Karen Champenois[1], Liliana Sampaio Costa Mendes[4], Lia Laura Lewis-Ximenez[5], Yazdan Yazdanpanah[1,6], Constance Marie Meiners-Chabin[*,7], Sylvie Deuffic-Burban[1]. *[1]Université Paris Cité and Université Sorbonne Paris Nord, Inserm, IAME, Paris, France; [2]Brazilian Ministry of Health, Brasilia, Brazil; [3]Departement of Epidemiology, Biostatistics and Clinical Research, Hôpital Bichat-Claude Bernard, Paris, France; [4]Hospital de Base do Distrito Federal, Brasília, Brazil; [5]Fiocruz, Institute Oswald Cruz, Rio de Janeiro, Brazil; [6]Service de Maladies Infectieuses et Tropicales, Hôpital Bichat-Claude Bernard, Paris, France; [7]Ministry of Development, Industry, Trade and Services, Brasilia, Brazil*
Email: ms.everton@gmail.com

Background and aims: Brazil's current hepatitis C virus (HCV) screening strategy targets people at high risk of infection through a complex algorithm. Despite the availability of antiviral treatment, the country is struggling to identify infected individuals. However, improved early detection and treatment are essential for achieving the World Health Organization (WHO) targets for HCV by 2030. We aim to evaluate the cost-effectiveness and budget impact of expanding HCV screening strategies in Brazil.
Method: A Markov model was used to simulate the prevalence of chronic hepatitis C (CHC), life years (LY), disability-adjusted life years (DALY), and costs in the Brazilian general population in 2024, aged 18 to 80, undiagnosed for CHC. We compared different one-time screening strategies: S1 = risk-based screening (status quo); S2 = S1 and all individuals aged 40 and over; S3 = all individuals between 18 and 80 years old (universal). Antiviral treatment was proposed once diagnosed for CHC and linked to care. Data were derived from published literature. Future costs and clinical benefits were discounted at 5% per year using a lifetime horizon. We assessed the budget impact of universal screening by projecting undiscounted costs over five years. The public health system perspective was adopted.
Results: The universal screening strategy led to the lowest CHC prevalence in 2030 (0.25% compared to 0.26% with S2 and 0.28% with S1), and the lowest incidence of clinical complications from 2024 to 2030 (32,471 cases of hepatocellular carcinoma and 34,130 cases of decompensated cirrhosis, compared to 32,928 and 34,538 cases with S2, and 35,304 and 36,508 with S1). Universal screening was the most effective and least expensive strategy, i.e. cost-saving. This strategy saved $548 million, achieved a gain of 75,870 LYs, and prevented 73,782 DALYs over lifetime compared to S1. Deterministic sensitivity analyses were performed including, but not limited to, seroprevalence and people at high-risk of HCV infection to account for regional differences: the universal screening remained cost-saving. The probabilistic sensitivity analysis indicated that universal screening was the most cost-effective strategy over 76% of iterations, regardless of the willingness-to-pay threshold. To achieve the WHO target of treating 80% of people diagnosed with CHC by 2030, coverage rates of universal screening and linkage to care must exceed 84%. The budget impact analysis showed that universal screening could save around U$ 26.6 million over five years for an additional 25.6 million people tested compared to S1.
Conclusion: Our findings demonstrate that universal HCV screening in the general population is a promising strategy for hepatitis C elimination in Brazil. Such recommendation could also simplify the

current complex algorithm used to screen specific sub-populations at high-risk of infection.

SAT-026

Delta in Denmark: prevalence of hepatitis delta virus infection

Hugh Watson[1], Peter Jepsen[2,3], Hendrik Vilstrup[2], Henrik Krarup[4,5].
[1]Aarhus University, Aarhus, Denmark; [2]Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark; [3]Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus, Denmark; [4]Aalborg University Hospital, Department of Clinical Medicine, Aalborg, Denmark; [5]Aalborg University Hospital, Department of Molecular Diagnostics, Aalborg, Denmark
Email: profhughwatson@gmail.com

Background and aims: Recent reviews of the global prevalence of hepatitis delta virus (HDV) infection have revealed the scarcity of data from general population studies and absence of information from many countries, including Denmark. We aimed to estimate the current prevalence of HDV in Denmark.
Method: Data on diagnoses, blood tests for hepatitis B and D infection, and demographic data were obtained from the Danish national health records for the period from 1992 to January 2024. The susceptible population was defined by a positive test for HBsAg or a diagnostic code for hepatitis B (HBV). History of HDV was defined by diagnostic code or positive test for anti-HDV Ab or HDV-RNA. Current HDV infection was defined by a positive test for HDV-RNA with no subsequent negative test.
Results: 8.1% of individuals with HBV had a history of HDV and were resident in Denmark on 1st January 2024. Of those tested for HDV-RNA, 39% had at least one positive test, and 37% were positive for HDV-RNA on their last recorded test. Thus, 8.1% * 37% = 3.0% of HBV-positive individuals in Denmark were estimated have current coinfection with HDV. This figure did not vary significantly by age, sex and native-born or foreign-born patients. Only amongst Greenland-born HBV-positive individuals was there some evidence for a higher rate of current HDV infection. The overall prevalence for Denmark translates into an estimated 236 cases of current HDV infection, or 4 cases per 100,000 in the general population.
Conclusion: Three percent, a small, but not negligible, proportion of the HBV-infected population in Denmark have a current coinfection with HDV, justifying routine testing amongst the chronic HBV population.

SAT-027

Therapy of HCV infections among patients of ukrainian origin during the influx of war refugees to Poland

Robert Flisiak[1], Dorota Zarębska-Michaluk[2], Diana Martonik[1], Justyna Janocha-Litwin[3], Hanna Berak[4], Marek Sitko[5], Włodzimierz Mazur[6], Ewa Janczewska[7], Beata Lorenc, Jakub Klapaczynski[8], Łukasz Laurans[9], Dorota Dybowska[10], Piekarska Anna[11], Magdalena Tudrujek-Zdunek[12], Krystyna Dobrowolska[2], Anna Parfieniuk-Kowerda[1]. *[1]Medical University of Białystok, Białystok, Poland; [2]Jan Kochanowski University, Kielce, Poland; [3]Wrocław Medical University, Wrocław, Poland; [4]Hospital for Infectious Diseases in Warszawa, Warszawa, Poland; [5]Jagiellonian University, Kraków, Poland; [6]Medical University of Silesia, Chorzów, Poland; [7]Medical University of Silesia, Katowice, Poland; [8]National Medical Institute of the Ministry of the Interior and Administration, Warszawa, Poland; [9]Pomeranian Medical University, Szczecin, Poland; [10]Faculty of Medicine, Nicolaus Copernicus University, Bydgoszcz, Poland; [11]Medical University of Łódź, Łódź, Poland; [12]Medical University of Lublin, Lublin, Poland*
Email: robert.flisiak1@gmail.com

Background and aims: The wave of war migration from Ukraine has raised a number of concerns about infectious diseases, the incidence of which is higher in Ukraine than in the host countries and these include hepatitis C virus (HCV) infection.
Method: Our analysis aimed to assess the share of HCV-infected Ukrainians in Polish centers providing diagnostics and antiviral therapy, the assessment of their characteristics, and the effectiveness of direct-acting antiviral (DAA) treatment compared to Polish patients. The study included patients from the EpiTer-2 database treated due to HCV infection, which is an ongoing, retrospective, multicenter, national study initiated by investigators.
Results: Of the 3,911 individuals included in the study, 429 (11%) were patients of Ukrainian origin (UKR). The highest percentage of UKR patients among all treated patients (>20%) was recorded in centers located in northern and southern Poland, while the lowest (<3%) was in the eastern part of the country. UKR population was significantly younger and had a higher proportion of females. No significant differences were observed in BMI, and proportion of nonresponders to previous therapy. UKR population was characterized by less advanced liver disease, as expressed by a significantly (p = 0.017) lower percentage of patients with F3 or F4 (32.2% vs. 38.1%), significantly lower liver stiffness assessed by elastography (10.3 ± 9.7 vs. 12.0 ± 11.4 kPa) and MELD score (7.6 ± 2.5 vs 7.8 ± 2.5). UKR patients had significantly less frequently comorbidities and comedications, less frequently had a history of hepatocellular carcinoma and decompensation, as well as the presence of esophageal varices or ascites at the start of therapy. HIV co-infection was reported significantly more often in UKR population, while the incidence of HBV co-infection was comparable. In UKR population infections with genotypes 2 and 3 occurred significantly more frequently than in POL population (34.2% vs. 21.1%), and genotype 1 was less frequent (48.2% vs. 69.4%). Patients regardless of nationality received similar types of therapy, with glecaprevir/pibrentasvir being the most common. The proportions of patients who completed therapy according to plan were similar, but significantly more often UKR patients did not report for a visit assessing the effectiveness and were considered lost to follow-up. As a result, the sustained virologic response (SVR) rate among Ukrainians was significantly lower in the intent-to-treat analysis, but the SVR calculated per protocol exceeded 97% and were similar in both study populations.
Conclusion: Differences in patient characteristics did not affect the effectiveness of the antiviral therapy, which exceeded 97% in both populations, but among Ukrainian patients, there was a higher percentage of people lost to follow-up.

SAT-028

The impact of peers on sustaining hepatitis C elimination in people who inject drugs - a network based model

Chloe Brown[1], Martin Siegele-Brown[2], Mark Wright[3], Stuart Smith[4], Leila Reid[5], Ryan M. Buchanan[1]. *[1]University of Southampton, Southampton, United Kingdom; [2]Sussex University, Brighton & Hove, United Kingdom; [3]University Hospital Southampton, Southampton, United Kingdom; [4]Hepatitis C Trust, London, United Kingdom; [5]Hepatitis C trust, London, United Kingdom*
Email: ryan.buchanan@soton.ac.uk

Background and aims: The United Kingdom (UK) is on target to meet the World Health Organisation (WHO) objective to eliminate Hepatitis C (HCV) by 2030. The elimination programme in the UK has involved a multifaceted and multi-agency approach. Peers have been utilised to support people who inject drugs (PWID) engage with HCV testing and treatment services. There is however uncertainty concerning the role for peers after HCV elimination is achieved.
Method: We used a validated dynamic network-based model connecting PWID. 100 simulations were conducted in 100 network structural iterations matching properties of UK-net (a validated network structure). At baseline HCV prevalence matched the WHO defined elimination threshold for Southampton (UK) - a large city in the South of England with an estimated 689 people actively injecting drugs. HCV transmission, testing rates and treatment engagement parameters matched real-world (Southampton, UK) and published empirical data. At monthly intervals HCV was transmitted within the

network and a fixed proportion of the nodes in the network underwent testing. A proportion of tested nodes were then treated with directly acting antiviral therapy. As per published empirical data the likelihood of a positive node achieving sustained virological response was higher with peer support. The primary outcome was prevalence of HCV 5 years after the HCV elimination was achieved with and without peers to support treatment engagement.
Results: 5 years post the elimination target being met, without peer support the prevalence increased from 11.68% to 15.75% (95% CI is 15.7–15.8). With peer support the prevalence of HCV in the network continued to decline from 11.68% to 9.11% (95% CI is 15.32 to 5.10%). In the network simulation without peer support, 94 (95% CI 93.3–94.0) tests were needed to maintain the prevalence of HCV at the elimination threshold. In the network simulation with peer support, 47 (95% CI 31.8 to 88.8)) tests per month were needed.
Conclusion: Without continued peer support the elimination of HCV in networks connecting PWID will be more difficult to sustain. Further research is needed to assess cost-effectiveness and the additional impact of peer support on engagement with HCV testing and harm reduction services.

SAT-029
Hepatitis C incidence in Pakistan – large scale test and recall analysis shows that infection rates can be reduced by pro-active 'find and treat' programs
Saad Niaz[1], Saeed Sadiq Hamid[2], Asad Chaudhry[3], Naheed Choudhry[4], Graham R Foster[5], HepFreePak Consortium[4], Huma Qureshi[6]. *[1]Dow University, Karachi, Pakistan; [2]Aga Khan University, Karachi, Pakistan; [3]Chaudhry Hospital, Gujranwala, Pakistan; [4]QMUL, London, United Kingdom; [5]QMUL, Barts Health, London, United Kingdom; [6]Doctors Plaza, Karachi, Pakistan*
Email: g.r.foster@qmul.ac.uk

Background and aims: Elimination of HCV requires treatment of sufficient intensity to reduce the incidence to very low levels. The prevalence of HCV in Pakistan is the highest in the world (estimated at 6.8%) and treatment programs with sofosbuvir/daclatasvir are being rolled out nationwide in an effort to eliminate the infection. The efficacy of these, predominantly local, programs on preventing new infections is unclear and it is not known whether 'treatment as prevention' strategies are effective in high prevalence settings.
Method: HepFreePak is an observational 25,000 person study of the impact of sofosbuvir/daclatasvir treatment in Pakistan that examines, prevalence, incidence over 12 months in uninfected and successfully treated patients and response to current standard of care (sofosbuvir/daclatasvir for 12 weeks in people with an APRI score of <1.5 or 24 weeks in those with features of cirrhosis). We examined incidence of new infections by re-testing people 12 months after a negative test and we studied re-infection by testing people 12 months after achieving SVR12. We examined three different treatment programs: a 'door-to-door' case finding approach (Malir, Karachi); an urban clinic and community testing events (Karachi) and a community camp based 'test and treat' strategy (Gujranwala).
Results: In a 'door-to-door' test and treat strategy in Malir, Karachi 12,021 people (from 14,523 due to be assessed - 83%) were tested for new infections and 22 (incidence rate = 0.18%) were infected, 530 people post SVR (from 930 treated (57%)) were re-tested and 1 was reinfected (0.18%). In an urban clinic and community testing program in Karachi 2064 people (from 3960–52%) were retested and none had developed a new infection but 3 of 189 (1.6%) people with an SVR (from 540 treated –35%) were reinfected. In Gujranwala in a rural outreach community screening program 21 people of 1986 retested (from a cohort of 3247–64%), were newly infected (incidence of 1.06%) and 8 of 94 people (8.5%) with an SVR (from 305 treated –31%) were reinfected.
Conclusion: Assessment of HCV incidence in high prevalence settings by direct assessment is possible, although recall rates are sub-optimal. High intensity treatment programs with domicile based testing and treatment led to low incidence and re-infection rates but rural opportunistic clinics may be associated with higher rates of infections. Effective elimination programs in high prevalence settings will need strategies that have high rates of testing and treatment in defined geographical areas in order to maintain low levels of infection.

SAT-030-YI
Eliminating hepatitis C in Nouvelle Aquitaine, the largest region of France: the SCANVIR® project
Sandrine Francois[1], Gwennaick Villain[2], Samy Yahiaoui[3], Christine Silvain[2], Brigitte Reiller[3], Veronique Loustaud-Ratti[1], Maryline Debette-Gratien[1]. *[1]University Hospital Center, Limoges, France; [2]University Hospital Center, Poitiers, France; [3]Risk-reduction centers for drug users (CAARUD Planterose), Bordeaux, France*
Email: sandrine.francois@chu-limoges.fr

Background and aims: Achievement of Hepatitis C virus (HCV) elimination means getting closer to at-risk individuals outside conventional care structures. The SCANVIR® project aims to "create the event on dedicated days" to optimize screening efficiency and initiate HCV treatment and patient's return to the care pathway. With three teams based in Limoges, Poitiers and Bordeaux, we visited 43 facilities throughout the Nouvelle Aquitaine region to offer screening and treating days.
Method: Since May 2017 for Limoges team and 2019 for the 2 others, dedicated screening days were organized to bring together in each structure the multidisciplinary staff involving hepatologists/infectiologists, addictologists, nurses and social workers, and the screening tools (HCV, HBV, HIV RDTs, FibroScan®, GeneXpert® Point-of-Care molecular testing for HCV RNA detection). A risk prevention, addiction and psychosocial management were proposed at the same time.
Results: Since May 2017, 222 dedicated days have been scheduled and 1706 patients (sex ratio between 2.5 to 3.7 and median age between 39.8 and 46) in 43 different structures taking care of IVDU, migrants or prisoners. Globally, 19.3% were active injectors, 38.2% had substitution treatment, 59.5% excessive alcohol consumption, and 77.3% smoked. 98.9% of patients accepted FibroScan®.17% were suspected to have advanced fibrosis (FS > 8 kPa) and severe fibrosis (FS > 12 kPa) was very likely in 7.2% of the participants. Among the 234 patients in whom CAP was available with FS, 18% had severe steatosis (CAP > 300 dB/m). Depending on structures, RDTs were accepted by 77% to 99% of the participants with 1.6% AgHBs+ and 0.3% HIV Ab+. On average, over the region, 23.6% (390 patients) were HCV Ab+; the percentage of replicating patients varied from 22.6% to 54% (162 patients). Between 82 and 85% of patients have started treatment, of which 80% have been cured or still undergoing treatment. Mean of 10% were not treated.
Conclusion: The Scanvir project is an innovative pathway promoting the "Test, Treat and Prevent" strategy to eliminate HCV. Created in 2017 in Limoges, the SCANVIR® concept has been extended to the whole Nouvelle Aquitaine region with two other teams based in Poitiers and Bordeaux. This concept makes diagnostic testing cost-effective for high-risk patients far from healthcare facilities, with an HCV cure rate of up to 85%. In addition to the educational role played by FibroScan® in "catching" patients who refused RDTs, we highlighted the interest of screening for liver fibrosis and steatosis, a consequence of increasingly frequent alcoholic and metabolic disorders in this population. SCANVIR® is an European trademark registered by Limoges University Hospital.

SAT-031-YI

The cost of HCV elimination in Kazakhstan based on the current disease burden

Samantha Hall[1], Alexis Voeller[1], Kulpash Kaliaskarova[2], Kulkayeva Gulnara Utepergenovna[2], Alma Aubakirova[3], Shakhlo Sadirova[4], Homie Razavi[1]. *[1]Center for Disease Analysis Foundation, Lafayette, United States; [2]National Research Oncology Center (NROC), Astana, Kazakhstan; [3]National Research Center for Health Development (NRCHD), Astana, Kazakhstan; [4]Center for Disease Analysis Foundation, Tashkent, Uzbekistan*
Email: shall@cdafound.org

Background and aims: Kazakhstan faces challenges in meeting WHO elimination targets for hepatitis C virus (HCV) by 2030 without scaling up its effort in screening, diagnosis and treatment. This study evaluates the current and future burdens of HCV, estimates the economic impact and provides a roadmap for achieving overall elimination goals.
Method: A comprehensive analysis was conducted using a literature review, consultation with local experts and mathematical modelling to assess the HCV burden and associated costs in Kazakhstan. Two scenarios were modelled: the 2024 base case (status quo in the country) and a WHO elimination scenario (outlining interventions required to achieve designated targets). Cost-effectiveness comparisons were made between a national elimination program and the existing healthcare framework, highlighting the elimination scenario's feasibility.
Results: At of the end of 2024, Kazakhstan is estimated to have 340,140 RNA-positive HCV infections, with 89% of cases concentrated in the 20–69 age group, representing only 58% of the country's total population. To meet WHO elimination targets, the country must annually diagnose 13,000 individuals starting in 2025 incrementally increasing to 73,000 by 2028. They also need to annually treat 3,900 patients beginning in 2025 incrementally increasing to 52,200 by 2028. A national elimination program could reduce HCV prevalence by 51% relative to 2024, preventing 1,700 cases of decompensated cirrhosis, 2,180 hepatocellular carcinoma cases and 1,890 liver-related deaths. Simplified diagnostics, including rapid testing, cost-effective PCR assays, along with decentralized care, having general practitioners treat non-cirrhotic patients, would significantly reduce healthcare costs. Although expanding screening and treatment will increase short-term costs, an elimination program will result in long-term savings by reducing direct costs associated with hospitalization, transplantation and cancer treatment, currently accounting for 55 million USD annually.
Conclusion: Implementing a national elimination program is the only path forward for Kazakhstan to meet WHO targets by 2030. Investment in expanded targeted screening within the young to middle-aged adult cohort could identify over 80% of HCV cases. This along with simplified diagnostics and decentralized care will reduce the HCV burden, prevent liver-related deaths and result in long-term cost savings, ensuring better health outcomes for the country.

SAT-033

Using community partnerships to achieve micro-elimination of HCV and HIV in inner-city Vancouver

Shana Yi[1], Christina Wiesmann[1,2], David Truong[1], Brian Conway[1,2]. *[1]Vancouver Infectious Diseases Centre, Vancouver, Canada; [2]Simon Fraser University, Burnaby, Canada*
Email: shana.yi@vidc.ca

Background and aims: Vancouver's inner city has some of the highest rates of HCV and HIV in Canda. It is therefore crucial to examine the efficacy of approaches being used to eliminate these diseases among this community. We aimed to determine whether the current approach VIDC is using to identifying and treating PWIDs in Vancouver's inner city has led to a reduction in the number individuals viremic for both HCV and HIV.
Method: Since 2022, the Vancouver infectious diseases centre (VIDC) has been hosting weekly or twice-weekly community pop-up clinics, or CPCs, at various locations in Vancouver's inner city. At each event, point-of-care HCV and HIV antibody testing is offered to up to 30 individuals. Individuals testing antibody positive for HCV often have their blood drawn on site and those confirmed to be viremic are followed up with by outreach. Individuals confirmed to be viremic for HCV and/or HIV are engaged in treatment under a multi-disciplinary model of care which includes immediate access to OAT and/or safe supply and treatment within a multidisciplinary program of care to address all medical, social, psychological and addiction-related needs in a comprehensive manner. As part of a partnership with Atira housing society, since 2022 CPCs have regularly been held in the common spaces of Atira buildings with the goal of achieving micro-elimination of HCV, and virologic suppression of HIV, among the individuals living in these spaces.
Results: As a preliminary analysis, we chose to evaluate the prevalence of HCV and unsuppressed HIV in 4 Atira buildings, each of which was visited 6 times in 2022 through 2024. We evaluated both the proportion of individuals viremic for HCV and HIV. We saw a clear reduction in the proportion of individuals who are viremic for HCV (14% in 2022 vs. 4% in 2024; $p = 0.1$). We saw a similar trend in the number of individuals unsuppressed for HIV (3.7% in 2022 vs. 1.5% in 2024); however, due to the small number of people in this sample statistical significance can not be evaluated.
Conclusion: This study has demonstrated while PWID may be a particularly difficult demographic to target for HIV and HCV treatment, with the help of community partnerships and a multidisciplinary approach to care we can achieve HCV and HIV micro-elimination. Our findings show that through the use of community partnerships, continued testing and follow-up, and a multidisciplinary model of care, we are on our way to achieving elimination of HCV, and HIV viremia, among the residents of Vancouver's inner city.

Early diagnosis of HCV in people who inject drugs in the Czech Republic: preliminary results of a pilot project

Soňa Fraňková[1], Nikola Stourac[2], Katerina Hejcmanova[2], Tereza Dianova[2], Ondrej Majek[2], Jan Sperl[1], Barbara Janikova[3], Viktor Mravcik[3]. *[1]Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [2]National Screening Centre, Institute of Health Information and Statistics, Brno, Czech Republic; [3]Společnost podané ruce, Brno, Czech Republic*
Email: sona.frankova@ikem.cz

Background and aims: The Czech Republic is a country with a low HCV prevalence (0.5%); nevertheless, people who inject drugs (PWID) represent an important HCV reservoir. Despite regular screening in addiction services and low-threshold centres, only a small number of patients start antiviral treatment and achieve sustained virological response (SVR). The Programme of Early Diagnosis of HCV in PWID, organised by the National Screening Centre of the Institute of Health Information and Statistics of the Czech Republic, aims to describe the HCV cascade of care among PWID, identify gaps, and explore barriers to HCV care.
Method: A single-arm prospective pilot multicentre study of adult former, recent and current PWID has been conducted in 25 low-threshold centres and street work facilities lasting from 12/2023 to 12/2025, performing anti-HCV screening by capillary blood or saliva tests in a targeted number of 3,000 PWID, terminating according to which occurs first. Patients screened positive for HCV are linked to antiviral (DAA) treatment at 13 dedicated healthcare facilities (HCF) providing direct-acting antiviral therapy. The study's primary endpoints are to assess anti-HCV prevalence in PWID and linkage to HCV treatment centres; secondary endpoints include DAA initiation and completion of therapy.

Results: During the first 11 months of the project (12/2023–10/2024), 1,581 individuals were recruited, 1,019 (64.5%) males and 561 (35.5%) females, 42.9% of the individuals belonging to the 30–39 year-old age group. The prevalence of anti-HCV positivity at screening was 31.4% (496 individuals); 149 (30.0%) individuals reported anti-HCV treatment in the past. Forty anti-HCV individuals had negative HCV RNA point-of-care test, 419 individuals were subsequently referred to HCF, and 33 people refused further evaluation. Only 164/419 (39.1%) individuals underwent an HCV assessment in an HCF. 112 (68.3%) patients had positive HCV RNA results, and 96 (85.7%) initiated anti-HCV treatment. The prevalence of cirrhosis (liver stiffness measurement ≥12.5 kPa) was 10.6%, and the most prevalent genotype was genotype 3 (39 individuals, 34.8%). So far, 40 patients have completed antiviral therapy, and 15 of them have achieved an SVR.
Conclusion: The study shows that the unsatisfactory referral from addiction services to anti-HCV treatment centres represents the main gap in the cascade of care in PWID living with HCV. The establishment of PWID-friendly treatment centres and assistance to HCF visits by social and peer workers could enhance linkage to care. The pilot project is funded by Operational Program Employment Plus (Ministry of Labour and Social Affairs of the Czech Republic) and co-funded by the EU.

SAT-035

Results of the national program for the elimination of viral hepatitis in Uzbekistan

Shakhlo Sadirova[1], Rano Kasimova[2], Umad Ismailov[3], Erkin Musabaev[2], Laziz Tuychiev[2], Rafael Ibragimov[4], Homie Razavi[5]. *[1]Research institute of virology, Center for Disease Analysis Foundation, Tashkent, Uzbekistan; [2]Research institute of virology, Tashkent, Uzbekistan; [3]Research Institute of Virology, Tashkent, Uzbekistan; [4]Sanitary-Epidemiological Welfare and Public Health Committee under the Ministry health of the Republic of Uzbekistan, Tashkent, Uzbekistan; [5]Center for Disease Analysis Foundation, Lafayette, United States*
Email: ssadirova@cdafound.org

Background and aims: In 2022, Uzbekistan implemented the National Program for the Elimination of Viral Hepatitis B and C. The program's primary objectives are to annually screen the population for hepatitis B and C viruses and provide antiviral treatment for individuals infected with hepatitis C virus (HCV).
Method: Testing was conducted using rapid tests in primary healthcare facilities, with subsequent confirmation of positive results by enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) in regional hepatology centers. HBV-positive patients were provided with a complimentary quantitative HBsAg analysis, while patients were charged for the quantitative PCR test. Residents with a positive anti-HCV antibody were offered a complimentary qualitative PCR test. Individuals with a positive PCR test were provided with antiviral therapy (Sofosbuvir + Daclatasvir) for 12 weeks without cirrhosis and 24 weeks with cirrhosis, manufactured in the Arab Republic of Egypt. All data pertaining to the examined residents were entered into the Redcap electronic database.
Results: From January 1, 2024 to November 20, 2024, 1,100,278 individuals underwent testing for HBV and 1,100,118 for HCV. Of these, 34,186 (3.1%) were HBsAg positive and 41,869 (3.8%) were anti-HCV positive. A quantitative confirmatory test for HBsAg was performed on 5,572 (16.3%) of those who tested positive for HBsAg which were provided with anti-viral treatment if met the national treatment guidelines. HBeAg positivity rate was less than 5%. PCR testing was conducted for 25,747 people (61.5%) of those who were anti-HCV positive. On average, 1,488 patients with HCV are identified every month, according to Redcap database. A positive result for HCV RNA was detected in 17,934 people (69.7%) of those who underwent PCR testing. A total of 19,300 HCV patients were treated during this period.
Conclusion: According to the study, the prevalence of HBV in Uzbekistan was 3.1%, while the prevalence of HCV was 3.8%. The lower prevalence of HBV compared to HCV could be attributed to the introduction of HBV vaccination in Uzbekistan in 2000. The low rates of confirmatory quantitative HBsAg were primarily due to the fact that these tests were financially supported by the state. In the case of HCV, the rate of PCR diagnostics and antiviral therapy (61.5% and 69.7%, respectively) underscored the necessity for enhanced awareness regarding the complications of viral hepatitis among both the general population and primary care professionals.

Email: zobair.younossi@cldq.org

Background and aims: There is limited guidance regarding hepatitis C virus (HCV) treatment in pregnancy but emerging data suggests direct acting antiviral (DAA) therapy for these patients is safe and effective. We performed a global survey among gastro-hepatologists (GI-hep), infectious disease (ID) specialists, obstetricians (ob-gyn), and primary care physicians (PCPs) to explore current perspectives on HCV treatment in pregnancy.
Method: A 39-item survey was designed by members of The Global Liver Council (GLC) through an iterative process including revisions by experts at GLC, American College of Obstetricians and Gynecologists (ACOG), and the Coalition for Global Hepatitis Elimination (CGHE). The survey was distributed electronically starting in 9/2024 through GLC, CGHE, ACOG and institutional

provider networks. Multivariable regression was performed to evaluate predictors of willingness to treat HCV in pregnancy.
Results: To date, 442 surveys have been completed from 49 countries (53% GI-hep, 29% PCPs, 18% Ob-Gyns, 10% ID). 30% of respondents reported that ≥50% of their patients were women of childbearing age. Regarding HCV knowledge, 66% of providers self-assessed as adequate or superior (89% GI-hep, 49% PCPs, 26% Ob-Gyn, $p < 0.01$), and 63% reported being comfortable treating HCV (88% GI-hep, 42% PCP, 21% Ob-Gyn, $p < 0.01$). Majority (80%) reported discussing pregnancy plans with HCV-positive women; 77% screen for pregnancy prior to initiation of DAAs. Only 12% reported treating a pregnant woman with DAAs (8% GI-hep, 13% PCP, 22% Ob-gyn, $p < 0.01$), and 21% would consider treating these patients (14% GI-hep, 24% PCP, 37% Ob-Gyn, $p < 0.01$). The main reasons for not considering DAAs in pregnancy were lack of safety data for DAAs in pregnancy (60% of responders) and adequate guidelines (56%). Majority of Ob-Gyns (57%) would refer to specialty care for HCV treatment during pregnancy. If an individual became pregnant while on DAAs, 29% would continue, 31% would stop, 23% would refer to another specialist, and 13% did not know. Across regions of the world, the highest acceptance of DAA use in pregnancy was in North America (45% vs. <20% in other regions ($p < 0.01$). In multivariate analysis, the only predictor of a greater willingness to treat HCV in pregnancy was having ≥10% of practice that are injection drug use population (adjusted OR (95% CI) = 2.5 (1.5–4.2)) while GI-hep specialty was associated with a lower willingness (OR = 0.4 (0.2–0.7)).
Conclusion: Despite adequate levels of HCV knowledge, few providers have experience with HCV treatment in pregnancy or would consider it. Ob-gyns are more in support of HCV treatment in pregnancy, but less comfortable treating themselves, which can lead to referral to specialists who are reluctant to treat. Further availability of safety evidence and inclusion of specific recommendations in guidelines could increase uptake of DAAs for pregnant individuals.

SAT-037
The clinical characteristics and antiviral treatment status among chronic HBV mono and HDV co-infected patients

Tuvshinjargal Ulziibadrakh[1], Ganbolor Jargalsaikhan[1], Oyungerel Lkhagva-Ochir[1], Zolzaya Doljoo[1], Barkhas Batkhuu[1], Munguntsetseg Batkhuu[1], Khandmaa Narantsetseg[1], Sumiya Byambabaatar[1], Bekhbold Dashtseren[1], Purevjargal Bat-Ulzii[1], Baigal Narantuya[1], Uurtsaikh Baatarsuren[1], Enkhtuvshin Khorolgarav[1], Nomuunaa Bayarbat[1], Byambasuren Ochirsum[1], Enkhnomin Ochirbat[1], Orkhonselenge Davaadamdain[1], Erdenechuluun Sainbayar[1], Sharawdorj Gur[1], Orkhon Gombosuren[1], Regzedmaa Tsognemekh[1], Javzandolgor Nyamsambuu[1], Anujin Batkholboo[1], Badamsuren Mend-Amar[1], Munkhzaya Munkhbaatar[1], Altankhuu Mordorjyn[1], Zulkhuu Genden[1], Dahgwahdorj Yagaanbuyant[1], Andreas Bungert[1], Naranbaatar Dashdorj[1], Naranjargal Dashdorj[1]. [1]*The Liver Center, Ulaanbaatar, Mongolia*
Email: tu@livercenter.mn

Background and aims: The prevalences of Hepatitis B virus (HBV) and Hepatitis D virus (HDV) infection were respectively estimated with 11.1% of the general population, and with more than 60% of HBsAg carriers in Mongolia. Among those co-infected with HBV and HDV, 70–80% of those have a threefold increased risk of developing cirrhosis and liver cancer. In this study, we assessed the rates of chronic infection and liver cirrhosis in individuals with chronic HBV mono-infection and those co-infected with HBV and HDV, as well as their use of antiviral treatment.
Method: This study involved 63 participants with chronic HBV mono-infection and 233 participants with HBV and HDV coinfection, who voluntarily participated in the study named Detect HCC at the Liver Center, Mongolia. The information on blood tests, antiviral drug usage, and Fibroscan, CE-MRI, AFP, and PIVKA II tests were collected from study participants. qHBsAg and qAnti-HCV tests were detected by the chemiluminescence analyzer (HISCL-5000 analyzer, Sysmex, Japan), and HDV infection was assessed using the ELISA test. HBV-DNA level was measured using Genexpert (Cepheid, USA), and RT-PCR quantified HDV RNA.
Results: A total of 296 participants were included in the study, of which 21.2% (n = 63) had mono HBV infection and 78.7% (n = 233) had HBV+HDV co-infection. The mean age was 47 ± 11.2 years and 47.5 ± 9.3 years, respectively. Among those with mono HBV infection, 93.6% (n = 59) had chronic hepatitis (CH) and 6.4% (n = 4) had liver cirrhosis (LC). In the HBV+HDV co-infection group, 55.3% (n = 129) had CH and 44.6% (n = 104) had LC, with 79.8% (n = 83) in Child-Pugh A, 12.5% (n = 13) in Child-Pugh B, and 7.6% (n = 8) in Child-Pugh C. Regarding the NUC status, 66.7% (n = 42) of those with mono HBV infection had indications for antiviral therapy, and 33.3% (n = 21) were on NUC treatment. In contrast, 38.2% (n = 89) of the HBV+HDV co-infection group had indications for NUC therapy, and 61.8% (n = 144) were receiving NUC treatment. Only 0.6% (n = 3) of the co-infected group were on antiviral treatment for HDV, including Peg-Interferon and Bulevirtide. Liver inflammation was significantly higher in the HBV +HDV co-infection group compared to the mono HBV group.
Conclusion: Our study revealed that individuals with HBV+HDV co-infection have a higher rate of LC compared to those with mono HBV infection. Regarding the treatments for HBV and HDV, among those with mono HBV infection, only 33.3% are currently on NUC treatment while only 0.6% of HBV+HDV co-infected participants on antiviral treatments including peg-IFN and BLV. The elevated liver function indicators and the higher incidence of cirrhosis in HBV and HDV-infected individuals emphasize the urgent need for treatment against HDV.

SAT-038
Atherosclerotic cardiovascular disease risk in chronic hepatitis C patients with metabolic dysfunction-associated steatotic liver disease after viral eradication: a multi-center cohort study

Wan-Long Chuang[1], Pei-Chien Tsai[2], Jee-Fu Huang[1], Ming-Lun Yeh[3], Chung-Feng Huang[1], Chiayen Dai[1], Ming-Lung Yu[3]. [1]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan;* [2]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan;* [3]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Kaohsiung Medical University, Center of Excellence for Metabolic Associated Fatty Liver Disease and School of Medicine, College of Medicine, National Sun Yet-sen University, Kaohsiung, Taiwan*
Email: waloch@kmu.edu.tw

Background and aims: Steatotic liver disease (SLD) and cardiometabolic risk factors (CMRF) are not uncommon in chronic hepatitis C (CHC) patients. The risk of atherosclerotic cardiovascular disease (ASCVD) in CHC patients achieving sustained virological response (SVR) is unclear. This study aimed to assess the impact of CMRF grade and items on ASCVD risks among CHC SLD patients after HCV eradication.
Method: We constructed a nationwide multi-center registry cohort in Taiwan. SLD was identified via ultrasonography and hepatic steatosis index (HSI) >36. Metabolic dysfunction-associated steatotic liver disease (MASLD) was defined when SLD with at least one of five CMRFs. Competing risks of death and liver transplant were considered using Gray's cumulative incidence method and Cox sub-distribution hazards.
Results: Among 8,755 CHC patients achieving SVR with SLD, 624 (7.1%) developed ASCVD over a median follow-up of 3.9 years. MASLD patients had a higher ASCVD incidence than those in simple SLD patients (190.2 vs. 84.0 per 10,000 person-years, $P < 0.001$). Adjusted

hazard ratios showed a dose-dependent ASCVD risk increase with higher CMRF grades in MASLD (aHR: 1.72 for grade 1, P = 0.013, 1.78 for grade 2, P = 0.010, 2.21 for grade 3, P < 0.010, 2.33 for grade ≥4, P < 0.001, respectively). Hypertension (aHR: 1.43, P < 0.001) was the major CMRF increasing ASCVD risk. Subgroup analysis indicated increased ASCVD risk with MASLD, CMRF grades, and CMRF items in non-cirrhotic or normal renal function patients, but not in those with liver cirrhosis or abnormal renal function.
Conclusion: ASCVD risk management is crucial for CHC MASLD patients post SVR, especially in those non-cirrhotic and normal renal function.

SAT-039
Revisiting hepatitis B and delta viral infections in the brazilian Amazon: current epidemiological, clinical and molecular characteristics
Wornei Braga, Michael Berg[1], Mary Rodgers[1], Antonio da Costa[2], Francisco Averhoff[1], Cássia Silveira[2], Esper Kallas[2], Marcia Castilho[3], Yanka Rodrigues[3], Michele Gouvea[2], Leidiane Ribeiro[2], Matheus Thomazella[2], Layla Honorato[2], Tania Mendoza[2], Noely Ferreira[2], Steven Witkin[4], Gavin Cloherty[1], Maria Cassia Mendes-Correa. *[1]Infectious Diseases Research, Abbott Diagnostics, 100 Abbott Park Road, Abbott Park, IL 60064, USA, Chicago, United States; [2]Sao Paulo University Medical School, Sao Paulo, Brazil; [3]Fundação de Medicina Tropical Dr. Heitor Vieira Dourado, Manaus, Brazil; [4]Sao Paulo University Medical School, Department of Obstetrics and Gynecology, Weill Cornell Medicine, Sao Paulo, Brazil*
Email: maria.cassia@hc.fm.usp.br

Background and aims: Updated estimates of the prevalence, clinical and molecular characteristics of hepatitis B (HBV) and delta (HDV) virus infections are crucial to formulate public health strategies aimed at eliminating viral hepatitis as a public health threat by 2030, as proposed by the World Health Organization. The aim of the present study was to analyze current epidemiological, clinical and molecular characteristics of HBV- and HDV- infected individuals in the Brazilian Amazon.
Method: This was a descriptive and prospective study, performed with HBV- infected individuals (HBsAg +) followed at two Viral Hepatitis Referral Units in the state of Amazonas, Brazil, from October 2022 until February 2024. All patients consecutively seen at these two reference units were invited to participate and to respond to a specific questionnaire regarding clinical and epidemiological issues and aspects related to access to medical care. Additional clinical and laboratory information was taken from medical records. Blood samples collected after the interview were evaluated for HBV and HDV serological markers. Commercial kits (Architect i1000TM, Abbott Diagnostics, Brazil and DiaSorin®, Italy) were used to detect HBsAg, anti-HBc, anti-HBs, HBeAg, and anti-HDV. HBV DNA and HDV RNA were also tested by commercial kits (Abbott RealTime HBV Viral Load Assay and Altona Diagnostic RealStar® HDV RT-PCR kit) and subjected to genome sequencing by the Sanger method.
Results: A total of 356 were included in the study, the mean age was 45 years, and most, 51.4% (183), were female. Most, 75.6% (n = 269) tested positive for HBsAg+ without markers for HDV (anti-HDV-). Overall, 275 (77.6%), were HBV DNA positive, and11 (3.2%) were HBeAg positive. Among 275 HBV DNA positives, the HBV genotypes identified were: A1 (12.7%), A 2 (0.9%), D1 (0.9%), D2 (5.5%), D4 (2.7%), F1 (20%), F2 (57.3%). Of the 356 total participants, 87 (24.4%) tested anti-HDV positive, of which 43 (49.4%) were HDV RNA positive. All HDV positive samples tested were genotype 3. When asked about previous care for hepatitis, 162 (45.8%) reported that this was the first time they sought or had access to a health unit dedicated to viral hepatitis care; 65 (29.3%) presented with signs and symptoms of advanced liver disease; 36 (10.7%) reported previous or current HBV treatment; 28 (9.4%) reported they were previously receiving care but have since discontinued. Among 87 anti-HDV positive individuals: 22 (33.5%) presented with signs and symptoms of advanced liver disease.
Conclusion: We confirmed the presence of HDV-3 and the prevalence of HBV genotypes A, D and F in the Brazilian Amazon. Our data also revealed that access to medical care and medication for HBV and HDV infections were limited to a restricted proportion of affected individuals in this area. HBV and HDV elimination by 2030 are probably not a realistic goal given the current medical and logistic approach to detection and treatment.

SAT-040
Identifying people who are HBV positive but undiagnosed: a model-based approach informed by health administrative data
Julien Smith-Roberge[1], Samantha Drover[2], Stanley Wong[3], Andrew Mendlowitz[4], Jordan J. Feld[4], Christina Greenaway[5], Naveed Janjua[3], Beate Sander[6], William W. L. Wong[1]. *[1]School of Pharmacy, University of Waterloo, Kitchener, Canada; [2]ICES, Toronto, Canada; [3]British Columbia Centre for Disease Control, Vancouver, Canada; [4]Toronto Centre for Liver Disease, University Health Network, Toronto, Canada; [5]Jewish General Hospital, Lady Davis Research Institute, McGill University, Montreal, Canada; [6]Toronto General Hospital Research Institute, University Health Network, Toronto, Canada*
Email: wwlwong@uwaterloo.ca

Background and aims: Hepatitis B virus (HBV) infection continues to pose a major public health threat worldwide. The development of effective and tailored strategies to ensure access to HBV care requires an understanding of trends in the geographic and demographic distribution of the disease burden in terms of the number of infections and, more importantly, the number of patients who remain undiagnosed, as the majority of infections remains asymptomatic until the onset of late-stage disease. Such evidence can guide strategic planning and resource allocation of programs to reduce disease transmission, improve screening, and improve treatment uptake. Our objective is to estimate the chronic hepatitis B (CHB) prevalence and undiagnosed proportion in two Canadian provinces, British Columbia (BC), and Ontario, using a back-calculation modeling approach informed by population-level health administrative data.
Method: We first conducted population-based retrospective analyses of health administrative data for the two provinces from 2003 to 2018 to generate the annual incidence of patients with newly diagnosed hepatocellular carcinoma (HCC), decompensated cirrhosis (DC) and CHB as well as patients treated for HBV. We then developed a back-calculation framework to estimate the historical prevalence of CHB. We used a Bayesian Markov Chain Monte Carlo (MCMC) algorithm to back-calculate the historical CHB prevalence and the undiagnosed proportion through a calibration process. The algorithm constructs the probability distribution of the historical CHB prevalence and the undiagnosed proportion by comparing the model-generated predictions of the annual number of CHB health events against observed health administrative data such as the diagnosed HCC and diagnosed DC incidences generated in the retrospective analysis.
Results: Our results indicated a decreasing trend in the undiagnosed CHB proportion and CHB prevalence over time in the two provinces. The mean prevalence estimates for BC, and Ontario in 2018 were 0.834% (95% CI: 0.719%–0.975%), and 0.424% (95% CI: 0.399%–0.460%), respectively. The undiagnosed proportion estimates for BC, and Ontario were 21.8% (95% CI: 17.3% – 26.8%), and 17.3% (95% CI: 15.2%–20.1%) in 2018, respectively.
Conclusion: This is the first study to estimate CHB prevalence and undiagnosed proportion in Canada using provincial health administrative data. Our findings provide evidence to guide decision-making on HBV screening strategies and linkage to care to reach undiagnosed individuals and help meeting the elimination target.

Fazirsiran for alpha-1 antitrypsin deficiency-associated liver disease: long-term efficacy and safety results from a phase 2 extension study

Pavel Strnad[1], Gourab Choudhury[2], William J.H. Griffiths[3], Mattias Mandorfer, Jeffrey H. Teckman[4], Christian Trautwein[1,5], Nirav K. Desai[6], Susana Gonzalez[6], James Hamilton[7], Seth Pixton[6], Thomas Schluep[7], Lisi Wang[6], Anne E. Wyman[6], Yanwei Zhang[6], Rohit Loomba[8]. *[1]University Hospital, RWTH, Aachen University, Aachen, Germany; [2]Royal Infirmary of Edinburgh University Hospital, University of Edinburgh, Edinburgh, United Kingdom; [3]Addenbrooke's Hospital, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; [4]St. Louis University School of Medicine, St Louis, MO, United States; [5]ifADo, Leibniz Research Centre for Working Environment and Human Factors, Dortmund University, Dortmund, Germany; [6]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [7]Arrowhead Pharmaceuticals, Inc., Pasadena, CA, United States; [8]University of California San Diego, San Diego, CA, United States*
Email: pstrnad@ukaachen.de

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disease. The protease inhibitor (Pi)*ZZ genotype causes accumulation of Z-alpha-1 antitrypsin (Z-AAT) in the liver, which may lead to AATD-associated liver disease (AATD-LD). We report data from the long-term extension phase of the phase 2 AROAAT-2002 trial (NCT03946449; primary study: Strnad *et al. NEJM* 2022) that evaluated the efficacy and safety of fazirsiran (an investigational small interfering RNA therapy for AATD-LD) in patients (pts) with AATD-LD.
Method: In the primary study, 16 adults with the Pi*ZZ genotype and liver fibrosis received fazirsiran 200 mg (cohorts 1 [n = 4] and 2 [n = 8]) or 100 mg (cohort 1b [n = 4]) on Day 1 and Week (W) 4 and then every 12 weeks (Q12W) for 24 weeks (cohorts 1/1b) or 48 weeks (cohort 2). Pts who entered the extension phase received fazirsiran 200 mg Q12W for up to 36 months. Efficacy and safety endpoints were assessed.
Results: In total, 15/16 pts who completed the primary study entered the extension phase; mean (standard deviation [SD]) follow-up across both phases was 172 (36) weeks. Mean (SD) total intrahepatic Z-AAT declined from baseline (N = 16; 60 [36] nmol/g) to W24 (n = 8) by 81% (8%), to W48 (n = 7) by 90% (9%), to W72 (n = 3) by 93% (2%) and to W96 (n = 2) by 93% (7%). Mean (SD) serum Z-AAT declined from baseline (255 [55] μg/mL) to W40 (N = 16) by 83% (10%) and to W148 (n = 15) by 88% (5%). Periodic Acid-Schiff staining with diastase globule burden score improved in all pts in the primary and extension phases. METAVIR fibrosis stage improved in 7/15 (47%) pts during the primary study and 3/5 (60%) in the extension phase. Two pts in the primary study and no pts in the extension experienced worsening of fibrosis. Mean (SD) liver stiffness, measured via vibration-controlled transient elastography, declined from baseline (N = 16; 10 [4] kPa) to W24 (n = 8) by 10% (15%), to W48 (n = 7) by 15% (35%), to W72 (n = 7) by 14% (16%) and to W96 (n = 6) by 24% (30%). Mean (SD) Pro-C3 declined from baseline (N = 16; 20 [6] μg/L) to W40 (N = 16) by 14% (25%) and to W148 (n = 15) by 26% (18%). Liver enzymes that normalized during the primary study remained in the normal range through the extension phase. Treatment emergent adverse events (TEAEs) were reported in all pts, most were mild/moderate, and none led to treatment discontinuation; 8 (50%) pts experienced ≥ 1 serious TEAE and none were considered treatment-related. The most common TEAEs were nasopharyngitis (n = 13, 81%) and COVID-19 (n = 10, 63%). Variability in pulmonary function tests was observed, but there was no overall decline throughout the study.
Conclusion: Fazirsiran showed sustained activity and long-term (≤3 years) safety in pts with AATD-LD during the extension phase. Fazirsiran was associated with reductions in liver/serum Z-AAT, improvements in measures of AATD-LD and a long-term safety profile that supports further clinical development in pts with AATD-LD.
Study/writing funding: Takeda Development Center Americas, Inc.

Single-cell sequencing reveals heterogeneity differences in cholangiocyte organoids derived from biliary atresia patients compared to non-biliary atresia controls

Adi Har-Zahav[1,2], Yara Hamody[1,2], Keren Danan[3], Keren Rozen[3], Michael Gurevich[4], Raanan Shamir[1,2], Irit Gat-Viks[3], Orith Waisbourd-Zinman[1,2,5]. *[1]Gastroenterology, Nutrition and Liver Diseases, Schneider Children's Medical Center of Israel, Petach Tikvah, Israel; [2]Felsenstein Medical Research Center, Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel; [3]The Shmunis School of Biomedicine and Cancer Research, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel-Aviv, Israel; [4]The Organ Transplantation Division, Schneider Children's Medical Center, Petach Tikva, Israel; [5]Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, Pennsylvania, Philadelphia, United States*
Email: adi.harzahav@gmail.com

Background and aims: Biliary atresia (BA) is a poorly understood cholangiopathy characterized by progressive extrahepatic bile duct obstruction in newborns, making it the leading cause of pediatric liver transplantation worldwide. Despite extensive research, its etiology and pathogenesis remain elusive. The primary treatment, Kasai portoenterostomy, aims to restore bile flow but yields unsatisfactory outcomes, highlighting the need for deeper insights into disease mechanisms to drive therapeutic development. Human organoids have emerged as powerful in vitro models for studying toxicology, drug discovery, and disease modeling. Here, we utilized BA and non-BA extrahepatic human cholangiocyte organoids (EHCOs) to investigate transcriptional heterogeneity at the single-cell level and uncover novel insights into BA pathophysiology.
Method: EHCOs were generated from extrahepatic bile ducts of BA patients undergoing Kasai portoenterostomy and non-BA controls undergoing liver transplantation for metabolic syndromes. EHCOs from six BA patients and six non-BA controls were dissociated into single cells with >90% viability and processed using the 10x Genomics Chromium platform. Libraries were prepared per manufacturer protocol and sequenced on the Illumina NextSeq 500 platform. Single-cell data were analyzed using 10x Cell Ranger software (v3.01) and mapped to the GRCh38 human genome.
Results: Single-cell analysis revealed eleven distinct cell clusters across BA and non-BA EHCOs. Differentially expressed gene analysis revealed significant transcriptional differences between BA and non-BA EHCOs, consistent with previous findings. BA-derived EHCOs exhibited remarkable heterogeneity, for example, MMP7, previously implicated in BA, was consistently overexpressed in BA EHCOs but showed substantial variability in expression levels across cell clusters, suggesting heterogeneous disease effects. Interestingly, cell clusters enriched for markers of other cell types were identified, despite all EHCOs originating from extrahepatic bile ducts. In non-BA controls, a specific cluster expressed hepatocyte markers, indicating potential cholangiocyte-to-hepatocyte differentiation, a capacity that appeared restricted in BA-derived EHCOs.
Conclusion: BA-derived EHCOs exhibit distinct and heterogeneous transcriptional patterns compared to non-BA controls. This heterogeneity may reflect variability in cellular responses within the diseased bile ducts. Additional analysis and functional studies are carried out in order to understand the relevance of this data to BA etiology. Further studies are needed to define these transcriptional

patterns and uncover their implications for BA pathophysiology, potentially paving the way for targeted therapeutic approaches. Understanding the transcriptional heterogeneity and impaired differentiation capacity of BA-derived EHCOs may inform personalized therapeutic approaches or regenerative strategies targeting bile duct repair.

WED-325

The omega-3 fatty acids, eicosapentaenoic acid and docosahexaenoic acid, improve the response to fibrates in human liver cell models

Audrey-Anne Lavoie[1,2,3], Mélanie Verreault[1,2], Olivier Barbier[1,2,3].
[1]*Axe Endocrinologie-Néphrologie, Centre de recherche du CHU de Québec - Université Laval, Québec, Canada;* [2]*Centre de recherche Nutrition, Santé et Société (NUTRISS), INAF, Université Laval, Québec, Canada;* [3]*Faculté de pharmacie, Université Laval, Québec, Canada*
Email: audrey-anne.lavoie@crchudequebec.ulaval.ca

Background and aims: The accumulation of toxic bile acids (BA) in the liver is a key factor in the development of primary biliary and sclerosing cholangitis (PBC and PSC), two autoimmune liver diseases deprived of any curative options. *Reducing hepatic BA concentration is thus an important pharmacological target for the treatment of PBC and PSC.* Currently, ursodeoxycholic acid (UDCA) and obeticholic acid (OCA) are two of the few drugs approved for the treatment of PBC, while no drugs are available for PSC. However, even if these drugs have many beneficial effects, including the lowering of hepatic BAs, a significant proportion of PBC patients either do not respond to or are intolerant to UDCA and/or OCA. *Therefore, there is still a need for new therapeutic options.* Fibrates, such as fenofibrate and bezafibrate, are currently tested in off-labeled trials. Since we already reported that omega-3 polyunsaturated fatty acids, such as the eicosapentaenoic (EPA) and docosahexaenoic acids (DHA), improve the response to UDCA and OCA, we sought to test the possibility that similar improvement also occurs with fenofibrate and bezafibrate.
Method: Human HepG2 cells were treated for 24H with vehicle (DMSO-ethanol 0.01%/0.01% v/v), 100μM fenofibrate and 100μM bezafibrate, in the presence or absence of EPA/DHA (50:50μM). Afterward, the expression of essential genes related to BA transport, synthesis and detoxification was quantified by qRT-PCR.
Results: In the presence of EPA/DHA, liver cells exhibited a stronger response to fenofibrate and bezafibrate when compared to the drugs alone. Indeed, when used alone, fenofibrate and bezafibrate caused an inhibition of respectively 37% and 34% in the CYP7A1 transcript levels. However, the addition of EPA/DHA led to a stronger reduction of this rate-limiting enzyme in BA synthesis by 58% and 52% with the same dosage of fenofibrate and bezafibrate. Accordingly, the addition of EPA/DHA to fenofibrate ($p < 0.001$) and bezafibrate ($p < 0.01$) caused a 58% and 47% reduction of the CYP27A1 synthesis gene, encoding another essential BA-synthesizing enzyme, while when used alone, the 2 drugs failed to modulate this gene expression. Moreover, the combination EPA/DHA + fenofibrate also reinforced the overexpression of the MRP2 export gene from 1.5 to 29-fold over control. A similar inhibition was also observed for the NTCP transcripts but only with the EPA/DHA + bezafibrate combination.
Conclusion: The addition of EPA/DHA to fibrates seems to be a promising way to reduce hepatic BA concentration. Further analysis is, however, required to validate this hypothesis.

WED-326

A potent tool to study progressive familiar intrahepatic cholestasis: urine – derived human induced – hepatocytes

Benedetta Blarasin[1,2], Serena Buzzi[1,2], Eva Dariol[1,3], Claudio Tiribelli[1], Cristina Bellarosa[1]. [1]*Liver Brain Unit - Italian Liver Foundation, Trieste, Italy;* [2]*Department of Life Sciences, University of Trieste, Trieste, Italy;* [3]*EPIGET Lab, Department of Clinical Sciences and Community Health (DISCCO), University of Milan, Milan, Italy*
Email: benedetta.blarasin@fegato.it

Background and aims: Human induced hepatocytes (hiHeps) derived from human induced pluripotent stem cell (hiPSC) represent a potent tool to study Progressive Familial Intrahepatic Cholestasis (PFIC). Urine is an advantageous source of cells since it can be obtained in a non-invasive way. Proximal tubular epithelial cells (PTEC) have a remarkable ability to be reprogrammed into hiPSC. This study aimed to improve the yield of the process for generating hiHeps from iPSC obtained from PTEC.
Method: 108 urine samples were collected from 6 healthy donors (3 females, 3 males, 6 samples/day for 3 days) added with antibiotics and stored at 4°C for 24 h before being processed after urine strips analysis. In step 1, PTEC were isolated from urine samples, in step 2 reprogrammed into hiPSC, and in step 3 differentiated into hiHeps. Improved step 1 protocol involves the addition of phosphate buffer (final concentration 0,5 M) and the use of 20 uM cells strainers. For step 3, protocol 1 (doi: 10.1016/j.jhep.2019.03.031), protocol 2 (doi: 10.1007/978-1-0716-2557-6_4), protocol 3 (doi: 10.1002/9780470151808.sc01g04s26) and protocol 4 (STEMdiff™Hepatocyte Kit) were compared to study the expression of hepatic genes and the release of albumin.
Results: Yield is critical in step 1 and 3. A higher percentage of urinary cells adhesion was found in male samples (37% ± 30%) compared to female samples (6% ± 10%); moreover, two out of the three female samples failed to give cells. The adhesion percentage for samples with a pH ≥ 7 was significantly higher than samples with a pH <7. Using 20 uM cell strainers to filter squamous cells during preparation and adding phosphate buffer to increase pH, cell yield increased in female samples from 6% ± 10% to 26% ± 20%. PTEC were obtained even from the two female samples from which we had previously been unable to obtain cells, reducing also the standard deviations and obtaining a final yield comparable between the two sexes. Three out of four protocols of step 3 showed albumin release into the medium (35,5 ng/mL; 58 ng/mL; 18 ng/mL) with a similar mRNA behavior. Protocol 3 and 4 showed the higher number of hepatic markers expressed with the higher expression.
Conclusion: Buffering the pH and using cell strainers increased the yield of PTEC. Selecting the most effective hepatocytes differentiation protocol enabled optimization of this long process to maximize its efficiency. Improvements allow this tool to be more applicable for studying PFIC.

WED-327-YI

Rare but not forgotten - comprehensive molecular and histological analysis of the primary yolk sac tumor of the liver and corresponding patient-derived cell line

Darko Castven[1], Diana Becker[2], Jovana Castven[1], Carolin Zimpel[1], Stefanie Heilmann-Heimbach[3], Wilfried Roth[2], Nils Hartmann[2], Beate Straub[2], Hauke Lang[2], Peter R. Galle[2], Jens U. Marquardt[1].
[1]*University Hospital Schleswig-Holstein, Lübeck, Germany;* [2]*University Medical Center Mainz, Mainz, Germany;* [3]*University of Bonn, Bonn, Germany*
Email: castvendarko@gmail.com

Background and aims: Primary yolk sac tumor (YST) of the liver is uncommon disease with less than 15 cases reported worldwide and is often misdiagnosed as HCC. It is a type of germ cell tumor that arises from embryonic tissue left over from fetal development and may be initiated by the occurrence of genetic alterations or oncogenic mutations. Survival can vary widely depending on the stage of the tumor and the effectiveness of therapy. Therefore, in-depth molecular and histological characterization of YST and the development of representative models are essential to better understand and diagnose this disease and to develop patient-specific therapeutic options.
Method: Samples of adjacent liver and core tumor tissue were collected and processed from a 66-year-old female patient. Long-term culture of primary cell line (PCL) was established. Morphological and histological characteristics of the obtained

tissues, xenograft tumors and cell line were analyzed by immunohistochemistry (IHC) and immunofluorescence (IF). Immune cell composition was inferred from RNA-seq data and validated by IHC. Transcriptomic profiling was performed by RNA sequencing followed by time-course, GSEA and IPA analyses. Key oncogenic alterations and potentially actionable mutations were identified by targeted NGS. Dose-response and synergistic effects between classical and targeted therapies were determined.
Results: Tumor tissue showed a solid trabecular growth pattern with the presence of necrosis. The newly derived cell line fully resembled the morphological features of the primary cancer in vitro and in vivo. IF and IHC showed expression of typical YST markers AFP, CK19, which were effectively maintained in xenografts, PCL and spheroids. Transcriptomic profiling revealed activation of embryonic markers, enrichment of T cells and reduction of macrophages and allowed identification of potentially effective therapeutics. In addition, the study revealed previously unknown genomic alterations and the presence of a novel driver mutation. Amplifications on chromosomes 22q12.2, 9q34.11, 8q24.3, previously associated with poorer survival in pancreatic neuroendocrine tumors, were detected, suggesting a potentially more aggressive disease. NGS approaches confirmed that key oncogenic mutation TP53 as well as potentially actionable mutation KDR were present in tumor and were highly conserved in PCL. Specific targeting of detected actionable mutation confirmed superior response and sustained sensitivity to specific inhibition compared to non-mutated control cells.
Conclusion: Here, for the first time, we were able to dissect the liver YST at an unprecedented molecular level and at the same time establish a primary cell line. We identified molecular alterations that could be used to effectively predict patient response to targeted therapy and serve as an effective model for this extremely rare disease.

Integrated multiomic analysis of hepatoblastoma and patient-derived organoids
Darien Yeung[1], Thomas Kluiver[1], Yuyan Lu[1], Stephanie Schubert[1], József Zsiros[1], Ronald de Krijger[1], Weng Chuan Peng[1]. *[1]Princess Maxima Center, Utrecht, Netherlands*
Email: d.b.yeung@prinsesmaximacentrum.nl

Background and aims: Hepatoblastoma (HB) is the most common liver malignancy in children and often involve an N-terminal mutation in β-catenin, inducing unregulated WNT signaling. Currently, there are no targeted therapies. General chemotherapy is often used as a first line approach, followed by surgical resection. This disease is commonly stratified via histology and the two most common subtypes are known as “fetal” (more differentiated) and “embryonal” (stem-cell like). We recently demonstrated through single cell analysis that these two subtypes can be distinguished through the expression of two transcription factors: HNF4A for fetal HB and LEF1 for embryonal HB. The transcriptional profiles of the two subtypes indicate a divergence in WNT signaling. In this study, we investigate the downstream consequences from this divergence in terms of alterations to the (spatial) gene expression that contributes to metabolic programming and modulation of the immune environment.
Method: Biopsy, resection, and patient-derived xenograft tissues and organoid models were analyzed by single cell RNA-seq, ATAC-seq or Visium spatial RNA-seq. The output data were analyzed using Seurat, ScanPy and SquidPy.
Results: In total, we analyzed tissues and organoid models resulting in transcriptional data from over 30 unique cases of HB. This revealed a clear segregation of the two tumor subtypes via the expression of HNF4A and LEF1. These subtypes are often present in the same tumor and exhibit mutually exclusive expression of their respective markers. Building on our previous observations, we will further elucidate the metabolic programming of the fetal subtype, which has higher expression of genes involved in the urea cycle and glycolysis than the embryonal subtype, which favors beta-oxidation and lactic acid metabolism. The difference in metabolism can be advantageous for targeted pharmacological interventions to disrupt the associated enzymes that are preferentially enriched in the embryonal subtype. Beyond metabolic differences, there is a consistent immune suppression in the tumor microenvironment (TME) amongst both subtypes where lymphocytes are staged at the periphery of the TME with minimal propensity for invasion.
Conclusion: In summary, we present an integrated analysis for investigating tumor heterogeneity and TME for a substantial cohort of HB cases. We have identified that divergence in WNT signaling between fetal and embryonal tumor cells correlates with differences in metabolic programming. Finally, both HB subtypes have low numbers of infiltrating lymphocytes in the tumor microenvironment. Our findings in this study will provide insights into future targeted therapies to treat different cases of HB.

WED-333-YI
Recreating Wolman disease in human liver organoids: a new model for pathophisiology and therapeutic exploration
Davide Selvestrel[1], Beatrice Anfuso[1], Caterina Da Rodda[1], Suresh Velnati[1], Luca Fava[2], Giovanni Sorrentino[1,3]. *[1]International Centre for Genetic Engeneering and Biotechnology, Trieste, Italy; [2]University of Trento, Trento, Italy; [3]University of Trieste, Department of Medicine, Surgery and Health Sciences, Trieste, Italy*
Email: davide.selvestrel@icgeb.org

Background and aims: Wolman disease (WD) is a rare genetic disorder inherited in an autosomal recessive pattern, resulting from mutations in the lysosomal acid lipase (LAL) gene. It is characterized by the accumulation of cholesteryl esters and triglycerides within lysosomes, which leads to severe dysfunction of the liver and other organs. At present, there is no cure for this debilitating disease, and available treatments are limited to supportive care. The goal of this project is to create an in vitro model of WD using human liver organoids (HLO) derived from human induced pluripotent stem cells (iPSCs) and test potential treatments for the disease.
Method: To this aim, we implemented a reproducible method to derive multi-cellular human liver 3D.
organoids are composed of hepatocyte-, stellate-, biliary- and Kupffer-like cells. LAL KO iPSCs were obtained by CRISPR-Cas9 technology, differentiated toward a hepatocyte-like state and treated with fatty acids to induce metabolic stress. Single cell RNA sequencing (scRNA-seq) was then used to characterize this model.
Results: scRNA-seq revealed the presence of all the expected cell populations within the HLOs, confirming that the organoid model accurately mirrors the cellular composition of human liver tissue. Furthermore, scRNA-seq analysis identified differential gene expression patterns related to pathways which might be key contributors to disease progression in WD. LAL KO organoids displayed hallmark features of Wolman disease, including the accumulation of lipid droplets, which led to steatosis, as well as activation of inflammatory pathways and fibrotic changes. These phenotypic characteristics were observed in a multi-step, time-dependent manner, closely resembling the progression of the disease in vivo.
Conclusion: This study successfully establishes a robust and reproducible human liver organoid model derived from both WT and LAL KO iPSCs, offering a powerful platform for studying the molecular and cellular underpinnings of Wolman disease. The model recapitulates key disease features, including lipid accumulation, inflammation, and fibrosis, providing valuable insights into the pathophysiology of the disorder.

WED-334

Prognostic factors and regulatory pathways in porto-sinusoidal vascular disorder: a longitudinal cohort and transcriptomic study

Subin Heo[1], Do Kyung Yoon[2], Ho-Su Lee[2], Won-Mook Choi[3].
[1]*Department of Radiology and Research Institute of Radiology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South;* [2]*Department of Biochemistry and Molecular Biology, Brain Korea 21 Project, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South;* [3]*Department of Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South*
Email: dr.choi85@gmail.com

Background and aims: Porto-sinusoidal vascular disorder (PSVD) is a rare liver disease marked by portal hypertension in the absence of cirrhosis. This study explored prognostic factors and regulatory pathways implicated in PSVD progression by integrating clinical data with transcriptomic analyses.
Method: A total of 114 PSVD patients were included, with 78 followed longitudinally for liver-related events. RNA sequencing was conducted on 21 liver samples and compared to six histologically normal controls. Associations between clinical features, such as the liver-to-spleen volume ratio (LSVR) and fibrosis stage, with liver outcomes were evaluated. Transcriptomic profiling, including co-expression networks and cell deconvolution, was performed based on these parameters.
Results: Of the 114 patients, 32 (28.1%) underwent liver transplantation at diagnosis. Fibrosis stage was strongly associated with liver transplantation risk (per 1-stage increase: adjusted OR, 14.88; 95% CI, 3.72–59.58) and correlated with LSVR. Over a median follow-up of 4.9 years, 8 (10.8%) of the longitudinal cohort experienced liver-related events. LSVR was identified as a reliable prognostic indicator, with a threshold of 1.33 predicting liver-related events. Transcriptomic analysis based on LSVR and fibrosis stage revealed distinct gene expression patterns and cellular changes in PSVD, including shifts in liver sinusoidal endothelial cell (LSEC) distribution, an increased hepatic stellate cell population, and upregulation of IL-6 signaling, while immune cell composition remained unchanged across disease progression.
Conclusion: This study highlights LSVR as a novel prognostic marker in PSVD and suggests that IL-6 trans-signaling-induced endotheliopathy in LSECs may drive pro-inflammatory and fibrotic processes during disease progression.

WED-335

Ex vivo application of chemically derived hepatic progenitors for the treatment of maple syrup urine disease (MSUD)

So Young Jeon[1], Elsy Soraya Salas Silva[1], Hyeon Woo Im[2], Myounghoi Kim[1], Ji Hyun Shin[1], Sangsu Bae[2], Dongho Choi[1]. [1]*Hanyang University, Seoul, Korea, Rep. of South;* [2]*Seoul National University, Seoul, Korea, Rep. of South*
Email: jsyoung7845@naver.com

Background and aims: Maple syrup urine disease (MSUD) is a rare metabolic disorder inherited in an autosomal recessive manner. This condition can result in neonatal mortality as a consequence of the buildup of branched chain amino acids (BCAAs) in the blood. MSUD patients are unable to decompose BCAAs due to dysfunction of branched chain alpha keto acid dehydrogenase complex (BCKDC) caused by mutation in one of BCKDHA, BCKDHB, or DBT gene.
This study aims to approach the development of cell therapy for the fundamental treatment of MSUD.
Method: Due to the low survival rate, we isolated mouse primary hepatocytes (mPHs) from the BCKDHA-/- mouse at postnatal day 7, using the magnetic associated cell separation (MACS) with an E-cadherin antibody. A full length human BCKDHA gene sequence was efficiently inserted in the established BCKDHA-/- mCdHs using advanced gene editing technologies, including twin prime editing (twin PE) and integrase.
Results: We observed significantly increased BCAA concentrations in plasma and decreased BCKDHA expression levels in BCKDHA-/- mice which had a survival rate of less than 11 days after birth. Additionally, we successfully established BCKDHA-/- mCdHs with the capability to differentiate into hepatocytes by treating HGF, A83-01 and CHIR99021. The edited mCdHs developed in this study are anticipated to be suitable for ex-vivo cell therapy applications.
Conclusion: In conclusion, our study indicated the feasibility of ex vivo cell therapy for the treatment of MSUD by utilizing mCdHs, which possess proliferative capabilities distinct from hepatocytes. The gene editing technology utilized in this study allows a stable editing while minimizing off-target efficiency and does not interfere with the types of mutations associated with the disease, suggesting its potential as a clinically applicable gene editing method.
Supported by: This research is funded by National Research Foundation of Korea (NRF) grants funded by the Ministry of Science and ICT (MSIT) of the Korean government (2021M3A9H301539023) and Ministry of Food and Drug Safety (RS-2024-00332401).

Background and aims: Progressive familial intrahepatic cholestasis type I (PFIC1) is a rare congenital hepatopathy caused by mutations in the *ATP8B1* gene that may lead to liver transplantation (LT). Patients, after LT, can develop diarrhea and graft steatosis and fibrosis. The underlying pathophysiology may be due to the disturbance of enterohepatic circulation of bile acids (BA) and interplay with the gut microbiome. Here we aim to study the gut microbiome and enterohepatic circulation of BA in PFIC1 patients pre and post-LT.
Method: The study is a multicenter basic research project integrating clinical course and patient characteristics with multi-omics to study the enterohepatic circulation in pediatric PFIC1 patients pre and post-LT. Shotgun-metagenomic-sequencing is used to profile the gut microbiome. Claudin-3, lipopolysaccharide (LPS) binding-protein (LBP), fibroblast-growth-factor-19 (FGF19) and C4 levels are measured in fasting serum samples. Healthy individuals and biliary atresia patients post-LT are used as controls.
Results: At this stage of interim analysis, 67 sampling time points (27 pre, 40 post-LT) of 46 PFIC1 patients are included. Gut microbiota is altered in PFIC1 patients, even after LT, compared to controls ($p < 0.001$). Abundance of commensial *Faecalibacterium prausnitzii* is reduced and abundance of *Escherichia coli* is increased in PFIC1 patients compared to controls (all $p < 0.001$). This is corroborated by differential abundance analysis. Here, abundance of *Escherichia coli* and *Veillonella parvula* differentiate controls from PFIC1 and PFIC1 subtypes. Microbial metabolic LPS abundance analysis showed increased levels in PFIC1 post-LT. Serum LBP, claudin-3 and FGF19 levels are increased in PFIC1 patients before and after LT compared to healthy controls ($p < 0.001$). C4 serum levels did not differ between groups.
Conclusion: Gut microbial community structure, altered gut barrier homeostasis, bacterial translocation and enterohepatic signaling is disturbed in patients with PFIC1. This is even pronounced after restoration of bile flow after LT. Increased gut leakiness and bacterial translocation might drive hepatic inflammation and fibrotic changes.

WED-337
Matrix metalloproteinase-7 and osteopontin secretion are specifically upregulated in a novel human precision-cut liver slices model of biliary atresia-associated liver fibrosis

Jeske Fridrichs[1], Mark Nomden[1], Sarah Mitchel[2], Jeffrey Sewdihal[2], Alan Gorter[2], Dorenda Oosterhui[2], Marius van den Heuvel[1], Henkjan J. Verkade[1], Vincent de Meijer[1], JBF Hulscher[1], Peter Olinga[2]. *[1]University Medical Center Groningen, Groningen, Netherlands; [2]University of Groningen, Groningen, Netherlands*
Email: p.olinga@rug.nl

Background and aims: Biliary atresia (BA) is a rare cholangiopathy affecting the neonatal bile ducts, leading to significant liver injury early in life. BA is surgically treated with Kasai portoenterostomy (KPE), though liver fibrosis often progresses afterwards. The mechanisms underlying the ongoing fibrosis is incompletely understood, as is the role of matrix metalloproteinase-7 (MMP-7) and osteopontin (OPN) as potential biomarkers. Precision-cut-liver slices (PCLS) provide an *ex vivo* model to study organ function *in vitro* while preserving natural cell-cell and cell-matrix interactions. This study aims to establish a novel model using PCLS to investigate BA-associated liver fibrosis post-KPE and to compare their viability with PCLS from healthy and disease controls.
Method: Precision-Cut Biliary Atresia Liver Slices (PCBALS) were prepared from liver explants obtained during transplantation of BA patients who had undergone prior KPE. PCBALS were cultured and sampled up to 48 h. Viability was evaluated by measuring ATP/protein content and histology (H&E staining). MMP-7 and OPN secretion into the culture medium was quantified via ELISA to examine its association with BA pathology. Additionally, liver explants from healthy and disease control livers were used to prepare Precision-Cut Healthy Liver Slices (PCHLS), Primary Biliary Cholangitis Liver Slices (PCPBCLS), and Primary Sclerosing Cholangitis Liver Slices (PCPSCLS). The ATP/protein content and ELISA results are shown as mean with standard error (SE).
Results: PCBALS were generated from four BA patients, with a mean time of 123 (SE: ± 46.8) days between KPE and transplantation. The mean ATP/protein content of PCBALS was 5.1 ± 1.2 pmol/µg at 24 h and remained constant at 4.9 ± 1.9 pmol/µg at 48 h. The percentage of viable hepatocytes on H&E staining showed variability (mean 29 ± 9%), correlating strongly with ATP/protein content (Pearson r 0.96; $p = .0001$). After 48 h, the mean ATP/protein content of PCBALS was comparable to PCPSCLS (6.0 ± 0.9 pmol/µg; n = 8), PCPBCLS (6.1 ± 0.6 pmol/µg; n = 3) and PCHLS (7.4 ± 1.1 pmol/µg; n = 9). The mean MMP-7 secretion after 48 h was profoundly higher in PCBALS (35.1 ± 5.0 ng/mL; n = 4) compared to PCPSCLS (6.0 ± 2.5 ng/mL; n = 3), PCPBCLS (5.5 ± 1.0 ng/mL; n = 3) and PCHLS (0.5 ± 0.4 ng/mL; n = 2). Similarly, the mean OPN secretion was upregulated in PCBALS (73.7 ± 28.9 ng/mL; n = 4) compared to PCPSCLS (5.9 ± 2.4 ng/mL; n = 3), PCPBCLS (19.5 ± 7.0; n = 3) and PCHLS (2.3 ± 0.4 ng/mL; n = 2).
Conclusion: PCBALS can be cultured for 48 h and secreted markedly higher levels of MMP-7 and OPN compared to healthy and disease controls, aligning with known features of BA-associated liver fibrosis. We conclude that PCBALS provide a promising *ex vivo* platform for investigating the mechanism and possible treatments of BA-associated liver fibrosis.

A promising new treatment for Wilson disease: 64Cu-Methanobactin (ARBM-101) pharmacokinetics examined in animal models by whole-body PET

Julie Loft Nagel[1,2], Ole Lajord Munk[2,3], Aage Kristian Olsen Alstrup[2,3], Mie Ringgaard Dollerup[3], Emilie Munk Lynderup[1,2], Frederik Kirk[1,2], Maja Kanstrup Jørgensen[1,2], Karina Højrup Vase[3], Frank Viborg Mortensen[2,4], Andrea Lund[2,4], Peter Ott[1,2], So-Young Eun[5], Hans Zischka[6], Mikkel Holm Vendelbo[3,7], Thomas Damgaard Sandahl[1,2]. *[1]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark; [2]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark; [3]Department of Nuclear Medicine & PET–Centre, Aarhus University Hospital, Aarhus, Denmark; [4]Department of Surgery, HPB Section, Aarhus University Hospital, Aarhus, Denmark; [5]R&D Center, ArborMed Company Ltd, Seoul, Korea, Rep. of South; [6]Institute of Molecular Toxicology and Pharmacology, Helmholtz Center Munich, Munich, Germany; [7]Department of Biomedicine, Aarhus University, Aarhus, Denmark*
Email: julnag@rm.dk

Background and aims: Wilson disease (WD) is caused by a malfunction in the copper-transporting protein ATP7B, essential for hepatic copper clearance. Methanobactins (MB), copper-chelating peptides, demonstrate potential in removing hepatic copper in WD animal models. The MB biodistribution is largely unknown and therefore, this study investigates the biodistribution and excretion of ^{64}Cu-MB in ATP7B$^{-/-}$ rats and healthy pigs.
Method: The MB, ARBM-101, was pre-bound with ^{64}Cu (^{64}Cu-ARBM-101). ATP7B$^{-/-}$ rats were PET-scanned after i.v. injection of either ^{64}Cu or ^{64}Cu-ARBM-101. Five healthy pigs received i.v. 50 MBq ^{64}Cu and

eight healthy pigs received i.v. 50 MBq ^{64}Cu-ARBM-101, followed by a 90-minute dynamic PET/CT scan. Arterial blood samples were continuously collected. In three of the ^{64}Cu-ARBM-101-injected pigs, flow probes were surgically implanted on the hepatic artery and portal vein and catheters were placed in the portal and liver vein. The hepatic extraction fraction of ^{64}Cu-ARBM-101 was quantified based on blood and flow measurements.
Results: In ATP7B$^{-/-}$ rats, ^{64}Cu accumulated in the liver, while most ^{64}Cu-ARBM-101 was localized in the gut 90 minutes after injection. In the pigs, ^{64}Cu accumulated in the liver reaching 26.6% (± 5.55 SD) of the injected dose (%ID) after 90 minutes. The ^{64}Cu-ARBM-101 PET-scans demonstrated rapid hepatic uptake, peaking at 31.5%ID (± 4.46 SD) within 10 minutes, followed by a 73% reduction (%ID liver, $p < 0.001$). Minimal ^{64}Cu excretion to the gut was observed, while ^{64}Cu-ARBM-101 showed significant excretion, reaching 47.6%ID (± 9.10 SD) at 90 minutes ($p < 0.001$). Furthermore, ^{64}Cu accumulated in the renal parenchyma, while ^{64}Cu-ARBM-101 was excreted to the urinary bladder (%ID renal at 90 minutes, $p < 0.001$). There was no notable accumulation of ^{64}Cu-ARBM-101 in other organs. The hepatic ^{64}Cu-ARBM-101 extraction fraction was ~34% in the three pigs equipped with flow probes.
Conclusion: ^{64}Cu-ARBM-101 is rapidly excreted through the liver and kidneys. Hepatic elimination was observed in ATP7B$^{-/-}$ rats, and ^{64}Cu-ARBM-101 exhibits a faster elimination rate than ^{64}Cu in healthy pigs, demonstrating an ATP7B-independent hepatic elimination. The absence of ^{64}Cu-ARBM-101 accumulation in other organs supports that MB's primary pharmacological action is in the liver, the principal organ affected in WD.

WED-339
Modeling rare genetic cholestasis using human hepatocyte organoids

Katarina Balazova[1], Sarina Shabso[1], Hanxiao Chen[1], Johan van Es[1], Hans Clevers[1,2]. [1]*Hubrecht Institute, Utrecht, Netherlands;* [2]*Roche, Basel, Switzerland*
Email: k.balazova@hubrecht.eu

Background and aims: The liver hepatocytes produce and secrete bile into the bile canaliculi (BC). Disruptions of bile production and secretion lead to accumulation of bile in the hepatocytes, inducing liver damage. Progressive familial intrahepatic cholestasis (PFIC) is a rare disorder caused by mutations in genes essential for maintenance of BC and for hepatocyte function (*ATP8B1, ABCB11, ABCB4, TJP2, NR1H4, MYO5B,* and *PLEC)*. Currently, there are at least seven recognized PFIC subtypes, with the latest subtype identified as recently as 2019. Here, we use state of the art CRISPR base editing techniques in hepatocyte organoid models to emulate mutations found in PFIC patients and establish a biobank. Furthermore, we aim to develop a method to evaluate the severity of cholestasis as well as perform drug screening to develop new PFIC therapies.
Method: We combine human fetal hepatocyte organoids and CRISPR-based genome editing to generate disease models carrying clinically relevant patient-specific amino acid changes. We developed an organoid assay that allows us to assess the structural changes of the BC in the mutants using fluorescent bile analogs. We also assess hepatotoxicity levels and lipid accumulation in the mutants.
Results: We generated a biobank representing seven different mutations representing the different subtypes of PFIC. The mutants show difference in speed of growth and morphology. We are currently investigating phenotypic differences between these mutants, as well as their ability to transport bile acids. We are also able to monitor structural alterations of the canaliculi in organoid models bound between extracellular matrices.
Conclusion: The combination of state of the art CRISPR-based editing techniques and human fetal hepatocyte organoids allows us to rapidly generate human cholestatic models.

WED-340
10 year short-term outcomes of a therapeutic stepwise approach involving low-dose systemic thrombolysis for managing acute portomesenteric thrombosis

Kohilan Gananandan[1], Ahmed Hashim[1], Amine Benmassaoud[1], Aqib Chowdhury[1], Naz Kanani Alviri[1], Satheesh Iype[1], Pratima Chowdary[1], Dominic Yu[1], David Patch[1], Louise China[1]. [1]*Institute for Liver and Digestive Health, Royal Free Hospital, London, United Kingdom*
Email: k.gananandan1@nhs.net

Background and aims: Acute non-malignant portomesenteric thrombosis (PMVT) is associated with high morbidity and mortality in a young patient population. There are no prospective interventional studies assessing therapeutic options outside of standard anticoagulation and supportive care. We report the largest series of patients presenting with this condition who received a stepwise therapeutic protocol, published originally in 2019, it adopts an initial infusion of systemic low-dose tissue plasminogen activator (L-tPa) for 72 hours. Depending on the clinical and radiological response, the treatment is escalated to Transjugular Intrahepatic Portosystemic Shunt (TIPSS) followed by thrombectomy and Catheter-Directed Thrombolysis (CDT) when indicated.
Method: We conducted a retrospective analysis of clinical records of patients with acute PMVT transferred to a tertiary centre (Royal Free Hospital) for stepwise management between 2014–2024.
Results: 106 patients were included; 65 (61%) were males. The mean age was 47years (SD = 15). There was a known thrombophilia diagnosed in 37 patients. 2 had a recent COVID-19 infection and 3 received the ChAdOx1 vaccine. 8 patients had underlying chronic liver disease. All patients had thrombosis of the superior mesenteric vein (SMV) on imaging. Main portal vein thrombosis (PVT) was found in 93 (88%) patients. All patients had persistent abdominal pain despite standard anticoagulation prior to the initiation of L-tPa. The median time to initiation of L-tPa (n = 99) was 12 (IQR = 13) days of symptoms and the median duration of L-tPa infusion was 80 (IQR = 57) hours. TIPSS was inserted in 48 patients (45%) and remained patent at discharge in 41/48 (85%). CDT was undertaken in all TIPSS patients, of whom, 30/48 had the local therapy delivered through EKOS™ endovascular system. Overall, a degree of recanalization was observed in 73 (69%). At discharge 93% were pain free and 85% had intact gut with oral nutrition. 16 patients required small bowel resection (mean length 71 cm [SD = 51 cm]). 1 patient was discharged with a stoma and needed parenteral nutrition. Minor bleeding occurred in 57 patients. One death was recorded (due to bowel ischemia). A major complication was intracranial haemorrhage (n = 4). 65/107 patients were followed up at 3 months, 40/65 (61.5%) had complete symptom resolution – this further improved as length of follow up increased. 4/65 had required further IR intervention and 5 patients had occluded their TIPSS stent (2 asymptomatic).
Conclusion: Our protocol achieved good recanalization and patency rates, and sustained symptom control in the majority of patients. While some patients inevitably required surgical intervention, bowel continuity was eventually achieved in almost all cases. Serious adverse events are a concern. Prospective, randomised studies are required to expand the justification for using this approach in the future.

Bioanalytical Unit, Aarhus University Hospital, Aarhus, Denmark
Email: kastch@rm.dk

Background and aims: Copper (Cu) is toxic when in excess yet is essential for various cellular processes. Patients with Wilson disease are unable to excrete copper into the bile, while those with Menkes disease cannot absorb it. Both conditions can be life-threatening if left untreated. Still, the kinetics of copper transport by living cells remains little studied in dynamic terms, which limits the understanding of copper-related diseases and the development of new treatments. For the first time, we obtained data on cellular copper uptake by using the ligand tracer method.
Method: The Ligand Tracer White (Ridgeview, Uppsala, Sweden) system consists of a beta-emission detector and a tilted rotating platform holding a Petri dish. HepG2 cells were plated 48 h before experiments. The 135-min experiments included nine 15-min additions of increasing amounts of 1 µM copper chloride (Cu(II)Cl) and radioactive 64Cu, maintaining a constant tracer-to-tracee ratio. In 30-sec cycles, the Petri dish alternately immersed cells in the Cu-enriched medium and positioned them under the detector. The intracellular activity of 64Cu was recorded as counts per sec, which, given the constant tracer-to-tracee ratio, reflects the total uptake of Cu. In some experiments, silver nitrate, a specific competitor for the copper transporter, was added to the medium.
Results: As recorded in real-time, we found a linear copper concentration dependent increase in the cells' copper uptake until saturation. The average copper concentration required to achieve half-saturation of uptake (Km) was estimated to be 2.0 µM. This is consistent with the Km for the high-affinity primary copper transporter. The addition of silver markedly reduced the copper uptake.
Conclusion: The ligand tracer assay allowed for the characterization of real-time copper uptake kinetics in living liver cells. The Km value and the inhibition by silver support that our results reflect the activity of the primary copper transporter. This novel method provides new insights into cellular copper dynamics and holds potential for individualized drug-effect screening and treatment assessment.

Email: kay.washington@vumc.org

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disease that may lead to the development of AATD-associated liver disease (AATD-LD). Liver biopsy is the reference standard for assessing AATD-LD. There is a need for advanced artificial intelligence (AI)-driven methods of liver fibrosis quantification that incorporate collagen morphology and zonal distribution of fibrosis. This study aimed to compare second harmonic generation/two-photon excitation (SHG/TPE) and AI-driven qFibrosis analyses to pathologist-reported METAVIR fibrosis stage, non-invasive tests (NITs) of fibrosis and intrahepatic Z-alpha-1 antitrypsin (Z-AAT) burden using data from phase 2 clinical trials of fazirsiran.
Method: Samples from patients with AATD-LD who received fazirsiran/placebo in AROAAT-2001 (NCT03945292)/-2002 (NCT03946449) were included. Unstained liver biopsy samples were utilized for HistoIndex's proprietary SHG/TPE imaging and AI analysis platform (qFibrosis). Correlation of qFibrosis analyses (METAVIR stage, continuous value, zonal distribution) with pathologist-reported METAVIR fibrosis stage, intrahepatic Z-AAT burden assessed by Periodic Acid–Schiff staining with diastase (PAS-D), and other NITs were evaluated by Spearman correlation analysis. Further methodology is described in Strnad *et al*, *NEJM*, 2022 and Clark *et al, Gastroenterology*, 2024.
Results: Overall, 41 patients from the AROAAT-2001 (n = 25)/-2002 (n = 16) trials were analysed. qFibrosis (METAVIR) stage and continuous value showed a positive correlation with pathologist-reported METAVIR fibrosis stage (n = 78 [pre-/post-treatment visits combined]; $\rho = 0.56$ and $\rho = 0.60$, respectively; $p < 0.0001$) and with liver stiffness measurement (LSM) via FibroScan® (n = 70; $\rho = 0.58$ and $\rho = 0.59$, respectively; $p < 0.0001$) or magnetic resonance elastography (MRE; n = 39; $\rho = 0.39$ and $\rho = 0.40$, respectively; $p < 0.05$). Aspartate aminotransferase to platelet ratio index (APRI) significantly correlated with qFibrosis stage and continuous value (n = 73; $\rho = 0.42$ each; $p < 0.001$). Intrahepatic Z-AAT burden, assessed by PAS-D, positively correlated with qFibrosis stage and continuous value (n = 78; $\rho = 0.39$ and $\rho = 0.38$, respectively; $p < 0.001$). Zonal distribution of fibrosis demonstrated that periportal fibrosis specifically correlated with Z-AAT burden.
Conclusion: qFibrosis stage (METAVIR) and continuous value correlated with pathologist-reported METAVIR fibrosis stage, LSM via FibroScan/MRE and APRI, and identified a spatial correlation with distribution of Z-AAT burden. This suggests value in qFibrosis, an AI-driven, fully quantitative measure of fibrosis and its zonal distribution in AATD-LD. Novel digital pathology approaches may support therapeutic development in AATD-LD but require validation in larger cohorts. Study/writing funding: Takeda Development Center Americas, Inc.

WED-343
The metabolism of TH104; a new drug for the treatment of pruritus in primary biliary cholangitis

Nir Barak[1], Sireesh Appajosyula[2], Randy Milby[2]. *[1]Tharimmune Inc, Bridgewater, NJ, United States; [2]Tharimmune Inc, Bridgewater, United States*
Email: nir@tharimmune.com

Background and Aims: TH104 is a buccal nalmefene film developed for the treatment of pruritus in primary biliary cholangitis (PBC). Buccal administration avoids the liver first drug metabolism and therefore may be more suitable for use in patients with liver disease. We herein report, a comparison of nalmefene metabolism, between buccal and intravenous formulations.
Method: This was a single-dose, single-center, open-label, randomized, 2-way crossover study of TH104 with the comparator (nalmefene injection), involving 20 normal healthy volunteers (12 male and 8 female volunteers). After an overnight fast of at least 10 hours in each study period, subjects received a single dose of either TH104 (16 mg) or intravenous dose of nalmefene injection (1 mg) in a crossover design according to the 2-sequence randomization schedule. Adverse events (AEs) and vital signs were monitored throughout the study and for 7 days following the last study dose. Plasma samples were assayed for nalmefene and its metabolites nornalmefene, nalmefene glucuronide, and nalmefene sulfate.
Results: Twenty healthy adult subjects were enrolled in the study and are included in the safety population. A total of 20 subjects were dosed with the Test treatment (1 × TH104 16 mg nalmefene buccal film), and a total of 19 subjects were dosed with the Reference

treatment (1 mg nalmefene intravenous bolus injection). Adverse events profile was similar between the two formulations. Absorption was slower for the buccal formulation compared to IV administration. The median value of Tmax for nalmefene was 2 hours for Th104 compared to 10 minutes for the IV product. Tmax results for the metabolites followed similar trends. The ratio AUCinf of nalmefene glucuronide to nalmefene was about twice as high for the TH104 as for IV administration (average intrasubject ratio 1.97 ± 0.075) indicating that this metabolite was formed at a higher rate. Nalmefene sulfate and nornalmefene pK were significantly ($p < 0.05$) delayed with TH104 compared to the IV; levels were first detected 10 minutes after application (compared to 0 minutes in the IV) and steady state reached at 36 minutes (compared to 10 minutes in the IV).
Conclusion: Both drugs showed early phase 2 metabolism (glucuronidation), but TH104 showed a delayed phase 1 metabolism. As phase 1 metabolism are primarily catalyzed by cytochrome P450 enzymes, whereas phase 2 metabolism is through enzymatic conjugation reactions, this difference in metabolism may represent an advantage for TH104 formulation in patients with liver disease.

WED-344
The alpha-1 Pi*MZ genotype is an independent risk factor for hepatocellular carcinoma development in patients with advanced chronic liver disease

Email: paul.thoene@meduniwien.ac.at

Background and aims: Homozygosity for the SERPINA1 Pi*Z deficiency allele (i.e., the rare Pi*ZZ genotype) is the culprit of alpha-1 antitrypsin deficiency-related liver disease (AATLD), while harbouring a single Z allele (e.g., the common Pi*MZ genotype) is the strongest genetic risk factor for ACLD in steatotic liver disease as well as liver transplantation/death in established ACLD. While Pi*ZZ genotype predisposes to HCC in the general population, the impact of the Pi*MZ genotype on HCC development in patients who have already progressed to ACLD (i.e., those at high risk) has yet to be established. Thus, we investigated the impact of the Pi*MZ genotype on the development of HCC among thoroughly characterized and longitudinally followed ACLD patients.
Method: Patients undergoing hepatic venous pressure gradient (HVPG) measurement and genotyping at the Vienna Hepatic Hemodynamic Lab were included. Patients with HCC at baseline were excluded. Competing risk analyses with HCC as outcome of interest and death/liver transplantation as competing event were performed.
Results: We included 815 patients (mean age 54 ± 11 years; viral hepatitis: 53%, alcohol-related liver disease: 37%, and metabolic-dysfunction associated steatotic liver disease: 10%). Overall, 30 patients (4%) harboured the Pi*MZ genotype. During a median follow-up of 47.3 months, 68 patients developed an HCC (8/30 harbouring the Pi*MZ genotype). The SERPINA1 Pi*MZ genotype was associated with increased risks of HCC development in univariable as well as in multivariable analysis, the latter accounting for other important factors (i.e., age, sex, removal of the primary aetiological factor, AST, serum albumin level, and HVPG) identified by our analysis (adjusted subdistribution hazard ratio [aSHR]: 3.31 [95%CI: 1.26–8.65]; $p = 0.015$). Other common small nucleotide polymorphisms were not associated with HCC development during follow-up. The impact of the Pi*MZ genotype was further confirmed in a multivariable analysis adjusted for the aMAP score (aSHR: 2.94 [95%CI: 1.45–5.97]; $p = 0.003$).
Conclusion: The SERPINA1 Pi*MZ genotype is associated with a more than 3-fold increased risk of HCC development in patients who already progressed to ACLD, independently of other HCC risk factors.

WED-349-YI
Disruption of primary cilia in hepatobiliary development: insights into biliary atresia pathogenesis

Prasanna Ramachandran[1,2], Wolfram Goessling[3]. *[1]Boston Children's Hospital, Boston, United States; [2]Harvard Medical School, Boston, United States; [3]Harvard Medical School, Massachusetts General Hospital, Boston, United States*
Email: rprasan1985@gmail.com

Background and aims: Biliary atresia (BA) is a devastating paediatric liver disease characterized by extrahepatic and subsequently intrahepatic bile duct obstruction, liver fibrosis and eventual liver failure. Despite the severity of BA, its pathogenesis remains elusive. Emerging evidence suggests that defects in primary cilia – specialized cellular organelles crucial for signal transduction in vertebrate cells – may play a pivotal role in BA pathology. Notably, aberrations in cilia-associated signalling pathways, including Hedgehog, Wnt, and Notch, have been observed in biliary epithelial cells (BECs) of BA patients, indicating a ciliary basis for bile duct dysmorphogenesis. Moreover, pathogenic gene variants encoding ciliary proteins have been detected in over 30% of BA patients. A liver-specific knockout of one of the ciliary genes, polycystin-1-Like 1 *(PKD1L1*), recapitulates features of BA in a mouse model. How *PKD1L1* deficiency affects ciliary function and hepatobiliary development is unknown. In this work we investigated the role of primary cilia in hepatobiliary development in a zebrafish model. Zebrafish (*Danio rerio*) share highly conserved mechanisms of liver development with mammals, and their transparent embryos allow dynamic, live time-lapse visualization of hepatobiliary development during critical developmental windows.
Method: Zebrafish embryos were injected with morpholino constructs at the one-cell stage. Live *in vivo* imaging was performed on embryos at 5 days post-fertilization (dpf) using spinning disk confocal microscopy. qRT-PCR assays were performed on 5 dpf dissected livers.
Results: Morpholino-mediated knockdown of *pkd1l1* in zebrafish embryos resulted in profound hepatobiliary abnormalities, including reduced BEC density, malformed biliary networks, and expanded hepatocyte populations, closely mirroring the cholangiopathy observed in human BA. High resolution imaging with a cilia-specific reporter demonstrated disrupted ciliary structure and misorientation in BECs of *pkd1l1*-deficient embryos, directly linking ciliary dysfunction to defective biliary architecture. Further pathway analysis demonstrated aberrant upregulation of Hedgehog (Hh) signaling in *pk1l1*-deficient livers.
Conclusion: Together these findings suggest that loss of ciliary integrity through *pkd1l1* impairment amplifies Hh signaling and disrupts normal biliary tree development. Our study underscores the essential role of primary cilia in hepatobiliary development and offers mechanistic insights into how *PKD1L1* deficiency may drive BA pathogenesis. Ongoing work includes single-cell and spatially resolved transcriptomic analyses of *pkd1l1*-deficient livers to pinpoint gene expression alterations specific to intrahepatic vs extrahepatic biliary structures, advancing our comprehension of ciliary gene regulation in BA.

Missense mutation predominates in moldavian patients with Wilson's disease

Veronica Cumpata[1,2], Adela Turcanu[1,2], Victoria Sacara[3]. [1]*Nicolae Testemitanu State University of Medicine and Pharmacy, Kishinev, Moldova;* [2]*The Clinic of Gastroenterology and Hepatology/HELPA, Kishinev, Moldova;* [3]*Human Molecular Genetics Laboratory, Institute of Mother and Child, Chisinau, Republic of Moldova, Kishinev, Moldova*
Email: veronica.cumpataciorba@gmail.com

Background and aims: Wilson's disease (WD), being widespread across the globe and observed in all races and ethnic groups, is highlighted by the presence of variants specific to certain populations or geographical areas. In the Republic of Moldova, no data on genotypic peculiarities are known. Therefore, we aimed to analyze the genotypic expression of WD within the Moldovan population.
Method: A retrospective and prospective observational cohort study was conducted between 2020 and 2024, involving 53 Moldavian patients with a modified Leipzig score (2019) of ≥4 points. Genetic testing was performed using DNA sequencing by the Sanger method, with the Taq DyeDeoxy Terminator Cycle Sequencing Kit (Applied Biosystems) and an ABI-Prism 3100 genetic analyzer (Applied Biosystems).
Results: Mutations were identified in 46 of the 49 genetically tested patients, while testing was not feasible for 3 individuals at that moment. The mean age at diagnosis was 22.62 ± 9.63 years (range: 5–46 years), with 32.1% of patients diagnosed under the age of 18. Most participants were of Moldovan ethnicity, although other ethnic backgrounds were also represented. None of the patients reported consanguineous relationships or associations with isolated communities. In 60.97% of cases (25 patients), compound heterozygosity was observed. The group exhibited high mutational heterogeneity, with 19 different variants identified: 8 pathogenic, 4 probably pathogenic, and 7 benign. Most mutations were located in exons 3 and 8. Missense mutations were predominant (87.06%), followed by frameshift (7.05%), silent/synonymous mutations (3.53%), and nonsense (2.35%). The most common allele, p.H1069Q, located in exon 14, was found in 53% of alleles. Other notable variants included p.G1341D (14%), p.Met769Hisfs*26 (5%), and several mutations present in < 4% of alleles. A rare mutation, p.Phe764 = , considered probably pathogenic, was detected; in homozygosity or combined with another pathogenic variant, it is associated with WD. Regional analysis revealed distinct genotypic distributions: Northern region - p.A1227 T, p.Asn728Ile, and p.Ala1135GlnfsX13; Central region - p. E541K; Southern region - p.T991 T; Left Bank of the Dniester - p. Val845SerfsTer28 and p.Q544X; Nationwide - p.H1069Q, p.G1341D, and p.Met769Hisfs*26. A family with the paradoxical transmission of pseudodominant inheritance was also identified.
Conclusion: Our research group is characterized by a high genotypic variety with the detection of 19 mutations with different pathogenicity degrees. In 87.06% of patients, the missense mutation predominates. The most frequent pathogenic variant was p.H1069Q, with rare variants p.Phe764 = also being recorded. Regional analysis revealed distinct genotypic distributions.

Correction of the Wilson disease H1069Q point mutation by CRISPR/Cas9-mediated gene editing in induced pluripotent stem cells

Viktoria Iwan[1], Andree Zibert[1], Matthias Weiand[1], Oksana Nadzemova[1], Hartmut Schmidt[2], Phil Robin Tepasse[1], Jonel Trebicka[1], Vanessa Sandfort[1]. [1]*Department of Internal Medicine B, University Clinic of Münster, Münster, Germany;* [2]*Clinic for Gastroenterology, Hepatology and Transplantation Medicine, University Clinic of Essen, Essen, Germany*
Email: vanessa.sandfort@ukmuenster.de

Background and aims: Wilson disease (WD) is characterized by toxic copper (Cu) accumulations, mainly in the liver and central nervous system. With up to 40%, the point mutation H1069Q is the most common mutation of the Cu transporter ATPase7B in western populations. The aim of this study was to assess if a CRISPR/Cas9-mediated gene correction of H1069Q in WD induced pluripotent stem cells (iPSCs) may interfere with their ability to differentiate into hepatocyte-like cells (HLCs) and confer Cu resistance.
Method: In this study, urinary epithelial cells of WD patients, carrying the compound heterozygous mutation H1069Q/N1270S, were reprogrammed into iPSCs using transient transfection methods. For initiation of homology-directed repair, iPSCs were transfected with the plasmid PX459.H1069Q, which carries the H1069Q-specific sgRNA sequence and the sequence for the Cas9 enzyme, plus a set of single-stranded-oligodeoxynucleotides (ssODNs), which serve as repair templates. Single iPSC clones were analysed by Sanger sequencing. Corrected iPSC clones were differentiated into HLCs and analysed for hepatocyte-specific marker genes via real-time RT PCR. The cell viability of ATP7B-corrected and uncorrected HLCs were determined via MTT assays after incubation in toxic Cu concentrations.
Results: 46% of all analysed iPSC clones were successfully corrected after CRISPR/Cas9-mediated repair. The second mutation was not affected. Corrected iPSC clones were differentiated into HLCs. The corrected HLCs showed an upregulation of hepatocyte-specific marker genes (e.g. Albumin, AFP, HNF4α), confirming their hepatic character, as well as an improved resistance to high Cu concentrations.
Conclusion: This study demonstrates that CRISPR/Cas9 engineering is highly efficient in iPSCs and does not affect their ability to differentiate into HLCs. This technology has a remarkable therapeutic potential to correct the ATP7B gene, leading to an improved Cu resistance, thus further contributing to new therapeutic approaches for WD.

Human biliary atresia extra-hepatic cholangiocyte organoids: elevated ER and oxidative stress, altered drug metabolism, and modified cell-to-cell junction

Yara Hamody[1], Adi Har-Zahav[2], Keren Danan[3], Raanan Shamir[2], Irit Gat-Viks[3], Orith Waisbourd-Zinman[2]. [1]*Felsenstein Medical Research Center, Faculty of Medical and Health Sciences, Tel-Aviv University, Tel-Aviv, Israel, Tel-Aviv, Israel;* [2]*Felsenstein Medical Research Center, Faculty of Medical and Health Sciences, Tel-Aviv University, Tel-Aviv, Israel, Gastroenterology, Nutrition and Liver Diseases, Schneider Children's Medical Center of Israel, Petach Tikva, Israel, Petach Tikva, Israel;* [3]*The Shmunis School of Biomedicine and Cancer Research, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel, Tel-Aviv, Israel*
Email: yarahamody@gmail.com

Background and aims: Biliary atresia (BA) is a form of biliary fibrosis typically diagnosed in previously healthy newborns before the age of 3 months, with extrahepatic bile duct obstruction and progressive liver fibrosis. The etiology of the disease is unknown. We previously showed that BA-derived human cholangiocyte organoids (HCOs) display abnormal shape in culture compared to normal controls and thus performed RNA-seq analysis to determine the pathway of injury of extra-hepatic cholangiocytes in BA. Based on RNA sequencing (RNAseq) analysis we aimed to functionally assess the role of Endoplasmic reticulum (ER) stress and unfolded protein response (UPR) response in BA HCOs. In addition, the analysis revealed differences in drug metabolism between BA patients and controls and cell-to-cell adhesion alterations.
Method: we isolated and propagated extrahepatic human cholangiocyte organoids from both biliary atresia (BA) patients and non-BA controls to explore the molecular mechanisms of BA. We performed RNAseq on these organoids to identify critical pathways and gene expression linked to the disease. We performed RT-PCR to verify the results along with immunofluorescence (IF) staining for various

proteins and electron microscopy (EM) to look at the ER. Additionally, we investigated the role of cytochrome P450 enzymes in ER stress by inhibiting cytochrome P450 using HET0016.

Results: RNAseq analysis revealed differences between BA and controls in ER stress, UPR, cell-to-cell adhesion, and drug metabolism. We studied epithelial integrity by IF staining the cholangiocyte organoids to E-cadherin which regulates cell-to-cell adhesion and mobility, Sox17 which has a role in cell polarity, and RhoU which has a role in cell adhesion. Patients with BA had decreased E-cadherin and Sox17 staining of the cholangiocyte organoids and increased RhoU compared to controls. We determined gene expression related to ER stress and unfolded protein response using RT-PCR. BiP which alleviates the cellular stress in the ER had increased in BA patients and PERK which is activated in response to UPR had increased in BA patients compared to controls. We looked at ER morphology using EM and found that BA-derived EHCOs display irregular and dilated ER structures. To look for differences in drug metabolism, we performed RT-PCR for CYP4A isoforms which have been implicated in the modulation of endoplasmic reticulum stress and were highly expressed in BA patients compared to control. To determine if cytochrome activity may influence ER stress, we inhibited CYP4A activity using HET0016, which resulted in a reduced ER stress marker compared to BA patients with non-treated.

Conclusion: Our findings suggest that human organoids from BA patients demonstrate increased ER stress and abnormal polarity and inhibiting cytochrome P450 attenuates ER stress. These results pave the way for further investigation into targeted therapeutic strategies that may facilitate ER stress in BA, potentially altering the disease course.

Email: jaferrusquia@tauli.cat

Background and aims: Sarcopenia is a recognized prognostic factor in cirrhosis, but its role in porto-sinusoidal vascular disorder (PSVD) remains unclear. This study investigates sarcopenia prevalence in patients with PSVD and its impact on prognosis.

Method: We conducted a retrospective, multicenter observational study in three phases. First, using data from two European tertiary care centers, we evaluated the prevalence of sarcopenia in PSVD patients (n = 197; mean age 49 ± 16 years; 57% male) and compared it to that in advanced chronic liver disease (ACLD) patients (n = 720; mean age 55 ± 12 years; 61% male) matched for sex, ascites and Child-Turcotte-Pugh score (CTP) using propensity score matching. Sarcopenia was defined as a transversal psoas muscle thickness (TPMT) of <8 mm/m in females and <12 mm/m in males, measured at the L3 level using cross-sectional imaging. Secondly, we conducted a competing risk regression analysis in a cohort of 606 PSVD patients from 20 VALDIG centers to identify factors associated with the composite endpoint of first/further hepatic decompensation and liver-related death. Finally, in a subset of 126 patients, TPMT was independently measured in a blinded manner by two expert radiologists to assess interobserver variability using the intraclass correlation coefficient (ICC).

Results: The prevalence of sarcopenia in PSVD patients was similar to that in propensity score-matched ACLD patients (18% vs 16%; p = 0.592). The overall VALDIG cohort of patients with PSVD (age 49 ± 16 years, 59% male; CTP score 6 ± 1 pts; 33% decompensated) was followed-up during a median time of 53 (IQR: 21–105) months. Multivariable competing risk regression analysis identified age, history of decompensation, CTP score, creatinine, and sarcopenia as independent predictors of liver-related survival free of first/further hepatic decompensation (adjusted subdistribution hazard ratio [aSHR] for sarcopenia: 1.48 [95%CI, 1.01–2.17], p = 0.045). These results remained consistent after adjustment for the recently proposed PSVD prognostic score (aSHR: 1.53 [95%CI, 1.04–2.24], p = 0.029). Sarcopenia had a more pronounced impact on prognosis

among patients with a history of hepatic decompensation. The reproducibility of TPMT measurements was excellent (ICC: 0.919; p < 0.001) in a subset of 126 patients.
Conclusion: The prevalence of sarcopenia in PSVD mirrors that observed in ACLD when matched for liver dysfunction severity. Sarcopenia independently predicts poor outcomes, highlighting the potential of exercise- and nutrition-based interventions to improve prognosis in PSVD.

Standalone medical therapy versus early endovascular intervention as the first step in the management of patients with primary Budd-Chiari syndrome: a randomized controlled trial
Sagnik Biswas[1], Shekhar Swaroop[1], Shubham Mehta[1], Arnav Aggarwal[1], Sarthak Saxena[1], Samagra Agarwal[1], Deepak Gunjan[1], Shivanand Gamangatti[1], Shalimar Shalimar[1]. [1]*All India Institute of Medical Sciences, New Delhi, New Delhi, India*
Email: drshalimar@gmail.com

Background and aims: There is no randomized clinical trial comparing early endovascular intervention to medical therapy alone as the initial management of Budd-Chiari syndrome (BCS).
Method: Symptomatic patients with primary BCS having either hepatic vein (HV) obstruction [Type II disease] or combined obstruction of HV and inferior vena cava (IVC) [Type III disease] were enrolled. Patients were randomized to receive SMT for 12 weeks or medical therapy with early endovascular intervention guided by vascular anatomy and length of obstruction. The primary outcome measure was complete clinical response at 12 weeks defined as resolution of ascites, normalization of serum bilirubin, prevention of first episode of variceal bleeding or its recurrence and absence of spontaneous bacterial peritonitis.
Results: Of 44 patients randomized, 23 received SMT and 21 received early endovascular intervention. The baseline characteristics of both groups were comparable. In the early intervention group, 12 (52.2%) patients had Type II BCS (6 patients underwent TIPS and 6 underwent HV angioplasty and stenting), while 9 (47.8%) patients had Type III BCS (1 underwent IVC angioplasty alone while 8 underwent TIPS with IVC angioplasty). A significantly higher proportion of patients undergoing early intervention (19 [90.5%, 95%CI: 69.6%–98.8%]) achieved complete clinical response at 12 weeks, compared to those receiving SMT (4 [17.4%, 95%CI:4.9%–38.7%]; p < 0.01). Early endovascular intervention was associated with significant improvement in hepatic congestion (mean reduction in LSM of −16.9 [−24.9 to −8.8]) kPa as compared to the SMT group (−2.0 [−11.8 to 7.8]; p = 0.02) over 12 weeks. Patients in the SMT group had a higher (3, 13%) but statistically insignificant mortality rate than those in the early intervention group (0, p = 0.23).
Conclusion: Early endovascular intervention combined with medical management is associated with higher rates of clinical response and resolution of hepatic congestion compared to standalone medical therapy in symptomatic primary BCS patients. (CTRI/2022/10/046661).

Automated reflex testing for AAT deficiency in liver dysfunction: is it worth it?
Sava Handjiev[1,2], Jennifer Nobes[1,2], Damien Leith[1,2], Paul Brennan[1,2], Christopher Byrne[1,2], John F. Dillon[1,2], Ruairi Lynch[1,2]. [1]*University of Dundee, Dundee, United Kingdom;* [2]*NHS Tayside, Dundee, United Kingdom*
Email: sava.handjiev@nhs.scot

Background and aims: Guidelines recommend an aetiological liver screen for all patients with abnormal liver function tests (LFTs). Patients with low serum alpha-1 antitrypsin (AAT) concentration and specific phenotypes may have a modified risk of developing liver disease (PiMZ) and/or an increased risk of developing fibrosis and liver cancer (PiSZ and PiZZ). The population prevalence of these phenotypes is ~1:30 (MZ), 1:500 (SZ) and 1:2000 (ZZ), however, penetrance is variable. Intelligent LFT [iLFT] is an automated aetiological screen that is performed on patients in primary care with abnormal LFTs (ALT > 30 U/L, ALP > 200 U/L and/or GGT > 73 U/L) in NHS Tayside (NHST). We aimed to: 1) determine the frequency of abnormal phenotypes identified using reflex AAT measurements within the iLFT pathway and compare this to routine clinical care; 2) investigate the impact of reflexing AAT based on suspicion of fibrosis rather than elevated liver enzymes.
Method: All AAT concentration and phenotype results in adult patients (18 or older) between August 2018 and July 2023 were extracted from the NHST laboratory database and grouped by requesting indication (iLFT vs routine clinical care). Phenotyping is automatically added where AAT is <1.0 g/L. Fibrosis-4 indices (FIB-4) from iLFT patients were evaluated using age specific cut-offs: ≥1.3 (18–64) or ≥2.0 (65 and above).
Results: 18,215 AAT tests were performed of which 1,754 were phenotyped: MM, n = 682 AAT median level 1.08 g/L (interquartile range [IQR] 0.97–1.15); MZ, n = 568, 0.83 g/L (0.74–0.91); MS, n = 372, 0.97 g/L (0.91–1.06); SZ, n = 49, 0.55 g/L (0.47–0.68); SS, n = 31, 0.55 g/L (0.78–0.95); ZZ, n = 11, 0.15 g/L (0.10–0.24). 41 rarer deficiency alleles were identified and 30 were not phenotyped due to pre-analytical error. Overall prevalence for phenotypes implicated in liver disease were 3.12% MZ, 0.27% SZ, and 0.06% ZZ. Median ALT (IQR) for each phenotype were 55 U/L (38–79), 57 U/L (40–85), and 66 U/L (41–79), respectively. In the iLFT subgroup (n = 15,141), prevalences were 3.06% MZ, 0.22% SZ, 0.04% ZZ. Prevalences in the routine clinical care group (n = 3,074) were significantly higher at 3.42%, 0.49%, and 0.16%, respectively (Chi-square, p = 0.013). Using elevated FIB-4 as an additional gatekeeper for AAT testing in iLFT would have identified only 17.3% of MZ, 23.5% of SZ and 50.0% of ZZ cases, although with a saving of 11,715 tests (77.4%).
Conclusion: iLFT identifies pathological AAT phenotypes at proportions in keeping with prevalence studies. Whilst still low, the yield of pathology was higher in the routine clinical care group where we would anticipate more targeted assessment. Using elevated FIB-4 as an additional gatekeeper for AAT would reduce overall testing by >75% but miss over 80% of abnormal phenotypes. Healthcare providers need to balance the cost of testing with the clinical utility of diagnosing AAT deficiency when deciding who and how to test.

A 10-year review of obstetric admissions to a quaternary liver intensive care unit: learning from morbidity and mortality
Esme Gardiner[1], Charlotte Sewell[1], Abhishek Chauhan[1], Mansoor Bangash[1], Fiona Thompson[1], Ellen Knox[2], James Ferguson[1], Neil Rajoriya[1]. [1]*Liver Unit, University Hospital Birmingham NHS Foundation Trust, Birmingham, United Kingdom;* [2]*Birmingham Women's and Children's NHS Foundation Trust, Birmingham, United Kingdom*
Email: esme.gardiner@uhb.nhs.uk

Background and aims: Maternal mortality in the UK is at its highest in two decades, with increasing proportions of high-risk obstetric patients. A challenging patient cohort are those with liver pathology, which includes pre-existing liver disease, gestational specific liver disorders and non-pregnancy related new liver pathology. This study aims to review the outcomes of obstetric patients with liver pathology requiring admission to a quaternary care liver centre's intensive care unit (ICU).
Method: A retrospective single centre study of pregnant/post-natal patients identified from the hepatology ICU handover archives (Jan 2014–Dec 2023). Electronic records were reviewed collating demographics, labs and admission outcomes including maternal and foetal mortality.
Results: 42 patients were identified, comprising of 9 (21.4%) patients with pre-existing liver disease, including 2 acute on chronic liver failure (ACLF), 28 (66.7%) pregnancy specific liver pathologies and 5 (11.9%) non-pregnancy related new liver pathologies. 29 patients

were post-partum. The other 13 had a median gestation of 24 weeks (range 8–38 weeks). Pre-existing liver disease included autoimmune hepatitis (AIH) cirrhosis, alcohol related liver disease, Budd Chiari Syndrome (BCS) and various causes of non-cirrhotic portal hypertension. Pregnancy specific liver pathology included hyperemesis gravidarum with ischemic hepatitis, Acute Fatty Liver of Pregnancy (AFLP) and Haemolysis, Elevated Liver enzymes, and Low Platelet count (HELLP syndrome). New onset non-pregnancy specific aetiologies included acute liver failure (ALF) secondary to paracetamol overdose, acute hepatitis B infection, herpes simplex hepatitis and Hemophagocytic lymphohistiocytosis (HLH). Mean duration of critical care admission was 5 days (range 1–60 days). 2 patients received liver transplantation- 1 patient on the ACLF tier for decompensated AIH cirrhosis and 1 on the super urgent list for ALF secondary to hepatitis B with transplantation taking place during pregnancy at 25+5 gestation. 6 (66.7%) patients with pre-existing liver disease presented with a variceal bleed. There were 4 cases of maternal mortality, which were due to HLH, ischaemic hepatitis and 2 patients with ACLF. There were 12 foetal or neonatal deaths, including 2 medical terminations of pregnancy and 1 miscarriage. There were 8 intrauterine deaths, 4 associated with HELLP, 1 due to AFLP and 3 in patients presenting with a variceal bleed. 1 baby died at 8 days old due to HSV infection.

Conclusion: In this cohort of patients, pre-existing liver disease was associated with half of the maternal deaths and a third of foetal deaths, confirming the high-risk nature of these pregnancies. This emphasises the importance of multi-disciplinary care between obstetricians and hepatologists to ensure these patients receive pre-pregnancy counselling and antenatal monitoring.

Email: abaigesa@clinic.cat

Background and aims: Long-term anticoagulation in patients with non-cirrhotic splanchnic vein thrombosis (SVT) is only indicated for those with underlying thrombophilia. However, approximately 25% of patients without such indications experience recurrent thrombosis (RT). Elevated factor VIII (≥150%), D-dimer (≥500 ng/mL), and high mutation risk (HMR) variants detected via next-generation sequencing (NGS) have been proposed as predictors of RT risk. This study aimed to compare the prognostic value of these markers in a cohort of patients with idiopathic or local factor-associated SVT, excluding those with thrombophilia or criteria for long-term anticoagulation.

Method: A multicenter, retrospective, observational study including 123 patients with idiopathic or local factor-associated SVT who underwent factor VIII and NGS testing. D-dimer was measured in 60 patients. The primary endpoint was the occurrence of RT, defined as either splanchnic or extra-splanchnic thrombosis.

Results: During a mean follow-up of 89.3 months (IQR 36–129), 33 patients (27%) experienced 36 venous RT events (24 splanchnic, 12 extra-splanchnic), with a cumulative incidence of 6%, 8%, and 11% at 5, 10, and 20 years, respectively. Factor VIII ≥150% was independently associated with RT risk (HR 4.43, 95% CI 1.12–17.62, p = 0.03). HMR (Log-rank 2.95, p = 0.08) and D-dimer ≥500 (Log-rank 3.76, p = 0.052) showed trends toward significance. Multivariate analysis confirmed factor VIII ≥150% (HR 4.43, 95% CI 1.12–17.62, p = 0.03) and HMR (HR 4.97, 95% CI 1.00–24.75, p = 0.05) as independent predictors of RT. HMR provided additional prognostic value only in patients with factor VIII <150% (RT 8% in NGS-negative patients vs. 17% in NGS-positive patients, p = 0.45). In patients with factor VIII ≥150%, NGS did not enhance risk stratification. These results were reproducible when splicing the cohort according to idiopathic or local factor-associated SVT.

Conclusion: Patients with idiopathic or local factor-associated SVT remain at risk for RT. Factor VIII ≥150% is a reliable marker for identifying high-risk patients. NGS adds prognostic value in cases with factor VIII <150%, while the role of D-dimer is promising but requires further validation in larger cohorts.

Background and aims: Progressive familial intrahepatic cholestasis (PFIC) is a group of rare pediatric cholestatic liver diseases. Our retrospective "NAtural Course and Prognosis of PFIC and Effect of Biliary Diversion" registry allowed us to identify genotype-phenotype relationships for FIC1- and BSEP-deficiency. Recently, however, more PFIC subtypes have been characterized and in addition, ileal bile acid transporter inhibitors (IBATi) are increasingly used for treatment. Therefore, we initiated a prospective analysis of the treatment of PFIC, TreatFIC, in 2023. The objective of TreatFIC is to determine the natural history of all PFIC subtypes and collect real world data on the efficacy and safety of current treatments, including IBATi. Here, we provide the first update on TreatFIC.
Method: This multicenter prospective registry includes genetic and clinical data from individuals with genetically confirmed PFIC subtypes. For each individual demographic and clinical characteristics were collected retrospectively and, after entering TreatFIC, prospectively every 6 months using REDcap.
Results: Upon starting in January 2023, legal procedures with 43 centers worldwide have started, of which 25 centers have full IRB approval and data transfer agreements as of November 2024. The average patient inclusion rate has increased from 2 per quarter to ~10 per quarter since May 2024. As of November 2024, 84 individuals from 13 centers across Europe and Asia have been included. The included individuals encompass different PFIC subtypes, including FIC1- (n = 17), BSEP- (n = 41), MDR3- (n = 15), MYO5B- (n = 2), TJP2- (n = 1), and USP53-deficiency (n = 3) and others (n = 5). Twenty nine individuals are using odevixibat, 4 individuals used odevixibat in the past, 9 individuals are using maralixibat and 42 individuals are not treated with an IBATi. The first analyses will be presented.
Conclusion: TreatFIC is rapidly expanding and provides prospective data on the treatments of individuals with PFIC and its efficacy. The number of included individuals has grown rapidly since its initiation in 2023. TreatFIC will allow to assess real-world data on the current treatments for PFIC diseases. To further increase the impact of the registry, centers that treat children or adults with PFIC are invited to participate (pfic@bkk.umcg.nl).

SAT-325
Quantitative biliary metrics may add to predictive ability of liver stiffness in patients with primary sclerosing cholangitis

Aisha Alawi[1], Leila Amiri[1], Kristel Leung[1], Sarah Finnegan[2], Amy Herlihy[2], Elizabeth Shumbayawonda[2], Tom Davis[2], Bettina E. Hansen[3,4], Gideon M. Hirschfield[1], Kartik Jhaveri[5], Aliya Gulamhusein[1]. *[1]Toronto General Hospital, Toronto, Canada; [2]Perspectum Ltd., Oxford, United Kingdom; [3]University of Toronto, Toronto, Canada; [4]Erasmus University Rotterdam, Rotterdam, Netherlands; [5]University Health Network, Toronto, Canada*
Email: aishaali.alawi@uhn.ca

Background and aims: Primary Sclerosing Cholangitis (PSC) is a rare chronic cholestatic liver disease that can progress to liver failure requiring liver transplant (LT). Quantitative magnetic resonance cholangiopancreatography (qMRCP) uses artificial intelligence (AI) to generate quantitative measurements of the biliary tree from standard MRCP data. We aimed to investigate the individual and combined ability of qMRCP and liver stiffness (LSM) using transient elastography in predicting outcomes in patients with PSC.
Method: Patients with PSC followed at the Toronto Centre for Liver Disease undergoing non-contrast 3D MRCP as part of standard of care were retrospectively included. All patients had a baseline MRCP and at least 2 follow up scans over the follow-up period. LSM was obtained using transient elastography (Fibroscan) and was available for 106 patients. Stepwise time-dependent Cox proportional hazards models were used to estimate the ability of qMRCP and LSM to predict a) death or LT, b) hepatic decompensation or cancer, and c) a composite of a and b. A qMRCP model, LSM model, and combined model were created for each outcome. A qMRCP model for different stages of disease (advanced > LSM 11.1 kPa) was also generated for each outcome. The C-index was used to assess discriminative ability of the individual models.
Results: 140 patients meeting eligibility were included. The mean age at PSC diagnosis was 39 years, 55% (n = 77) were male, 91% (n = 127) had large duct disease, and 74% (n = 103) had IBD. The median follow up time was 14 years (IQR 11–18). Quantitative biliary metrics, such as biliary dilation and/or stricture scores, were significantly associated with death/LT (HR 2.87 [95% CI 1.05–7.87], p = 0.04), hepatic decompensation (HR 26.49 [95% CI 5.39–130.08], p < 0.01), and the composite of death/LT/decompensation (HR 1.71 [95% CI 1.11–2.65], p = 0.01). LSM independently predicted death/LT (HR 1.04 per 1 kPa increase [95% CI 1.03–1.06], p < 0.01), hepatic decompensation (HR 1.06 [95% CI 1.04–1.07], p < 0.01), and the composite death/LT/decompensation (HR 1.05 [95% CI 1.04, 1.07], p < 0.01). LSM showed superior discriminatory ability than qMRCP metrics for death/LT (c-index 0.79 vs. 0.67), hepatic decompensation (c-index 0.81 vs. 0.79), and the composite of death/LT/decompensation (c-index 0.77 vs. 0.76). In the combined model, qMRCP did appear to improve discriminative performance when added to LSM in predicting death/LT (c-index 0.80), hepatic decompensation (c-index 0.89), and the composite of death/LT/decompensation (c-index 0.84). qMRCP performed better in predicting outcome in patients with more advanced disease when predicting death/LT (c-index 0.80 vs. 0.67), decompensation (c-index 0.85 vs. 0.79), and the composite of death/LT/decompensation (c-index 0.80 vs. 0.76).
Conclusion: LSM is a robust predictor of outcome in patients with PSC. Quantitative and objective biliary metrics over time may add additional predictive value in assessing risk of outcome in these patients.

SAT-326
HLA associations with specific anti-nuclear antibody reactivity in people living with primary biliary cholangitis

Aisha Alawi[1], Jinguo Wang[2,3], Shani Nagler[1], Madeline Cameron[1], Claire Gage[1], Ripandeep Kaur[1], Aliya Gulamhusein[1], Gideon M. Hirschfield[1]. *[1]Toronto General Hospital, Toronto, Canada; [2]University of Toronto, Toronto, Canada; [3]University Health Network, Toronto, Canada*
Email: aishaali.alawi@uhn.ca

Background and aims: Primary biliary cholangitis (PBC) is the archetypal autoimmune liver disease. Although anti-mitochondrial antibodies represent the characteristic serologic profile, highly specific anti-nuclear antibody reactivity (e.g. against gp210 and sp100) are pathognomic. Prior genetic studies have confirmed human leukocyte antigen (HLA) associations with disease, and have

identified *DRB1*03:01*, *DRB1*15:01*, *DRB1*01*, and *DPB1*03:01* as being associated with sp100 positive serology. No genetic associations have been reported for gp210 positivity. We sought to replicate associations identified in existing literature between HLA genotype and sp100 and gp210 status in unselected sequential patients with PBC attending the Autoimmune and Rare Liver Disease Programme in Toronto.

Method: 94 subjects (94.7% female, median age 61, 75.5% Caucasian) were sequentially recruited. Blood was drawn and the full HLA panel sequenced via next-generation sequencing (NGS). Serologic profiles were abstracted from chart review (EUROLINE Autoimmune Liver Diseases 9 antigen Immunoblot assay). Patients were identified as sp100 positive (+ve) or negative (–ve), and gp210 +ve or –ve. The hospital deceased donor (DD) transplant cohort (n = 1492) was used as a control. Association analysis using chi square tests was performed. Tests were done to evaluate distribution of *DRB1*03:01*, *DRB1*15:01*, *DRB1*01* and *DPB1*03:01* between sp100 +ve vs. sp100 –ve patients, sp100 +ve vs. the DD control, sp100 –ve vs. the DD control, gp210 +ve vs. gp210 –ve patients, gp210 +ve vs. DD control, and gp210 –ve vs. the DD control. P values were reported as significant if $p < 0.05$.

Results: The chi-square test was significant for *DRB1*03:01* distribution among sp100 +ve vs. sp100 –ve patients ($p = 0.0045$) and sp100 +ve vs. the DD control ($p = 0.0035$). Hence, in our cohort, the *DRB1*03:01* allele was found to be over-represented in sp100 +ve PBC patients (44%, as compared to 15.9% in sp100 –ve and 20.2% among the DD control). For gp210, chi square tests were significant for *DRB1*01* distribution among gp210 +ve vs. –ve patients ($p = 0.0078$) and gp210 –ve vs. the DD control ($p = 0.027$). Therefore, within our cohort, the *DRB1*01* allele was found to be over-represented in gp210 –ve patients as compared to the DD control (29.4% vs 18.6% respectively), and under-represented in gp210 +ve patients (3.5%) as compared to gp210 -ve patients (29.4%).

Conclusion: We replicate the association between *HLA DRB1*03:01* and sp100 positivity, and identify a potential new HLA association for gp210 seropositivity.

SAT-327-YI

Advanced phenotyping of hepatic involvement in AL Amyloidosis: the D-Amy-LIPHE study

Anna Sessa[1], Amira Zaroui[1], Margaux Charles[2], Stefano Caruso[3], Julien Calderaro[2], Shaodian Xu[4], Sébastien Mulé[2], Emmanuel Itti[2], Thibaud Damy[2], Vincent Leroy[2]. *[1]Henri Mondor Hospital, IMRB U955 Inserm, Upec Paris Est University, Créteil cedex, France; [2]Henri Mondor Hospital, Créteil, France; [3]IMRB U955 Inserm-UPEC Paris Est University, Créteil, France; [4]IMRB U955 Inserm- UPEC University, CRETEIL, France*
Email: asessa1990@gmail.com

Background and aims: Light-chain (AL) amyloidosis is a systemic disease caused by monoclonal light chain deposition in various organs, including the liver. Hepatic involvement, though common, is poorly defined, relying on criteria like hepatomegaly (>15 cm) or elevated ALP (>1.5 times the upper limit of normal). While 123I SAP scintigraphy is highly sensitive for detecting amyloid, its limited availability restricts use. Conversely, 99mTc-labeled bisphosphonates are widely available but inconsistently applied. This study aimed to evaluate the prevalence of hepatic dysfunction or amyloidosis, classified patients using clustering, and assessed the prognostic impact of hepatic involvement.

Method: This retrospective study included 200 AL amyloidosis patients with cardiac involvement treated at a French center (2008–2020). Hepatic involvement was defined by MRI/CT-confirmed hepatomegaly or elevated ALP. Liver uptake was evaluated using early-phase (10-minute) 99mTc-HMDP bone scintigraphy, assessed both visually by an experienced nuclear medicine physician and via liver-to-mediastinum (H/M) ratio (>0.7 considered positive). The diagnostic performance of early-phase liver uptake for hepatic amyloid deposits was evaluated using the ROC curve (AUC). Logistic regression identified predictors of hepatic involvement and liver uptake. Unsupervised clustering (Self-Organizing Maps) classified patients in subgroups, and survival analysis assessed mortality differences across clusters.

Results: Hepatic involvement was identified in 71 patients (35%), with liver uptake observed in 38 patients (24%). Among those with hepatic involvement, scintigraphy showed positive liver uptake in 20 patients (35%). Multivariate logistic regression identified platelet count (OR 4.46, $p = 0.04$), gastrointestinal amyloidosis involvement (OR 4.91, $p = 0.002$), and right atrial volume (OR 4.98, $p = 0.009$) as significant predictors of hepatic involvement. For liver uptake, troponin (OR 1.73, $p = 0.04$) and hepatic involvement (OR 2.53, $p = 0.02$) were significant predictors. Clustering analysis identified three subgroups: Group 1 predominated by cardiac involvement and Group 3 characterized by hepatic and renal dysfunction, which had the highest 6-month mortality. Early-phase liver uptake (H/M ratio ≥0.7) demonstrated high diagnostic performance for hepatic amyloid deposition, with 84% sensitivity, 83% specificity, and an AUC of 0.891.

Conclusion: Hepatic abnormalities are prevalent in AL amyloidosis and are associated with both amyloid deposition and cardiac dysfunction. Hepatic involvement correlates strongly with hepatic uptake on scintigraphy. Early-phase scintigraphy emerges as a reliable diagnostic tool for detecting hepatic involvement, offering high sensitivity and specificity. Clustering analysis revealed phenotypic variability with distinct prognoses, providing valuable insights for stratifying patients by risk.

SAT-328

Comparison of disease presentation features, morbidity and mortality rates of screening or index cases in patients with Wilson's disease

Kadir Demir[1], Aslı Çifcibaşı Örmeci[1], Bilger Çavuş[2], Sezen Genç Uluçeçen[1], Zülal İstemihan[1], Kanan Nuriyev[1], Aynure Rustamzade[1], Filiz Akyuz[1], Fatih Beşışık[1], Sabahattin Kaymakoğlu[1]. *[1]Istanbul University, Faculty of Medicine, İstanbul, Türkiye; [2]Istanbul University, Faculty of Medicine, Istanbul, Türkiye*
Email: kadirdmr@yahoo.com

Background and aims: Wilson disease (WD) is a genetic disease transmitted by autosomal recessive inheritance. Due to the wide variety of clinical manifestations, diagnosis is difficult if not suspected. Early diagnosis is important for preventing morbidity and irreversible complications of the disease. Family screening is one of the most important steps in early diagnosis of WD. We aimed to reveal the diagnostic features of screening and index cases in the Wilson disease group.

Method: Diagnostic criteria of patients followed up with a diagnosis of Wilson's disease in a tertiary university hospital were retrospectively evaluated from the outpatient clinic files of the patients.

Results: Of the 336 patients followed up with the diagnosis of WD, 194 (57.7%) were male. The mean age at diagnosis of the entire patient group was 21.7 ± 11.9 years. The type of involvement was hepatic in 53% of the patients, neurological in 16% of the patients, and mixed in 31% of the patients. Of the WD, 69 (21.8%) were screening cases. The consanguineous marriage rate was 42.2% in the entire group, while 42% of screening cases were consanguineous. The age at diagnosis in the screening group was younger than the index cases and was 21.82 ± 11.51 years and 21.66 ± 13.45 years, respectively ($p = 0.048$). In terms of the type of WD involvement, hepatic involvement was more common in screening cases than in index cases, 69.5% vs. 49% ($p = 0.02$). In screening cases, 15.25% had neurological and 15.25% had mixed type involvement. The rate of mixed type involvement in index cases was 35% and was higher than in screening cases ($p < 0.05$). The rate of cirrhosis at the time of diagnosis was 49% vs. 23% in index and screening cases, respectively ($p < 0.05$). The mean Leipzig score was 5.49 ± 1.5 vs. 5.2 ± 1.4 in index and screening cases, respectively ($p < 0.05$). Kayser Fleischer ring was detected in 30.2% of patients in the

screening group, while it was present in 54.8% of index cases (p = 0.05). 24-hour urine copper was 448.34 ± 900.29 µg vs 518.20 ± 635.03 ± µg in the screening and index case groups, respectively (p = 0.81). In the mutation analysis of the ATP7B gene, positivity was detected in 40% of the index cases, while the screening cases had a positivity rate of 45% (p < 0.05). When index cases and screening cases were compared in terms of mortality and need for liver transplantation, mortality and liver transplantation rates were higher in index case patients (p < 0.05).

Conclusion: Mortality and liver transplantation need were found to be lower in Wilson's disease patients detected by family screening compared to index cases.

SAT-333

Quality of life of patients living with vascular LIVEr diseaseS: Results of the LIVES european project

Email: aurelie.plessier@aphp.fr

Background and aims: Vascular liver diseases (VLD) are rare chronic diseases with scarce data on quality of life (QoL). This study aimed to assess QoL in patients with VLD and to identify associated socioeconomic and clinical factors.

Method: A questionnaire was sent to all eligible patients with non-cirrhotic portal vein thrombosis (PVT) or Budd-Chiari syndrome (BCS) from 4 centres in France, Spain and Switzerland in 2024. QoL outcomes included health-related quality of life (HRQoL; EQ-5D-5, from 0 to 1), fatigue (modified fatigue impact 5-items, from 0 to 20) and depression (PHQ-9 > = 10). Linear and logistic regression analyses were used to identify factors associated with QoL measures.

Results: Of the 1168 eligible patients with clinical data, 52% completed the questionnaire and 31% all QoL scales. Of the 363 respondents, 55% were men, 26% had BCS and 74% had PVT. Associated diseases were present in 58% and 26% had myeloproliferative neoplasm. The median age [interquartile range (IQR)] was 53 [43–64] years and the median time since diagnosis was 8.9 [4.9–14.2] years. A severe prognosis was identified in 11% of BCS patients (Rotterdam score class III) and 1% of PVT patients (intestinal resection for mesenteric infarction). Treatments for VLD included anticoagulation (78%), angioplasty or transjugular intrahepatic portosystemic shunt (9%) and liver transplantation (1.4%). Educational level was high in 53%, 15% were unemployed or unable to work, 13% were born outside the European Union (EU), and 12% had severe financial difficulties. Median [IQR] HRQoL and fatigue scores were 0.93 [0.86–0.98] and 8 [5–12] respectively, while 25% of patients experienced depression (32% among those <45 years). QoL outcomes were similar in patients with BCS and those with PVT. In multivariable analysis, being born outside the EU and having severe financial difficulties were associated with poorer HRQoL (adjusted coefficient (aCoeff) [95% confidence interval (CI)]: −0.74 [−1.36; −0.12] and −0.94 [−1.58; −0.31]), increased fatigue (aCoeff [95% CI]: 2.94 [1.10;4.78] and 5.17 [3.38;6.95]) and depression (adjusted odds ratio (aOR) [95% CI]: 2.18 [1.12;4.27] and 5.60 [2.38;13.16]). Associated diseases were linked to worse HRQoL (aCoeff [95% CI]: −0.46 [−0.74; −0.17]) and greater fatigue (aCoeff [95% CI]: 1.64 [0.50; 2.77]). Female gender was associated with more depression (aOR [95% CI]:2.35 [1.37; 4.04]).

Conclusion: HRQoL scores were comparable to those observed in the general population, but a significant proportion of patients reported fatigue and depression, likely due to the high physical and psychological burden of their condition. Socioeconomic factors were more associated with QoL than clinical variables. Implementing tailored therapeutic education programs for the most vulnerable patients is needed to provide psychological support or help them manage fatigue.

SAT-334

Fatigue is common in adults with PBC and PSC: prospective analysis of two cohorts encompassing 1267 patients

Beata Kruk[1], Joanna Raszeja-Wyszomirska[2], Marcin Krawczyk[3,4], Piotr Milkiewicz[2,5]. *[1]Laboratory of Metabolic Liver Diseases, Department of General, Transplant and Liver Surgery, Medical University of Warsaw, Warsaw, Poland; [2]Liver and Internal Medicine Unit, Department of General, Transplant and Liver Surgery, Medical University of Warsaw, Warsaw, Poland; [3]Department of Gastroenterology, Hepatology and Transplant Medicine, Medical Faculty, University of Duisburg-Essen, Essen, Germany; [4]Laboratory of Metabolic Liver Diseases, Department of General, Transplant and Liver Surgery, Centre for Preclinical Research, Medical University of Warsaw, Warsaw, Poland; [5]Translational Medicine Group, Pomeranian Medical University, Szczecin, Poland*
Email: beata.kruk@wum.edu.pl

Background and aims: Fatigue, a common symptom of chronic cholestasis, is often observed in primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC). While its etiology remains unclear, it significantly affects quality of life (QoL) and is frequently associated with pruritus, cognitive symptoms, and emotional burden (Younossi, J Hep 2024). In this study, we compared the severity of fatigue and its correlates in PBC and PSC using data from two large cohorts of Polish patients.

Method: A total number of 1267 adult Polish Caucasian patients with PBC and PSC (514 PBC: age range 23–87, 470 females, 38% cirrhosis; 753 PSC: age range 18–74, 257 females, 20% cirrhosis), were enrolled in the study. All patients were prospectively recruited between 2006 and 2023. Health-related quality of life (HRQoL), including pruritus, was assessed in all patients using the PBC-40 questionnaire. Clinically significant fatigue was defined as a score exceeding 33 points in the fatigue domain.

Results: Fatigue was more prevalent and severe in PBC patients as compared to the ones with PSC. The median fatigue in patients with PBC was 30 (range: 11–54), compared to 23 (range: 11–55) in PSC (p < 0.001). In total, 37% of patients with PBC reported clinically significant fatigue, which was present in 22% of patients with PSC. Females in the PSC cohort reported significantly higher fatigue than males (p < 0.001). We also detected a trend (p = 0.058) for higher fatigue in females in the PBC cohort. Fatigue correlated with ALP and GGTP levels in PSC (p < 0.001 and p = 0.027, respectively) and with cirrhosis in PBC (p = 0.018). Patients with the lowest pruritus also had the lowest fatigue in the PBC and PSC cohorts, indicating a correlation between the two symptoms (p < 0.001 in both cohorts).

Conclusion: Fatigue is common in patients with PBC and PSC. While the etiology of this symptom remains unclear, it significantly affects patient's quality of life and might be associated with pruritus. These

results underscore the need of developing new therapeutic strategies to alleviate fatigue in patients with PBC and PSC.

SAT-335

Genetic variant analysis in low phospholipid-associated cholelithiasis patients of the HiChol registry

Carola Dröge[1], Somayeh Alinaghi Arjas[1], Lisa Knopp[1], Toni Herta[2], Janett Fischer[2], Sabine Lieb[2], Thomas Berg[2], Tom Luedde[3], Denny Schanze[4], Marko Rak[4], Martin Zenker[4], Verena Keitel-Anselmino[1]. *[1]Department of Gastroenterology, Hepatology, and Infectious Diseases, University Hospital, Medical Faculty, Otto von Guericke University Magdeburg, Magdeburg, Germany; [2]Department of Medicine II, Division of Hepatology, Leipzig University Medical Center, Leipzig, Leipzig, Germany; [3]Clinic for Gastroenterology, Hepatology and Infectious Diseases, University Hospital Düsseldorf, Medical Faculty, Heinrich Heine University Düsseldorf, Düsseldorf, Germany; [4]Institute of Human Genetics, University Hospital, Medical Faculty, Otto von Guericke University Magdeburg, Magdeburg, Germany*
Email: carola.droege@med.ovgu.de

Background and aims: Low phospholipid-associated cholelithiasis (LPAC) syndrome is a specific gallstone disease affecting around 1% of adult hospitalized symptomatic gallstone patients. Half of the LPAC patients carry a potentially relevant variant in the ABCB4 gene, encoding the multidrug resistance protein 3 (MDR3), responsible for biliary phospholipid secretion. Reduced phospholipid secretion promotes cholesterol crystallization and recurrent gallstone formation, often persisting after cholecystectomy (CCE). Genetic variants in other genes can contribute to gallstone formation, including ABCB11 encoding the bile salt export pump (BSEP) which maintains a balanced bile composition. Method: Patients fulfilling the clinical LPAC criteria are included in the prospective multicenter HiChol registry, funded by the Federal Ministry of Education and Research (01GM2204A). Approval by the respective local ethics committee and the patients' written informed consent for genetic analysis and clinical data collection was obtained. Genetic variants were determined via panel and whole exome sequencing (WES) and subsequent bioinformatics analysis. Specific questionnaires were used to determine quality of life data and clinical aspects regarding disease onset, symptoms, interventions, medication, lab values, and personal and family medical history.
Results: The HiChol registry data from Magdeburg comprises 20 LPAC patients, 19 (95%) of whom underwent CCE at a median age of 32 years. The gender distribution showed a slight predominance of females (11 patients, 55%) over males (9 patients, 45%). WES results revealed heterozygous potentially pathogenic variants in ABCB4/MDR3 in 6 patients (30%), reinforcing the established genetic basis of the disorder. In around two-thirds of this cohort, no relevant ABCB4/MDR3 variant was detectable. In these cases, variants affecting ATP8B1, ABCB11, NR1H4, MYO5B, ABCC12, and ABCC4, representing genes involved in bile metabolism and transport, were detected. In Leipzig and Düsseldorf, another 15 patients (53% female) with a LPAC phenotype were included in the HiChol registry. At least one potentially relevant ABCB4/MDR3 variant was detected in 40% of these patients. Analyzing WES data sets is currently ongoing for further LPAC patients included in the HiChol registry. Moreover, clinical and quality of life data is assessed for a genotype-phenotype correlation.
Conclusion: LPAC was clinically diagnosed in 35 patients included at three sites of the HiChol registry. Next generation sequencing analysis revealed ABCB4/MDR3 variants underlying about one third of the cases. Suspected pathogenic variants in other cholestasis-related genes may contribute to a LPAC-similar phenotype of recurrent gallstone disease requiring further detailed analysis regarding potential pathomechanisms.

SAT-336

Prevalence and characterization of hepatobiliary involvement in cystic fibrosis patients at a referral hospital

Carla de Sárraga[1], Andrea Peña[1], Mercedes Vergara[1,2], Mireia Miquel[2,3], Meritxell Casas[1,2], Cristina Solé[1,2], José Ferrusquía-Acosta[1,2], Valentí Puig-Diví[1], Alba Lira[1], Javier Pomares[1], Concepción Montón[1], Claudia Torras[1], Isabel Laucirica[1], Judith Cortada[1], Mar Salas[1], Laura Llovet[1], Jordi Sánchez[1,2]. *[1]Parc Taulí Hospital Universitari. Email: cdesarraga@tauli.cat

Background and aims: Cystic fibrosis (CF) is an autosomal recessive genetic disease that affects the CFTR gene and has multi-organ involvement, including hepatobiliary complications. Various definitions have been proposed to assess liver involvement. Koh's classification defined Cystic Fibrosis Liver Disease (CFLD). In 2024, new definitions were published that classify patients into Cystic Fibrosis Hepatobiliary Involvement (CFHBI) if hepatomegaly, hepatic steatosis, elastrography >5.95 kPa, persistenly abnormal blood markers, cholelitiasis or hepatolithiasis; and Advanced CFLD (aCFLD) if nodular liver, elastography >8.7 kPa, cirrohosis with or without portal hypertension or noncirrothic portal hypertension). The aim of this study is to evaluate and characterize the prevalence of hepatobiliary involvement and compare the different definitions.
Method: This is a single-center, retrospective, observational study of a cohort of adult CF patients at our center. Demographic, radiological, analytical data, risk scales (FIB-4, APRI, Forns, Liver Risk Score), and elastography were analyzed to evaluate the prevalence of hepatobiliary involvement.
Results: Thirty-six patients were included, with a mean age of 33 years (53% male). Ninety-two percent had a typical CF mutation (DF508/DF508 or DF508/other). Twenty-three patients (69%) had started treatment with modulators, of whom five (15%) discontinued due to gastrointestinal side effects or hypertransaminasemia. Regarding liver involvement, 22.2% showed persistent analytical abnormalities, predominantly elevated AST and ALP levels. On ultrasound, 11.1% had cholelithiasis, 13.8% showed a homogeneously hyperechoic pattern, and 2.7% had a nodular pattern. The mean elastography value was 4.4 kPa (IQR 1.7 kPa), and the values for FIB-4, APRI, Forns, and Liver Risk Score were 0.52 (IQR 0.71), 0.22 (IQR 0.155), 1.73 (IQR 2.38), and 4.75 (IQR 1.27), respectively. According to the definitions, 8.3% met Koh's criteria, 36.1% met CFHBI criteria, and 5.5% met aCFLD criteria. No statistically significant differences were found in analytical data or elastography between patients with and without CFHBI. However, in patients meeting Koh and aCFLD criteria, significant differences ($p < 0.05$) were observed in elastography (aCFLD 15 kPa [IQR 6.3] vs 4.4 kPa [IQR 1.7]; Koh 8.7 kPa [IQR 7.05] vs 4.4 kPa [IQR 1.62]), APRI (aCFLD 1.94 [IQR 1.54] vs 0.21 [IQR 0.12]; Koh 0.41 [IQR 1.54] vs 0.21 [IQR 0.09]), and LRS (aCFLD 11.5 [IQR 2.02] vs 4.7 [IQR 1.1]; Koh 9.48 [IQR 3.86] vs 4.63 [IQR 1.04]).
Conclusion: The prevalence of CFHBI in our cohort is 36%, similar to that reported in the literature. Koh's and aCFLD classifications identify patients with advanced liver involvement. CFHBI may detect patients with early involvement who could benefit from close monitoring. APRI, LRS, and elastography indices identify advanced liver involvement in CF patients.

SAT-337

Liver disease is highly prevalent in patients with hereditary transthyretin-related amyloidosis

Concetta Pitrone[1], Roberto Filomia[1], Maurilio Barresi[1], Lucio Teresi[2], Paolo Liotta[2], Maria Stella Franzè[1], Gaia Caccamo[1], Massimo Russo[3], Marcella De Luca[3], Anna Mazzeo[3], Irene Cacciola[1], Gianluca Di Bella[2], Carlo Saitta[1]. *[1]Division of Medicine and Hepatology, University Hospital of Messina, Messina, Italy; [2]Division of Cardiology, University Hospital of Messina, Messina, Italy; [3]Division of Neurology, University Hospital of Messina, Messina, Italy*
Email: csaitta@unime.it

Background and aims: Hereditary transthyretin-related amyloidosis [ATTRv amyloidosis (AA)] is a rare and progressive disease characterized by the deposition of transthyretin amyloid in various organs, mostly in the heart (cardiac phenotype) and peripheral nerves (neurological phenotype). However, data on the possible co-presence of liver damage in patients with AA are scant. Aims of the study were to assess prevalence and characteristics of possible liver disease in a cohort of patients with AA.
Method: Consecutive patients with AA, regularly followed up at the Cardiology and Neurology referral centres of the University Hospital of Messina, were enrolled. Demographic, clinical, laboratory, transthoracic echocardiography and electromyography data were collected. All patients were evaluated at the Unit of Medicine and Hepatology by means of liver biochemistry, elastography and ultrasonography. Liver stiffness measurement (LSM) was considered abnormal when stiffness values were above 8 kPa, and ultrasonography was considered altered when signs of chronic liver disease or cirrhosis were present.
Results: Fourty-six patients (37 males, mean age 70.3 ± 11 years) were enrolled. Twenty-five (54.3%) had a cardiac phenotype, 13 (28.3%) neurological manifestations, and 8 (17.4%) a mixed phenotype. Overall, 19/46 (41.3%) patients had alteration of liver biochemistry and/or stiffness and/or ultrasonography. No patient had viral or autoimmune hepatitis, nor alcohol use disorder. Fourteen/46 patients (30.4%) had LSM > 8 kPa, and they were older (median age 76.8 vs 67.7 years, $p = 0.007$), with larger spleen diameter (11 vs 10 cm, $p = 0.02$) and lower platelet count (150×10^9/L vs 212.5×10^9/L, $p < 0.0001$) than patients with lower LSM; no differences in prevalence of diabetes, obesity and dyslipidemia was found among patients with different LSMs. Ten/14 patients with LSM > 8 kPa had cardiac and 4/14 a neurological phenotype, while patients with LSM <8 kPa had cardiac phenotype in 15/32 cases, neurological in 9/32, and mixed in 8/32 (p = n.s.). Overall, liver stiffness was directly correlated with NT-proBNP and troponin I values ($p = 0.003$ and $p = 0.005$, respectively), and inversely related to platelet count and portal vein flow ($p < 0.0001$ and $p = 0.02$, respectively).
Conclusion: Patients with AA have a high prevalence of liver disease and should therefore promptly be referred to liver centres for a careful assessment of possible liver damage. Liver involvement seems independent of the AA phenotype and associated with markers of advanced stages of cardiomyopathy in patients with cardiac phenotype.

SAT-338-YI

The role of metabolic factors in alpha-1 antitrypsin deficiency

Christina Schrader[1], Malin Fromme[1], Paul Ellis[2], Audrey Payancé[3], Mattias Mandorfer, Jan Stolk[4], Bart van Hoek[5], Katrine Thorhauge[6,7], Monica Pons[8,9], Marc Miravitlles[10], Guido Stirnimann[11], Soňa Fraňková[12], Jan Sperl[12], Andreas E. Email: christina.schrader@rwth-aachen.de

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a prevalent rare genetic condition that increases the risk of developing lung emphysema and liver fibrosis. We assessed the relevance of key metabolic factors, i.e. body mass index (BMI) and diabetes, including their impact on the development of liver and lung endpoints.
Method: We collected an international, multi-centric Pi*ZZ cohort of 1,862 individuals from 17 different countries with severe AATD (Pi*ZZ), of whom 929 had a follow-up examination after a minimum of 6 months. At baseline, participants received a thorough liver assessment including clinical evaluations, laboratory tests, and liver stiffness measurement (LSM) via transient elastography (Fibroscan®). Subjects with liver comorbidities and hepatic decompensation before baseline were excluded. Liver endpoints were defined as liver transplantation, liver-related mortality, and first hepatic decompensation. We compared the results with data from 16,715 Pi*MZ and 415,208 non-AATD (Pi*MM) individuals from the population-based UK Biobank.
Results: At baseline, 64 Pi*ZZ participants had diabetes, 614 were overweight (BMI 25.0–29.9 kg/m²), and 295 obese (BMI ≥30 kg/m²). Participants with diabetes had significantly higher liver transaminases compared to those without (21/44% vs. 11/18%). A surrogate of

advanced fibrosis (APRI ≥1.0 units/LSM ≥15.0 kPa) was four to five times more frequent in subjects with diabetes (18/21%, aOR = 3.7/5.0, p < 0.01). Among normal-weight Pi*ZZ individuals, elevated transaminases were rare (9/12%), but more common in overweight (14/23%; aOR 1.7/2.1) and obese individuals (17/29%; aOR 2.2/3.1). APRI ≥1.0 units was more than five times more frequent in obese individuals (8.2%; aOR 5.4, p < 0.001) and almost three times more frequent in overweight individuals (5.3%; aOR 2.5, p = 0.006). During a median follow-up of 4.5 years, 56 Pi*ZZ participants experienced a liver and 55 a lung endpoint. Diabetic and obese Pi*ZZ participants had an increased risk of hepatic endpoints (aHR = 4.1/5.7, p < 0.001), whereas overweight status was associated with a decreased risk for lung endpoints (aHR = 0.3, p = 0.004). In the diabetic Pi*MZ and Pi*MM subcohorts from the UK Biobank, the ORs for elevated liver markers, advanced fibrosis, and hepatic endpoints were smaller than in the diabetic Pi*ZZ subcohort, whereas overweight and obese status conferred similar aHRs in all genotypes. Overweight was associated with a decreased (aHR = 0.6/0.8, p = 0.001) and diabetes with an increased risk (aHR = 2.1/2.3, p < 0.001) for lung endpoints in Pi*MZ and Pi*MM subjects.

Conclusion: Diabetes and obesity are associated with elevated liver surrogate markers and an increased risk of decompensation, independent of genotype. However, the individual impact is most pronounced in Pi*ZZ individuals. These findings will inform daily patient counseling and risk stratification.

SAT-339

Comparison of pyogenic liver abscess of biliary and non-biliary origin

Cheuk Ming Chan[1]. [1]*Pok Oi Hospital, Hong Kong, Hong Kong*
Email: danielchan932003@gmail.com

Background and aims: Biliary pathologies, including common bile duct stone (CBDS), cholecystitis, and recurrent pyogenic cholangitis, are the major identifiable causes of pyogenic liver abscess (PLA) and may be associated with poor prognosis. We conducted this retrospective study to identify the association factors for biliary PLA by comparing their characteristics with non-biliary PLA. We will also review the results of magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound (EUS) performed for certain PLA patients to further investigate biliary pathologies.

Method: The demographics, comorbidities, clinical features, investigation results, management strategies, and outcomes of PLA patients were studied. Univariate and multivariate analyses were conducted to identify the association factors for biliary PLA. Additional biliary findings in follow-up MRCP or EUS would be investigated.

Results: Two hundred seven PLA patients were included. Biliary pathologies were the most commonly identifiable cause (22.7%). CBDS, stricture, or cholangitis were the most frequent biliary etiologies. Transabdominal ultrasound and computed tomography identified more than 90% of biliary pathologies. EUS identified two more cases of CBDS. Two patients without follow-up imaging developed cholangitis later. In univariate analysis, patients with biliary PLA had higher mean age and alkaline phosphatase levels and more incidences of cerebrovascular accident history, Escherichia coli, Enterococcus, or polymicrobial infection, surgical drainage, and recurrence. In multivariate analysis, advanced age (p = 0.004; odds ratio (OR), 1.047; confidence interval (CI), 1.015–1.080), polymicrobial PLA (p = 0.036; OR, 3.681; 95% CI, 1.087–12.469), and recurrent PLA (p = 0.015; OR, 4.534, 95% CI 1.337–15.371) were associated with biliary PLA.

Conclusion: Biliary pathologies are common and significant causes of PLA. They should be considered in patients with advanced age, polymicrobial PLA, and recurrent PLA.

SAT-340

Liver disease and prevalence of liver transplantation in ZZ alpha-1 antitrypsin deficiency – a systematic review and meta-analysis

Dimitra Georgantaki[1], Adam Syanda[1,2], Muhammad Awsaf[1], Tamir Rashid[1]. [1]*Imperial College London, London, United Kingdom;* [2]*King's College London, London, United Kingdom*
Email: dg920@ic.ac.uk

Background and aims: Alpha-1 antitrypsin deficiency (A1ATD) is a monogenic inherited metabolic disorder caused by a mutation (ZZ) in the SERPINA1 gene. This mutation leads to the misfolding, polymerisation and accumulation of alpha-1 antitrypsin (A1AT) within hepatocytes, causing cellular dysfunction, inflammation, cirrhosis, and increased cancer risk. Patients are also prone to lung pathology due to unopposed neutrophil elastase activity in the lungs. The severity of A1ATD-associated liver disease is highly variable, necessitating further quantification and characterization. This study aims to investigate the extent of liver disease, and liver transplantation rates in ZZ A1ATD (PiZ) patients.

Method: We conducted a comprehensive systematic review and meta-analysis of studies investigating liver disease and liver transplantation in PiZ patients. Several established databases including Ovid, EBSCO, PubMed and Cochrane Library, were searched from inception to May 12, 2024. Data on liver disease, blood markers, and liver transplantation were pooled using random effects model and study weight was calculated using the inverse variance method. Crude odds ratios (cOR) were calculated using homozygous wild type participants as the comparator. The study was registered in PROSPERO (CRD42022335666).

Results: Of the 4,420 studies identified, 45 studies and 8,638 PiZ patients (38.8% female) were included. Of PiZ patients, 19.26% experienced transaminitis, characterised by elevated liver enzymes, with cOR 2.01 [95% CI 1.43, 3.08] for ALT, 6.18 [95% CI 2.01, 18.97] for AST, 2.34 [95% CI 0.89, 6.15] for GGT, and 1.85 [95% CI: 0.60, 5.74] for ALP. Additionally, these patients demonstrate an increased risk of liver diseases compared to controls, including steatosis (cOR): 1.52 [95% CI: 1.21, 1.91]), fibrosis (cOR: 9.85 [95% CI: 5.70, 17.03]), cirrhosis (cOR: 10.43 [95% CI: 5.51, 19.73]), and liver cancers (cOR: 14.12 [95% CI: 6.50, 30.66]). The prevalence for liver transplantation is considerable, with rates reaching 4.97% [95% CI: 0.00, 12.34].

Conclusion: Our findings confirm the substantial burden of liver disease in PiZ patients, including subclinical manifestations such as transaminitis, steatosis and fibrosis that may remain undetected and thus screening patients with known AATD for liver pathology may be beneficial. Given the lack of approved treatments for A1ATD-associated liver disease, prioritising the development of novel therapies to stop or reverse liver disease is essential.

SAT-341

Propranolol for primary prophylaxis for variceal bleed in infants and children with biliary atresia – results of a single blind placebo controlled randomized controlled trial (BABB-Trial)

Anmol Anmol[1], Rajeev Khanna[1], Seema Alam[1], Vikrant Sood[1], Bikrant Bihari Lal[1]. [1]*Institute of Liver and Biliary Sciences, Delhi, India*
Email: drrajeev_khanna@rediffmail.com

Background and aims: Non-selective beta-blockers (BB) decrease portal pressure and thus bleeding and non-bleed decompensation in cirrhotic adults. Portal hypertension (PHT) is progressive in biliary atresia (BA) and is a reason for listing children for Liver transplantation (LT). Usage of BB in infants and children with BA has not been studied in a controlled manner. In this single blind randomized controlled trial we aimed to study the effect of propranolol in comparison to placebo for primary prophylaxis on bleed free survival and survival with native liver (SNL) at 18 months.

Method: Infants and children under-5 years of age with BA were screened for presence of esophageal varices starting at the age of 6 months. Those with varices (small or large) were randomized in a 1:1 ratio to receive either propranolol at 1–4 mg/kg/day (dose titrated to

achieve heart rate reduction to 25%) or placebo in a single blind manner. Primary and secondary outcomes were bleed-free survival and SNL at 18 months. Predictors of bleed were analysed using multivariate Cox regression analysis. Fine and Gray competing risk analysis was done considering death and LT as competing events, sub-distribution hazard ratios (SHR) were calculated. Trial was registered as NCT04494763 following ethical clearance.
Results: Total 50 BA children (19 females) were enrolled at a median age of 8.2 (6.4, 12) months. Three children had large varices, while rest had small varices, one-third of whom were high risk with presence of red colour signs. 26 received propranolol while 24 received placebo. At 18 months from the time of enrolment, 2 lost to follow-up – 8 patients developed variceal bleed (5 in propranolol, 3 in placebo, $p > 0.05$) at a median interval of 4 (1.5, 12) months from first endoscopy. There were 20 LT and 9 deaths (6 following variceal bleed). Bleed-free survival (115 vs 115 days, $p = 0.786$) and SNL (40% vs 39%, $p = 0.951$) at 18 months was not different between the 2 arms. On multivariate cox-regression analysis, albumin [Exp(B) 0.060, $p = 0.002$], unsuccessful Kasai [Exp (B) 31.2, $p = 0.016$] and INR [Exp (B) 60.3, $p = 0.019$] were found to be predictors of bleed. On competitive risk analysis, weight (SHR 0.63, $p = 0.033$), height (SHR 0.89, $p = 0.010$), albumin (SHR 0.33, $p = 0.006$) and gastric varices (SHR 6.44, $p = 0.010$) predicted death or LT, however none of the variables was significant on multivariate analysis.
Conclusion: PHT in infants and children with BA show poor response to BB. Heterogeneity due to bilirubin and drop-outs due to competing events (death and LT) affected the results. Larger studies on BB with uniform cohorts of BA based on bilirubin levels are required.

SAT-342
Modified leipzig versus leipzig score: an agreement for diagnosis in wilson disease
Anmol Anmol[1], Seema Alam[1], Rajeev Khanna[1], Vikrant Sood[1], Bikrant Bihari Lal[1]. [1]*Institute of Liver and Biliary Sciences, Delhi, India*
Email: dranmol1991@gmail.com

Background and aims: Leipzig score was developed at 8th international meeting in Leipzig, Germany, in 2001 and is a scoring system validated in adults and children (sensitivity 94.3%, specificity 94.4%, positive predictive value 90.9%, and negative predictive value 96.6%). In 2019, "modified leipzig score" was derived, where additional points were allotted to positive family history, ceruloplasmin <5 mg/dl, and magnetic resonance imaging (MRI) changes whereas D-penicillamine challenge test was removed. The aim of this study was to determine agreement between leipzig score and modified leipzig score for diagnosis in wilson disease.
Method: This was retrospective, single centre study (2017–2024), whereby 59 genetically proven patients with wilson disease previously diagnosed using Leipzig score were reassessed with modified leipzig score.
Results: 59 genetically proven wilson disease patients (69.4% male) were enrolled at median age of disease onset 9 years (7.2–10.2 years). 61% children were compound heterozygous and remaining were homozygous for ATP7B mutation. 86% of patients had Kayser-Fleischer (KF) ring positive with median ceruloplasmin 6 (3–10), 24 hour urinary copper 529 (242–1212). 72.8% of patients had direct coomb's test (DCT) negative hemolysis with median reticulocyte count of 3 (1.56–4.36). Using JASP software for statistical analysis comparison as well difference between calculated score i.e leipzig score and modified leipzig score was performed. Results to determine agreement between two score was done using Bland Altman analysis. The mean difference between modified leipzig score and leipzig score was 0.703 (95% CI 0.565–0.841). Pearson's correlation was done, which showed significant correlation between the two scores ($p < 0.001$). Results were depicted using bland altman plot, rain cloud plot.
Conclusion: The agreement (mean difference of 0.703) and its effect size showed this difference is not clinically meaningful. And the positive correlation between the two scores is present. In resource limited areas the modified leipzig score can play an important role in the absence of genetic mutational analysis.

Email: e.vendel@lapp.nl

Background and aims: Wilson disease (WD) is an autosomal recessive disorder that is characterized by a mutation in the ATP7B gene which in turn results in an impaired copper homeostasis and subsequent copper accumulation in the body. Chelating agents like trientine dihydrochloride (TETA-2HCl) are a treatment for WD patients which helps reduce copper levels. The effects of TETA-2HCl have been demonstrated in both non-clinical and clinical studies. The aim of the present analysis was to develop a population pharmacokinetic (PK) model for trientine (TETA), based on the up-titration phase in study TR-004 ("UNITED").
Method: A population PK model was developed and fitted to data collected over the first 4 weeks of treatment from both adult and paediatric patients, including those with predominantly hepatic symptoms and those with predominantly neurological symptoms. In this period, the initial dose was set at 3 mg/kg, which was up-titrated to 8 and 13 mg/kg at biweekly intervals (visits 2, 3 and 4 respectively). The influence of patient characteristics, like weight, age, and copper parameters, on relevant model parameters, such as apparent clearance and apparent volume of drug distribution, was evaluated. Once the PK modelling and covariate analysis were finalized, the final population PK model was used to compute TETA concentrations for each individual patient and quantified by the following exposure metrics: the predicted TETA maximum concentration (Cmax), the predicted TETA trough concentration (Ctrough), and the predicted TETA area under the curve (AUC). Additionally, a model-based simulation was performed to assess the impact of dose strength on TETA exposure metrics.
Results: The final population PK model was a linear 2-compartment model with first-order absorption and intra-individual variability on the absorption rate constant (Ka) and bioavailability (F1). Exposure for visit 2 was observed to be higher than for the other visits, which was described by a higher bioavailability relative to these visits. No covariates were found to affect TETA PK. The final population PK model described plasma TETA concentrations well, as demonstrated by several numerical and graphical assessments. All parameters were estimated with good precision. Using the model and model-based

simulation, exposure metrics could be derived and compared between age groups and symptom classes, as well as between different dosing strengths.
Conclusion: Plasma TETA concentrations in both adult and paediatric WD patients enrolled in study TR-004 ("UNITED") were well described by a linear 2-CMT model with first-order absorption and a higher bioavailability at visit 2 relative to the other visits. No covariates, including age and body weight, were found to affect TETA PK. A comparison of TETA concentrations and exposures was made between different age groups, symptom classes and dose strengths.

Long-term outcome of sinusoidal obstruction syndrome secondary to hematopoietic stem cell transplantation

Edilmar Alvarado-Tapias[1], Alexandre Sayadi[2], Aurélie Plessier[3], Valérie Paradis[4], David Michonneau[5], Pierre-Emmanuel Rautou.
[1]Department of Hepatology, Hospital Santa Creu i Sant Pau, Autonomous University of Barcelona (UAB), Department of Medicine, Inflammatory Diseases Department, Biomedical Research Institute Sant Pau (IIB Sant Pau), Barcelona, Spain, Centre for Biomedical Research in Liver and Digestive Diseases Network (CIBERehd), Instituto de Salud Carlos III, Madrid, Spain, Barcelona, Spain; [2]AP-HP, Hôpital Beaujon, Service de Pathologie, DMU DREAM, Clichy, France, Paris, France; [3]AP-HP, Hôpital Beaujon, Service d'Hépatologie, DMU DIGEST, Centre de Référence des Maladies Vasculaires du Foie, FILFOIE, ERN RARE-LIVER, Clichy, France, Paris, France; [4]AP-HP, Hôpital Beaujon, Service de Pathologie, DMU DREAM, Clichy, France, Paris, France; [5]Hematology and Transplantation Unit, Saint Louis Hospital, AP-HP, Paris, France, INSERM U976, Human Immunology, Pathophysiology, Immunotherapy, IHU Institut de la Leucémie Paris Saint Louis, Paris Cité University, Paris, France, Paris, France
Email: pierre-emmanuel.rautou@aphp.fr

Background and aims: Sinusoidal obstruction syndrome (SOS) is a potentially life-threatening liver complication of conditioning regimens of hematopoietic stem cell transplantation (HSCT). Its long-term outcome is unknown. This study aimed to investigate the long-term liver outcomes of patients with liver biopsy-proven SOS.
Method: This study is a retrospective analysis of a prospective database of patients undergoing a liver-catheterism at our center. We included all patients with histologically proven SOS related to conditioning of HSCT between 1994–2023, and who survived 6 months or more after HSCT. Two expert pathologists reviewed all liver biopsies. Development of signs of portal hypertension (PH) and liver-related events were collected. Cumulative incidence of death was compared between groups using Gray's test.
Results: 23 patients with SOS were included. Median time between HSCT and SOS diagnosis was 18 days (IQR, 14–30). Median follow-up after SOS was 6.1 years (IQR, 2.4–8). During this period, 10 (44%) patients developed signs of PH (portosystemic collaterals n = 10; esophageal varices, n = 6; portal vein thrombosis, n = 1), and 8 (35%) of them liver-related events (ascites n = 8; spontaneous bacterial peritonitis, n = 1; hepatic encephalopathy, n = 3; variceal bleeding, n = 3), in median 1.3 years (IQR, 0.89–4.17) after SOS. Cumulative incidence of appearance of signs of PH was 50%, 60%, and 90% at 1, 3, and 10 years, respectively. Cumulative incidence of liver-related events was 30%, 60%, and 80% at 1, 3 and 10 years, respectively. Patients who developed liver-related events during follow-up received less commonly ursodeoxycholic acid (10% *vs.* 46%, p = 0.042) and defibrotide (30% *vs.* 77% (p = 0.024) than patients who did not; no other clinical feature at baseline differed between the two groups, including risk factors for liver diseases. Histological features on baseline liver biopsy associated with the development of liver-related events during follow-up included periportal fibrosis (40% vs 0%, p = 0.005) and any steatosis (30% vs 0%, p = 0.043). Out of the 10 patients who developed signs of portal hypertension during follow-up, 3 underwent a second liver biopsy 1.3 (IQR, 1.0–2.7) years after SOS diagnosis, and all biopsies showed features of porto-sinusoidal vascular disorder and 6 additional patients underwent liver-stiffness measurement showing values ranging from 6 to15 kPa (median 13 kPa). Cumulative incidence of death was significantly higher in patients who developed signs of portal hypertension than in those who did not (HR: 10.88 (1.29–91.65, p = 0.028)).
Conclusion: Development of PH and liver-related events are common following SOS secondary to HSCT, particularly when patients did not receive ursodeoxycholic acid and defibrotide, and impact patients' survival. Histologically, SOS evolves towards features consistent with portosinusoidal vascular disorder.

SAT-349

Liver disease in adults with fontan circulation: a cross-sectional study from a tertiary center in western Sweden

Elin Hultgren[1,2], Amanda Kullander[2], Zacharias Mandalenakis[3,4,5], Mikael Dellborg[2], Wai Giang Kok[2], Peter Eriksson[2,4,5], Frida Dangardt[2,6], Charlotte de Lange[7], Nikolaos Papachrysos[1,2].

Background and aims: Fontan surgery represents a series of palliative procedures performed early in life for children with complex congenital heart defects, resulting in univentricular heart circulation. However, there has been increasing reports that these patients are at risk of developing Fontan-associated liver disease (FALD), which may increase morbidity and mortality. The assessment of FALD and its predictors remains unclear. This study aimed to determine the prevalence of liver disease in adults with Fontan circulation in Western Sweden and to characterize liver-related and clinical features in those with and without significant liver disease.
Method: This single-center, cross-sectional observational cohort study, included patients with Fontan circulation attending Adult Congenital Heart Disease Center at Sahlgrenska University Hospital/Östra from 2019–2023. Participants were identified through ICD codes in an administrative database. Data were retrospectively collected from medical records, including demographics, clinical history, laboratory results, imaging findings, and cardiopulmonary assessments. Participants were divided into two groups based on liver imaging: those with radiological signs of fibrosis, cirrhosis, and/or hepatomegaly (FALD group) and those without (non-FALD group). Liver imaging modalities included ultrasound, magnetic resonance imaging and computed tomography of the abdomen.
Results: Of 99 eligible participants, 96 were included (median age 26.5 [IQR 21.5, 31.0] years; 59.4% male). Liver imaging was available for 86 individuals, 64 (74%) of whom showed findings compatible with FALD, with 42 (66%) demonstrating signs of advanced fibrosis or cirrhosis. In the FALD group median liver and spleen Shear wave elastography was 14.4 kPa [IQR 9.3, 22.3] and 27.9 kPa [22.6, 37.0], respectively. Portal hypertensive gastropathy and esophageal varices were present in 64.3% and 31% of those who underwent upper endoscopy. Ascites was more common in the FALD group (20.3% vs 4.5%). Advanced FALD (per EASL criteria) was observed in 42 individuals (66%). Significant differences between groups included higher body mass index (23.8 vs 21.7 kg/m^2, p = 0.013), spleen length (13.5 vs 11.9 cm, p = 0.008), inferior vena cava pressure (15.0 vs

10.0 mm Hg, p = 0.038), and prevalence of liver focal lesions (26 vs 2, p = 0.002), predominantly hyperechogenic vascular nodules. No cases of hepatocellular carcinoma were identified. Common laboratory abnormalities included elevated gamma-glutamyltransferas and thrombocytopenia.
Conclusion: FALD is highly prevalent in adults with Fontan circulation, with nearly two-thirds showing signs of advanced liver disease. These findings are consistent with previous studies and underscore the importance of routine liver disease screening in early adulthood for this vulnerable patient group.

SAT-350
Wilson disease: presentation, clinical course and complications in a large cohort of patients attending San Paolo hospital of Milan
Federica Samartin[1], Sara Vavassori[1], Andrea Crosignani[1], Emanuela Bertolini[1], Luca Pastorelli[2], Pier Maria Battezzati[2]. *[1]ASST Santi Paolo e Carlo, Milan and European Reference Network on Hepatological Diseases (ERN RARE-LIVER), Milan, Italy; [2]ASST Santi Paolo e Carlo, Milan and European Reference Network on Hepatological Diseases (ERN RARE-LIVER), Department of Health Sciences, University of Milan, Milan, Italy*
Email: piermaria.battezzati@unimi.it

Background and aims: Wilson disease (WD) is a rare hereditary illness characterised by pathological copper accumulation due to mutation in ATPTB, a gene that transcribes a protein involved in copper metabolism. The present study was aimed at describing the clinical course and treatment strategies in a cohort of patients suffering from WD followed in our Center.
Method: We analysed the medical records of 193 patients (100 M, 93 F) suffering from WD, followed in our Center between 1972 and 2023. The mean follow-up time was 12 years (from 0 to 49 years). Patients were classified according to presentation: investigations for familiarity with WD (IFW), hepatological involvement (HEP), neuropsychiatric presentation (NP) and mixed presentation (HNP), with neuropsychiatric symptoms associated with hepatological alterations.
Results: Of the 193 patients, 17% were diagnosed after IFW, while 56% presented with HEP involvement, 22% with NP and 5% with both. The mean age at the onset of disease was 18.5 (±14) years. Patients in the HEP group were the youngest at the time of presentation, with a mean age of 14.7 years, in comparison to the NP group (22 years - *p value* = 0.001) and HNP group (38.5 years - *p value* = 0.0007).
In the study population, liver cirrhosis was present in a relevant percentage of subjects at the time of presentation (44%). Interestingly, the frequency of liver cirrhosis was elevated even in patients diagnosed after IFW, representing the 42% of patients of this group.
Among patients with cirrhosis, one third experienced at least one major complication, that is, ascites, variceal bleeding, hepatic encephalopathy and hepatobiliary neoplasms during follow-up. Incidence of hepatobiliary neoplasms was 3.85 × 1000 patient-years. Regarding survival, 8 patients performed liver transplantation, while 9 died during the observation period, 5 from causes related to WD (two for hepatobiliary neoplasms).
Between therapy options, D-Penicillamine was the most chosen drug, mostly as first line therapy. The second most used was zinc, mainly as second line therapy in patients intolerant to D-penicillamine or as maintenance therapy. Trientine, only recently available in Italy, have had a more limited use. We observed a significant occurrence of adverse events with D-Penicillamine (58/166 users), mostly dangerous needing drug interruption, and even with Zinc (24/113 users), mainly for gastrointestinal intolerance.
Conclusion: The HEP presentation was the most frequent and had the earliest onset. At the onset, a substantial proportion of patients already had advanced liver disease, regardless of the mode of presentation. Approximately one-third of cirrhotic patients developed at least one major complication of cirrhosis during follow-up, including liver tumors. Penicillamine was the most widely chosen drug as first line therapy, but potentially leading to severe adverse events. The use of Trientine was limited until the availability of its tetrahydrochloride form and may represent an alternative treatment option.

SAT-351
Biochemical and immunological markers show limited accuracy in predicting histological remission in paediatric autoimmune hepatitis: results from a multicenter study
Francesca Trevisan[1], Eleonora Munaretto[1,2], Marco Bolzonella[3], Claudia Mescoli[4], Claudio Palmeri[3], Claudia Cozzolino[3], Paola Gaio[1], Vincenzo Baldo[3], Mara Cananzi[1], Marianne Samyn[2]. *[1]Unit of Paediatric Gastroenterology, Digestive Endoscopy, Hepatology and Care of the Child with Liver Transplantation, Department of Women's and Children's Health, Padua, Italy; [2]Paediatric Liver, GI and Nutrition Centre, King's College Hospital, London, United Kingdom; [3]Department of Cardiac, Thoracic, Vascular Sciences, and Public Health, University of Padova, Padua, Italy; [4]Surgical Pathology and Cytopathology Unit, Department of Medicine (DIMED), University Hospital of Padova, Padua, Italy*
Email: francesca.trevis@gmail.com

Background and aims: Paediatric autoimmune hepatitis (pAIH) is an immune-mediated disease that can lead to serious health implications if left untreated or inadequately controlled. Although immunosuppression achieves remission rates of 60–90%, the risk of relapse remains considerable during the course of disease and upon therapy discontinuation. Whilst ongoing histological disease activity increases the likelihood of relapse, the value of liver biopsy to decide on discontinuation remains debated. This study investigates the value of biochemical and immunological markers in predicting histological disease activity in children with pAIH.
Method: We conducted a retrospective, observational, multicenter study involving patients diagnosed with pAIH per ESPGHAN criteria between January 2000 and May 2024, at the Unit of Paediatric Hepatology, University Hospital of Padua (Italy), and the Pediatric Liver Centre, King's College Hospital, London (UK). The endpoints for pAIH treatment, evaluated using non-invasive parameters - biochemical response (BR; normal transaminases), immunological response (IR; normal immunoglobulin levels), complete biochemical response (CBR; normal transaminases and immunoglobulin levels), and serological remission (SR; negative autoantibodies) - were compared with histological remission (HR), defined as a modified hepatitis activity index (mHAI) <4. Concordance analysis using a confusion matrix was performed to assess agreement between invasive and non-invasive outcome measures in follow-up biopsies.
Results: The study included 71 patients (58% female) diagnosed with pAIH at a median age of 11 years (range 1–19), AIH-1 77%, AIH-2 21% seronegative 2%. Follow-up biopsies were performed at a median age of 14 years after an average time of 5 years after diagnosis, with evaluating HR before discontinuing immunosuppression (68%) as most common indication. Median mHAI score was 2 (range 0–14). BR and CBR were discordant with HR in 20% of cases. A confusion matrix was performed to assess the accuracy of non-invasive parameters in predicting HR. BR predicted HR in 80% of patients (accuracy 0.84, kappa test 0.64) and CBR in 81.6% of patients (accuracy 0.81, kappa test 0.6). IR and SR predicted HR in 68% and 80% of cases, but demonstrated poor concordance, with kappa values of 0.3 and 0.2, respectively.
Conclusion: BR and CBR are not reliable indicators of histological remission in pAIH, as 20% of patients with normal transaminases ± immunoglobulin levels still exhibit active histologic disease. Despite the inherent limitations of this retrospective analysis, our findings underscore the importance of follow-up liver biopsies for accurately assessing histological remission.

SAT-352

Genetic and epidemiological profile of a large brazilian cohort of acute hepatic porphyria

Cibele Franz[1], Barbara Cristina Vieira de Aquino[2], Liliana Sampaio Costa Mendes[1], Karina Lebeis Pires[3], Francismar Prestes Leal[4], Maria Chiara Chindamo[1], Wladimir Bocca Vieira de Rezende Pinto[5], Paulo Lima Serrano[6], Paulo Sgobbi[6]. [1]*Comissão de doenças raras – Sociedade brasileira de hepatologia (SBH), Rio de Janeiro, Brazil;* [2]*Neuron – hospital rio grande, Rio de Janeiro, Brazil;* [3]*Universidade federal do estado do rio de janeiro (UNIRIO), Rio de Janeiro, Brazil;* [4]*Private Clinic, Maringá, Brazil;* [5]*Universidade federal de são paulo (UNIFESP), São Paulo, Brazil;* [6]*Universidade federal de são paulo (UNIFESP), Sao Paulo, Brazil*
Email: pvsgobbi@gmail.com

Background and aims: Porphyrias constitute a rare group of inborn errors of metabolism, with a genetic etiology related to defects in the heme biosynthesis pathway, resulting in abnormal production and toxic accumulation of heme precursors. Acute Hepatic Porphyrias (AHPs) comprise a group of four diseases (Acute Intermittent Porphyria, Variegate Porphyria, Hereditary Coproporphyria, and ALA Dehydratase Deficiency Porphyria or Doss Porphyria) with worldwide distribution, affecting individuals of both sexes and all age groups, and are clinically characterized by recurrent episodic neurovisceral symptoms. Unfortunately, the porphyrias are usually underrecognized reflecting a lack of medical and disease awareness as well as few studies about natural history in large cohorts of patients. The main aim of this article is present consistent data about genetic and epidemiological profile of patients with AHPs in Brazil.
Method: We conducted a national cross-sectional registry with retrospective clinical data of Brazilian patients.
Results: A cohort of 150 patients was analysed in which 105 (70%) patients had the diagnosis of acute intermittent porphyria (AIP), 32 (21.3%) variegate porphyria (VP), 11 (7.3%) hereditary coproporphyria (CPOX) and 2 (1.3%) ALAD deficiency. In our cohort patients needed a mean of 62.04 medical visits and 9.6 years to achieve a definitive diagnosis. About AHP cohort, the most common first clinical manifestation was abdominal pain in 94 (62.6%) patients and acute muscle weakness in 38 (25.3%) with 73 (48.6%) patients presenting only one attack during disease course and 37 (24.6%) exhibiting 4 or more attacks in the last year. The most common variants were the c.973C>T (p.Arg325*) on *HMBS* gene present in 45 patients with AIP, c.503G > A (p.Arg168His) on *PPOX* in 23 patients with VP. Of note, 105 (70%) patients with AHP reported chronic manifestations between attacks.
Conclusion: Brazilian patients with AHP had a higher prevalence of chronic disabling manifestations and a and a higher proportion of patients with recurrent attacks than previously reported and a higher frequency of VP than reported worldwide.

SAT-353-YI

Management of Wilson disease across europe: an international physician-oriented survey by the ERN-RARE liver group

Frederik Kirk[1,2], Karina Rewitz[1,2], Wiebke Papenthin[2,3], Zoe Mariño[2,4], Eduardo Couchonnal[2,5], Nicolas Lanthier[2,6], Marina Berenguer[2,7], Aurélia Poujois[2,8], Gerald Denk[2,9], Thomas Damgaard Sandahl[1,2]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus N, Denmark;* [2]*European Reference Network on Rare Liver Disorders (ERN-RARE Liver), Hamburg, Germany;* [3]*German Association for Wilson disease Patients (Morbus Wilson e.V.), Kürnach, Germany;* [4]*Liver Unit, Hospital Clínic, IDIBAPS, CIBERehd, Barcelona, Spain;* [5]*Unité d'Hépatologie, gastroentérologie et Nutrition pédiatrique, Hôpital Femme Mère et Enfant, Hospices Civils de Lyon, Bron, France;* [6]*Service d'Hépato-Gastroentérologie, Cliniques universitaires Saint-Luc, Brussels, Belgium;* [7]*Hepatology and Liver Transplant Unit, IIS La Fe & CIBER-EHD, Universitary and Politecnic Hospital La Fe, Valencia, Spain;* [8]*Centre de Référence de la Maladie de Wilson et autres Maladies Rares Liées au Cuivre, Paris, France;* [9]*Department of Medicine II, University Hospital, LMU Munich, Munich, Germany*
Email: frkirk@rm.dk

Background and aims: Diagnosis and treatment of Wilson Disease (WD) is complex and highly specialized. It is crucial to understand the differences in the management of WD across the European Union, as international clinical and scientific collaboration becomes more common. We aimed to investigate differences in WD diagnosis and management as well as patient related perspectives across European centers.
Method: A 37-question questionnaire was distributed among physicians involved in the management of WD patients across European WD centers. Each physician responded on behalf of a WD center. Questions related to diagnosis, treatment, and monitoring of WD as well as questions addressing patient perspectives and background information from the respondent. Responding centers were classified as small or large by number of patients seen per year (</>30). Data was assessed in total as well as by managing specialty and center size.
Results: 58 physicians from 20 countries responded to the survey. 91% of centers adhered to international guidelines and 88% utilized Leipzig diagnostic criteria. Most centers had a wide range of diagnostic tools available, e.g. 24-hour urinary copper, slit-lamp examination and genetics (98%, 95% and 93% respectively). Some were less commonly available, e.g. liver biopsy for copper quantification, penicillamine challenge test and non-ceruloplasmin bound copper (74%, 53% and 43%).
21% of small centers did not offer trientine, cost was a limiting factor to some. Initial treatment of hepatic WD was uniform, whereas variability was observed for neurological presentations with 56% of centers using chelation therapy ± zinc. Neurological departments were more likely to offer chelation therapy (80% of centers, n = 5). Recommendations for copper restricted diet varied widely, with 48% recommending temporary low copper diet and 38% recommending it indefinitely.
Large centers were more likely to follow guidelines and offer more diagnostic tools and therapies, though overall there was little difference between small and large centers.
Conclusion: In conclusion, this physician-oriented survey shows adherence to international WD guidelines among European centers. The survey also uncovers important differences amongst centers particularly related to the initial treatment of non-hepatological WD, availability of trientine and recommendations for low copper diet. The survey highlights numerous areas in WD care in which evidence is lacking.

SAT-354

Liver and spleen stiffness measure by transient elastograghy: a promising tool for the clinical management of patients after Fontan-type surgery circulation

Barbara Coco[1], Lamia Ait Ali[2], Giovanni Petralli[3], Lorenzo De Stefano[1], Piero Colombatto[1], Ranka Vukotic[1], Antonio Salvati[1], Ferruccio Bonino[4], Pieluigi Festa[5], Maurizia Brunetto[1,4,6]. [1]*Hepatology Unit, University Hospital Pisa, Pisa, Italy;* [2]*Institute of Clinical Physiology, CNR Massa, Massa, Italy;* [3]*Department of Surgical, Medical, Molecular and Critical Area Pathology, University of Pisa, Pisa, Italy;* [4]*Institute of Biostructure and Bioimaging, National Research Council, Naples, Italy;* [5]*G. Monasterio Foundation, Massa, Italy;* [6]*Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy*
Email: b.coco@ao-pisa.toscana.it

Background and aims: Haemodynamic changes after Fontan palliation in infant patients with univentricular heart promote so-called Fontan-associated-liver-disease (FALD). FALD is not adequately monitored by traditional liver clinical scores (e.g. MELD-XI, VAST score) and progression risk biomarkers and non-invasive tools are missing. Liver and spleen stiffness (LSM and SSM) measured by transient elastography might be useful technique. Aim was to study

correlations between LSM-SSM and FALD stages in adult post-Fontan patients.
Method: 56 consecutive pts with compensated FALD (median age 25.1 y, 21.3–31.9 y; 14 F) were studied. We recorded liver morphology/structure by ultrasound-scan and LSM (Fibroscan®), biochemical liver tests, radiologic and/or upper endoscopic signs of portal hypertension and cardiological functional parameters. In a 33-pts sub cohort (26.8 y, 22.9–37.3 y; 8 F) SSM (Fibroscan®) was measured too.
Results: Median LSM and SSM were 17.9 (13.5–25.3) kPa and 30.4 (24.4–42.8) kPa respectively and significantly correlated (r = 0.546, p = 0.001). LSM was correlated with g-GT levels (r = 0.365, p = 0.009), total bilirubin (r = 0.403, p = 0.005), and spleen bipolar diameter (SBD, r = 0.465; p < 0.001), while SSM was associated only with SBD (r = 0.408, p = 0.023). Pts with advanced liver involvement had significantly higher LSM (p = 0.010) and SSM (p = 0.022): 24.5 and 39.1 kPa in VAST >1 vs 16.6 and 26.8 kPa in VAST 0–1 pts, respectively. LSM for VAST score >1 identified an AUROC of 0.727 (p = 0.004) and a 16.4 kPa cut off with 93% sensitivity and 48% specificity; SSM for VAST score >1 identified an AUROC of 0.776 (p = 0.009) and a 30.7 kPa cut off with 88% sensitivity and 77% specificity. Both LSM and SSM were correlated with left ventriculus disfunction in logistic regression (r = 0.298 p = 0.019 and r = 0.342 p = 0.049, respectively), and only LSM was associated with NTproBNP (r = 0.427, p = 0.002). SSM was higher in pts on diuretic (39.2 vs 26.1 kPa, p = 0.030) and betablockers therapy (34.0 vs 26.1 kPa, p = 0.020); LSM presented the same trend (21.3 vs 16.6 kPa, p = 0.037 and 21.1 vs 16.6, p = 0.064).
Conclusion: LSM and SSM appear promising tools for the clinical management of pts with Fontan circulation. LSM >16.4 kPa and SSM > 30.7 kPa predicted with high sensitivity advanced FALD. LSM and SSM are significantly higher in patients with worst cardiological function, suggesting their potential role in the prognostic stratification of this challenging population. These preliminary results prompt prospective studies on larger cohorts of pts after Fontan's surgery.

SAT-355
The HepQuant DuO test finds linkage between liver blood flow, portal-systemic shunting and cardiac hemodynamics in Fontan-associated liver disease

Yuli Kim[1], Michael McRae[2], Jack Rychik[3], Greg Everson[4], Maarouf Hoteit[5]. *[1]Hospital of the University of Pennsylvania, Division of Cardiovascular Medicine, Philadelphia, Pennsylvania, United States; [2]Custom DX Solutions LLC, Houston, Texas, United States; [3]Children's Hospital of Philadelphia, Division of Cardiology, Philadelphia, Pennsylvania, United States; [4]HepQuant, LLC, Denver, Colorado, United States; [5]Hospital of the University of Pennsylvania, Division of Gastroenterology, Philadelphia, Pennsylvania, United States*
Email: greg.everson@hepquant.com

Background and aims: Fontan-associated liver disease (FALD) is a common condition in single ventricle patients following Fontan palliation, but it remains inadequately characterized by existing laboratory and imaging techniques. We aim to measure afferent hepatic flow using the dual oral cholate challenge test (HepQuant DuO) and compare results with hemodynamic variables characteristic of those with FC.
Method: This was a single center cohort study of 35 adults with FC. The HepQuant DuO test involved oral dosing of isotopically-labelled d4-cholate, blood samples collected at 20 and 60 min, and quantitation by LC-MS/MS to yield portal hepatic filtration rate (HFR, clearance adjusted to body weight). Systemic HFR was derived using a model based on body size and concentrations of d4-cholate. SHUNT% is defined as systemic HFR/portal HFR. Total hepatic blood flow was calculated as systemic HFR/[(normal intrinsic hepatic extraction 0.78) × (1 – Hct)] and fractional hepatic arterial (HA) and portal venous (PV) flows were derived. Cardiac output, Fontan pressure, and oxygen saturation were obtained by cardiac catheterization and cardiac magnetic resonance imaging. Healthy individuals (n = 50) served as controls.
Results: Patients with FC (91% White, 54% female) had mean (SD) age of 31 (7) years and BMI 26 (6) kg/m^2 with platelet count 180,000 (66,000) μL^{-1}, hematocrit 44.5% (3.9%), MELD-XI 10.6 (1.4), FIB-4 1.1 (0.6), and APRI 0.44 (0.19). DuO test values were significantly worse in those with FC versus controls (all $p < 0.001$): SHUNT%, 30.6% (10.6%) vs. 20.4% (4.3%); portal HFR, 16.2 (8.7) mL/min/kg vs. 27.4 (9.0) mL/min/kg; systemic HFR, 4.3 (0.9) mL/min/kg vs. 5.3 (0.7) mL/min/kg. Higher Fontan pressure was associated with decreased PV flow ($r = 0.56$, $p = 0.013$). Patients with lower PV flow had a trend towards lower oxygen saturation ($r = 0.32$, $p = 0.058$). Cardiac output was not associated with afferent hepatic flow. Increasing SHUNT% is accompanied by reduction in PV flow and increase in HA flow.
Conclusion: HepQuant DuO demonstrated reduced cholate clearances and increased portal-systemic shunting (SHUNT%) in adults with Fontan circulation (FC). Increased Fontan pressure and desaturation, markers of Fontan circulatory failure, are associated with decreased PV inflow and compensatory increase in HA inflow as estimated by the DuO test. The HepQuant DuO test could be useful in measuring severity of hepatic impairment and shunting in FALD.

SAT-356
Porto-sinusoidal vascular disease: epidemiology, clinical features and treatments

Hamza Benazzouz[1], Maryeme Kadiri[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Mohamed Borahma[2], Fatima Zahra Ajana[1]. *[1]Ibn Sina Hospital, MOHAMMED V UNIVERSITY, Rabat, Morocco; [2]Ibn Sina Hospital, MOHAMMED V UNIVERSITY, Rabatmo, Morocco*
Email: hamzabenaz@gmail.com

Background and aims: Porto-sinusoidal vascular disease (PSVD) encompasses various disorders characterized by abnormalities of the small vessels within the liver. Liver biopsy is essential for diagnosing PSVD, relying on the absence of cirrhosis and specific histological lesions or signs of portal hypertension. The aim of our study was to describe epidemiological, clinical, paraclinical, therapeutic, and prognostic aspects.
Method: This was a retrospective descriptive study conducted in a hepatogastroenterology department over a 7-year period from 2017 to 2024, involving all patients diagnosed with PSVD who underwent liver biopsy. Data were collected from patient records and during their follow-up.
Results: A total of 43 patients were diagnosed with PSVD, with a mean diagnostic age of 42.4 ± 12.6 years, with sex ratio M/F = 0.79. Clinical presentations included hemorrhagic decompensation in 12 (28%), abdominal pain in 14(32.6%), and anemic syndrome in 17 (39.5%). All patients had portal hypertension when diagnosed, with decompensation occurring in 36% of cases. This included hemorrhagic decompensation in 12(28%), while ascites was present in only 3(7%) of cases.
The most common laboratory finding was a pancytopenia in 28 (67.4%), cytolysis in 6(13.9%), cholestasis in 13(30%), hepatocellular insufficiency in 8(18.6%) of cases. On upper endoscopy, esophageal varices were found in 31(75%), gastroesophageal varices in 19.5%(8), and portal hypertensive gastropathy in 9(22.5%). Portal vein thrombosis was present in 25.6% (11) and portal cavernoma in 4 (9.3%) of cases. PSVD diagnosis was based on histological criteria in 60.5%(26), with 65.5%(17) exhibiting specific signs. 21(48.8%) patients had associated conditions, prothrombotic disease were found in 14(32.6%) of cases, 5(11.6%) of the patients had immunological disorders and 2(4.8%) blood diseases. Band ligation was performed for 30(69%) of patients, while beta-blockers were indicated in 60%. Anticoagulation was used to treat thrombosis in more than one-third of the cases. Whereas, splenectomy and splenorenal shunt was used to treat hypersplenism, in respectively 7 and 4% of the cases. Complications included hepatic decompensation in 18(42.9%) of cases and two deaths were reported due to hepatocellular failure and acute leukemia.

Conclusion: Recently, clear histological and clinical criteria for diagnosing PSVD have emerged. However, this disease is still poorly recognized because symptoms usually appear only after complications of portal hypertension occur. In our study, female sex was predominant; all patients presented with portal hypertension, decompensation occurring in one-third of cases. All patients underwent a biopsy, with 65% showing specific signs. Protein S and/or C deficiency was the most common etiology.

SAT-357

Etiological reclassification of cryptogenic cirrhosis after liver transplantation : insights and impact on outcomes

Hèdi Arar[1], Ilias Kounis[1], Faouzi Saliba[1], Cyrille Feray[1], Eric Vibert[1], Filomena Conti[2], Teresa Antonini[3], Pauline Houssel-Debry[4], Mylène Sebagh[1], Astrid Laurent Bellue[1], Anne Spraul[5], Audrey Coilly[1]. *[1]Hôpital Paul Brousse, Villejuif, France; [2]Hôpital de la Pitié Salpetrière, Paris, France; [3]Hôpital de la croix rousse, Lyon, France; [4]CHU de Rennes, Rennes, France; [5]Hôpital Bicêtre, Le Kremlin Bicêtre, France*
Email: hedi.3arar@gmail.com

Background and aims: Cryptogenic cirrhosis (CC) remains a significant indication for liver transplantation (LT), despite advances in diagnosing metabolic-associated steatotic liver disease (MASLD). However, systematic efforts to reclassify CC after transplantation remain limited. This study aimed to reassess CC cases transplanted over two decades, uncover hidden etiologies through a multidisciplinary approach, and evaluate their impact on graft and patient survival.

Method: We conducted a retrospective study at Paul Brousse Hospital, including patients transplanted for CC. A control group consisted of patients transplanted for cirrhosis of known etiology. Reclassification was performed in two phases: Phase 1 entailed an exhaustive review of clinical, histological, and imaging data, followed by a multidisciplinary expert panel evaluation in Phase 2. Genetic analyses employed a targeted panel of 165 genes. Post-LT survival outcomes were compared between reclassified CC patients and those with known etiologies.

Results: Among 3001 LT performed during the study period, 1355 were for cirrhosis, including 68 for CC. CC patients were younger than the control group (47.7 vs. 51, $p = 0.038$) and included a higher proportion of females (42.7% vs. 30.9%, $p = 0.041$). They also had higher mean total bilirubin levels at listing (209.5 vs. 157.3 µmol/L, $p = 0.043$), though MELD score were similar between the groups. The mean wait time on transplant list was similar (168 vs. 191 days, $p = 0.3$). Phase 1 allowed the identification of etiologies in 24 patients. In Phase 2, expert panel reviewed 33 cases, leading to a definitive diagnosis in 15 patients, a probable diagnosis in 4, and 14 cases remaining undetermined. Overall, 68.4% of CC cases were reclassified. Identified etiologies included metabolic steatohepatitis (25%), alcohol-related liver disease (21%), autoimmune diseases (14%), and rare genetic disorders. Among the 12 patients who underwent genetic sequencing, 3 received a molecular diagnosis: LPAC syndrome (ABCB4 mutation), congenital hepatic fibrosis (PKHD1 mutation), and ciliopathy with renal and hepatic involvement (TTC21B mutation). Additionally, 7 patients presented variants of interest without a definitive molecular diagnosis. Post-transplant survival rates were comparable between reclassified CC patients and those transplanted for known causes ($p = 0.3$).

Conclusion: This study demonstrates the value of systematic post-transplant reclassification of CC, combining comprehensive clinical evaluation, genetic sequencing, and expert panel review. Following the reclassification process, only 14 cases (0.47% of all the LT on the period) remained without a definitive etiological diagnosis, highlighting the effectiveness of the multidisciplinary approach in resolving CC cases. Identifying hidden etiologies provides critical insights into the underlying causes of CC and supports the development of personalized strategies to optimize long-term management for transplant recipients.

SAT-358

Dynamics and prognostic implications of splanchnic volumetry in patients withportosinusoidal vascular liver disorder

Email: jaferrusquia@tauli.cat

Background and aims: Splanchnic volumetry is a valuable predictor of poor outcomes in cirrhosis. However, its prognostic impact in portosinusoidal vascular disorder (PSVD) remains unclear. This study aimed to evaluate splanchnic volumetry, its dynamics, and its influence on the prognosis of this rare disease.

Method: We conducted a retrospective, multicenter observational study, including all PSVD patients with an available CT scan from 10 centers in the VALDIG network. The volumes of Couinaud liver segments I-III (LLV) and IV-VIII (RLV), total liver volume (TLV), and total spleen volume (TSV) were measured using manual or semi-automated segmentation on CT imaging. All these volumes were normalized for height (ht). Patients were followed until death, liver

transplantation (LT), loss to follow-up, or last follow-up visit. Uni- and multivariate Cox regression analyses identified factors associated with the composite endpoint of first/further hepatic decompensation and all-cause mortality. The dynamics of splanchnic volumetry were assessed in patients who had a second CT scan performed at least one year after the baseline scan.

Results: A total of 177 PSVD patients were included (age: 51 ± 16 years, 60% male, 50% with high-risk varices, 44% decompensated, Child-Pugh score 6 ± 2 pts, MELD score 10 ± 4 pts). The mean normalized volumes were: LLV-ht 230 ± 118, RLV-ht 580 ± 242, TLV-ht 810 ± 281, and TSV-ht 843 ± 657 cc^3/m. During a median follow-up of 32 (IQR 10–57) months, 23% experienced first or further hepatic decompensation, 6% underwent LT, and 17% died with 53% of deaths being unrelated to liver disease. Patients meeting the composite endpoint had a larger TLV-ht (885 ± 290 vs. 773 ± 270; p = 0.008) driven by an increased RLV-ht (648 ± 266 vs. 546 ± 223; p = 0.013), while LLV-ht and TSV-ht were similar. Multivariable Cox regression analysis identified age, comorbidities associated with PSVD and hepatomegaly (defined as a TLV-ht > 904 cc^3/m corresponding to the 75th percentile) as independent predictors of worse survival free of first/further hepatic decompensation (adjusted hazard ratio [aHR] for hepatomegaly: 1.87 [95% CI 1.07–3.27], p = 0.028). The presence of hepatomegaly was associated to a higher proportion of at least one cardiovascular risk factor (CVRF; 68% vs 49%; p = 0.026), particularly arterial hypertension (36% vs 19%; p = 0.017), dyslipidemia (30 vs 11%; p = 0.002) and obesity (16% vs 4%; p = 0.006). A total of 76 patients had a second CT scan available, with a median interval of 32 months (IQR 18–70) between scans. Of these, 25% showed a mean increase of 19% in TLV, while 75% exhibited a mean decrease of 16%.

Conclusion: The presence of hepatomegaly is linked to worse prognosis in PSVD, potentially due to its association with a higher prevalence of CVRF. As the disease progresses, liver volume tends to decrease, similar to what is known to occur in cirrhosis.

SAT-359-YI

Counselling young adults with liver disease on alcohol use: a survey of clinical practices across Europe

Janne Suykens[1,2], Caren Ramien[2,3], Ruth de Bruyne[1,2], Helena Degroote[2,4], Ansgar W. Lohse[2,3], Marianne Samyn[2,5], José Willemse[6], Henriette Ytting[2,7,8], Youth Panel[2], Marianne Hørby Jørgensen[2,9]. *[1]Ghent University Hospital, Department of Paediatric Gastroenterology, Hepatology and Nutrition, Ghent, Belgium; [2]European Reference Network on Hepatological Diseases, Hamburg, Germany; [3]University Medical Centre Hamburg-Eppendorf, I. Medical Department, Hamburg, Germany; [4]University Hospital Brussels, Brussels Health Campus, Department of Gastroenterology and Hepatology, Brussels, Belgium; [5]King's College Hospital NHS Foundation Trust, Paediatric Liver, GI and Nutrition Centre, London, United Kingdom; [6]Dutch Liver Patients Association, Rotterdam, Netherlands; [7]Hvidovre University Hospital and Righospitalet, Departments of Medical Gastroenterology and Hepatology, Copenhagen, Denmark; [8]Copenhagen University, Department of Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen, Denmark; [9]Rigshospitalet, Department of Paediatrics and Adolescent Medicine, Copenhagen, Denmark*
Email: janne.suykens@ugent.be

Background and aims: Alcohol is a part of young people's social interactions. This survey aimed to get an overview of how young people with chronic compensated liver disease are counselled on the use of alcohol across Europe.

Method: Within ERN Rare Liver, we designed a survey to assess how clinicians counsel about alcohol intake to patients with liver disease <25 years. The survey was distributed via mailing lists and newsletters to both paediatric service (PS) and adult service (AS).

Results: 142 clinicians (86 AS, 52 PS and 4 in both) from 27 countries responded. All but one counselled about alcohol. While 71% felt comfortable with their counselling (69% PS, 74% AS), 28% were only sometimes comfortable. Only 35% reported having enough knowledge to feel secure in their counselling (26% PS and 39% AS), with 56% reporting some knowledge gaps (63% PS, 52% AS) and 8% reporting lacking sufficient knowledge (9% PS, 8% AS). There was more variability in recommendations when liver disease is 'in remission' (34% PS, 51% AS always recommending complete abstinence; 44% PS, 18% AS never) 'mild' (51% PS, 65% AS always; 17% PS, 9% AS never) or 'without cirrhosis' (34% PS, 60% AS always; 25% PS, 9% AS never). Consensus increases when liver disease is 'active' (80% PS, 95% AS always; 3% PS, 0% AS never), 'with cirrhosis' (75% PS, 93% AS always; 7% PS, 1% AS never) or 'with advanced cirrhosis' (88% PS, 99% AS always; 2% PS, 0% AS never). Recommendations given to patients with liver disease were mostly stricter than those given to the general public (e.g. in remission 84% PS, 81% AS, with advanced cirrhosis 94% PS 91% AS). Compared to AS, PS set a specific limit more often (e.g. in remission 44% PS, 34% AS) and were less likely to advise complete abstinence (e.g. with advanced cirrhosis 88% PS, 99% AS) at all stages of liver disease. If any, the 'specific limit' that was given to patients showed a larger range in countries with higher national recommendations (e.g. in remission Denmark = 2–3 units/w, UK = 1–14 units/w). 83% of participants agreed that a position paper from the ERN in cooperation with the major scientific societies would be helpful for daily practice.

Conclusion: Across Europe, the recommendations about counselling young adults and adolescents vary greatly depending on clinician, country, and liver status, as well as pediatric or adult service. Counselling for complete abstinence increases when liver disease worsens, leading to more consensus within and between services, but is never fully reached. Moreover, PS were less likely to advise complete abstinence and more frequently counselled for a low minimum alcohol intake, possibly recognizing the social pressures and exploratory behaviours typical of this age group. The variability in recommendations may lead to confusion and inconsistencies in patient adherence and trust, especially upon transferring to a different service. Despite general confidence, many clinicians acknowledged knowledge gaps and reported that further clinical guidance, education and patient materials would be useful.

SAT-360-YI

Screening, high risk symptomatology and outcomes of Wilson's disease in 56,606 new referrals in a large tertiary psychiatric population

James Liu Yin[1], Richard Thompson[1], David Okai[2], Aftab Ala[1]. *[1]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom; [2]Neuropsychiatry Department, South London and Maudsley NHS Foundation Trust, London, United Kingdom*
Email: aftab.ala1@nhs.net

Background and aims: Wilson's disease (WD) can present with purely hepatic, neurological or psychiatric symptoms and also as multiple combinations of these three. There are very limited data on the psychiatric pattern of symptoms of WD and the consideration of WD in the psychiatric assessment. South London and Maudsley NHS Foundation Trust (SLaM) is an international leader in mental health and is the largest provider of secondary mental health services in the UK receiving receive referrals from a wide and diverse catchment area. Our work investigates considerations of WD at SLaM and the pattern/overlap of symptoms at presentation of WD.

Method: We utilised the Clinical Records Interactive Search system at SLaM, which included a natural language processing algorithm (identifying 58 different psychiatric symptoms), and hospital episodes statistics data to collect new referrals from 2017 to 2019. This also allowed us to gather patient demographics, blood tests and the nature of the psychiatric presentation. Statistical analyses were conducted using Excel, R, and STATA.

Results: We identified 56,606 new referrals to SLaM over the 2 year period. 9.5% had liver function (LFT) and 0.1% had ceruloplasmin (Cp) requested, with only 27 of the abnormal LFT also having Cp requested. 81 patients were identified as diagnosed with WD on electronic records. Diagram 1 shows their top 5 combination of symptoms, which include cognitive impairment, anxiety, sleep disturbance, tearfulness, and hallucinations. 16,575 patients in our cohort had these 'higher risk' symptoms. Of these, 19% had blood tests requested, 5.4% had abnormal LFT and only 0.27% had LFT and Cp requested. The average age at referral was 32 years with a gender ratio of 44F: 37M. There were 22 deaths with mean age of 50years (range 18–89) and mean time after first referral was 83 months (range 7–204). 36 patients were referred after WD was diagnosed (mean time 5.56 years), and 21 were referred before diagnosis (mean time 6.64 years). Using generalised linear modelling, no association was found between age, gender, deprivation score, or ethnicity and the length of time to diagnosis.
Conclusion: The phenomenology of the presentation is of interest with many of the symptoms being likely linked to the subcortical nature of the disease pathology. We conclude that the psychiatric presentation in WD differs from the type of presentation seen in depressive or psychotic conditions and key differences in symptoms identified may be of use to aid diagnosis of WD. Our data indicate that WD remains under-screened among psychiatric patients, with only a small percentage (0.1%) being evaluated for the condition. It also highlights that 29% of new referrals were linked to a combination of 'higher-risk psychiatric symptoms.' We suggest that any patient with raised liver function ± a combination of 'higher risk' symptoms should be screened with Cp as minimum standard of care.

SAT-365-YI
Effectiveness of cystic fibrosis transmembrane conductance regulator modulator triple therapy in patients with advanced cystic fibrosis related liver disease
Julian Yeh[1,2,3], Victoria Homer[4,5], Joanna Whitehouse[6], Philip N. Newsome[7]. [1]*The Liver Unit, Queen Elizabeth University Hospital, Mindelsohn Way, Birmingham, United Kingdom;* [2]*National Institute for Health Research, Biomedical Research Centre at University Hospitals Birmingham NHS Foundation Trust and the University of Birmingham, Birmingham, United Kingdom;* [3]*Centre for Liver & Gastrointestinal Research, Institute of Immunology and Immunotherapy at University of Birmingham, Birmingham, United Kingdom;* [4]*National Institute for Health Research, Biomedical Research Centre at University Hospitals Birmingham NHS Foundation Trust and the University of Birmingham, Birmingham, United Kingdom;* [5]*Cancer Research UK Clinical Trials Unit, University of Birmingham, Birmingham, United Kingdom;* [6]*West Midlands Adult Cystic Fibrosis Centre, University Hospitals Birmingham NHS Trust, Birmingham, United Kingdom;* [7]*Roger Williams Institute of Liver Studies, School of Immunology and Microbial Sciences, Faculty of Life Sciences and Medicine, King's College London, Foundation for Liver Research and Kings College Hospital London, UK, London, United Kingdom*
Email: julian.yeh@nhs.net

Background and aims: Cystic Fibrosis related liver disease (CFLD) can cause focal biliary cirrhosis with bile duct plugging. Cystic fibrosis transmembrane conductance regulator (CFTR) modulators reduce disease severity, pulmonary exacerbations and the need for lung transplant. To understand their use in CFLD from a perspective of impact on liver outcomes, we analysed a UK tertiary cohort started on triple CFTR modulator therapy.
Method: Analysis of electronic records for patients on Elexacaftor/Tezacaftor/Ivacaftor therapy with CFLD since UK approval in 2020. Liver bloods, fibrosis non-invasive tests (NITs), spleen size and UKELD clinical scores were captured. A composite clinical endpoint of death, liver transplant or decompensation (ascites, variceal bleed, encephalopathy or primary liver cancer) was also assessed. A one-sample Wilcoxon test was used to assess if the median value differs from 0.
Results: 20 patients were identified from the CFLD clinic at University Hospitals Birmingham. Patients receiving liver or lung transplant prior to starting triple therapy (n = 5) were excluded, as were patients with inadequate data (n = 3) or concurrent non-CF liver disease (n = 1) leaving 11 patients for analysis. Median follow up was 44months (22–56 months), median age 26 years (15–51) and 55% male. 64% had compensated cirrhosis at treatment initiation, 100% had pancreatic insufficiency and 55% had history of CF related intestinal complications. Median ALP reduced with treatment (change from baseline −35%, IQR −47 to −20; p = 0.01), with stability of other biochemical markers. Fibrosis NITs remained stable as did spleen size. Only 1 patient progressed to the composite clinical end point, which in that case was death due to respiratory complications of CF albeit with concurrent ascites. UKELD was stabilised with treatment.
Conclusion: Treatment with CFTR modulator triple therapy in patients with advanced CFLD led to reduction in biochemical markers of liver injury. Less than 10% of patients with advanced CFLD treated progressed to liver decompensation suggesting stabilisation.

SAT-366
Relative exchangeable copper: an accurate biomarker for the diagnosis of Wilson disease

Email: karboy@rm.dk

Background and aims: Wilson disease (WD) is a rare genetic disorder affecting copper metabolism, leading to copper accumulation primarily in hepatic and cerebral tissues. WD diagnosis remains challenging and is currently based on the Leipzig score. Several new diagnostic markers have been proposed. The exchangeable copper (CuEXC) methodology quantifies the non-ceruloplasmin-bound copper fraction in serum. Relative exchangeable copper (REC), defined as the ratio of CuEXC to total serum copper (Total Cu), was proposed as a potential diagnostic biomarker for WD (El Balkhi *et al.*, 2009) with a cut-off value of > 18.5% for REC (El Balkhi *et al.*, 2011 and Guillaud *et al.*, 2017). This study aimed to validate the diagnostic performance of these biomarkers in WD.
Method: This cross-sectional study includes patients with and without WD (*total n* = 332) from two European centers (Aarhus (Denmark) and Barcelona (Spain)). CuEXC was quantified using the standardized procedure described by El Balkhi *et al.* REC, CuEXC, and Total Cu levels were determined and compared among groups: patients with newly diagnosed untreated WD (*n* = 13); treated WD (*n* = 91); non-Wilsonian hepatic disease (*n* = 206); and non-Wilsonian acute liver failure (*n* = 22). Diagnostic performance was assessed by receiver operating characteristic (ROC) analyses.
Results: Median REC was significantly elevated among patients with WD (*n* = 104) compared to the other groups combined (23.6% vs. 5.0%, p < 0.001). Median Total Cu was significantly lower in WD compared to non-WD groups (3.5 mcmol/L vs. 16.7 mcmol/L, p < 0.001), whereas median CuEXC was significantly elevated in WD compared

to non-WD groups (0.69 mcmol/L vs. 0.82 mcmol/L, p = 0.004). Both median REC and CuEXC levels were significantly elevated in newly diagnosed patients with WD compared to treated-WD (29.1% vs. 21.6%, p = 0.008 and 2.59 vs. 0.63 mcmol/L, p < 0.001, respectively). ROC analyses comparing newly diagnosed patients vs. those with non-Wilsonian hepatic disease yielded the following optimal diagnostic cut-offs: for REC, ≥13.8% (sensitivity 100% and specificity 99.6%, AUC: 0.998); for Total Cu, ≤7.1 mcmol/L (sensitivity 61.5% and specificity 99.1%, AUC: 0.911); and for CuEXC, ≥1.87 mcmol/L (sensitivity 76.9% and specificity 99.6%, AUC: 0.905).
Conclusion: Our data support the diagnostic value of REC for WD diagnosis. The more broadly available Total Cu was also found to be discriminative and may be useful in the initial diagnostic work-up. We suggest including relevant copper biomarkers in a future revision of the Leipzig score.

SAT-367

UNITED study: results of the up-titration phase of an open label, multicenter, prospective study to characterize the pharmacokinetics and pharmacodynamics of trientine dihydrochloride and to investigate the efficacy and safety in Wilson disease patients

Isabelle Mohr[1], Anna Czlonkowska[2], Piotr Socha[3], Aurélia Poujois[4], Aftab Ala[5], Thomas Damgaard Sandahl[6], Sanjay Bansal[7], Eduardo Couchonnal[8], Michael Praktiknjo[9], Celine Leemhuis[10], Carlot Kruse[11], Karl Heinz Weiss[12], Anil Dhawan[13]. *[1]Internal Medicine IV, Department of Gastroenterology, University Hospital Heidelberg, Heidelberg, Germany; [2]Department of Neurology, Institute of Psychiatry and Neurology, Warsaw, Poland; [3]Departments of Gastroenterology, Hepatology, Nutritional Disorders and Pediatrics, The Children's Memorial Health Institute, Warsaw, Poland; [4]Département de Neurologie, Centre de Reference de la Maladie de Wilson, Hopital Fondation Adolphe de Rothschild, Paris, France; [5]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom; [6]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark; [7]Department of Pediatric and Pediatric Liver GI and Nutrition Center and Mowat Labs, King's College Hospital, London, United Kingdom; [8]Hospices Civils de Lyon - Hopital Femme Mère Enfant, Hépatologie, Gastroentérologie et Nutrition pédiatrique, Centre de Référence de la maladie de Wilson, Bron, France; [9]Department of Internal Medicine B, University Hospital Münster, Münster, Germany; [10]Univar Solutions B.V., Rotterdam, Netherlands; [11]Univar Solutions. Email: isabelle.mohr@med.uni-heidelberg.de

Background and aims: Trientine dihydrochloride (TETA-2HCl) has been used for the treatment of Wilson Disease for almost 40 years. Although its ability to chelate metal ions has been demonstrated in both non-clinical and clinical settings, no dedicated dose-response studies are available. Therefore, this study aims to investigate a possible pharmacokinetic (PK) - pharmacodynamic (PD) relationship of TETA-2HCl and further evaluate its efficacy and safety. The results of the Up-Titration Phase are presented here.
Method: This study is designed as an open label, multicenter prospective study containing PK, PD, efficacy and safety assessments to evaluate a potential dose-exposure-response relationship as well as to determine the long-term efficacy and safety of TETA-2HCl (Cufence®). The study also contains a PKPD sub-study including data of all patients who completed Visit 4 (Week 4) (i.e. the Up-Titration Phase). At baseline, treatment was initiated, and patients were up-titrated per visit [Visit 2 (3 mg/kg/day), Visit 3 (8 mg/kg/day), Visit 4 (13 mg/kg/day)]. Plasma PK as well as serum copper (Cu), serum ceruloplasmin (Cp) and 24-hour urinary copper excretion (24-hr UCE) levels were measured at each visit. Non-Ceruloplasmin Bound Copper (NCC) was determined at all visits both by calculation as well as directly in serum. This was complimented by neurological, hepatic and psychiatric assessments.
Results: A total of 51 patients were enrolled in study TR-004 "UNITED" and data was collected at 9 sites in Germany, France, Poland, Denmark and the UK. The mean (SD) age of the patients was 34.9 (17.29) years, and 32 patients [62.75%] were male. The majority presented with predominantly hepatic features (n = 34 [66.67%]). When analyzed per visit, the highest mean plasma concentrations were observed at 1 h post administration of TETA-2HCl. Overall, no clear trend towards an influence of predominant symptomatic presentation or age of the patients on mean plasma concentration could be determined. The same trends as described for TETA-2HCl could be observed for its metabolites (MAT and DAT). When looking at Cu, Cp, 24-hr UCE and NCC following TETA-2HCl administration, the strongest changes were seen for asymptomatic patients at all individual study visits. Furthermore, a trend was observed when comparing the different age groups. Also, a clear increase of 24-hr UCE could be observed for all patient groups, reaching the highest values for asymptomatic patients and in the age group ≥18 years. The liver endpoints did not show any change and no serious TEAEs or deaths were observed during the up-titration phase.
Conclusion: The results of this "UNITED" PKPD sub-study show that up-titration of TETA-2HCl in multiple bodyweight dependent steps is generally safe and well tolerated, and that there are possible indications for a relationship between the PK, PD and pre-symptomatic presentation of disease and age.

SAT-368

Outcomes in Navajo neurohepatopathy patients who have undergone liver transplant

Katie Cox[1], David Carpentieri[1], Mitchell Shub[1], Sheetal Wadera[1].
[1]Phoenix Children's Hospital, Phoenix, United States
Email: kcox2@phoenixchildrens.com

Background and aims: Navajo Neurohepatopathy (NNH) is a rare mitochondrial depletion syndrome, caused by a mutation in the MPV17 gene. Prognosis is poor, with progression of disease in childhood with developmental delays and regression, neurologic decline, and liver failure. Liver transplant has been controversial for patients with this diagnosis; however, the purpose of this report is to recommend against liver transplant as it has not been seen to affect long-term outcomes or patient survival.
Method: We investigated outcomes for patients with NNH who had undergone liver transplant and subsequently followed at our institution. Their growth, neurologic status, and development was monitored closely for months to years after transplant. Data for this study was exclusively collected from review of the patients' medical charts from 2002–2023, including documentation of clinic visits with Gastroenterology, Hepatology & Nutrition; Neurology; General Pediatrics and/or inpatient records.
Results: Three patients underwent liver transplant and followed in multidisciplinary clinics post-transplant. All transplanted patients, now at 4 years, 5.5 years, and 14 years post-transplant, have evidence of neurologic decline and failure to thrive, similar to progression of disease seen in non-transplanted patients.
Conclusion: In the Navajo population, a homozygous R50Q MPV17 mutation leads to a rare mitochondrial DNA depletion syndrome. This rare disease is characterized by progressive neurological decline, liver dysfunction, and liver failure. The natural course of NNH inevitably leads to irreversible neurological deterioration, with varying degrees of severity and age at onset. While liver transplant specifically addresses hepatic failure associated with NNH, it does not play a role in altering the neurological manifestations of the disease. Knowing that affected transplanted patients will inevitably develop neurologic decline due to the natural progression of the disease, it is our view that liver transplant is not a reasonable solution to offer this patient population. While this is a small cohort of patients, our approach to

patient management may be applicable to other systemic mitochondrial disorders associated with liver disease.

SAT-369-YI

Isolated metabolic syndrome is a risk factor for splanchnic venous thrombosis and recurrence of vascular event

Hélène Larrue[1], Killian Dobigny[1], Marie-Angèle Robic[1], Théo Izopet[1], Clémence Vignon[1], Lucie Cavailles[1], Sophie Metivier[1], Jean Marie Peron[1], Christophe Bureau[1]. [1]*Department of Hepatology, University Hospital and Toulouse III - Paul Sabatier University, Toulouse, France*
Email: larruehelene@gmail.com

Background and aims: Recent non-cirrhotic, non-neoplastic portal vein thrombosis (PVT) is most commonly caused by a prothrombotic condition or a local risk factor. However, no risk factor is identified in one-third of cases. Preliminary work in our center has shown that abdominal obesity is a risk factor for PVT. The aim of this study was to assess the impact of metabolic syndrome (MetSd) on the risk of thrombotic recurrence in patients with PVT.
Method: This is a monocentric, retrospective, observational study. All patients with acute non-cirrhotic, non-neoplastic PVT not related to liver vascular disease between 2003 and 2023 were included. The inclusion date was the date of imaging at the diagnosis of PVT. Routine clinical, biological, and imaging data were collected, both at baseline and during follow-up. The search for risk factors, according to recommendations, was systematically performed. Patients were classified into three groups: patients with at least one identified recognized risk factor, patients with no identified risk factor (idiopathic group = I), and patients with isolated MetSd according to NCEP-ATPIII criteria (MetSd group = II). The thrombotic event was defined by new venous thrombosis (splanchnic or other) or an arterial event (acute coronary syndrome (ACS) or stroke). Event-free survival rates were assessed using the Kaplan-Meier method and compared by the Log-Rank test.
Results: From 2003 to 2023, 105 patients were included (58% male, mean age 50 years (±14)). At diagnosis, 98% had abdominal pain and 27% had fever. The mean waist circumference was 101.6 cm (±13.5) and the mean BMI was 28.3 kg/m² (±5.8). Median C-reactive protein level was 77 mg/L (0–350), and median factor VIII was 242% (23–523). The most frequent form (36%) was extensive thrombosis, involving portal venous trunk, superior mesenteric vein, and splenic vein. A major thrombosis risk factor was found in 30% of cases, and a minor risk factor in 80% of cases. MetSd was present in 34 patients (33%). Among these, 15 patients (14%) had MetSd as the sole risk factor (group II). 27 patients (26%) had no identified risk factor (group I), classifying their PVT as idiopathic. Anticoagulants were stopped in all patients of the group I and in 14/15 patients in group II. 21/105 patients (20%) experienced a thrombotic recurrence. Among the extra-splanchnic recurrences, 4 were arterial (3 ACS, 1 stroke) and 10 were venous (6 deep vein thromboses and 4 pulmonary embolisms). The probability of being free of recurrence at 7 years was 83% in group I vs 37% in group II (p = 0.006).
Conclusion: These results suggest that MetSd is associated with an increased risk of thrombotic recurrence after PVT further reinforcing its role as a risk factor of splanchnic vein thrombosis. The potential benefit of long-term anticoagulation should be evaluated in these patients, even in the absence of other identified risk factors.

Disease penetrance and survival in HFE p.C282Y/p.H63D compound heterozygous and p.H63D homozygous individuals - a population-based cohort study

Lorenz Pammer[1], Bernhard Pfeifer[2,3], Sabrina Neururer[2,3], Wolfgang Straka[1], Rosa Schmidl[1], Maria Rosina Troppmair[1], Marlene Panzer[1], Sonja Wagner[1,4], Elke Pertler[1,4], Florian Kronenberg[5], Claudia Lamina[5], Herbert Tilg[1], Heinz Zoller[1,4], Benedikt Schaefer[1]. Email: lorenz.pammer@i-med.ac.at

Background and aims: Hemochromatosis is a common genetic disorder characterised by iron overload. Of all common HFE genotypes, homozygosity for p.C282Y has the highest penetrance. A wide variation in disease penetrance estimates for p.C282Y/p.H63D compound heterozygosity has been reported, with low estimates in screening studies and higher penetrance in liver clinic populations. Homozygosity for p.H63D is generally not considered a disease-associated genotype. This study aims to assess age- and sex-specific risk of iron overload, cancer incidence, and life expectancy in a large cohort of HFE-genotyped individuals referred to a liver clinic.
Method: This study was conducted in Tyrol, Austria, and included 8,839 individuals referred for HFE genotyping between 1997 and 2021. Patient demographics, comorbidities, blood test results, and causes of death were extracted from health records. Demographics, laboratory parameters, and survival were analysed using health records. Penetrance, survival rates, and cancer incidence were determined from electronic patient records, health insurance and cancer registries. Outcomes were compared with a propensity score-(PPS)-matched, population-based control group.
Results: We included 507 p.C282Y/p.H63D compound heterozygous and 301 p.H63D homozygous individuals and compared them with 542 individuals homozygous for p.C282Y and PPS-matched controls. Among liver clinic referrals, the prevalence of provisional iron overload at the time of genotyping was 25.1% in p.C282Y/p.H63D compound heterozygotes, compared to 55% in p.C282Y homozygotes. Penetrance of provisional iron overload in p.H63D homozygotes was 25.3% as compared to 11.5% in individuals with normal HFE genotype. On a population level, cumulative lifetime risk for the development of provisional iron overload was significantly lower in p.C282Y/p.H63D compound heterozygotes (1.18%) and p.H63D homozygotes (0.45%) as compared to 18.83% in p.C282Y homozygous patients. Median life expectancy was sig. lower in in p.H63D and p.C282Y homozygous individuals when compared to population-matched controls. HFE p.H63D homozygotes had the greatest burden of comorbidities.
Conclusion: Lifetime penetrance for provisional iron overload is 20 times lower in p.C282Y/p.H63D compound heterozygosity and 50 times lower among p.H63D homozygotes compared to p.C282Y homozygosity. Data from the present study suggest that p.H63D has minor effects on the penetrance of provisional iron overload and the observed higher mortality is rather determined by comorbidities than by HFE genotype.

SAT-371-YI

Prognostic role of endoscopic ultrasound guided direct portal pressure gradient measurement in porto-sinusoidal vascular disorder

Lucia Giuli[1], Gianenrico Rizzatti[1], Maria Pallozzi[1], Francesca Romana Ponziani[1], Brigida Eleonora Annicchiarico[1], Giulia Tripodi[1], Andrea Contegiacomo[1], Alessandro Posa[1], Roberto Iezzi[1], Rosa Talerico[1], Antonio Gasbarrini[1], Alberto Larghi[1], Francesco Santopaolo[1]. [1]*Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy*
Email: lucia.giuli92@gmail.com

Background and aims: Hepatic venous pressure gradient (HVPG) is considered the gold standard for the diagnosis of clinically significant portal hypertension (CSPH), a condition linked to the risk of developing hepatic decompensation events. However, HVPG is an indirect method to measure portal pressure and its application in pre-sinusoidal form of portal hypertension (PH), as in porto-sinusoidal

vascular disorder (PSVD), is hindered by low accuracy. Recently, endoscopic ultrasound (EUS)-guided Portal Pressure Gradient (PPG) measurement, which allows direct measurement of portal pressure, has emerged as a safe method, potentially addressing the limitations of HVPG. However, data on its application in patients with CSPH and pre-sinusoidal form of PH remain lacking. This study aims to evaluate the safety and usefulness of EUS-PPG compared to HVPG in a cohort of patients with PSVD and CSPH.

Method: In this prospective single-center study, patients with a diagnosis of PSVD who presented a clinical suspicion of CSPH underwent HVPG and EUS-guided PPG baseline measurements. A second EUS-PPG measurement was performed in patients naïve to non-selective beta-blockers (NSBBs) to evaluate hemodynamic response to therapy. The definition and severity of adverse events (AEs) was determined according to the newly introduced AGREE classification for AEs in GI endoscopy. The prognostic role of EUS-PPG was assessed in term of prediction of hepatic decompensation.

Results: Twenty patients were enrolled (mean age 54.9 ± 15.6; male 60%) and a total of 20 HVPG and 27 EUS-PPG measurements were performed, without any adverse events. Mean EUS-PPG was 18.2 ± 4.5 mmHg, significantly higher than mean HVPG value (5.9 ± 2.9 mmHg). Patients with a previous episode of hepatic decompensation had higher mean EUS-PPG values compared to those without decompensation (21.9 ± 2 vs 15.7 ± 3.9 mmHg, p = 0.001). In seven NSBB-naïve patients, the mean baseline EUS-PPG was 17.7 ± 3.8 mmHg, decreasing to 16 ± 2.7 mmHg after maximum NSBB titration. A significant hemodynamic response (>20% EUS-PPG reduction or <12 mmHg absolute value) was observed in only three patients (42.8%). At univariate logistic regression, EUS-PPG was associated with hepatic decompensation (p = 0.025).

Conclusion: EUS-PPG measurement is safe and might have a prognostic role in patients with PSVD and CSPH, outperforming HVPG.

SAT-372

Spleen stiffness in porto-sinusoidal vascular disorder: link to portal hypertension and varices

Lydie Ponselet[1], Nicolas Lanthier[2], Bénédicte Delire[1], Stéphanie André-Dumont[1], Géraldine Dahlqvist[1].

Email: geraldine.dahlqvist@saintluc.uclouvain.be

Background and aims: Porto-sinusoidal vascular disorder (PSVD) represents a recently recognized clinical entity. Patients with PSVD commonly present presinusoidal portal hypertension along with its associated complications. In the case of PSVD, spleen stiffness measurement (SSM) could help us in identifying patients with portal hypertension (PH) and who are at high risk of developing esophageal varices and bleedings. The aim of the SPLENO-HYPE study is to prospectively follow patients with PSVD who have benefited from an assessment, by measuring liver and SSM, and to study the links between SSM and complications.

Method: Interim (6-month) analysis of our prospective monocentric study of PSVD patients defined following the recent guidelines. Data include demographic data, clinical, biological and radiological data, liver biopsies findings and liver stiffness measurements (LSM) and SSM with the FibroScan® Expert 630.

Results: During the first 6-month period, 22 patients with PSVD were included, 20 with nodular regenerative hyperplasia (NRH) and 2 with incomplete septal fibrosis on the liver biopsy. Among the 22 patients, the majority (20/22, 90.91%) exhibited clinical and biological markers of significant PH. Thrombocytopenia (platelet count <150,000/mm³) was observed in 77% of patients as well as splenomegaly with an average spleen size of 16.5 ± 2.7 cm. Oesophageal varices were present in 85% of the cohort (17/20) including 7 with grade 2 and 5 with grade 3 varices. The mean LSM was 12.6 ± 8.7 kPa. Half of the patients had values below 10 kPa, 27% had values between 10 and 15 kPa, and 23% exceeded 15 kPa. Notably, most patients with values below 10 kPa showed signs of significant PH, including thrombocytopenia, splenomegaly (8/11), and esophagogastric varices (9/11). All patients without significant PH had values under 15 kPa. The mean SSM was 65.6 ± 25.3 kPa. A weak positive correlation was observed between SSM and the grade of esophageal varices (R^2 = 0.178), while the correlation was stronger between platelet count and esophageal varices (R^2 = 0.441). Only three patients had values below 40 kPa. These patients showed no signs of significant PH. On all patients with SSM > 40 kPa, only one patient did not have evidence of significant PH. When comparing patients with SSM <40 kPa (n = 3) to those with increased SSM, there were no significant differences in terms of platelet count, spleen size, ALBI score, or LSM. However, the presence of esophageal varices differed significantly (p < 0.001).

Conclusion: Patients with PSVD commonly present with significant PH features. Elevated SSM, > 40 kPa threshold observed in cirrhosis, together with a LSM incompatible with cirrhosis indicates a diagnosis of PSVD and may serve as a useful marker for screening esophageal varices. Integrating platelet count into the assessment could further enhance screening strategies. Validation in larger cohorts is needed.

Background and aims: Wilson's Disease (WD) is a rare systemic disorder with few published epidemiologic data in Portugal. We aimed to characterize WD nationwide, by estimating its prevalence

and assessing its clinical presentation, treatment and monitoring across the country.
Method: Multicentric cross-sectional study in adults living in Portugal diagnosed with WD, with an ongoing hospital follow-up and updated records by the end of December 2023 at a national liver database (Liver.pt, sponsored by the program "Hepatologia em Rede"). We collected data regarding demographic and clinical characteristics since diagnosis until the patients' last appointment. Only living patients were considered for analysis.
Results: 156 patients with WD, followed in 20 different Portuguese hospitals. 95% were Portuguese, mean-aged 44 ± 13 years (min-max. 18–80 years) with 52% males.
We estimated a WD prevalence in Portugal of 1.89 cases per 100,000 inhabitants, considering that we were able to include all patients diagnosed and none remained undiagnosed. This was calculated using the official population numbers published by our statistics national institute in 2022, reporting 8,264,506 inhabitants between 18–80 years. The mean age at WD diagnosis was 23 ± 14 years. Most patients (60%) presented exclusively with liver-related symptoms, 18% with neurological manifestations and 18% with both. Regarding the liver-related symptoms, 46% of the patients presented with elevated liver enzymes without advanced fibrosis, 20% had liver cirrhosis (LC) (Child-Pugh A in 68% and B in 32%), 9% acute liver failure and 3% acute hepatitis without liver failure. Four percent were asymptomatic and diagnosed through family screening. Around two-thirds of patients were initially treated with penicillamine, 18% with trientine and 16% with zinc. Currently, after excluding the transplanted patients, there are 45% patients under penicillamine, 33% on trientine and 21% on zinc. We registered a mean of 1.23 drugs per patient during a median follow-up of 21 years, which included 102 drug discontinuations (52 of penicillamine, 38 of zinc and 12 of trientine). The most common reasons for penicillamine withdrawal were side effects (33%) and stock rupture in 2006 (31%). Disease progression was the most frequent reason for zinc (57%) and trientine (44%) discontinuation. Intolerance was recorded in 14% with zinc, 11% with trientine and 10% with penicillamine. During follow-up, 32 patients (20%) underwent liver transplantation (LT). LC at diagnosis was associated with a 4.5 times increased risk for LT.
Conclusion: Our estimated prevalence of WD in the Portuguese population was similar to the numbers reported in the literature (1:30,000–50,000). The course of WD was characterized by multiple therapeutic regimens and therefore needs close monitoring for adhesion and side effects, since in fact one fifth of the patients finally needed LT, although under follow-up and treatment. This was the first nationwide epidemiologic study of WD in Portugal.

Email: marina.gomes@live.fr

Background and aims: Porto-sinusoidal vascular disorder (PSVD) is a chronic and rare liver disease leading to the development of portal hypertension. There is no data concerning health related quality of life (HRQoL) in patients with PSVD. This study aimed to assess the HRQoL in patients with PSVD with signs of portal hypertension and to identify clinical characteristics associated with impaired HRQoL.
Method: This is a French prospective, observational, multicenter study, ancillary to the APIS phase III randomized controlled trial (NCT04007289), that included patients with PSVD and signs of portal hypertension, according to VALDIG criteria. We assessed HRQoL at inclusion in the trial using the SF-36 questionnaire, a generic score, and the CLDQ questionnaire, a liver disease-specific score. Lower values of these scores indicate poorer HRQoL. We compared HRQoL to data reported in the literature for other liver diseases. We then assessed characteristics associated with impaired HRQoL using univariate analyses, followed by stepwise regression with Benjamini-Hochberg correction (q value).
Results: Between June 2019 and December 2023, 166 patients with PSVD and sign of portal hypertension were included; 143 and 157 patients filled out the SF-36 and CLDQ questionnaires, respectively. Median age was 55 years and 53% were men. 67% had porto-systemic collaterals, and 36% had high-risk varices. Median prothrombin index was 86%. The physical component summary (PCS) and even more the mental component summary (MCS) of the SF-36 score were altered (45 ± 9 and 44 ± 12, respectively), and below the normative value of 50 for healthy U.S. populations. The overall CLDQ score was 5.0 ± 1.16. As compared with data available in the literature, patients with PSVD patients reported poorer HRQoL than those with viral hepatitis, MASLD, or cholestatic liver disease, particularly concerning the mental component of the SF-36 and CLDQ scores. Conversely, HRQoL in PSVD patients was higher than that of patients with severe or decompensated cirrhosis. Comparisons with MASH and hepatocellular carcinoma were less conclusive. Lower serum albumin, lower hemoglobin levels, and a history of upper gastrointestinal bleeding were associated with trends towards lower PCS scores ($q = 0.062$ for each). HIV infection and diabetes were significantly associated with lower MCS scores ($p = 0.029$ each). Lower hemoglobin concentration was strongly associated with a reduced overall CLDQ score ($q = 0.003$).
Conclusion: Patients with PSVD and signs of portal hypertension have an impaired HRQoL, particularly in terms of mental components of the scores. Their HRQoL is poorer than that of patients with viral hepatitis, MASLD or cholestatic liver disease, and higher than that of patients with decompensated cirrhosis. Features associated with

lower HRQoL scores included lower hemoglobin concentration, diabetes, and HIV infection.

SAT-375

Frequency of ATP7B gene variants in brazilian patients with Wilson's disease

Maria Chiara Chindamo[1], Ida Vanessa Schwartz[2], Gabriel Quintana[2], Carla C. Judice[3], Bruno Pereira Ribeiro da Rocha[4], Paulo Sgobbi[5], Thais Guaraná[6], Vivian Rotman[1], Luciana Agoglia[6], Cibele Franz[7], Renata Perez[1]. *[1]Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; [2]Federal University of Rio Grande do Sul, Porto Alegre, Brazil; [3]State Campinas University, Campinas, Brazil; [4]Hospital da Criança, Rio de Janeiro, Brazil; [5]Federal University of São Paulo, São Paulo, Brazil; [6]Fluminense Federal University, Rio de Janeiro, Brazil; [7]Universidade Federal do Rio de Janeiro -UNIRIO, Rio de Janeiro, Brazil*
Email: mchiara@terra.com.br

Background and aims: Wilson's disease (WD) is a rare genetic disorder with over 900 variants identified in the *ATP7B* gene. Understanding the regional distribution of these variants can improve WD diagnosis and direct future treatments based on disease phenotype. This study aimed to evaluate the frequency of *ATP7B* variants in a Brazilian WD cohort and their association with clinical phenotypes.
Method: Genetic analysis was performed using massive parallel sequencing of the 21 exons and exon-intron junctions of *ATP7B* (Mendelics Genomic Analysis Laboratory) in patients diagnosed with WD and their first-degree relatives under investigation. Participants were recruited from two Brazilian centers. Demographic data and predominant clinical presentations were assessed.
Results: Forty-one individuals were included (58% female; mean age 26 ± 12 years): 38 with confirmed WD and 3 heterozygous relatives without clinical disease. Among WD patients, phenotypes were distributed as follows: 21/38 (55%) with isolated hepatic manifestations, 7/38 (18.5%) with hepatic and neurological symptoms, 7/38 (18.5%) with isolated neurological manifestations, and 3/38 (9.0%) asymptomatic. A total of 76 *ATP7B* variants were identified. The pathogenic variants c.3402delC, c.2123T > C, and c.3818C > T showed the highest allele frequencies at 19.8%, 14.5%, and 10.5%, respectively. Most patients (87.0%) exhibited compound heterozygosity, while 8.0% had homozygosity and 5.0% simple heterozygosity. Variants c.2145C > T, c.1552T > C, c.2866-6T > G, c.2562G > C, and c.3188C > T were classified as of undetermined significance, whereas c.2072G > T, c.3551T > C, exon 3–4 deletion, c.3694A > C, and c.3071_3072delTG were classified as likely pathogenic. Regarding the disease phenotype, patients with variants c.3402delC CG > C and c.2123T > C presented equal distribution of the isolated hepatic or hepatic plus neurological phenotype, while c.3818C > T variant was associated with predominantly hepatic phenotype. Presence of exon 2 deletion was associated with severe neurological manifestations.
Conclusion: The *ATP7B* variants c.3402delC, c.2123T > C, and c.3818C > T were the most prevalent in this Brazilian cohort. Variants of undetermined significance, such as c.2145C > T and c.3188C > T, were identified in confirmed WD cases. A high genotype heterogeneity was observed, correlating with diverse phenotypic presentations.

Email: mfromme@ukaachen.de

Background and aims: Liver disease in severe alpha-1 antitrypsin (AAT) deficiency (Pi*ZZ genotype) displays a biphasic pattern with the first peak in early childhood and the second, adult peak after the age of 40 years. Our aim was to histologically characterize the pediatric and adult liver disease.
Method: We recruited 67 adults and 48 Pi*ZZ children aged four weeks to 17 years from six countries who underwent a liver biopsy/transplantation. A blind histological scoring was performed by two histopathologists.
Results: Pediatric Pi*ZZ samples originated more often from liver transplantation (64.6 vs. 21.2%, $p < 0.0001$) and children displayed significantly higher liver enzymes than adults. Compared to adults, children presented a significantly higher fibrosis stage according to METAVIR (4.0 vs. 2.5, $p < 0.0001$). Higher liver steatosis was more prevalent in Pi*ZZ adults, while bile plugs and duct paucity were significantly more common in Pi*ZZ children (bile plugs: 43.8 vs. 10.4%, $p < 0.0001$; duct paucity 58.3 vs. 1.5%, $p < 0.0001$). No difference in AAT accumulation scores according to Clark was found. When subdividing the pediatric cohort based on age (<1 year, 1–5 years and 6–17 years), cirrhosis was more common in both older age groups than in younger children (64.7 vs. 75.0 vs. 30.8%, $p = 0.045$). There were no differences in liver steatosis, inflammation, or cholestasis parameters, but youngest children displayed less AAT accumulation and less frequently had larger aggregates.
Conclusion: Our study reveals unique histological patterns in Pi*ZZ children and adults thereby providing basis for patient counseling and further mechanistic studies.

SAT-381

Rapid liver disease progression after first hepatic decompensation in individuals with severe alpha-1 antitrypsin deficiency (Pi*ZZ genotype)

Email: mfromme@ukaachen.de

Background and aims: Although severe alpha-1 antitrypsin deficiency (AATD, Pi*ZZ genotype) predisposes to liver disease, the role of AATD in decompensated liver cirrhosis is unclear. The aim of this study was to evaluate the impact of the Pi*ZZ genotype on the further course of liver disease after the first hepatic decompensation event.
Method: We retrospectively included 59 Pi*ZZ individuals with decompensated cirrhosis from 12 European centres and applied propensity score matching for Child-Turcotte-Pugh (CTP) score as well as age/sex to compare the natural disease course with other cirrhosis etiologies. After first decompensation as baseline event, subjects were followed until further decompensation, liver transplantation, or liver-related death.
Results: Most patients were male (75%) and had a mean age of 55 years. The most common first hepatic decompensation event was ascites (68%), followed by variceal bleeding (22%) and overt hepatic encephalopathy (10%). At first decompensation median CTP/MELD scores were 8/14 points and at listing/liver transplantation 16/20 points, respectively. Median time on transplantation list was 2.9 [IQR 1.1–7.2] months. Compared to Pi*ZZ individuals, patients with other etiologies (SHR: SLD 0.62, $p = 0.007$; abstinent ALD 0.50, $p < 0.001$; HCV 0.56, $p = 0.004$) presented with significantly lower risk of further hepatic decompensation, liver transplantation, or liver-related death. Exchanging further decompensation by ACLF yielded comparable results.
Conclusion: Our study defines the natural disease course of Pi*ZZ individuals with decompensated liver cirrhosis that was more progressive than in other etiologies thereby underlining the need for disease-specific therapies and early listing for liver transplantation after first decompensation.

SAT-382
Can drug metabolites predict outcome of Wilson disease?

Moinak Sen Sarma[1], Ashish Gupta[2], Amresh Kumar[1], Ujjal Poddar[1], Anshu Srivastava[1]. [1]*Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India;* [2]*Center for Biomedical Sciences, Lucknow, India*
Email: moinaksen@gmail.com

Background and aims: D-penicillamine (DP) is bound to proteins, metabolised in the liver in a Phase II reaction and excreted in urine. Its metabolites are not routinely measured for drug monitoring. We aimed to study if there is any correlation of hepatic metabolites of DP in clinical response and toxicity in Wilson disease (WD).
Method: WD children completing >1 year of therapy were prospectively assessed for DP metabolites in urine. Urine samples were collected 5 hours after the ingestion of 15–20 mg/kg of DP. Samples were processed by proton nuclear magnetic resonance (^{1}H-NMR) spectroscopy. The pH dependent longitudinal ^{1}H NMR spectra of patient urine samples were recorded with pH from 4.5 to 9.0, with 0.5 increment; at 25°C with water suppression using pre-saturation single pulse experiment. The findings were validated using liquid chromatography and mass spectroscopy. The ratios of the metabolites were assessed. Response was defined as near-normalisation of liver enzymes and synthetic functions. Adequate chelation was defined as exchangeable copper <0.87 micromol/L.
Results: 61 WD children, aged 11.8 (6–19) years on 5(1.5–10) years of chelation had baseline pediatric end-stage liver disease (PELD) score of 3(−9 to 43). 77% had predominant excretion of penicillamine-disulphide (PD) and penicillamine-cysteine-disulphide (PCD) while 23% excreted S-methyl cysteine (SMC) or N-acetyl penicillamine (NAP) with median levels 54 (1.8–778), 123 (5.1–2501), 20 (0.5–556) and 7.3 (0.3–200) micromol/L respectively. 74% were responders and 47% had adequate chelation. CuEXC was lower in responders than non-responders [0.73(0.2–1.78) vs 1.08(0.44–2.73) micromol/L, $p = 0.009$], Those showing adequate chelation had higher PCD/SMC ratio as compared to SMC/NAP ratio ([5.6 (0.12–49) vs 3.2 (0.5–470, $p = 0.03$]. Non-responders had significantly higher PD/NAP as compared to other metabolite ratios. 8 (13%) patients with bone marrow toxicity had higher NAP/PCD than other metabolites. 5 patients with subnephrotic proteinuria had higher SMC [15 (6.8–49) vs 2.3 (0.12–25) micromol/L, $p = 0.03$] than patients without proteinuria.
Conclusion: Dominant metabolic pathways and the ratio of their metabolites may determine the outcome in hepatic Wilson disease.

SAT-383-YI
Non-invasive stratification of portal hypertension in patients with BCR::ABL1-negative myeloproliferative neoplasms

Can Hopp[1], Lina Degenfeld-Schonburg[1], Lorenz Balcar, Georg Kramer[1], Irene Graf[1], Lucie Simonis, Christian Sillaber[1], Heinz Gisslinger[1], Tobias Meischl[1], Albert Friedrich Stättermayer[1], Mattias Mandorfer, Thomas Reiberger, Michael Trauner, Bernhard Scheiner[1], Maria-Theresa Krauth[1], Georg Semmler. [1]*Medical University of Vienna, Vienna, Austria*
Email: n12025931@students.meduniwien.ac.at

Background and aims: The course of BCR::ABL1-negative myeloproliferative neoplasms (MPN) is frequently complicated by thromboembolic events in the splanchnic venous system, resulting in portal hypertension. The introduction of spleen stiffness measurement (SSM) might improve the diagnosis of portal hypertension in these patients. Therefore, the aim of this study was to evaluate the clinical utility of SSM (performed by using the 100 Hz probe) in non-invasive stratification of portal hypertension in patients with MPN.
Method: We performed a retrospective, mono-centric, cross-sectional analysis including all patients with MPN attending the haematological outpatient clinic at the Medical University of Vienna with available liver stiffness (LSM)/SSM from 10/2023 to 09/2024. LSM/SSM were linked to signs and events of portal hypertension.
Results: Fifty-nine patients were included (mean age 58.5 ± 14.0 years, 70% females, polycythaemia vera and essential thrombocythaemia as main entities). One fourth of patients had portal vein thrombosis. While 18 patients (30.5%) had specific, 29 patients (49.2%) had unspecific signs of portal hypertension. Twelve patients (20.3%) experienced portal hypertensive events prior to study inclusion. LSM/SSM adequately stratified patients with vs. without portal hypertension. SSM was independently linked to portal hypertension and showed numerically higher model characteristics compared to LSM. LSM <5/≥15 kPa as well as sequential SSM <21/≥50 kPa can adequately rule-in and -out portal hypertension with a remaining grey zone of 24%.

Conclusion: LSM/SSM were associated with portal hypertension in patients with MPN. A sequential application of easy-to-remember cut-offs for ruling-in and ruling-out of portal hypertension might improve the clinical management and decision-making in patients with MPN.

SAT-384

Antinuclear antibodies target unknown autoantigens in porto-sinusoidal vascular disorder without portal hypertension

Nicola Pugliese[1], Antonio Tonutti[1], Natasa Isailovic[1], Davide Polverini[1], Angela Ceribelli[1], Stella De Nicola[1], Maria De Santis[1], Carlo Selmi[1], Alessio Aghemo[1]. [1]*Department of Biomedical Sciences, Humanitas University, Milan, Pieve Emanuele, Italy, Milan, Italy*
Email: nicola.pugliese@live.com

Background and aims: Recent evidence links porto-sinusoidal vascular disorder (PSVD) to connective tissue diseases. Antinuclear antibodies (ANA) are a hallmark of these conditions, but their prevalence and significance in patients with PSVD without portal hypertension (noPH-PSVD) remain unclear.
Method: Sera from patients with noPH-PSVD were analyzed for ANA using indirect immunofluorescence (IIF) on HEp-2 substrates (HEp-2 IIF). ANA-positive cases underwent RNA immunoprecipitation (RNA-IP) to identify autoantibodies for specific ribonuclear proteins. Patients with cytoplasmic staining on HEp-2 IIF, underwent ELISA for antimitochondrial antibodies (AMA), targeting the E2 subunit of the pyruvate dehydrogenase complex (anti-E2-PDH).
Results: Sixteen patients were enrolled, with a median age of 42 years (range 22–58), and 56% were female. Autoimmune comorbidities included thyroiditis in 4 patients, multiple sclerosis in one. PSVD diagnosis was based on histological evidence of nodular regenerative hyperplasia identified on liver biopsy performed for unexplained liver enzyme abnormalities. ANA were found in 8 out of 16 (50%) patients using HEp-2 IIF with titers ranging from 1:80 to 1:320. A cytoplasmic reticular/AMA-like pattern was observed in 4/16 (25%) patients, a speckled pattern in 1/16 (6.25%), a nucleolar pattern in 2/16 (12.5%; one co-occurring with a cytoplasmic reticular pattern) and a mitotic pattern (mitotic centrosome and NuMA-like) in 2 out of 16 (12.5%) cases. RNA-IP did not identify autoantibodies against specific ribonuclear proteins in any patient. Moreover, none of the patients with a cytoplasmic reticular/AMA-like pattern tested positive for anti-E2-PDH autoantibodies via ELISA.
Conclusion: In this noPH-PSVD cohort, ANA were detected in 50% of cases using gold-standard techniques. Despite 25% showing an AMA-like pattern, anti-E2-PDH testing by ELISA was negative, suggesting these ANA may target mitochondrial antigens distinct from those in primary biliary cholangitis. A notable proportion of ANA-positive patients showed mitotic staining, uncommon in connective tissue diseases. Although ANA prevalence was high, RNA-IP did not reveal specific autoantibodies, highlighting the need for further testing like protein immunoprecipitation or immunodiffusion.

SAT-385

The prevalence and risk factors of metabolic dysfunction - associated steatotic liver disease in patients with transfusion dependent thalassemia

Nikolaos Fragkou[1], Vasileios Rafailidis[2], Euthimia Vlahaki[3], Ioannis Goulis[4], Emmanouil Sinakos[4]. [1]*Fourth Department of Internal Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece;* [2]*Department of Clinical Radiology, AHEPA University Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece;* [3]*Adult Thalassemia Unit, Second Department of Internal Medicine, Hippokration General Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece;* [4]*Fourth Department of Internal Medicine, Hippokration General Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece*
Email: nikosfragkoy@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing concern in individuals with transfusion-dependent thalassemia (TDT), a disease characterized by chronic anaemia requiring lifelong blood transfusions. Limited data exist on the MASLD prevalence in this population. This study evaluates the prevalence of MASLD in patients with TDT using magnetic resonance imaging proton density fat fraction (MRI-PDFF) and identifies associated risk factors, including the adherence to the Mediterranean Diet (MD).
Method: Patients with TDT were prospectively recruited and underwent MRI-PDFF to assess hepatic fat content. Liver iron concentration (LIC) was measured using T2* calculations. Liver stiffness (LS) and Controlled Attenuation Parameter (CAP) were measured via transient elastography. Adherence to the MD was assessed using the Mediterranean Diet Adherence Screener (MEDAS) questionnaire. Clinical and laboratory data was collected including all known cardiometabolic factors. Steatosis was staged based on MRI-PDFF as follows: grade S0 (<5.75%), grade S1 (5.75–15.5%), grade S2 (15.5–21.35%), and grade S3 (≥21.35%). MASLD was defined as the presence of hepatic steatosis (MRI-PDFF ≥5.75%) in patients without secondary causes of liver fat accumulation and the existence of ≥1 cardiometabolic factor per EASL guidelines. Individual risk factors for the development of hepatic steatosis were identified using multivariable linear regression. Patients with severe LIC (LIC >15 mg Fe/g), chronic viral hepatitis and suspected alcohol abuse were excluded.
Results: The cohort included 60 patients (53.3% women; mean age of 47.2 ± 8.1 years). Ten patients (16.7%) had steatosis ≥S1, all of whom had at least one cardiometabolic factor. The mean PDFF value was 3.77 ± 3.75%. Mean LS value was 5.6 ± 2.4 kPa and mean CAP value was 221.5 ± 36.3 dB/m. CAP values were significantly higher in patients with MASLD compared to those without the condition (251 vs 216 dB/m, $p < 0.01$). Multivariable linear regression analysis identified that factors such as BMI > 25 kg/m^2 (adjusted beta = 1.84, $p = 0.046$), homeostasis model assessment-estimated insulin resistance (HOMA-IR, adj. beta = 2.27, $p = 0.003$), poor adherence to the MD, as indicated by the MEDAS questionnaire (adj. beta = –0.32, $p = 0.099$) and LIC (adj. beta = 1.072, $p < 0.001$) constitute individual factors, which influence the MRI-PDFF value.
Conclusion: Our study is one of the first to indicate that MASLD is becoming a prevalent condition in TDT patients, due to metabolic and dietary factors and possibly related to the current greater life span of these patients. The identified risk factors underscore the need for integrated clinical strategies focusing on insulin resistance management, LIC reduction and dietary modifications, including enhanced adherence to the MD, to mitigate the risk of MASLD in this population.

SAT-386

The Alpha-1 foundation research registry: liver disease among alpha-1 antitrypsin deficiency patients in a United States cohort

Alison Keaveny[1], Nadine Nuchovich[1], Monica P. Goldklang[2], Jennifer Illarramendi[1], Randel Plant[1], Jeanine M. D'Armiento[1,2]. [1]*Alpha-1 Foundation, Coral Gables, United States;* [2]*Columbia University Irving Medical Center, New York, United States*
Email: akeaveny@alpha1.org

Background and aims: While Alpha-1 Antitrypsin Deficiency (AATD) is commonly known as genetic COPD, certain variants can lead to an increased susceptibility of severe liver disease. The Alpha-1 Foundation (A1F) has maintained a database of AATD patients since 2019, which collects ongoing data on the characterization of AATD across over 20 different genotypes within the United States. We aim to highlight characteristics among liver-affected patients with AATD within this longitudinal study.
Method: The Alpha-1 Foundation Research Registry (A1F Registry) enrolled over 3800 participants from all 50 states through REDCap between June 2019 to November 2024. Over 1,300 discrete data points per patient were captured. Utilizing the patient reported questionnaire, liver-affected patients were defined as A1F Registry participants who responded yes to any liver disease (MASH, liver

cirrhosis, fatty liver disease, mild/moderate/severe liver disease, cholestasis,) or have had a history of childhood jaundice, variceal bleeding, ascites, abnormal liver enzymes, or spontaneous bacterial peritonitis.

Results: Overall, among all Registry participants who responded to reasons for AATD testing (n = 2988), 10% reported AATD diagnosis due to liver symptoms, with other reasons including lung symptoms (43%), family history (32%), and incidental findings on direct-to-consumer testing (7%). Though AATD testing was reported in 10% due to liver symptoms, 46.7% reported to be liver-affected (n = 2962), of which 51.7% reported fatty liver disease, 54.5% reported abnormal liver function tests and 10.2% MASH. Liver-affected Registry participants identify largely as female (69.3%), with a mean age of 54.1 ± 16.26 years (range <1–91 years) (n = 1386). Of those reporting genotypes (n = 1349), 40% were PiZZ, 11.3% PiSZ, 28.5% PiMZ, 10.4% other rare genotypes and 9.8% unknown. Participants with liver disease reported standard of care liver assessments, such as Fibroscan (17.1%) or abdominal ultrasound (56.9%) (n = 1228). Among Registry participants who are liver-affected (n = 1386), 39.4% also reported a diagnosis of COPD or emphysema. Current augmentation therapy usage was reported in 26.2% of liver-affected patients.

Conclusion: The complete profile of liver-affected AATD patients including symptomology, diagnosis, and treatment demonstrated in the A1F Registry allows a better understanding of liver disease in this population. This longitudinal study contains clinical data beyond phenotype that can be utilized to determine liver disease burden in the community and allow for targeted recruitment efforts in clinical trials. This initiative empowers the Alpha-1 community and highlights the need to further characterize liver disease in AATD patients with a robust natural history study.

SAT-387

Trajectories of serum bile acid levels and their determinants in progressive familial intrahepatic cholestasis: insights from the NAPPED consortium

Background and aims: Bile Salt Export Pump (BSEP) deficiency, also known as Progressive familial intrahepatic cholestasis type 2 (PFIC 2), is a rare genetic liver disease characterized by chronic cholestasis. Treatment strategies to decrease serum bile acid (sBA) levels have been shown to improve the prognosis of patients with BSEP deficiency. This study aimed to identify trajectory patterns of sBA levels in a natural history cohort of individuals with BSEP deficiency, that could help target therapeutic interventions.
Method: Data were obtained from the NAtural Course and Prognosis of PFIC and Effect of biliary Diversion (NAPPED) Registry, a leading worldwide PFIC patient database. We included individuals not treated with IBAT inhibitors, and censored their follow-up at age 18, surgical biliary diversion, or liver transplantation. A latent class mixed-effects model was used to identify classes of sBA trajectories. sBA measurements were log-transformed to address right skewness. We modelled the progression of sBA from birth to age 18 years using natural cubic splines—which allow for flexible nonlinear changes over time—with knots at the 0.05, 0.35, 0.65, and 0.95 percentiles. The optimal number of trajectory classes was determined using the Akaike and Bayesian information criteria and requiring each subgroup to include at least 10% of the total study population.
Results: We analysed data from 317 individuals with BSEP deficiency, who collectively contributed 1,224 sBA measurements. Each individual had at least one sBA measurement (median 2.0, interquartile range [IQR] 1.0–5.0), with a median follow-up duration of 2.8 years (IQR 0.9–7.8). Our analysis identified two log-sBA trajectories: (1) a high-stable trajectory (82% of the individuals) with a plateau at ~165 µM, (2) a "horizontal hockey-stick" trajectory (18%), characterized by a similar start sBA followed by a decline towards a plateau ~8 µM from around age 5 years. Among individuals who were censored because of transplantation or surgical biliary diversion, 94% and 96%, respectively, belonged to the high stable trajectory, compared to 6% and 4% in the second trajectory group.
Conclusion: This study identified two distinct sBA trajectories in BSEP deficiency, with one trajectory strongly associated with liver transplantation and surgical biliary diversion. These findings suggest heterogeneous disease progression and support the development of trajectory-specific management strategies.

SAT-388
Integrated PK-PD model relating serum copper concentrations, urinary copper clearance and trientine pharmacokinetics in Wilson disease: initial insights from the UNITED study

Email: p.vis@lapp.nl

Background and aims: In Wilson Disease (WD) patients, a mutation in the ATP7B gene results in an impaired copper homeostasis and copper accumulation in the body. Chelator treatment of patients with WD, including trientine dihydrochloride (TETA-2HCl) therapy, aim to reduce copper levels by its sequestration and enhanced elimination. While the effects of TETA-2HCl have been demonstrated in both non-clinical and clinical studies, no dedicated pharmacokinetic (PK) – pharmacodynamic (PD) modelling was ever performed. The aim of the present analysis was to reveal and quantify the relationships between the systemic trientine (TETA) exposure, its effect on serum copper markers and urinary copper excretion, as well as the influence of patient characteristics on these relationships in a broad WD patient population by means of PK-PD modelling, based on data collected during the up-titration phase of study TR-004 ("UNITED").
Method: A population PK-PD model was developed to describe the data collected during the first four weeks of study TR-004 ("UNITED"). The model was constructed as follows: first, a population PK model was developed and fitted to the data over the first 4 weeks of TETA-2HCl treatment. Then, the modelled individual TETA PK parameters were related to total 24 hour urinary copper excretion (24h-UCE) and serum non-ceruloplasmin bound copper (NCC) concentrations using an integrated population PK-PD model. As a main characteristic of the model, urinary exchangeable copper clearance (CUCL; L/h) was modelled, while the 24h-UCE and serum NCC concentrations were fitted to the data. CUCL was related to 24h-UCE (ug) through a modelled median serum NCC (ug/L).
Results: The final population PK-PD model described a baseline CUCL (BL), extended by a TETA-induced CUCL. Serum NCC was expressed as a balance between copper influx and copper efflux and was the driver of BL. To account for the observed relationship between serum NCC and the effect of TETA on CUCL (quantified by the slope; SL), a multiplicative model was incorporated, in which CUCL was affected by TETA in a multiplicative fashion (i.e. CUCL = BL*(1+SL*TETA)). Inter-individual variability (IIV) was included on all parameters of the model (BL, SL, and serum NCC). Covariate analysis revealed a positive relationship between baseline alanine transferase (ALT) and serum copper influx (Kin) as well as a positive relationship between body weight and SL. The model described both the 24h-UCE and serum NCC data well, as demonstrated by several numerical and graphical assessments. All parameters of the model were estimated with good precision.
Conclusion: The final population PK-PD model described the relationship between TETA and 24h-UCE well and indicated potential effects of baseline ALT and weight on urinary excretion parameters. The model may form the basis of a response-guided dosing for TETA-2HCl in WD.

Background and aims: Wilson disease (WD) is an inherited disease leading to dysfunction of ATP7B protein responsible for the biliary excretion of excess hepatocellular copper (Cu) and bioincorporation of 6 Cu atoms into each ceruloplasmin (Cp) molecule. In unaffected individuals, Cp bound Cu (CpCu) accounts for 90–95% of total circulating Cu, and only the remaining 5–10% is bioavailable. This bioavailable fraction is elevated in untreated WD and lowering its value is a treatment goal. Estimating bioavailable Cu by the standard formula NCC-Cal (mcrg/L) = Total Cu (mcrg/L) - 3.15 * Cp (mg/L) has recognized limitations. Newer methods that do not require Cp measurement include exchangeable Cu (NCC-Ex), based on chelation of bioavailable Cu with EDTA followed by ultrafiltration, and chromatographic protein speciation followed by measurement of Cu in the Cp peak (NCC-Sp). We compared these methodologies in WD patients on chelation therapy included in a clinical trial.
Method: This is a post-hoc analysis of data from the Chelate Study (Lancet Gas-Hep 2022;7: 1092). We examined measurements of Total Cu (by ICP-MS), Cp (enzymatic method), NCC-Ex (Anal Bioanal Chem 2009;394:1477), and NCC-Sp (Anal Bioanal Chem 2021;414:13) in serum samples from WD patients stable on penicillamine (DPA) during a 12 weeks run-in screening period (N = 77) and during further 48 weeks after randomization (N = 53) to either continued DPA dose or same dose of trientine tetrahydrochloride (TETA4).
Results: Measurement of Cp was available in 344 samples from 76 patients. In 127 (37%, 100 received DPA at time of measurement, and 27 TETA4) with Cp above the LLOQ for the assay (52 mg/L). Total Cu was available in 118 (92 DPA/27 TETA4) for calculation of NCC-Cal, and these values were compared with NCC-Sp (n = 118; 92 DPA/27 TETA4) and NCC-Ex (n = 108; 85 DPA, 20 TETA4). While the NCC-Ex/NCC-Sp ratio was 1.10 ± 0.44 (Mean ± SD), the NCC-Cal/NCC-Sp ratio was 2.36 ± 1.42 (mean ± SD), and the NCC-Cal/NCC-Ex ratio 2.32 ± 1.24. As evaluated by linear regression NCC-Cal mcrg/L = (1.26*NCC-Sp+62) mcrg/L, R^2 0.17, $p < 10^{-5}$, and NCC-Cal (mcrg/L) = (NCC-Ex*2.12+14) mcrg/L, $R^2 = 0.26$, $p < 10^{-7}$). These relations were not affected by treatment at time of blood sampling. In 2/127 samples, NCC-Cal was negative.
Conclusion: While NCC-Ex and NCC-Sp differed slightly, NCC-Cal was 2.3–2.4 times higher, adding to the known concerns about inter-laboratory variation and negative values of NCC-Cal. Treatment targets in WD should be method specific and recalibration of appropriate treatment ranges is needed. NCC-Sp and NCC-Ex should replace NCC-cal as a study and clinical endpoint as direct estimations of bioavailable copper (NCC-Sp and NCC-Ex) are not subject to the limitations of Cp measurement. Further work is needed to determine the Cu/Cp ratio in WD to explore potential differences from unaffected patients.

Background and aims: Zinc salts (Zn) constitute a well-known treatment for Wilson disease (WD) by reducing copper intestinal uptake (Munk E, 2021). Current WD guidelines (EASL 2012, AALSD 2022) advocate for the use of chelators as first-line therapy, whereas Zn is mainly reserved for asymptomatic patients or maintenance treatment. There is limited experience with Zn as first-line therapy, with some studies suggesting suboptimal outcomes (Weiss, 2011). We aimed to describe the characteristics and clinical outcomes of WD patients treated with first-line monotherapy with Zn in Spain.
Method: Descriptive analysis of patients within the Wilson AEEH Registry (27 centers involved, >500 patients) receiving Zn monotherapy as first-line therapy in Spain. Clinical and analytical data were collected at diagnosis, as well as treatment changes and hepatic outcomes. Variables were expressed as median (IQR) and n (%). Statistical analysis was performed with SPSS.
Results: One-hundred and nine WD patients from the Registry (21%) received Zn (94% acetate, 6% sulfate) as first-line therapy in Spain (59% male, 68% index cases, 54% adults). Only 43 (39%) of them were classified as "asymptomatic" and had a theoretical indication for Zn. Among symptomatic patients (61%), 90% had hepatic involvement (11% acute, 89% chronic) with 2% presenting with cirrhosis. After 6 months of Zn, adverse effects were reported in 29 (27%) patients, primarily digestive discomfort (83%), elevated transaminases (14%), and skin-related issues (3%). In these patients, a switch to chelators was required in 16 (55%), dose adjustments in 6 (21%), and no modifications were made in the remaining cases. After a median follow-up of 10 (6–16) years, 73 (67%) patients remained on Zn, whereas 36 (33%) required alternative treatments (78% D-penicillamine, 20% trientine, 2% liver transplantation). The main reasons for changing Zn therapy were lack of response (59%), adverse events (36%) or protocol guidance (5%). Patients who remained on Zn monotherapy were more frequently asymptomatic at diagnosis (51% vs. 21%, p = 0.01), had lower baseline ALT levels (64 IU/L vs. 130 IU/L, p = 0.02), and tended to have lower elastographic baseline values (6.3 KPa vs. 9.3 KPa, p = 0.66) (n = 19). At the end of follow-up, no significant differences were observed in liver disease severity between patients on Zn vs. chelators, assessed by elastography or ALT levels, although 3 new cases of cirrhosis were collected on the Zn-monotherapy group.
