Conclusion: In this multicentric Spanish cohort, 21% of WD patients from the Registry received Zn as first-line therapy, despite being 61% of them symptomatic. On the long-term, a significant proportion of patients required change to chelators due to adverse events or lack of response. Patients who remained on Zn had milder clinical

phenotypes. These findings should be interpreted with caution and further investigated.

SAT-391

Switching from zinc salts to Trientine Tetrahydrochloride in Wilson disease: the ZICUP study

Dominique Debray[1], Rodolphe Sobesky[2], Mickael Alexandre Obadia[1], Nouzha OussediK-Djebrani[3], Eduardo Couchonnal[4], Olivier Guillaud[5], Aurélia Poujois[6]. *[1]French National Reference Center for Wilson's Disease and Other Copper-Related Rare Diseases, Rothschild Foundation Hospital, Paris, France, Paris, France; [2]Hepatobiliary Centre, Competence Centre for Wilson Disease, Paul Brousse Hospital, Villejuif, France, Villejuif, France; [3]Toxicology Laboratory, AP-HP, Lariboisière University Hospital, Paris, France, France, Paris, France; [4]Department of Hepatogastroenterology, Edouard Herriot Hospital, Hospices Civils de Lyon, Lyon, France; French National Reference Center for Wilson's Disease and Other Copper-Related Rare Diseases, Femme Mère Enfant Hospital, Bron, France, Lyon, France; [5]Department of Hepatogastroenterology, Edouard Herriot Hospital, Hospices Civils de Lyon, Lyon, France, French National Reference Center for Wilson's Disease and Other Copper-Related Rare Diseases, Femme Mère Enfant Hospital, Hospices Civils de Lyon, Bron, France; [6]French National Reference Center for Wilson's Disease and Other Copper-Related Rare Diseases, Rothschild Foundation Hospital, Paris, France, Department of Neurology, Rothschild Foundation Hospital, Paris, France, Paris, France*
Email: apoujois@for.paris

Background and aims: Wilson disease (WD) is a rare genetic disorder characterized by excessive copper accumulation, primarily affecting the liver and brain, leading to hepatic and/or neurological symptoms. Lifelong treatment aims to prevent copper accumulation and its associated complications. Zinc salts (ZS) are commonly used during the maintenance phase or for asymptomatic patients but are associated with significant gastrointestinal side effects, poor adherence, and reduced efficacy over time. Trientine tetrahydrochloride (TETA4HCL), a copper chelator, offers an alternative for patients who are intolerant to or fail ZS therapy. This study evaluates the clinical and biochemical outcomes of transitioning from ZS to TETA4HCL over a two-year period in patients with Wilson disease, including those with mixed hepatic and neurological symptoms.
Method: A prospective study based on the French WD Registry assessed patients transitioning from ZS to TETA4HCL since 2019. Clinical Global Impression (CGI), treatment adherence, biochemical parameters, Unified Wilson's Disease Rating Scale (UWDRS), adverse events, and dose adjustments were analyzed. A subgroup analysis focused on patients with neurological symptoms.
Results: Twenty patients (14 with hepatic forms and 6 with mixed hepato-neurological forms) were included. The main reasons for transitioning to TETA4HCL were gastrointestinal intolerance (13 patients), loss of efficacy (6 patients), and practical considerations (1 patient). At baseline, 65% of patients presented elevated transaminases. After two years of TETA4HCL treatment, patients remained clinically stable, and adherence to therapy improved. To achieve normal transaminases and exchangeable copper levels, a 39% increase in the initial daily dose of TETA4HCL was necessary. Despite this adjustment, 45% of patients still showed slightly elevated ALT levels. A minimum daily dose of 675 mg TETA4HCL appears necessary. Among the neurological subgroup, UWDRS scores improved in four out of six patients, although brain MRI findings remained unchanged.
Conclusion: Transitioning from ZS to TETA4HCL maintains clinical stability in WD patients, improves adherence, and demonstrates a favorable safety profile. Optimizing dosing remains challenging, as a subset of patients failed to achieve complete biochemical normalization, suggesting potential underdosing. Further studies are needed to confirm optimal posology. These findings support TETA4HCL as a viable therapeutic alternative for patients intolerant to or failing ZS therapy, including those with neurological involvement, emphasizing the importance of ongoing monitoring and individualized dose optimization - Funding: Orphalan Pharma.

SAT-392

Profiling patients with Wilson's disease using a behavioral diagnostic tool (Observia SPUR™): insights into adherence challenges and personalized care strategies

Rodolphe Sobesky[1], Claire Vanlemmens[2], Eduardo Couchonnal[3], Gersende Faton[4], Kevin Dolgin[4], Olivier Guillaud[3]. *[1]Centre Hepatobiliaire, Hopital Paul Brousse, Centre Maladies Rares : Maladie de Wilson et autres maladies rares liées au cuivre, Villejuif, France; [2]Service d'Hépatologie, Hôpital Jean Minjoz, Centre Maladies Rares : Maladie de Wilson et autres maladies rares liées au cuivre, Besançon, France; [3]Service d'Hépato-Gastro-Entérologie et Assistance Nutritionnelle, Hôpital Edouard Herriot, Centre Maladies Rares: Maladie de Wilson et autres maladies rares liées au cuivre, Lyon, France; [4]Observia Group, Puteaux, France*
Email: rodolphe.sobesky@aphp.fr

Background and aims: Adherence to therapy is critical in managing chronic disease. Non-adherence in Wilson's disease (WD) may lead to clinical deterioration, including fatal outcomes. SPUR™ [1] is a behavioural diagnostic tool that assesses the non-adherence risk in patients with chronic illnesses, and the behavioural drivers underlying this risk (Social, Psychological, Usage of treatment, and Rational). Identifying the drivers enables better interactions between patients and healthcare professionals, tailoring communication to the patient's needs. We aimed to evaluate the utility of SPUR™' in WD patients and identify behavioural profiles predictive of non-adherence in WD patients.
Method: In four hepatology clinics in French WD reference centres, patients completed SPUR™ multiple choice questionnaire using digital tablet before consultations, identifying behavioural drivers and generates a non-adherence risk (NAR) score (0–100 increasing from low to high) representing an average of the scores for the 13 behavioural drivers, and the overall dimensions of S,P,U,R. Physicians received results prior to the consultation and tailored communication based on patient response. Feedback from physicians and patients was collected on SPUR™'s utility.
Results: Data from 100 patients, 100% fully completed, were analysed (18: asymptomatic, 55: hepatic symptoms 6: neurological symptoms, 21: mixed phenotype). Treatment regimens included D-penicillamine (49), trientine salts (27 patients on TETA4HCL; 11 on TETA2HCL) and zinc salts (13). 77% of patients reported taking 2–3 doses daily, 42% admitted forgetting treatment at least twice, and 13% missed more than five doses in the past three months. The WD population had a median (range) NAR score of 15,8 [0–86] with high disparities. This is comparable to HIV population. Key risks were societal challenges (societal social drivers: 45%; immediate social drivers: 24%), highlighting isolation risks. Financial burdens (27%) also emerged despite healthcare reimbursement. Psychological and rational adherence drivers were minimal. Despite reported partial adherence in 42% of cases, healthcare professionals did not modify their approach in 68%. SPUR™ was deemed useful in 80%, aiding patient understanding, saving consultation time, and addressing identified social/ financial challenges.
Conclusion: In this cohort, 42% of patients missed at least two doses in three months, with adherence risks linked to societal and financial factors. SPUR™ provided valuable insights, particularly for new patients. Non-adherence is multifactorial; digital tools may improve identification leading to targeted interventions. https://observia-group.com/en/what-is-spur.

SAT-397-YI

Long-term clinical outcomes, efficacy, and safety of transjugular intrahepatic portosystemic shunt in Budd Chiari syndrome

Shekhar Swaroop[1], Sagnik Biswas[1], Shubham Mehta[1], Arnav Aggarwal[1], Samagra Agarwal[1], Baibaswata Nayak[1], Shivanand Gamangatti[2], Shalimar Shalimar[1]. [1]*Department of Gastroenterology and Human Nutrition Unit, All India Institute of Medical Sciences, New Delhi, India;* [2]*Department of Radiodiagnosis, All India Institute of Medical Sciences, New Delhi, India*
Email: drshalimar@gmail.com

Background and aims: Budd-Chiari syndrome (BCS) is characterized by obstruction of hepatic venous outflow tract at any level between intrahepatic veins and right atrium due to thrombosis or primary disease of the venous wall. Transjugular intrahepatic portosystemic shunt (TIPSS) plays crucial therapeutic role in decompressing the congested liver in BCS. In this study, we aimed to assess the long-term outcomes and complications of TIPSS, and identify mortality and hepatic encephalopathy (HE) predictors in patients with BCS.
Method: In this single-centre retrospective analysis, we included BCS patients who underwent TIPSS between July 2011 and June 2024 at a tertiary care center in India. Clinical Response (CR) was defined using a modified version of EASL Clinical Practice Guidelines as absence of clinically detectable ascites in absence of diuretic therapy, or on low-dose diuretics (spironolactone 75 mg/d or furosemide 40 mg/d) and absence of first or recurrent portal hypertension related bleeding while on primary or secondary prophylaxis with non-selective beta blockers or with endoscopic therapy at 3 months. The outcomes assessed included rates of clinical response, ascites resolution, further decompensation, and complications of TIPSS such as hepatic encephalopathy and restenosis. Cox regression analysis was used to identify predictors of mortality and HE.
Results: Of 201 BCS-TIPSS patients, 184 were included, with a median follow-up duration of 4.3 (2.0–6.7) years. Among the 99 patients who underwent a hypercoagulable workup, 22 (22.2%) were found to have positive hypercoagulable conditions. Clinical response was observed in 147 (79.8%) patients. Complete and partial resolution of ascites was seen in 126 (78.2%) and 14 (8.6%) patients, respectively. Overt HE occurred in 30 (16.3%) patients, with a 1-, 5- and 10-year probability of 7.7%, 15.3%, and 22.1% respectively. Further decompensation occurred in 38 (20.6%) patients with a 1-, 5- and 10-year probability of 8.2%,17.0%, and 35.0% respectively. TIPSS restenosis occurred in 51 (27.7%) patients, with 1-, 5- and 10 year probability of 6.0%, 33.2%, and 41.9% respectively. During follow-up, 31 (16.8%) patients died with transplant-free survival probability at 1, 5 and 10 years of 93.9%, 81.7%, and 74.6% respectively. On multivariate analysis, non-response and diabetes mellitus at baseline were significant predictors of post-TIPSS HE. Non-response and post-TIPSS HE were significant predictors of mortality. A total of 15 (8.1%) patients experienced 17 immediate post-TIPSS complications. Bleeding complications related to anticoagulation occurred in 20 (10.8%) patients, with 28 bleeding episodes recorded, epistaxis being the most common complication (10 patients).
Conclusion: TIPSS is an effective, long-term therapy for BCS that leads to significant improvements in survival, ascites resolution, and bleeding prevention. Non-response to TIPSS and post-TIPSS hepatic encephalopathy are associated with increased mortality.

SAT-398

Prevalence and risk factors of liver function test abnormalities in celiac disease patients: Insights from the Kashmir, Pakistan

Usman Ghani[1], Abrar Hussain Azad[2], Sultan Salahuddin[2]. [1]*Divisional Headquarters Teaching Hospital Mirpur Azad Jammu and Kashmir, Mirpur, Pakistan;* [2]*Mohuddin Islamic Medical College Mirpur, Azad Jammu and Kashmir, Pakistan, Mirpur, Pakistan*
Email: sabzadaughani@gmail.com

Background and aims: Celiac disease, an autoimmune condition triggered by gluten, primarily affects the small intestine but can also involve other organ systems, including the liver. Liver function test (LFT) abnormalities are commonly observed in celiac disease, often reflecting liver involvement or complications. This study investigates the prevalence and types of LFT abnormalities in patients with celiac disease in the Kashmiri population of Mirpur, AJK.
Method: A cross-sectional study was conducted at Divisional Headquarters Teaching Hospital, Mirpur, AJK, between January and September 2024. The study included patients diagnosed with celiac disease based on serological tests (positive tissue transglutaminase antibodies) and intestinal biopsy (villous atrophy). LFT parameters, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and bilirubin levels, were measured. Patients were categorized according to the severity of LFT abnormalities, and various demographic, clinical, and nutritional factors were analyzed. Logistic regression was used to determine risk factors associated with abnormal LFTs.
Results: A total of 180 celiac patients (62% females, mean age: 31 ± 12 years) were included in the study. Among them, 30% exhibited abnormal LFTs, with the most common derangements being elevated ALT (22%), AST (18%), and ALP (15%). Factors significantly associated with LFT abnormalities included severe malnutrition (odds ratio [OR] = 3.2, $p = 0.02$), delayed diagnosis (OR = 2.8, $p = 0.03$), and coexisting autoimmune thyroid disease (OR = 2.5, $p = 0.04$). There was no significant difference in LFT abnormalities between rural and urban residents ($p = 0.09$).
Conclusion: Liver function test abnormalities are prevalent in patients with celiac disease in the Kashmiri population, with the most common derangements being elevated ALT and AST. Severe malnutrition, delayed diagnosis, and coexisting autoimmune thyroid disease are key risk factors. Routine monitoring of LFTs in celiac patients is essential for early detection of hepatic involvement and to prevent further complications. Future studies should explore the underlying mechanisms of liver dysfunction in celiac disease.

SAT-399-YI

Detection of rare mutations of Wilson's disease during family screening

Veronica Cumpata[1,2], Victoria Sacara[3], Adela Turcanu[1,2]. [1]*Nicolae Testemitanu State University of Medicine and Pharmacy, Kishinev, Moldova;* [2]*The Clinic of Gastroenterology and Hepatology/HELPA, Kishinev, Moldova;* [3]*Human Molecular Genetics Laboratory, Institute of Mother and Child, Chisinau, Republic of Moldova, Chisinau, Moldova*
Email: veronica.cumpataciorba@gmail.com

Background and aims: Wilson's disease (WD), a rare hereditary disorder with autosomal recessive transmission, necessitates clinical examination of family members (siblings, descendants, parents) of newly diagnosed patients. This is due to the potential for asymptomatic progression or a nonspecific clinical presentation in the early stages. Therefore, our objective was to screen the proband's family to facilitate timely diagnosis and enable early initiation of specific therapy.
Method: A retrospective and prospective study was conducted between 2015 and 2023, involving 13 Moldavian families that were clinically and genetically evaluated. The diagnosis was confirmed using the modified Leipzig score (2019). DNA sequencing by the Sanger method involved the use of the Taq DyeDeoxy Terminator Cycle sequencing kit (Applied Biosystems) with an ABI-Prism 3100 genetic analyzer (Applied Biosystems).
Results: In 6 out of 13 families, 8 new members with WD were identified (6 males and 2 females). The mean age at diagnosis was 16.25 ± 9.7 years (range 5–34 years). All patients were Caucasian, and originally from Moldova. No patient reported consanguineous relationships. The most common variants were p.H1069Q and p.G1341D, both as homozygous recessive and compound heterozygous. A rare mutation p.Phe764 = was also detected. In 5 cases there were first-degree relatives (siblings), and in 3 cases - second-degree relatives (cousins, nephews). 7 patients were asymptomatic, and 1

had neurological symptoms of unknown cause until that time. A family with the paradoxical transmission of pseudo-dominant inheritance was noted, and simultaneously a rare silent/synonymous mutation (p.Phe764 =) was identified in association with pathogenic missense and frameshift variants, in 3 of the 4 members affected by WD. In 4 families, although the parents are healthy carriers, both children developed WD, one member being diagnosed during family screening. In the case of the 6th family, the affected members were cousins. After clinical and paraclinical examination of the new members, in 6 cases the hepatic phenotype was determined, and in the other 2, a mixed phenotype was reported. All patients initiated chelator therapy.

Conclusion: Our study highlights the vital role of family screening in family members, genetic testing is a defining tool, especially in suspects with insignificant biological changes and uncertain clinical signs. Thus, the identification of the family with pseudo-dominant inheritance, the presence of WD in 100% of children in simple heterozygous partners, and the detection of rare mutations highlights the peculiarities of WD evolution in our cohort and the impact of genetic counseling in probands with this disease.

SAT-400

Estimating the diagnosis rate of alpha-1 antitrypsin deficiency: insights from population-based cohorts in the USA

Grahame Evans[1], Xinruo Zhang[2], Jennifer Below[1], Kari E. North[2], May Hagiwara[3], Chitra Karki[3], Tami Nussbaum[3], Suna Park[3], Kaili Ren[3], Virginia C. Clark[4]. *[1]Vanderbilt University, Nashville, TN, United States; [2]Department of Epidemiology, Gillings School of Global Public Health, University of North Carolina at Chapel Hill, Chapel Hill, NC, United States; [3]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [4]University of Florida, Gainesville, FL, United States*
Email: virginia.clark@medicine.ufl.edu

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disorder that can lead to liver and/or lung disease and is often underdiagnosed. A single protease inhibitor (Pi)*Z variant increases the risk for liver and/or lung disease; the (Pi)*ZZ genotype is associated with the most severe disease manifestations. Robust evidence on the frequency of diagnosis (Dx) in individuals with AATD genotypes is lacking. This study leverages genetic information from large electronic medical record (EMR)-linked biobanks in the USA to quantify the rate of AATD Dx and to characterize individuals with AATD genotypes by AATD Dx status.

Method: A retrospective cohort of individuals with any AATD genotype (Pi*ZZ/MZ/SZ/SS/MS) was identified using genetic data from All of US (AOU; nationwide volunteer-based recruitment) and BioVU (consented care recipients at Vanderbilt University Medical Center). Demographic/clinical characteristics were extracted from linked EMRs (2018–2022). The proportion of individuals with ≥1 ICD-9/-10-CM Dx code for AATD in their EMR was reported overall and by AATD genotype. Standardized mean difference (SMD) was used to compare clinical features between individuals with an AATD genotype with and without an AATD Dx code in their EMR (SMD > 0.1 is considered a notable difference).

Results: From AOU and BioVU respectively, a total of 139/25,774 (0.5%) and 133/8988 (1.5%) individuals had ≥1 AATD Dx code in their EMR; 121/17,932 (0.7%) and 125/8300 (1.5%) were White, and 35/68 (51.5%) and 57/83 (68.7%) had a Pi*ZZ genotype. In AOU and BioVU respectively, for all individuals with and without an AATD Dx code in their EMR, the mean (standard deviation [SD]) age was 55.4 (17.1) and 58.9 (22.2) years, and 59.4% and 55.6% were female. Comorbidities were more frequently observed in those with an AATD Dx code than without: liver disease (AOU: 41.0% vs 9.6%, SMD 0.775; BioVU: 26.3% vs 4.2%, SMD 0.647), lung disease (AOU: 47.5% vs 7.6%, SMD 0.999; BioVU: 12.8% vs 3.1%, SMD 0.366), diabetes (AOU: 23.7% vs 12.2%, SMD 0.304; BioVU: 20.3% vs 6.4%, SMD 0.417), obesity (AOU: 30.2% vs 15.6%, SMD 0.354; BioVU: 17.3% vs 4.0%, SMD 0.443). More individuals with an AATD Dx code than without had an aspartate aminotransferase to platelet ratio (APRI) >0.5.

Conclusion: In this study, <2.0% of individuals with AATD genotypes had an AATD Dx code in their EMR. Those with a Dx had a higher prevalence of liver/lung disease and other comorbidities than those without a Dx in their EMR. Among those with a Pi*ZZ genotype, AATD Dx rate ranged from ~50–70%, which may be attributed to greater symptom manifestations associated with this genotype. These findings provide quantitative evidence to improve the current understanding of AATD underdiagnosis, highlighting that many individuals may remain undiagnosed. Study/writing funding: Takeda Development Center Americas, Inc.

SAT-401

Liver disease progression in patients with alpha-1 antitrypsin deficiency and a Pi*ZZ genotype: a retrospective natural history study

Virginia C. Clark[1], May Hagiwara[2], Jeanine M. D'Armiento[3,4], Monica P. Goldklang[3,4], Jeffrey H. Teckman[5], Alice Turner[6], Gerald Lebovic[7], Flavia Soares Peres[7], Cláudia Ribeiro[7], Doneal Thomas[7], Chitra Karki[2], Ed G. Marins[2], Suna Park[2], Kaili Ren[2], Anne E. Wyman[2], Pavel Strnad[8]. *[1]University of Florida, Gainesville, FL, United Kingdom; [2]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [3]Columbia University Medical Center, New York, NY, United States; [4]Columbia University Irving Medical Center, New York, NY, United States; [5]St. Louis University School of Medicine, St. Louis, MO, United States; [6]University of Birmingham, Birmingham, United Kingdom; [7]IQVIA Real World Solutions, New York, NY, United States; [8]University Hospital RWTH Aachen, Aachen, Germany*
Email: virginia.clark@medicine.ufl.edu

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disorder that manifests as liver and/or lung disease. The protease inhibitor (Pi)*ZZ genotype confers the greatest risk of AATD-associated liver disease. To systematically evaluate liver disease progression among patients (pts) with AATD and the Pi*ZZ genotype across pt registries, an umbrella protocol design was established. This study is the first to report data from these registries.

Method: Adults with a recorded diagnosis of AATD and a Pi*ZZ genotype confirmed by genetic testing were enrolled in the alpha-1 liver fibrosis/natural history study at the University of Florida (Nov 2013–Sep 2019). The date of enrolment was the index date. The baseline period was from initial contact to index date. The baseline liver fibrosis staging assessment period was from the index date to Day 90 post-index. The follow-up period for the assessment of liver disease progression (liver fibrosis advancement from baseline) was from Day 91 until the first occurrence of loss to follow-up, completion of the study, or death. A hierarchical approach was utilized to define fibrosis stage: if available, fibrosis stage was assessed by biopsy (baseline and Year 3); if unavailable, secondary fibrosis measures were utilized (elastography, aspartate aminotransferase to platelet ratio index [APRI], Fibrosis-4; annually). For each pt, matched fibrosis staging required the same staging method to have been used at both baseline and follow-up. Statistical analyses included descriptive statistics.

Results: Overall, 98 pts were included in the liver progression analysis. Baseline matched fibrosis staging (F0/1, n = 61; F2, n = 28; F3, n = 8; F4, n = 1) was based on liver biopsy (n = 49) or secondary measures (n = 49). Median pt age was 56 years, all were White, 62% were female and 28% were categorized as obese. At baseline, 6% pts self-reported comorbid metabolic dysfunction-associated steatohepatitis/metabolic dysfunction-associated steatotic liver disease, 79% self-reported chronic obstructive pulmonary disease/emphysema and 73% received concomitant alpha-1 antitrypsin augmentation therapy. Using a matched fibrosis staging method, 23 (23%) pts experienced liver disease progression by Month 42, by baseline fibrosis stage: F0/F1, 12 (20%); F2, 7 (25%); F3, 4 (50%). Of the 23 pts with liver disease progression, 13 were based on liver biopsy and 10

were from a secondary measure (n = 9 elastography, n = 1 APRI). When unmatched fibrosis staging was considered, 36 (37%) pts had liver disease progression by Month 42, by baseline fibrosis stage: F0/F1, 23/64 (36%); F2, 9/26 (35%); F3, 4/8 (50%).
Conclusion: Among pts with AATD and a Pi*ZZ genotype, almost one in four experienced liver disease progression by 3.5 years based on matched fibrosis staging methods. Pts with more advanced fibrosis may have a higher proportion of liver disease progression.
Study/writing funding: Takeda Development Center Americas, Inc.

SAT-402
Combination of pharmacological and surgical interruption of the enterohepatic circulation can treat cholestasis and pruritus in patients with progressive familial intrahepatic cholestasis types 1 and 2 who proved unresponsive to either treatment alone
Willem Lexmond[1], Frank Bodewes[1], JBF Hulscher[2], Henkjan J. Verkade[1]. [1]*Division of Pediatric Gastroenterology and Hepatology, Department of Pediatrics, University Medical Center Groningen, Groningen, Netherlands;* [2]*Division of Pediatric Surgery, Department of Surgery, University Medical Center Groningen, Groningen, Netherlands*
Email: h.j.verkade@umcg.nl

Background and aims: Patients with progressive familial intrahepatic cholestasis (PFIC) commonly suffer from pruritus and elevated serum bile acid levels. In FIC1 deficiency (PFIC1) and bile salt export pump (BSEP) deficiency (PFIC2), cholestasis can be alleviated in approximately 40% of patients by either partial external biliary diversion (PEBD) or intestinal bile acid transporter inhibitors (IBATi). While surgical and pharmacological diversion both interrupt the enterohepatic circulation of bile acids, it is unknown if combining both therapies improves therapeutic efficacy. We recently demonstrated that IBATi in PFIC2 patients increase the intestinal reabsorption of unconjugated bile acids (Gastroenterology 2023; 165:496–98). We therefore hypothesized that PEBD could provide additional therapeutic benefit over treatment with IBATi alone.
Method: We combined IBATi and PEBD in three PFIC patients (ages 3–14) with persistently elevated bile acids and pruritus after long-term treatment with either IBATi (N = 2) or PEBD (N = 1) alone.
Results: Patient A (PFIC1) received IBATi for more than two years without improvement of bile acids or pruritus. Within days of his PEBD (while continuing IBATi), he became free of itch with normal bile acid levels for a total follow-up of six months. Patient B (PFIC1) had been symptom-free for over a decade after PEBD but was evaluated for liver transplant when cholestasis and invalidating pruritus had recurred for two years. Within three months after addition of IBATi, his bile acid levels were normal and he was itch free. Patient C (PFIC2) received IBATi for more than three years with no discernable effect on cholestasis or pruritus. PEBD in combination with IBATi has changed the disease phenotype to an episodic course, characterized by prolonged periods (8–10 months) of complete symptom resolution interspersed with periods of cholestasis likely triggered by viral infections.
Conclusion: We show proof of principle that the combination of pharmacological *and* surgical interruption of the enterohepatic circulation can effectively treat cholestasis and pruritus in patients with FIC1 or BSEP deficiency who were found to be unresponsive to either therapy alone. We believe that combination therapy should be considered before committing these patients to liver transplantation.

SAT-403
Rare variants in ABCB4 in intrahepatic cholestasis of pregnancy in the national genomic research library
Xi Yang[1], Omid Sadeghi-Alavijeh[2], Gabriel Doctor[2], Alexander Bracanovic[1], Daniel Gale[2], Catherine Williamson[1], Peter Dixon[1]. [1]*Imperial College London, London, United Kingdom;* [2]*University College London, London, United Kingdom*
Email: p.dixon@imperial.ac.uk

Background and aims: Genetic susceptibility makes a significant contribution to the aetiology of intrahepatic cholestasis of pregnancy (ICP). We quantified the contribution of rare genetic variants of ATP-Binding Cassette Subfamily B Member 4 (ABCB4) to the heritability of ICP.
Method: We extracted coding single-nucleotide variants and indels with minor allele frequency <0.1% from the Genomics England library, annotated with one of the following: missense, in-frame insertion, in-frame deletion, start loss, stop gain, frameshift, splice donor, splice acceptor. They were filtered using a combined annotation-dependent depletion (CADD) threshold score ≥20. The scalable and accurate implementation of generalized mixed model (SAIGE-GENE) was employed to ascertain whether rare coding variation was enriched in cases on a per-gene basis exome-wide. Odds ratio and heritability were estimated.
Results: 249 women with ICP and 3,128 non-ICP controls were identified. Rare variants were observed in 4% (10/249) of the ICP cases and 0.4% (14/3128) of the controls. There was a statistically significant enrichment of rare and predicted damaging *ABCB4* variants in the ICP group ($p = 9.1 \times 10^{-7}$). Women carrying a rare and predicted damaging *ABCB4* variant had an 8.25-fold increased risk of developing ICP (95%CI 3.23–20.5, $p = 6.3 \times 10^{-6}$). Collapsing rare *ABCB4* variants account for 2.5% of the total heritability of ICP.
Conclusion: The rare *ABCB4* variants are significantly enriched in women with ICP, explaining 2.5% of the heritability of the condition. These findings highlight and quantify the contribution of these rare genetic variants to the pathogenesis of ICP. This research was made possible through access to data and findings in the National Genomic Research Library via the Genomics England Research Environment.

SAT-404
Accuracy of non-invasive tools in excluding advanced fibrosis in Wilson disease: results from the Wilson disease registry and Barcelona cohorts
Zoe Mariño[1], Uyen Kim To[2], Isabelle Mohr[3], Regino González-Peralta[4], Sanjiv Harpavat[5], Sihoun Hahn[6], Thomas Damgaard Sandahl[7], Asim Ulcay[2], Hatice Maras[2], Sefa Keserci[2], Kaitlin Maciejewski[8], Yanhong Deng[8], Michael Schilsky[2]. [1]*Liver Unit, Hospital Clínic Barcelona, IDIBAPS, CIBERehd, ERN-RARE Liver, Universitat de Barcelona, Barcelona, Spain;* [2]*Yale Medical Center, Yale University, New Haven, Connecticut, United States;* [3]*Internal Medicine IV, Department of Gastroenterology, University Hospital Heidelberg, Heidelberg, Germany;* [4]*Advent Health for Children, AdventHealth Transplant Institute, Orlando, Florida, United States;* [5]*Baylor College of Medicine, Houston, Texas, United States;* [6]*Seattle Children's Hospital, Seattle, Washington, United States;* [7]*Department of Hepatology and Gastroenterology, Aarhus University Hospital, ERN-RARE Liver, Aarhus, Denmark;* [8]*Yale Center for Analytical Sciences, Yale University, New Haven, Connecticut, United States*
Email: zmarino@clinic.cat

Background and aims: Fibrosis is a critical prognostic factor for chronic liver disease with liver biopsy (LB) as the gold standard for staging. Noninvasive tools (NIT) for fibrosis evaluation include serum scores (APRI, FIB-4) and elastography (TE), validated in many liver diseases but with limited use in Wilson disease (WD) (*Paternostro, 2020; Schilsky, 2023*). A recent score (Steatosis-Associated Fibrosis Estimator, SAFE; *Sripongpun, Hepatol 2023*) based on laboratory testing (AST, ALT, platelets, globulins) and clinical data (diabetes, age, BMI) accurately identified patients at risk of fibrosis progression in Metabolic-Associated Liver Disease. Its use in WD is justified as hepatic steatosis is among the earliest reported histological changes. We hypothesized that SAFE score should outperform APRI and FIB-4 for fibrosis staging in WD. Data from the Wilson Disease Registry (WDR) and Barcelona WD (BWD) cohort was reviewed.
Method: Cross-sectional assessment of WD patients from WDR and BWD with available LB and fibrosis staging (METAVIR). Serum NIT (FIB-4, APRI, SAFE) were calculated at first WDR visit or time closest to

LB for BWD; TE data were collected (n = 38). Patients were grouped according to time from LB to NIT: ≤12 months (≤12 mo), between 1 - 5 years (1–5 y) and >5 years (>5 y). The accuracy of NIT for advanced fibrosis detection [F≥3] was calculated as AUC for continuous NIT and according to previously validated cutoffs (APRI ≥1.5, FIB-4 ≥3.25, SAFE ≥100, TE ≥9.9 Kpa). Data was expressed as median (IQR)/ n (%).
Results: Patients (n = 121, 54.5% female) were median age 32 y and time from diagnosis of 7 y. Group distribution ≤12 mo; 1–5 y; >5 y was 48; 29; 44 patients, respectively. LB staged F ≥3 in 47 (39%) patients [29%; 31%; 54% in ≤12 mo; 1–5 y; >5 y groups, respectively]. Serum NIT (SAFE, APRI and FIB-4) were all significantly higher for F≥3 vs F0–2 patients ($p < 0.001$) in the whole cohort. Only SAFE and APRI were significantly higher in F ≥3 patients ≤12 mo and 1–5 y ($p < 0.05$) groups. Differences were lost for all NIT when LB was >5 y away. TE was non-significantly higher in F≥3 vs F0–2 for the whole cohort and ≤12 mo group ($p > 0.05$). AUC for F ≥3 prediction for SAFE, APRI, FIB-4 and TE were 0.72, 0.69, 0.68 and 0.66 for the whole cohort, and 0.72, 0.68, 0.64 and 0.81 for ≤12 mo group. Validated cutoffs yielded negative predictive values (NPV) for excluding F≥3 of 97% (SAFE and APRI), 100% (FIB-4) and 86% (TE).
Conclusion: Serum NIT were higher in WD patients with advanced fibrosis, with SAFE and TE performing slightly better than APRI and FIB4. All NIT evaluated provided useful information with high NPV for advanced fibrosis. Effective WD treatment likely accounted for the lower correlation between serum NIT and LB performed >5 y. Further validation is required to establish WD specific cutoffs for NIT and determine their utility in longitudinal evaluation and prognostication.

Viral Hepatitis – Experimental and pathophysiology

STING activation suppresses viral replication but promotes liver inflammation and fibrosis in chronic hepatitis B concurrent with metabolic dysfunction-associated steatotic liver disease

Wenhui Wu, Suping Hai, Xitang Li, Qiang Gao, Binghui Yu[1], Feiyang Xu[1], Xizhe Zheng[1], Junjian Hu, Xiaojing Wang, Qin Ning.
[1]*Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China*
Email: 850409015@qq.com

Background and aims: Concomitant Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is common in patients with Chronic hepatitis B (CHB), but the implications on liver-related outcomes remain controversial. Stimulator of Interferon Genes (STING) plays a central role in innate immune activation. Here, we aim to investigate the role of STING in disease progression in CHB patients concurrent with MASLD.
Method: HBV transgenic mice and pAAV/HBV1.2 hydrodynamic injection mice fed with a high-fat diet (HFD) were both used to establish mouse models of CHB concurrent with MASLD. STING knockout, *Tmem173*$^{-/-}$ (*Sting*$^{-/-}$) and macrophage STING deficiency, *Tmem173*$^{f/f}$*Lyz2*$^{Cre+}$ (*Sting*$^{f/f}$*Lyz2*$^{Cre+}$) and liver-specific STING knock-in, *Alb*$^{cre+}$ *Sting-IRSE-EGFP*$^{ki/ki}$ (*Sting*$^{ki/ki}$*Alb*$^{cre+}$) mice and their controls were used in this study. THP1 and HepG2/HepG2.2.15 co-cultured cells were stimulated with palmitic acid (PA) or its control for 12 hours *in vitro*. Markers for STING, autophagy, and endoplasmic reticulum stress were assessed using Western blotting, immunohistochemistry, and immunofluorescence assays. The liver tissues obtained from patients were used for clinical validation.
Results: Compared with CHB or MASLD mice, the concurrent presence of CHB and MASLD in mice resulted in a significantly accelerated progression of liver inflammation and fibrosis, despite a decrease in HBV DNA levels observed within this group. Concomitant with disease progression, CHB mice concurrent with MASLD exhibited impaired autophagic flux and the upregulation of macrophage STING. The STING activation impaired the function of RAB7, thereby preventing STING from entering lysosomes for degradation. Damaged degradation of STING leads to its secretion via vesicles, which are subsequently captured by hepatocytes, triggering endoplasmic reticulum stress and exacerbating the progression of liver disease. Macrophage STING deficiency restored RAB7 function, enhanced autophagic flux, and consequently mitigated liver inflammation and fibrosis. The expression of STING, RAB7, and autophagy-related proteins was confirmed in liver tissue samples derived from patients.
Conclusion: The significant upregulation of macrophage STING expression in CHB concurrent with MASLD disease can inhibit HBV virus replication and exacerbate liver inflammation by activating antiviral and pro-inflammatory signals. Meanwhile, it impairs RAB7 function, impeding STING degradation and promoting its release through vesicles, which are then captured by liver cells and further exacerbate disease progression.

Long non-coding RNA SNHG4 is regulated by hepatitis B virus and promotes hepatocarcinogenesis

Belal Ahmad[1], Perumal Vivekanandan[1]. [1]*Indian Institute of Technology, New Delhi, India*
Email: vperumal@bioschool.iitd.ac.in

Background and aims: Hepatitis B virus (HBV) contributes to hepatocellular carcinoma (HCC), accounting for nearly 50% of cases; however, the underlying mechanisms remain largely unknown. Long non-coding RNAs (lncRNAs) are increasingly recognized for their roles in cancer and potential as biomarkers. Here, we investigated the role of HBV in regulating human lncRNAs in HCC progression.
Method: To identify HBV-regulated lncRNAs that promote HCC, we performed a comprehensive analysis of microarray datasets of liver samples from patients who were either HBV-infected or had HCC and focused on differential expression profiles. GEPIA2 was used for the interactive exploration of RNA sequencing data of tumors and normal samples from The Cancer Genome Atlas and the Genotype-Tissue Expression programs, examining prognostic values of HBV-mediated lncRNA and evaluating overall survival using the Kaplan-Meier method. *In vitro* studies employed HBV cell culture models to examine the expression of SNHG4 by HBV and its proteins using qPCR. To assess the correlation between SNHG4 expression and HBV load, qPCR was performed on liver biopsy specimens (n = 14) from HBV-infected patients. Functional studies were carried out using SNHG4 overexpression and CRISPR interference (CRISPRi)-mediated knockdown approaches. The impact of SNHG4 manipulation on cell proliferation, migration, and apoptosis was evaluated using cell-based assays.
Results: Our analysis of microarray datasets in liver samples from patients with HBV infection identified SNHG4 as an HBV-regulated lncRNA. SNHG4 is notably upregulated in liver samples from HBV-infected patients and in HCC, specifically in HBV-related HCC. Kaplan-Meier analysis revealed that higher expression of SNHG4 correlates with reduced overall survival. These findings were validated *in vitro*, showing that HBV and HBV proteins positively regulate SNHG4 in HBV cell culture models. SNHG4 shows a ~2-fold change with overexpression of HBV proteins, namely HBx and HBsAg. Furthermore, qPCR analysis reveals a significant correlation between SNHG4 expression levels and HBV load in liver biopsy specimens (n = 14) of patients infected with HBV. Next, we evaluated the oncogenic potential of SNHG4 by its overexpression and CRISPRi-based knockdown in various cell-based assays. SNHG4

overexpression in the presence of HBV promoted cell proliferation and migration while inhibiting apoptosis. SNHG4 knockdown in the presence of HBV using dCas9-KRAB-mCherry stable HepG2 cell line inhibits cell proliferation and induces apoptosis, suggesting its oncogenic potential.
Conclusion: In this work, we identify SNHG4, a clinically relevant HBV-regulated lncRNA in HCC, as a driver of hepatocarcinogenesis, thus offering novel insights into HBV-mediated HCC progression and novel avenues to target HBV-related HCC.

HDV infection induces cellular refractoriness to IFN-α, but not IFN-λ treatment
Claudie Eber[1], Roxanne Fouillé[2], Zoé Lebrun[1], Emma Gerges[1], Charlotte Bach[1], David Durantel[2], Thomas Baumert[1,3,4], Julie Lucifora[2], Eloi Verrier[1]. [1]*Institute for Translational Medicine and Liver Disease, Strasbourg, France;* [2]*Centre International de Recherche en Infectiologie, Lyon, France;* [3]*Institut hospitalo-universitaire (IHU), Service d'hépato-gastroentérologie, Hôpitaux Universitaires de Strasbourg, Strasbourg, France;* [4]*Institut Universitaire de France, Paris, France*
Email: claudie.eber@etu.unistra.fr

Background and aims: Chronic hepatitis D, caused by the co-infection of hepatocytes with hepatitis B and D viruses (HBV, HDV), is the most aggressive form of chronic viral hepatitis. To date, no treatment achieves viral clearance in infected patients. Current therapies available in Europe include the entry inhibitor bulevirtide and pegylated interferon-alpha (peg-IFN-α). However, the efficacy of peg-IFN-α is limited, and HDV replication is only moderately impacted by exogenous IFN-α treatment both in vivo and in vitro. Previous studies suggested an inhibition of IFN-α signaling pathway in HDV-infected cells but the molecular mechanism in unclear. Furthermore, the response of HDV-infected cells to IFN-λ has not yet been explored. This study investigates the response to both IFN-α and IFN-λ treatment in HDV-infected cells to better understand the interactions between HDV infection and innate immune pathways and responses.
Method: RNA sequencing was performed to analyze transcriptomic modulations in HDV-infected differentiated HepaRG (dHepaRG) cells stimulated with IFN-α or IFN-λ1. Key findings were validated in vitro and compared across HDV infection cellular models, which exhibit varying IFN responses to HDV infection. Mechanistic studies, including gain- and loss-of-function assays, elucidated the role of host proteins in the HDV-mediated inhibition of IFN responses.
Results: HDV-infected cells displayed a reduced ISG response to IFN-α, indicating cellular refractoriness to IFN-α treatment. Using cellular models impaired for innate immune response and HDV antigen expression, we demonstrated that the refractoriness to IFN-α was due to MDA5-mediated pre-activation of the innate immune response induced by HDV replication rather than active inhibition of IFN signaling by HDV antigens. In contrast, we observed additive ISG induction in HDV-infected cells treated with the type III interferon IFN-λ1, suggesting a specific inhibition of the IFN-α signaling pathway. Notably, knocking down the expression of USP18, known to selectively impair IFN-α signaling, rescued IFN-α-mediated ISG induction in HDV-infected cells.
Conclusion: Our findings provide a comprehensive list of ISGs modulated by type I and type III IFN treatments in the context of HDV infection. We demonstrated that the cellular refractoriness to IFN-α treatment in HDV-infected cells results from the pre-activation of the innate immune response by HDV and is specific to the type I IFN pathway. In this context, USP18 acts as a negative regulator of the IFN-α response and is a key factor in HDV resistance to IFN-α treatment. Interestingly, the antiviral potential of IFN-λ remains unaffected by HDV infection. In conclusion, this study provides new insights into the mechanisms underlying the limited efficacy of peg-IFN-α in patients and paves the way to the development of improved antiviral strategies against HDV infection.

FRI-227
Screening of different species reveals cat as a potential HBV infection model
Zaichao Xu[1], Yuchen Xia[1]. [1]*Wuhan University, Wuhan, China*
Email: 00032118@whu.edu.cn

Background and aims: Hepatitis B virus (HBV) research is hindered by its highly restricted species tropism and the lack of suitable animal models. This study aims to investigate the susceptibility of hepatocytes from various species to HBV infection and to establish novel HBV infection models for basic and translational research.
Method: Freshly isolated or cryopreserved primary hepatocytes from monkey, pig, cat, goat, bull, dog, rabbit, guinea pig, and hamster were tested for HBV susceptibility. The repair of covalently closed circular DNA (cccDNA) from synthetic relaxed circular DNA (rcDNA) was assessed by transfection. Hepatocytes were subjected to ectopic expression of the viral receptor human sodium taurocholate cotransporting polypeptide (hNTCP), followed by HBV infection. Viral replication was evaluated through the production of viral antigens, and inhibition by Myrcludex B was tested. Primary cat hepatocytes were directly infected with HBV, and their ability to support HBV replication was assessed via time-dependent secretion of HBsAg and HBeAg, as well as cccDNA formation and transcription of HBV RNAs using Southern and Northern blotting. Antiviral drug testing included Myrcludex B, Entecavir, and poly IC. Additionally, cats with or without immunosuppressive treatment were infected with HBV to evaluate the feasibility of cats as an animal model.
Results: All tested hepatocyte types supported the repair process from rcDNA to cccDNA, as indicated by viral antigen production. Primary monkey, pig, and cat hepatocytes expressing hNTCP supported HBV replication, which was blocked by Myrcludex B. Direct HBV infection of primary cat hepatocytes resulted in time-dependent secretion of HBsAg and HBeAg. cccDNA formation and HBV RNA transcription were confirmed in cat hepatocytes. These cells were also responsive to antiviral treatments, indicating their suitability for evaluating anti-HBV drugs. While direct infection of immunosuppressed cats was unsuccessful, the ectopic expression of horse NTCP conferred susceptibility to HBV, as evidenced by increased HBsAg levels in the sera.
Conclusion: This study demonstrates for the first time that primary cat hepatocytes support HBV infection, providing a potential new platform for HBV basic and translational research. The use of cats as an animal model is being explored and may further advance HBV research and therapeutic development.

FRI-228
CD300A+CD8+T cells promote functional cure in patients with chronic hepatitis B under PEG-IFN-α
Wen-Xin Wang[1], Peng Zhang[2], Fu-Sheng Wang, Chao Zhang[3], Junliang Fu[1]. [1]*Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, Peking University 302 Clinical Medical School, National Clinical Research Center for Infectious Diseases, Beijing, China;* [2]*The First Afiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, Beijing, China;* [3]*Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, Beijing, China*
Email: fjunliang@163.com

Background and aims: $CD8^+$ T cells are crucial in viral control and pathogenesis in HBV infection. However, the critical immunological

characteristics of $CD8^+$ T cells in functional cure (FC) of chronic hepatitis B (CHB) under pegylated interferon alpha (PEG-IFN-α) remain unclear.
Method: Cross-sectional peripheral blood mononuclear cells (PBMCs) were collected from 8 CHB patients undergoing PEG-IFN-α therapy and with serum HBsAg levels <3000 IU/ml at baseline for 10X Genomics single-cell RNA sequencing (scRNA-seq). 3/8 achieved FC, and 5/8 did not after follow-up. FC was defined as sustained clearance of serum HBsAg and HBV DNA after a finite course of treatment. Through determining the transcriptional profiles of immune cells, coupled with assembled T cell receptor (TCR) sequences, we analyzed the functional properties of $CD8^+$ T cells. Relevant findings were validated by flow cytometry analysis in another longitudinal cohort, including 5 FC and 5 non-FC patients after 48 weeks of PEG-IFN-α therapy.
Results: The scRNA-seq data revealed that $CD300A^+$ $CD8^+$ T cells were enriched in FC patients and expressing higher levels of cytotoxic genes (GNLY, GZMB, and PRF-1), and genes enriched in cell migration, cytokine production, such as IL-2, TNF, and IFNγ. Moreover, the SCENIC analysis indicated that the activities of BATF and TBX21, which were associated with effector functions, predominated in $CD300A^+$ $CD8^+$ T cells. Analysis of paired scRNA and TCR sequencing data revealed that $CD300A^+$ $CD8^+$ T cells displayed more pronounced clonal expansion than $CD300A^-$ $CD8^+$ T cells and tended to exhibit high activity in TCR signaling. In addition, HBV-specific $CD8^+$ T cells predicted by GLIPH highly expressed CD300A. Flow cytometry analysis in the longitudinal cohort validated that $CD300A^+$ $CD8^+$ T cells with enhanced cytotoxic activities were enriched in FC patients before and undergoing PEG-IFN-α therapy. Remarkably, the frequency of $CD300A^+$ $CD8^+$ Tcm cells at baseline was negatively correlated with the time to achieve FC.
Conclusion: These findings suggest that $CD300A^+$ $CD8^+$ T cells may serve as new therapeutic targets and be associated with achieving higher rates of functional cure in patients with CHB.

Interferon-α induces robust neutralizing anti-HBs production by restoring the HBsAg-specific B cell immune response in nucleos(t)ide analogues experienced chronic hepatitis B patients

Zhize Yuan[1], Da Huang[1], Di Wu[1], Yuying Chen[1], Jiang Chang[1], Yizhi Wu[1], Ran Zhao[1], Weiming Yan[1], Qin Ning[1]. [1]*Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China, Wuhan, China*
Email: 670335931@qq.com

Background and aims: Anti-HBs play an important role in HBsAg clearance and functional cure of chronic hepatitis B (CHB). In this study, we aimed to determine the biological function of anti-HBs appeared in CHB patients undergoing Pegylated-Interferon-a (Peg-IFN-a)-based treatment, and explore the underlying mechanisms by which IFN-a improves anti-HBs production by B cell.
Method: A total of 171 nucleos(t)ide analoges (NAs) experienced CHB patients undergoing a clinical trial (ANCHOR study, NCT02327416) were included and randomized to receive either Peg-IFN-a-based therapy (IFN group) or entacvir (ETV) therapy (ETV group) for 96 weeks. The neutralization activity (NAT) determined by blocking HBV infection in HepG2 cells expressing sodium taurocholate co-transporting polypeptide (NTCP) and Fc effector functions assessed by Fc γ RIIIa dimer binding assay, antibody dependent cell-mediated phagocytosis (ADCP) assay, and complement-mediated cytotoxicity (CDC) assay were performed on serum anti-HBs in CHB patients. In-vivo and ex-vivo regulation of phenotypic and functional characteristics of peripheral B cell subsets by IFN-a were evaluated by flow cytometry and The Elispot assay was employed to quantify the frequency of HBsAg-secreting B cells.
Results: The IFN group exhibited significantly higher cumulative anti-HBs positive rate and quantitative anti-HBs (qAnti-HBs) than the ETV group, obviously increased NAT but decreased Fc effector function compared to qAnti-HBs-matched healthy individuals who received vaccine immunization. IFN-a therapy and external stimulation resulted in more aboundant expression of activation markers CD86/CD95 on memory B cells and higher level of plasma cell, especially for patients with qAnti-HBs above 10 log10IU/mL at the end of treatment (EOT), as well as a close correlation between the increased proportion of plasma cell and the decreased proportion of memory B cell at week 48 and 72. Importantly, in the ex vivo culture system containing overlapping peptide pools derived from HBsAg, IFN-a was confirmed to be capable of promoting the generation of activated memory B cells, plasma cell, HBsAg-specific B cell and Anti-HBs (IgM/IgG) production.
Conclusion: IFN-a treatment could successfully reinvigorate HBsAg-specific B cells to produce robust neutralizing anti-HBs, thus contributing to functional cure of CHB.

FRI-230

Naïve C57BL/6 mice immunized with CLB-405 and CLB-505 combined with a saponin-based adjuvant TQL-1055 exhibit a dose-dependent humoral and cellular immune

Aditi Deshpande, Bharat Dixit[1], Aileen Rubio[1]. [1]*ClearB Therapeutics, Concord, United States*
Email: adeshpande@clearbtherapeutics.com

Background and aims: We have previously reported anti-viral activity of two modified Hepatitis B surface antigen (HBsAg) variants displaying clearance profile associated epitopes, CLB-405 and CLB-505, combined with a novel, semi-synthetic saponin-based adjuvant, TQL-1055 in two murine models of persistent Hepatitis B infection [AASLD 2024 posters 1305 and 1307]. These studies demonstrated that TQL-1055 adjuvant was able to invoke both a cellular and humoral antigen-specific immune response in infected mice, which may be beneficial in the situation of Chronic Hepatitis B (CHB) [Zhu, D. et al, Nat Prod Chem Res. 2016 Apr; 3(4): e113]. A dose response study was performed in naïve C57BL/6 mice to evaluate the humoral and cellular immune response of CLB-405 and CLB-505 combined with TQL-1055 with and without Alhydrogel.
Method: C57BL/6 mice were administered three injections of vaccine given on days 0, 14 and 28, containing 25 micrograms (mcg) of CLB-405 and CLB-505 antigens, adjuvanted with 20, 40, or 80 mcg of TQL-1055 adjuvant with and without 100 mcg Alhydrogel. The 40 mcg TQL-1055 dose was also evaluated at higher antigen concentration at 50 mcg of CLB-405 and CLB-505 each, with and without 100 mcg Alhydrogel. The mice were terminated 14 days post-last injection, and plasma and splenocytes were collected to assess antibody response measured as anti-CLB-405 and anti-CLB-505 endpoint titers and cellular immune response measured as IFN-gamma secreting splenocytes by ELISPOT.
Results: All mice dosed with the vaccine displayed robust anti-405 and anti-505 titers, with higher titers in the TQL-1055 adjuvanted groups compared to combination of the TQL-1055 and Alhydrogel adjuvants. All mice dosed with vaccine also displayed an increase in IFN-gamma secreting splenocytes collected on study termination, with higher response in the TQL-1055 adjuvanted groups compared to TQL-1055 and Alhydrogel adjuvanted groups. The immune titers as well as cellular immune response increased with increasing dose of TQL-1055 from 20 to 80 mcg, but no significant increase in titers was seen with increase in antigen dose from 25 to 50 mcg.
Conclusion: CLB-405 and CLB-505 combined with TQL-1055 adjuvant was highly immunogenic in naïve C57BL/6 mice with a dose-dependent increase in anti-CLB-405 and anti-CLB-505 antibodies and T cell response. This study established that there is no additional benefit of adding Alhydrogel to TQL-1055 which was used to guide the clinical vaccine presentation.

FRI-231

Inflammatory and oncogenic gene signatures in chronic hepatitis delta infection

Arshi Khanam[1], Abutaleb Ameer[2], Furkan Kaysin[3], Cihan Yurdaydin[3], Shyamasundaran Kottilil[4]. [1]*Institute of Human Virology University of Maryland School of Medicine, Baltimore, United States;* [2]*GW School of Medicine and Health Sciences, Washington, DC, United States;* [3]*Koc University School of Medicine, Istanbul, Türkiye;* [4]*Institute of Human Virology, University of Maryland School of Medicine, Baltimore, United States*
Email: akhanam@ihv.umaryland.edu

Background and aims: Hepatitis delta virus (HDV) causes the most severe form of chronic viral hepatitis due to rapid progression towards end-stage liver disease including cirrhosis and hepatocellular carcinoma (HCC). Factors driving disease acceleration need to be investigated to prevent advanced disease progression. We aimed to identify molecular signatures predicting the rapid onset of severe hepatic ailment in chronic HDV infection.
Method: We investigated peripheral blood transcriptomic profiles in chronic HBV and HDV coinfected (CHB/CHD-coinfection) patients and compared with CHB-monoinfection matched for liver fibrosis to recognize gene signatures associated with CHD-induced disease progression. Multiplex cytokine bead array and flow cytometry assays were performed to validate RNAseq and examine the markers of inflammation, fibrosis and immune exhaustion.
Results: Transcriptomic profile revealed significant upregulation of genes related to inflammation, oncogenesis, tumor growth, invasion, metastasis and inhibition of anti-tumor response such as CXCL2, 3, 8, TNFSF9, IFITM1, IL-17, IGHA2, AREG, SEMA3F, CSF1R, TREML4, ANGPTL4 and LILRB2 in CHB/CHD-coinfection than CHB-monoinfection. Interestingly, none of CHB/CHD-coinfected patients we analyzed had cirrhosis or HCC, yet these patients experienced significant elevation of inflammatory and oncogenic genes, indicating HDV triggers these genes much before the onset of cirrhosis or HCC that contributes to rapid disease acceleration towards end-stage disease. Analysis of the top canonical pathways further confirmed the association of these differentially expressed genes in severe inflammatory response and oncogenic process. ELISA further confirmed induction of inflammatory and fibrogenic cytokines (IL-17, CXCL2, CXCL13 and TGF-β) in the plasma of CHB/CHD-coinfection. Additionally, these patients experienced severe immune exhaustion in effector T cell (CD4 and CD8) compartment by displaying higher inhibitory receptors PD-1 and TIGIT, which then resulted in poor antiviral response in terms of IFN-gamma, TNF-alpha, perforin and granzyme B secretion along with impaired polyfunctional responses against HBV and HDV than CHB-moninfection alone.
Conclusion: HDV coinfection leads to a dichotomous immune response, whereby suppressing antiviral (HBV and HDV-specific) T cell immunity, while having an exaggerated inflammatory and oncogenic responses resulting in accelerated liver disease progression, cirrhosis and HCC.

FRI-232

Prolonged exposure to HBV suppresses the immunogenicity and antiviral efficacy of therapeutic vaccination

Anna D. Kosinska[1,2], Julia Festag[1], Edanur Ates-Öz[1], Jinpeng Su[1], Annabelle Vossius[1], Marvin Festag[1], Percy A. Knolle[2,3], Ulrike Protzer[1,2]. [1]*Institute of Virology, School of Medicine & Health, Technical University of Munich/Helmholtz Munich, Munich, Germany;* [2]*German Center for Infection Research (DZIF), Munich partner site, Munich, Germany;* [3]*Institute of Molecular Immunology, University Hospital rechts der Isar, Technical University of Munich, Munich, Germany*
Email: anna.kosinska@tum.de

Background and aims: Hepatitis B virus (HBV) persistence strictly correlates with scarce and dysfunctional virus-specific T-cell responses. Therapeutic vaccination is a promising strategy to activate antiviral T cells and treat chronic hepatitis B. Still, it may be limited by the long-term persistence of HBV at high titers, particularly after vertical transmission. Our clinical candidate TherVacB, a protein-prime/MVA-boost therapeutic vaccine, can efficiently break HBV-specific immunotolerance in HBV-transgenic mice and mice establishing persistent HBV-replication after infection with an adeno-associated virus carrying HBV genome (AAV-HBV). We found that high levels of HBV antigen expression in the liver negatively influence vaccine-induced immunity in both mouse models. How the duration of an HBV infection influences HBV-induced immune tolerance, however, remains open. In the present study, we aimed to determine the impact of the duration of an HBV antigen exposure on the efficacy of TherVacB.
Method: Age-matched C57BL/6 mice were transduced one or three months before TherVacB vaccination with AAV-HBV at the same dose. Both groups of mice showed comparable and persistent serum HBsAg and HBeAg levels. All mice received two prime vaccinations with adjuvanted, particulate HBs and HBcore antigens and a boost with an MVA vector expressing a range of HBV antigens.
Results: TherVacB induced anti-HBs and anti-HBe seroconversion in mice that received AAV-HBV one month before vaccination. In contrast, mice that were infected for 3 months showed no or only very low anti-HBs titers and no anti-HBe. Vaccination elicited similar numbers of HBV-specific CD8 T-cells in both groups of mice. However, HBV-specific CD8 T cells isolated from long-term HBV carrier mice showed a significantly lower expression of IFN-γ, TNF, and granzyme B than short-term HBV carriers. Interestingly, in contrast to high-level HBV carriers, there was no difference in the expression levels of checkpoint inhibitors, such as PD-1 or CTLA-4, on hepatic HBV-specific CD8 T cells, suggesting a distinct mechanism involved in suppressing the efficacy of TherVacB during long-term persistent HBV infection.
Conclusion: Prolonged exposure to HBV antigens resulted in more pronounced immune tolerance and significantly decreased the effector B- and T-cell responses induced by therapeutic vaccination without inducing a classical exhaustion phenotype.

FRI-237

Sustained off-treatment inhibition of HBV replication and HBsAg levels after long-term treatment with ABI-4334 in differentiated HepaRG cells and primary human hepatocytes

Maud Michelet[1], Audrey Diederichs[1], Camille Pascarel[1], Nuruddin Unchwaniwala[2], Anaëlle Dubois[1], Sarah Heintz[1], William E. Delaney[2], Kathryn M. Kitrinos[2], Fabien Zoulim[3], Barbara Testoni[1]. [1]*Université Claude-Bernard Lyon 1, Inserm, UMR 1350 PaThLiv, The Lyon Hepatology Institute EVEREST, Lyon, France;* [2]*Assembly Biosciences, South San Francisco, United States;* [3]*Université Claude-Bernard Lyon 1, Inserm, UMR 1350 PaThLiv, The Lyon Hepatology Institute EVEREST, Department of Hepatology, Croix Rousse hospital, Hospices Civils de Lyon, Lyon, France*
Email: barbara.testoni@inserm.fr

Background and aims: ABI-4334 is a next-generation class E capsid assembly modulator (CAM-E) with improved in vitro potency against pregenomic (pg)RNA encapsidation and covalently closed circular (ccc)DNA formation compared to first-generation class E CAMs (vebicorvir). Here, we aim at assessing the effect of long-term ABI-4334 treatment on HBV replication and established cccDNA pool in an *in vitro* HBV infection model and in primary human hepatocytes (PHHs).
Method: Differentiated (d)HepaRG cells were treated from day 6 post-infection (pi) with 0.1 or 1 µM ABI-4334, 1 µM vebicorvir (VBR) or 1 µM lamivudine (3TC) for 1 month, followed by 1 month off-treatment monitoring. A similar protocol was applied to PHHs, with 2 weeks of treatment followed by 2 weeks off-treatment monitoring. Harvested cells and supernatants were analyzed for HBeAg and HBsAg secretion by ELISA, intracellular HBV biomarkers (total HBV

DNA and RNA, 3.5Kb RNA and cccDNA, HBs protein) by qPCR and Western blot, cell viability and hepatocyte differentiation markers.
Results: In dHepaRG cells, ABI-4334 treatment resulted in potent, dose-dependent inhibition of HBeAg secretion at end of treatment (EOT), which was not observed in VBR or 3TC treated cells. Secreted HBsAg levels were unaffected at EOT and then gradually declined, reaching 90% inhibition at end of follow-up (EOFU). Western blot analyses demonstrated no intracellular accumulation of HBs. Similarly, cccDNA levels were not affected at EOT, but showed 60% and 90% decreases at EOFU following treatment with 0.1 and 1 µM ABI-4334, respectively. Contrary to VBR and 3TC, stopping ABI-4334 treatment did not result in rebound of HBV replication. Similar effects were observed in PHH, where a 50% decrease in HBeAg and HBsAg was observed at EOFU following ABI-4334 treatment and no HBV replication rebound was observed after drug withdrawal in the absence of detectable cell toxicity. Profound, dose-dependent inhibition of intracellular total HBV DNA and RNA and 3.5Kb RNA was observed at EOFU in dHepaRG cells. This antiviral effect was accompanied by no signs of cytotoxicity or reduced gene expression of *bona fide* hepatocyte differentiation markers. As expected, no effects on cccDNA, HBeAg or HBsAg were detected after VBR or 3TC treatments at any time points in both infection models.
Conclusion: Durable HBsAg decreases and a lack of HBV rebound was observed after stopping long-term ABI-4334 treatment in both HepaRG cells and PHH, which could be ascribed to the depletion and/or functional inactivation of intracellular cccDNA pool in these experimental conditions.

FRI-238-YI
A recent shift in the evolutionary dynamics of hepatitis A virus
Sanket Mukherjee[1], Jasmine Samal[2], Ekta Gupta[2], Manoj Menon[1], Perumal Vivekanandan[1]. [1]*Indian Institute of Technology Delhi, New Delhi, India;* [2]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: vperumal@bioschool.iitd.ac.in

Background and aims: Hepatitis A virus (HAV) has long been associated with humans, but successful vaccinations have significantly reduced HAV infections. While the incidence rate of HAV is strongly associated with socio-economic factors, we sought to explore the recent shifts in its epidemiology (i.e., a sudden spike in cases post-2018 with increased symptomatic infection among adults) by analysing sequential changes in all available full-length HAV genomes.
Method: To investigate whether changes in the viral genome caused the change in epidemiology, we analysed 313 full-length genomic sequences from the NCBI nucleotide database, with collection date information available, covering the period from 1957 to 2022. We used the sequence of the HM175 strain (genotype 1B, accession ID: NC_001489.1) as the reference, performed multiple sequence alignment with MAFFT v7.01, and analysed the genomic data using Biopython scripts.
Results: Our analysis reveals a sharp decline (> 50%) in the proportion of non-synonymous mutations, with an increase in synonymous mutations in HAV sequences post-2018. We identified the major amino acid changes in HAV sequences before and after 2018 and found six of them were also found in a chimpanzee that developed acute liver failure. Interestingly, post-2018, (a) the key synonymous mutations observed are linked to sub-optimal codon usage, (b) the proportion of C to T mutations and T to C mutations have increased by ~30%, suggesting an active role for host editing enzymes APOBECs and ADARs. Overall, the codon usage bias for HAV has significantly reduced post-2018 compared to that in HAV sequences before 2018 (Enc: 39 vs 47; $p < 0.0001$), suggesting gradual adaptation to humans. Of note, the median number of Zinc antiviral protein (ZAP)-motifs remains constant (n = 10/genome; lowest for any RNA virus infecting humans) both before and after 2018, indicating that ZAP-mediated editing has reached a saturation.
Conclusion: This study underscores the complex and dynamic evolutionary dynamics of HAV that may be influenced by innate immune responses and natural selection. The mutations identified in HAV post-2018 merit further investigation to understand their biological implications.

FRI-239
Detecting hepatocellular carcinoma by circulating cell-free DNA in patients with chronic hepatitis B
Bootsakorn Boonkaew[1], Pornjira Somnark[1], Pisit Tangkijvanich[1]. [1]*Center of Excellence in Hepatitis and Liver Cancer, Department of Biochemistry, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand*
Email: pisittkvn@yahoo.com

Background and aims: Hepatocellular carcinoma (HCC) has become a leading cause of cancer-related deaths worldwide, including in Thailand. Emerging evidence suggests that circulating cell-free DNA (ccfDNA) is a promising marker for cancer diagnosis, including HCC. Alterations in gene expression regulation through epigenetic control, such as aberrant methylation, are well-characterized in cancer biology and could serve as candidate markers for cancer detection. This study aims to measure ccfDNA methylation of septin 9 (SEPT9), an approved biomarker in colorectal cancer, but with limited studies in HCC patients.
Method: To assess SEPT9 methylation in HCC, DNA was extracted from paired tumor and adjacent normal tissues of 19 patients with HBV-related HCC (HBV-HCC), followed by bisulfite conversion and quantification using droplet digital polymerase chain reaction (ddPCR). Methylated SEPT9 was then quantified in ccfDNA from a total of 185 patients, including 108 patients with HCC and 77 patients with chronic HBV without evidence of HCC (CHB), serving as a control group.
Results: We found that copy number of methylated SEPT9 in HBV-HCC tissue was significantly higher in tumor tissue compared to normal tissue (138 copies versus 5.6 copies, $p = 0.001$). In plasma ccfDNA, HBV-HCC patients exhibited significantly higher copy number of methylated SEPT9 and methylation abundance than HBV patients (2.96 copies versus 0.44 copies, $p = 0.001$ and 12.06% versus 0.09%, $p < 0.001$). The SEPT9 methylation ratio in tumor tissue and ccfDNA showed a strong correlation ($r = 0.78$, $p < 0.001$). Based on methylation abundance, to distinguish between HCC and CHB, methylated SEPT9 demonstrated an area under the receiver operating characteristic curve of 0.83 ($p = 0.038$, 95% CI: 0.750–0.899), with a sensitivity and specificity of 69.44% and 100%, respectively (cut-off value, 0.5%).
Conclusion: Our preliminary results indicate that methylated SEPT9 in plasma ccfDNA could serve as a diagnostic biomarker for HCC.

FRI-240
Hepatitis B surface antigen specific CD4 T cell response in hepatitis B vaccinated individuals
Carolin Heni[1], Jill Werner[1], Maike Hofmann[1], Robert Thimme[1], Tobias Böttler[1]. [1]*Department of Internal Medicine II, University Hospital Freiburg, Freiburg, Germany*
Email: carolin.heni@uniklinik-freiburg.de

Background and aims: The global implementation of prophylactic hepatitis B virus (HBV) vaccination in 1984 led to a significant decrease in HBV infections. It also offers the opportunity to study immunological mechanisms of immune memory maintenance. While most individuals develop strong antibody responses against the hepatitis B surface antigen (HBsAg) after the vaccination, these titers are not universally maintained. Although the role of CD4 T cells in supporting antibody development and maintenance is well established, they have not been thoroughly investigated in this specific context.
Method: We screened our biobank for samples from individuals carrying the HLA DRB1*0101 or DRB1*0701 alleles and having

antibodies against HBsAg (anti-HBs) excluding individuals with antibodies against hepatitis B core antigen (anti-HBc). For ex vivo detection of HBsAg-specific CD4 T cells, we used peptide-loaded MHC class II tetramers restricted to the aforementioned alleles. In addition, we performed in vitro stimulation with overlapping peptides spanning the HBsAg for 10 days followed by an intracellular cytokine staining.

Results: So far, we identified and analyzed 47 individuals. 32% (15/47) had detectable HBsAg-specific CD4 T cells directly ex vivo. The highest frequencies were observed in individuals with anti-HBs titers >100 IU/l. Phenotypic analyses for different memory subsets are currently ongoing. Following in vitro stimulation with HBsAg, we identified cytokine-producing CD4 T cells in 81% of the individuals (n = 22). This is an ongoing study and additional results will be presented at the conference.

Conclusion: Our preliminary results suggest that the frequency of HBsAg-specific CD4 T cells is associated with the anti-HBs titers in vaccinated individuals. Whether this is driven by specific memory subsets and in how far this correlates with individual vaccination history is currently being investigated.

FRI-241

Longitudinal analysis of viral profiles in chronic HBV/HDV coinfected patients

Cristina Musolino[1], Valeria Chines[1], Daniele Lombardo[1], Domenico Giosa[2], Maria Stella Franzè[1], Giuseppina Raffa[1], Donatella Ferraro[3], Irene Cacciola[1], Vito Di Marco[3], Giovanni Raimondo[1], Teresa Pollicino[4]. *[1]University Hospital "G. Martino" of Messina, Messina, Italy; [2]University of Messina, Messina, Italy; [3]University of Palermo, Palermo, Italy; [4]University Hospital "G. Martino" of Messina, Messina, Messina, Italy*
Email: tpollicino@unime.it

Background and aims: Interactions between HBV and HDV in coinfected patients and the role of HDV genetic variability remain poorly understood. This study aimed to assess serum samples from HBV/HDV coinfected patients to provide a comprehensive analysis of viral profiles and HDV RNA variability.

Method: Serum samples collected over time from 43 consecutive patients (32 male, 74.4%; median age 46 years, IQR:39–59; all infected with HDV genotype 1) were analyzed. HDV RNA levels were quantified using the RoboGene HDV RNA Quantification Kit (Roboscreen), while HBsAg and HBcrAg levels were measured using the Elecsys HBsAg II quant II (Roche Diagnostics) and Lumipulse G HBcrAg assays (Fujirebio), respectively. HDV genetic variability was assessed using next-generation sequencing (NGS) on the Illumina MiSeq platform.

Results: In 10/43 patients (all on NUC therapy) with two serum samples collected over 1.8 to 5.8 years (mean 2.6 years), HBV DNA was undetectable or at very low levels (<20 IU/mL), while HDV RNA, HBsAg, and HBcrAg remained at elevated levels. Specifically, median HDV RNA levels were 158,000 IU/mL (1st sample) and 82,900 IU/mL (2nd sample; P = 0.7), HBsAg levels were 5,562 IU/mL (1st sample) and 1,861 IU/mL (2nd sample; P = 0.1), and HBcrAg levels were 3.16 kU/mL (1st sample) and 3.35 kU/mL (2nd sample; P = 0.2). NGS revealed the pairwise genetic distances between HDV consensus sequences from each patient and WHO HDV reference sequence varied from 3.4% to 26%, with the median of 14.2%. that 3/43 patients (6.3%) had high-frequency mutations in Cys211 (Cys211Ser) and Gln214 (Gln214Leu) of the CXXQ isoprenylation site of HDAg. Additionally, 41/43 patients (95%) had highly frequent mutations in the nuclear export signal (aa 198–211) and lower HBsAg levels. Notably, unedited HDV (producing a higher amount of small HDAg than large HDAg) predominated in 40/43 patients (93%). Furthermore, the analysis of genetic diversity revealed that the pairwise genetic distances between HDV consensus sequences from each patient and the WHO HDV reference sequence ranged from 3.4% to 26%, with a median of 14.2%.

Conclusion: Our findings demonstrate that HBsAg and HBcrAg are produced during HDV infection independently of HBV replication. Additionally, our results highlight the significant genetic variability of HDV. Specifically, the high frequency of mutations in key regions of HDAg and the predominance of unedited HDV genomes suggest mechanisms that may play a role in viral adaptation and persistence.

FRI-242

FXR agonists as broad-acting antivirals against HBV/HDV/HEV and other hepato(cyto)tropic viruses

Julie Lucifora[1], Roxanne Fouillé[1], Romain Barnault[1], Florentin Pastor[2], Eva Ogire[3], Anne-Flore Legrand[4], Vincent Lotteau[5], Raphaël Darteil[6], Eloi Verrier[7], Philip Meuleman[8], Cyrille Mathieu[3], Christophe Ramière[4], David Durantel[1]. *[1]Centre de Recherche en Infectiologie (CIRI), INSERM U1111, UMR_5308, CNRS, ENS de Lyon, UCBL1, HepVir team, Lyon, France; [2]Centre de Recherche en Infectiologie (CIRI), INSERM U1111, UMR_5308, CNRS, ENS de Lyon, UCBL1, Pulsalys SATT, Lyon, France; [3]Centre de Recherche en Infectiologie (CIRI), INSERM U1111, UMR_5308, CNRS, ENS de Lyon, UCBL1, Nitrovire team, Lyon, France; [4]Centre de Recherche en Infectiologie (CIRI), INSERM U1111, UMR_5308, CNRS, ENS de Lyon, UCBL1, Virimi team, Lyon, France; [5]Laboratoire P4 INSERM-Jean Mérieux, Lyon, France; [6]Enyo Pharma, Lyon, France; [7]Institut de Recherche sur les Maladies Virales et Hépatiques, INSERM, U1110, UMR_S1110, Université de Strasbourg, Strasbourg, France; [8]University of Ghent, Ghent, Belgium*
Email: david.durantel@inserm.fr

Background and aims: Chronic and acute viral infections of the liver are responsible for liver pathogenesis leading to sudden organ failure or end-stage liver diseases, including cirrhosis and HCC. If HBV and HDV induce in general rather slow evolving pathogenesis, other viruses, including HEV, YFV, as well as numerous other arbovirus (e.g. DENV, RVFV) or tick-borne viruses (CCHFV) can lead to faster liver failure. To prevent liver pathogenesis, it would be interesting to have broadly acting drugs targeting these evolutionary different viruses. In this respect, host targeting agents are of high interest. Hepatocytes are key players of metabolic regulations, and metabolism modulators are expected to alter virus/host cell interactions. This study investigates the effect of Farnesoid X receptor agonists (FXR-ago) on various hepatotropic viruses, in relevant cell-culture and mouse models.

Method: Using cell culture models, including primary human hepatocytes (PHH), differentiated HepaRG, and a novel cell line able to replicate all hepatotropic viruses, as well as a liver humanized mouse model, we have studied the replication (by PCR-based methods, western blot/immunofluorescence/ELISA analyses, and TCID assays) of eight viruses (HBV, HCV, HDV, HEV, YFV, DENV, HAZV (model of CCHFV), and TOSV (model of RVFV) and their susceptibility to FXR-ago agonists used alone or in combination with Peg-IFN-alpha. Some mechanistic studies (RNA seq, loss and gain of functions, molecular analyses (Run-On assay, etc…), and classical virological analyses) were also performed to decipher the mode of action of FXR agonists against some of the viruses studied.

Results: We generated a novel cell line derived from a Huh7.5 cells, expressing the HBV/HDV entry receptor NTCP. These cells could be partially re-differentiated into hepatocyte-like cells, as shown by transcriptomic profiling and capacity to produce VLDL. HBV, HDV, HEV could replicate in differentiated Huh7.5-NTCP, as well as in dHepaRG and PHH, and were inhibited by FXR-ago in all models. The antiviral effect of FXR-ago against HEV was also confirmed in liver-humanized mice. All other viruses could replicate in dHuh7.5-NTCP and were moderately to strongly susceptible to FXR-ago. The antiviral effect was mainly due to an alteration of the specific infectivity of viral particles, leading to an inhibition of viral spreading (nicely shown for HDV). For viruses with a nuclear episome (like HBV), additional antiviral activities came from direct transcriptional inhibition. Interestingly, an additive (likely synergistic in the case of HDV) antiviral effect of FXR-ago and Peg-IFNa was observed in vitro.

Conclusion: FXR agonists are broadly acting antivirals that could be used, in combination with other drugs (e.g. Peg-IFNa), to protect the liver from acute failure and help clearing chronically replicating viruses. Further preclinical studies are needed for the newly investigated viruses, but clinical trials could already be envisaged against HDV or HEV infections.

FRI-243-YI

VDAC1-mediated lipid droplet-mitochondria tethering promotes tumorigenesis and inhibits HBV replication in CHB patients concurrent with MASLD

Zhe Dai[1], Yin Gao[2], Guangde Zhou[3], Xiaoman Liu[4], Zhe Wang[1,5], Jie Li, Yijin Wang[1]. *[1]School of Medicine, Southern University of Science and Technology, Shenzhen, China; [2]Department of Biochemistry, Key Laboratory for Molecular Enzymology and Engineering of Ministry of Education, School of Life Sciences, Jilin University, Changchun, China; [3]Department of Pathology, Beijing YouAn Hospital, Capital Medical University, Beijing, China; [4]School of Medicine, Southern University of Science and Technology, Shenzhen, Guangdong, China, Shenzhen, China; [5]Life Sciences Institute, Zhejiang University, Hangzhou, China*
Email: wangyj3@sustech.edu.cn

Background and aims: The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) has increased among the general population and chronic hepatitis B (CHB) patients worldwide. The clinical impacts of MASLD on CHB progression are controversial from different studies and their interaction seem complex. We aimed to explore the impact and the underlying mechanism of concurrent MASLD in CHB pathogenesis.
Method: Spatial transcriptome sequencing were performed on liver biopsies from healthy controls and patients with MASLD, CHB, and CHB concurrent with MASLD to systematically investigate the heterogeneity and ecosystem of CHB patients with and without MASLD. rAAV8-1.3 HBV hydrodynamic injection mice fed with high-fat diet (HFD)- or high-fat methionine-restriction choline-deficient diet (HFMRCD) were used to establish CHB concurrent with MASLD models. HBV-transfected HepG2.2.15 and RIL-175 cells were stimulated with palmitic acid and oleic acid (PAOA) *in vitro*. Liquid chromatography-tandem mass spectrometry (LC–MS/MS) were used to screen proteins involved in lipid droplet-mitochondria tethering. RIL-175 cells reconstituted with wild-type rVDAC1 or rVDAC1(K161R) were injected intrahepatically into mice to assess the impact of K161R mutation on VDAC1-APOE interaction and associated downstream cascades.
Results: Spatial transcriptomic analysis revealed that patients in concurrent group exhibited markedly exacerbated mitochondrial dysfunction and aberrant immune cell infiltration. Although all enrolled CHB patients were in the immune-tolerant phase, concurrent MASLD significantly increased the infiltration of tumor-associated macrophages (TAMs) within the lesion areas. Compared with CHB or NAFLD patients, concurrent CHB and NAFLD patients presented upregulated Voltage-Dependent Anion Channel 1 (VDAC1) localized on mitochondria, accompanied by a marked increase in VDAC1 oligomerization. VDAC1 subsequently interacted with the lipid droplet protein Apolipoprotein E (APOE), resulting in lipid droplets-mitochondria tethering, oxidative stress and markedly exacerbated mitochondrial dysfunction, which developed a tumorigenic microenvironment by increasing lactate production and inhibiting apoptosis. Interfering with this cascade through blocking VDAC1-APOE interaction mitigated mitochondrial dysfunction, inhibited lactate production, promoted apoptosis and suppressed the development of a pro-tumorigenic hepatic microenvironment in mice. Meanwhile, oligomerization of VDAC1 in MASLD promoted the release of mitochondrial DNA (mtDNA), which inhibited HBV replication by activating the ISG-mediated innate immune response.
Conclusion: Concurrent MASLD promotes VDAC1-mediated lipid droplet-mitochondria tethering, which is associated with higher risk of HCC and lower HBV replication in CHB patients.

FRI-244

Analysis of intrahepatic cccDNA and HBV-DNA in patients with hepatocellular carcinoma attributed to non-HBV etiologies

Elena Vargas-Accarino[1,2], Thais Leonel[3], Monica Higuera[1], Maria Saez-Palma[3], Agnes Soriano-Varela[1], Maria Torrens[4], Sabela Lens[3], Ariadna Rando[5], Sofía Pérez-del-Pulgar[3], Beatriz Minguez[1,2,4], Maria Buti[1,2,4]. *[1]Liver Diseases Research Group. Vall d´Hebron University Hospital, Barcelona, Spain; [5]Microbiology and Biochemistry Department, Vall d'Hebron Universitary Hospital, Barcelona, Spain*
Email: mariabutiferret@gmail.com

Background and aims: Hepatitis B virus (HBV) is a well-recognized oncogenic virus. In previous studies, the presence of serum anti-HBc and HBV-DNA in HBsAg-negative patients have been associated with an increased risk of hepatocellular carcinoma (HCC), particularly in Asian patients. This study aimed to evaluate the presence of intrahepatic cccDNA and HBV-DNA in a cohort of HCC patients and explore its relation with serum HBV markers.
Method: Prospective cohort of 64 HBsAg-negative HCC patients from whom paired tumor tissue, adjacent non-tumor tissue, and serum samples were collected between January 2016 and January 2024. Covalently closed circular DNA (cccDNA) and intrahepatic HBV-DNA (iHBV-DNA) in both tumor and adjacent tissues were quantified using qPCR. Serum anti-HBc antibodies and HBV-DNA levels were determined using commercial assays (Roche Diagnostics). The cohort included 84% males, with a median age of 62 years; 91% were Caucasian, and 96% had underlying liver disease (HCV 36%, ALD 17%, and MASLD 16%). Additionally, 6 HBsAg-positive patients were included for comparison.
Results: Of the 64 HBsAg-negative HCC patients, 42% (27/64) had detectable iHBV-DNA in in either tumor or adjacent liver tissue [mean (SD): 0.005 (0.008) copies/cell], and 6% (4/64) also had cccDNA [0.004 (0.004)]. Serum anti-HBc was present in 19 (30%) patients,and iHBV-DNA was detected in 5 (26%) of these in either tumor or adjacent tissue. Among the 45 anti-HBc-negative patients, 22 (49%) had detectable iHBV-DNA (8 in tumor tissue, 7 in adjacent tissue, and 7 in both); cccDNA was also detected in 4 of these cases. There were no significant differences in the proportion of patients with iHBV-DNA (26% vs. 49%, $p = 0.09$) or its concentration in tissue (0.003 (0.003) vs. 0.005 (0.008) copies/cell, $p = 0.36$) based on anti-HBc status. Notably, none of the 4 patients with cccDNA had detectable HBV-DNA in serum. All 6 HBsAg-positive (and HBeAg-) patients had iHBV-DNA in both tumor and adjacent tissues [11.74 (11.51) and 3.57 (3.89) copies/cell], while cccDNA in 100% of adjacent tissues [0.59 (0.61)] and 50% of tumor tissues [0.56 (1.22)]. The levels of iHBV-DNA in these HBsAg-positive patients were significantly higher than in HBsAg-negative patients in both tumor [11.74 (15.37) vs. 0.008 (0.011), $p < 0.001$] and adjacent tissue [3.57 (3.89) vs. 0.0023 (0.0018), $p < 0.001$]. Among the 27 HBsAg-negative patients with detectable iHBV-DNA and/or cccDNA in tissue, underlying liver disease was attributed to HCV (37%), MASLD (33.3%), and other non-HBV-related causes. There were no significant differences in iHBV-DNA concentration based on etiology.
Conclusion: Nearly half of the HBsAg-negative patients with HCC attributed to other etiologies show intrahepatic HBV DNA or cccDNA. Its detection is not related to serum anti-HBc presence, indicating high exposure to HBV. Further molecular analyses are currently ongoing.

Email: emely.richter@rub.de

Background and aims: The hepatitis E virus (HEV) presents a significant global health concern with an estimated 20 million infections occurring annually, while no specific antiviral treatments are available. Our current understanding of the viral life cycle is limited, but it is essential for the development of novel antiviral strategies. The lysosomal cholesterol transporter NPC1 has been shown to prevent the entry of different viruses, including Ebola virus and SARS-CoV-2. However, the role of the cholesterol transporter Niemann-Pick-C1 (NPC1) during HEV infections remains unclear. Here, we investigated the role of NPC1 during the HEV infectious cycle and evaluated the antiviral potential of the clinically approved NPC1 inhibitor Itraconazole.
Methods: Using a robust HEV cell culture model, we investigated the dose-dependent effect of the two NPC1 inhibitors, Itraconazole and U18666 on the infection with (non-)enveloped HEV. In addition, we performed time-of-addition as well as subgenomic replicon assays to gain insights into the mode of action of the NPC1 inhibition. We further performed quantitative RNA fluorescence in situ hybridization (RNA-FISH) to localize HEV virions during NPC1 perturbation. The requirement of NPC1 during the HEV life cycle was further validated via siRNA-mediated knockdown and CRISPR/Cas9-mediated knockout. In addition, we evaluated the antiviral effect of the NPC1 inhibitors in primary human hepatocytes (PHH).
Results: Both NPC1 inhibitors, Itraconazole and U18666A, lowered HEV infectivity at nanomolar efficacy in hepatoma cells. Consistent with this, siRNA-mediated knockdown of NPC1 and CRISPR/Cas9-mediated knockout lowered the susceptibility to infection with (non-)enveloped HEV. Time-of-addition experiments showed that the NPC1 inhibitors exert their antiviral effect during virus entry, without affecting viral replication, as observed by replicon assay. In agreement with this, we observed cholesterol accumulation and enlargement of lysosomal compartments upon NPC1 perturbation and a blockage of RNA trafficking and productive infection. In PHH, Itraconazole exhibited a potent effect in reducing the HEV infectivity.
Conclusion: Overall, our data suggests that NPC1 plays a crucial role during the viral entry of HEV. Considering that the NPC1 inhibitor Itraconazole is clinically used in immunocompromised patients (unrelated to viral conditions), the pharmacological targeting of NPC1 might guide novel antiviral strategies against HEV infections in the future.

FRI-246

HBV cccDNA: The molecular reservoir of hepatitis B persistence and challenges in eradication

Gulce Sari[1], Mandy Berndsen[1], Jolanda Kreeft-Voermans[2], Harry L.A. Janssen[1], Annemiek Van der Eijk[2], Andre Boonstra[1].
[1]Erasmus MC Dept. of Gastroenterology and Hepatology, Rotterdam, Netherlands; [2]Erasmus MC Dept. of Virology, Erasmus MC Unit Klinische Virologie, Rotterdam, Netherlands
Email: g.sari@erasmusmc.nl

Background and aims: Hepatocytes in patients with chronic hepatitis B harbor covalently closed circular DNA (cccDNA), which acts as a stable, long-term template for viral replication, producing viral genomes and associated proteins. This viral mini-chromosome is difficult to eliminate with current treatment regimens: nucleos(t)ide analogs and interferon, and consequently viral replication occurs after stopping therapy. Novel treatment strategies are generally given in virally suppressed individuals, but accurate markers to monitor treatment efficacy in these patients are not available. In this study, we therefore develop sensitive and specific methods to assess the intrahepatic HBV viral reservoir, particularly cccDNA and its transcriptional activity via pre-genomic RNA (pgRNA).
Method: To address this need, we employed droplet digital PCR (ddPCR), which uses water-oil emulsion droplet technology for targeted amplification and detection, enabling us to distinguish between HBV rcDNA and cccDNA. We optimized this assay using the HepG2.2.15 cell line, which harbors a persistent HBV infection and produces all viral elements, achieving detection sensitivity down to 1% of infected cells within a non-infected HepG2 cell pool. Testing patient sera, which contain rcDNA but not cccDNA, with variable HBV DNA titers up to 10^9 IU/mL, all tested samples were negative for HBV cccDNA, confirming assay specificity. Further specificity was validated in liver samples from HBV- or HCV-derived hepatitis patients, with all HCV-infected samples testing negative for HBV cccDNA. This ddPCR assay provides a sensitive and specific approach for distinguishing HBV cccDNA from other viral forms, offering a valuable tool for studying the HBV reservoir and aiding in the evaluation of therapeutic strategies aimed at HBV eradication.
Results: Currently, we are utilizing this method to determine the correlation between PEGylated-IFNα treatment response and initial intrahepatic HBV cccDNA reservoir levels. This study aims to measure the baseline intrahepatic HBV cccDNA levels in patients before they began pegylated (PEG)-IFNα treatment, to explore cccDNA as a biomarker that could help identify those likely to benefit from this therapy. We also assess the transcriptional activity of HBV cccDNA, pre-genomic RNA (pgRNA) levels, to determine if treatment outcomes are influenced by either the baseline copy number or activity of HBV cccDNA. By quantifying HBV cccDNA and pgRNA levels after treatment, we want to understand how the HBV reservoir is affected post-PEG-IFNα treatment by comparing responders with non-responders.
Conclusion: Overall, our findings could provide early biomarkers to identify likely PEG-IFNα responders and offer HBV cccDNA measurement as a useful method to evaluate the efficacy of novel HBV therapeutics.

FRI-247

In vitro characterization of elebsiran (VIR-2218), an investigational siRNA therapeutic targeting hepatitis B virus

Hasan Imam[1], Jiayi Zhou[1], Tuyen Nguyen[2], Joseph Barry[2], Adam Castoreno[2], Florian Lempp[1], Andrea Cathcart[1], Gregory Camus[1].
[1]Vir Biotechnology, Inc., San Francisco, United States; [2]Alnylam Pharmaceuticals, Cambridge, United States
Email: gcamus@vir.bio

Background and aims: Therapeutic targeting of hepatitis B virus (HBV) with RNA interference has the potential to contribute to functional cure or chronic treatment of patients with chronic HBV infection and hepatitis Delta virus (HDV). Elebsiran is an investigational small interfering RNA (siRNA) that targets the highly conserved HBx region of the HBV genome present in all HBV transcripts. Here, the preclinical activity of elebsiran was evaluated using in vitro models of HBV infection and integration, and in silico analyses.
Method: HBsAg and HBeAg reduction were assessed following HBV infection and elebsiran treatment in HepG2 cells expressing Na+-taurocholate co-transporting polypeptide (NTCP). Pan-genotypic activity was determined using a luciferase reporter system encoding HBV genotypes A-J HBx genes, and HBV genotypes A-D 1.3-overlength genome system. Nucleotide polymorphisms in the elebsiran target sequence were identified using sequence alignments

of 7,517 sequences from the HBV database, HBVdb, and tested in vitro. Elebsiran was evaluated for HBsAg secretion inhibition in HBV-DNA integrated cells (huH1, Hep3B and PLC/PRF/5). Elebsiran knock-down of HBV transcripts and its effect on viral and host proteins expression was assessed using northern and western blot analyses of HBV-infected cells.

Results: Elebsiran showed potent reductions of HBsAg and HBeAg in HBV-infected HepG2-NTCP cells. HBx mRNA knockdown was observed for sequences from all 10 HBV genotypes, with 49–78% reduction at 50 nM of elebsiran. Treatment with elebsiran led to concentration-dependent decrease of secreted HBsAg and HBeAg in 13 isolates of HBV genotypes A-D with EC50 values 0.038–0.105 nM. Elebsiran also exhibited full inhibition (>99%) of HBsAg release in huH1 & Hep3B cells and partial inhibition (52–70%) in PLC/PRF/5 cells. Sequence analysis of PLC/PRF/5 cells revealed rare polymorphisms (<0.11% frequency based on HBVdb) in the elebsiran target site of some HBV integrants, which were associated with in vitro resistance. Finally, northern blot analysis in infected cells showed elebsiran-mediated knock-down of all HBV transcripts derived from covalently closed circular (ccc) DNA. Western blot analysis confirmed protein downregulation of all HBsAg isoforms and HBx, as well as rescue of the HBV restriction factor Smc5/6.

Conclusion: Elebsiran demonstrated potent reductions of HBV viral markers in two in vitro infection models and exhibited pan-genotypic activity. Sequence analysis revealed that target site substitutions are rare. Elebsiran showed potent antiviral activity against HBV from both integration and cccDNA. Elebsiran-mediated degradation of all HBV transcripts inhibits HBx expression and restores the HBV restriction factor Smc5/6 expression, suggesting additional downstream antiviral effects of targeting HBx.

FRI-248

Description of tenofovir levels in south african adults in the EVOLVE study: a pilot project to support therapeutic drug monitoring in HBV infection

Gloria Sukali[1,2,3], Katya Govender[1], Jacob Busang[1], Motswedi Anderson[1,2], Resign Gunda[1], Emily Wong[1], Theresa Smit[1], Gregory Jording-Jespersen[1], Janine Upton[1], Dickman Gareta[1], Elizabeth Waddilove[2], Kathy Baisley[1], Marion Delphin[2], Collins Iwuji[1,4], Philippa C. Matthews[2,3,5]. *[1]Africa Health Research Institute, Durban, South Africa; [2]The Francis Crick Institute, London, United Kingdom; [3]University College London, London, United Kingdom; [4]University of Sussex, London, United Kingdom; [5]University College London Hospital, London, United Kingdom*
Email: philippa.matthews@crick.ac.uk

Background and aims: Hepatitis B virus (HBV) treatment is based on nucleos/tide analogue (NA) drugs for viral suppression, which overlap with therapy used for HIV; the first line agent is tenofovir (TFV). Therapeutic drug monitoring (TDM) has not been explored to optimize therapy in HBV. However, TDM is established in the HIV field, providing a framework to fill evidence gaps for HBV. In this pilot project, we describe the distribution of free tenofovir (TFV) and its metabolite, tenofovir-diphosphate (TFV-DP), in a South African (SA) population offered treatment for HIV monoinfection or HIV/HBV coinfection.

Method: We studied Dried Blood Spot (DBS) obtained from 100 adults from EVOLVE, a project nested within the Vukuzazi programme in the KwaZulu-Natal province (KZN) of SA. Ethics approval was obtained from the relevant jurisdictions. Samples were selected to represent 40 HIV/HBV positive (coinfected), 40 HIV (monoinfected) and 20 HIV/HBV negative (control, presumed untreated), age and sex matched, participants. We used liquid chromatography-tandem mass spectrometry (LC-MS) to measure drug levels of free drug (TFV) and drug metabolite (TFV-DP). HBV viral suppression was defined as plasma HBV Viral load (VL) below the lower limit of quantitation, LLQ (<10 IU/mL). Statistical analysis was performed using Pearsons's or Kruskal-Wallis test, or logistic regression in R.

Results: In the HIV/HBV-negative control group, 1/20 individuals had detectable TFV (1077.94 fmol/punch) and TFV-DP (753 fmol/punch) and another had quantifiable TFV-DP (31.82 fmol/punch) only. In the remaining 80 samples, TFV and TFV-DP were both detected in 77/80 (96.3%) of participants, with a median level of 787 fmol/punch (IQR 524–1111) and 610 fmol/punch (IQR 372–802) respectively. TVF and TFV-DP levels correlated significantly ($R^2 = 0.59$ and $p < 0.001$). There was no significant difference in TFV and TFV-DP levels by sex ($p > 0.05$), but levels correlated positively with age ($p < 0.05$ for all). HIV VL was suppressed in all individuals, however, among the 40 individuals with HIV/HBV coinfection, 10 (25%) had HBV VL >LLQ (median VL: 195 (14, 13154 IU/mL)). Drug levels were not significantly different between HBV VL unsuppressed and suppressed individuals, (TFV: 544 vs 930 fmol/punch and TFV-DP: 464 vs 610 fmol/punch respectively), nor did they correlate with HBV status or VL ($p > 0.05$ for all).

Conclusion: We present early data to quantify TFV and TFV-DP levels in adults from SA. Drug levels were associated with age, but not sex, HBV status or HBV VL. Two HBV/HIV negative individuals tested positive for drug levels; this could be due to use of TFV for HIV pre-exposure prophylaxis. Data on treatment duration, self-reported adherence or the time between the last dose of treatment and sample harvesting is currently not available, and future work is needed to determine the relationship between drug levels and HBV virologic control.

FRI-253

Large spatial variation of intrahepatic HDV RNA levels without association with HBV core or S RNA levels in patients with HDV induced cirrhosis

Gustaf Rydell[1], Lucia Gonzales Strömberg[1], Johan Ringlander[1], Maria Andersson[1], Catarina Skoglund[2], Staffan Nilsson[1], Maria Castedal[2], Magnus Lindh[1]. *[1]Institute of Biomedicine, University of Gothenburg, Gothenburg, Sweden; [2]The Transplant Institute, Sahlgrenska University Hospital, Institute of Clinical Sciences, University of Gothenburg, Gothenburg, Sweden*
Email: gustaf.rydell@gu.se

Background and aims: Hepatitis D virus (HDV) infection is an important cause of cirrhosis and liver cancer. It occurs only as co-infection with hepatitis B virus (HBV), since it requires the surface antigen of HBV (HBsAg) to form viral particles. The aim of this study was to investigate correlations between levels of intrahepatic HDV RNA, HBV core and S RNA and serum markers.

Method: 10 pieces of tissue from each of five liver explants from patients that underwent transplantation because of HDV-induced liver disease were analyzed by digital droplet PCR.

Results: A large variation of the tissue levels of viral RNA was found between and within patients. An association was observed between tissue levels of HBV core and S RNA when values from tissue pieces from all patients were considered ($p < 0.0001$) and individually for two patients with a high core expression ($p < 0.05$, $p < 0.001$). However, no association was observed between HDV RNA and HBV core or S RNA except within one patient. Furthermore, there was no correlation between HDV RNA levels in serum and tissue. Instead, for the four patients with detectable serum HDV RNA, serum HDV RNA correlated positively with tissue levels of HBV core RNA ($p < 0.005$) and showed a trend towards correlation with tissue HBV S RNA levels. In addition, a significant correlation between the levels of HBsAg and HDV RNA in serum was observed ($p < 0.05$). A sample taken from the fifth patient five years prior to the transplantation showed the same relation between the two variables as the other patients.

Conclusion: The results suggest that HBsAg may be a limiting factor for HDV particle production, and that HBV infection is not required for cells to allow HDV genome replication. The results do not support repression of HBV replication by HDV since no negative correlation was observed between tissue levels of HDV RNA and HBV core RNA.

FRI-254-YI

Early immune responses define Peg-IFNα-mediated treatment outcome in chronic hepatitis D virus infection

Manfred Anim[1,2], Lisa Sandmann[1,2,3,4], Birgit Bremer[2], Heiner Wedemeyer[1,2,3,4], Helenie Kefalakes[1,2,3,4]. [1]*D-SOLVE Consortium, Hannover, Germany;* [2]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover, Germany;* [3]*Cluster of Excellence RESIST (EXC-2155), Hannover, Germany;* [4]*German Center for Infection Research, Partner Site Hannover-Braunschweig, Hannover, Germany*
Email: hkefalakes@gmail.com

Background and aims: Infection with the hepatitis D virus (HDV) induces the most severe form of chronic viral hepatitis, with almost 70% of patients developing liver cirrhosis and hepatocellular carcinoma within 5–10 years of infection. Pegylated interferon-α (Peg-IFNα) has been used to treat HDV-infected patients over the past decades with ∼20–30% of them achieving sustained virological response rates. The immunological mechanism of Peg-IFNα-induced viral control remains incompletely understood. The current study aims to identify immunological parameters that may predict Peg-IFNα-mediated treatment outcomes.
Method: Serum and liver samples were collected from patients treated within the HIDIT II study, where patients had received treatment with Peg-IFNα with or without tenofovir disoproxil fumarate for 96 weeks. Here, we re-grouped the patients based on on-treatment HDV viral decline and classified them into responders (HDV RNA decline below the lower limit of quantitation) and non-responders (sustained high HDV RNA levels). Healthy individuals and hepatitis B mono-infected patients were used as controls. Sera were tested for anti-IFNα and inflammatory cytokines. FFPE liver biopsies underwent *in-situ* immunofluorescence staining to identify immunological markers associated with treatment response.
Results: Baseline demographics showed no significant differences in age and gender between responders and non-responders. Responders demonstrated rapid HDV RNA decline, achieving undetectable levels by treatment week 48, while HDV RNA remained high in the non-responder group. Four-plex immunofluorescence staining demonstrated increased liver-resident immune cells in responders at baseline. Anti-IFNα antibodies were found in most of the patients, with some of them having pre-existing anti-IFNα antibodies. Although the levels declined in almost all responders under treatment, we observed significantly higher anti-IFNα antibody levels in the non-responders at treatment week 2. Also, plasma IFNα2 and IP10 levels, as well as tumor necrosis factor related apoptosis inducing ligand (TRAIL) were significantly increased in responders compared to non-responders at treatment week 8.
Conclusion: This study underscores the importance of anti-IFNα antibodies, as well as liver-resident immune cells in determining the success of Peg-IFNα treatment. Our current findings suggest that adaptive immunity may contribute to Peg-IFNα-mediated treatment response during chronic HDV infection.

FRI-255

Discordance between peripheral hepatitis B surface antigen (HBsAg) titres and hepatic expression in chronic HBV infection

James Lok[1], Yoh Zen[1], Nadina Wand[2], James Harris[2], Zillah Cargill[1], Kosh Agarwal, Jane McKeating[2,3], Ivana Carey[1]. [1]*Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom;* [2]*Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom;* [3]*Chinese Academy of Medical Sciences Oxford Institute, University of Oxford, Oxford, United Kingdom*
Email: james.lok@nhs.net

Background and aims: Serological profiling of hepatitis B surface antigen (HBsAg) remains central to diagnosing HBV infection and evaluating treatment response; in addition, the primary endpoint of functional cure is defined as a reduction in HBsAg (and HBV DNA) to below the limit of serum detection. To assess the validity of this approach, we explored the relationship between peripheral HBsAg titres and hepatic HBs expression.
Method: In this retrospective study, we identified subjects with chronic HBV infection (CHB) who have recently undergone a liver biopsy at King's College Hospital (UK tertiary centre). Archived FFPE liver tissue was stained for HBs and the percentage of HBs-positive hepatocytes was determined by a consultant histopathologist. HBs topography was described as "membranous" or "cytoplasmic," and results were expressed in a semi-quantitative manner (<10%, 11–50%, >50% of hepatocytes). Paired serum samples were evaluated for the following viral markers: total HBsAg (Abbott Architect®, $\log_{10}$ IU/ml), L-HBsAg (Abbkine, U/ml), HBV DNA (Roche Cobas® 6800, $\log_{10}$ IU/ml) and HBcrAg (Fujirebio, $\log_{10}$ U/ml). Differences between groups was assessed using non-parametric tests and a two tailed p value <0.05 was considered statistically significant.
Results: All subjects were HBV mono-infected and treatment naïve at the time of liver biopsy (n = 23, median age 38). Most were in the HBeAg negative phase of infection (78.3%), and a range of HBV genotypes were represented (Genotype E 39.1%, A 17.4%, B 17.4%, Other genotypes 26.1%). Median titres of total HBsAg and HBV DNA were 4.04 $\log_{10}$ U/ml (IQR 3.41–4.35) and 4.08 $\log_{10}$ U/ml (IQR 3.16–6.12), respectively, and 52.2% of patients recorded HBcrAg >3.0 $\log_{10}$ U/ml. F3/F4 fibrosis was present in 17.4% of biopsies and median necro-inflammatory score was 3 out of 18 (Ishak grading system). Extensive membranous HBs (defined as >50% of hepatocytes staining for HBs at the plasma membrane) was demonstrated in 39.1% of biopsies (including 6/18 HBeAg negative samples) and associated with higher peripheral titres of total HBsAg (p = 0.0008) & HBV DNA (p = 0.04); conversely, there was an inverse relationship between membranous HBs and peripheral L-HBsAg (p = 0.0002). Of note, there was no association between cytoplasmic HBs and any of the peripheral biomarkers (total HBsAg, p = 0.95; L-HBsAg, p = 0.99; HBV DNA, p = 0.35; HBcrAg, p = 0.79). Neither HBs-staining patterns were associated with necro-inflammatory scores (membranous HBs, p = 0.50; cytoplasmic HBs, p = 0.99) or fibrosis grade (membranous HBs, p = 0.80; cytoplasmic HBs, p = 0.96).
Conclusion: Serum HBsAg titres were reflective of membranous, but not cytoplasmic, HBs staining. Re-assessing the merits of this peripheral biomarker in defining functional cure, as well as evaluating treatment response, may be warranted.

FRI-256

Circulating miRNAs are downregulated in hepatitis delta patients that control viral replication

Email: javier.perez@vhir.org

Background and aims: Only a limited percentage of the hepatitis delta patients (HDV; anti-HDAg positive) can control the viral replication (undetectable HDV RNA). However, the mechanism behind this virological control remains unknown. The microRNAs (miRNAs) are small RNAs that participate in different biological

processes, including the host response against a viral infection. The present study aims to analyze the miRNAs profiles in HDV patients to identify potential biomarkers that differentiate those who control the infection.

Method: The study was conducted in two parts. First, miRNA profiles using MicroArray (Affymetrix) in plasma samples from 30 HDV patients (anti-HDAg positive - explorative cohort), grouped based on HDV RNA detectability: 15 with detectable and 15 with undetectable levels (confirmed by at least two consecutive measurements). The selected miRNAs were then validated by digital PCR (QIacuity). The cohort consisted of three longitudinal samples from 18 untreated, anti-HDAg patients, accounting for 54 plasma samples. These included patients with undetectable HDV-RNA (group A, n = 3) and chronic hepatitis delta patients (CHD) with detectable HDV-RNA (group B, n = 15). Group B was further divided based on their ALT levels into two subgroups: B1 with ALT <50 U/L (n = 6) and B2 with high ALT (n = 9). Notably, the first longitudinal samples (T0) were HDV-RNA positive in all included patients. A group of healthy donors (n = 7) was used as controls (HD).

Results: In the first part of the study, six differentially expressed miRNAs were selected (log2FC >1, *raw* p-valor <0.05 and mean expression>2): miR-122-5p, miR-192-5p, miR-194-5p, miR-23b-3p, miR-26a-5p and miR-4530, conforming two different patterns (miR-122-5p+miR-192-5p+miR-194-5p, and miR-23b-3p+miR-26a-5p). When quantifying the miRNAs in the longitudinal samples, we observed that patients with undetectable HDV-RNA (group A) had lower levels of all the miRNAs compared to those in the other groups, even at the first sample when HDV RNA was still detectable. Of note, the miR-23b-3p and miR-26a-5p, were particularly down regulated in all the HDV-positive samples in comparison to the HD (adjusted p-value <0.05).

Conclusion: Hepatitis delta patients that control viral replication exhibit a differential miRNA's profile from those with detectable and stable HDV RNA. The most differentially expressed miRNAs were generally down regulated in this group, suggesting that they can have an impact on viral replication. Further investigation is needed to understand the mechanisms behind the dysregulation of these miRNAs and their relationship with HDV replication. Study supported by the projects PI20/01692 and PI23/01065, funded by Instituto de Salud Carlos III and co-funded by European Union (ERDF, "A way to make Europe").

Next generation hepatitis B virus antisense oligonucleotides incorporating novel chemistries demonstrated significantly improved properties compared to current clinical candidates

Jin Hong[1], Vivek Rajwanshi[1], Jimmy Lu[2], Min Luo[1], Hyunsoon Kang[1], Kellan Passow[1], Jacquelyn Sousa[1], Dana Cho[1], John Cortez[1], Jieun Song[1], Lillian Adame[1], Cheng Liu[1], Sarah Stevens[1], Dinah Misner[1], Shane Daguison[1], Kusum Gupta[1], Aneerban Bhattacharya[1], Antitsa Stoycheva[1], Rostom Ahmed-Belkacem[1], Xuan Luong[1], Lawrence Blatt[1], Li Sun[2], David Smith[1], Julian Symons[1]. *[1]Aligos Therapeutics Inc., South San Francisco, United States; [2]Amoytop Biotech, Xiamen, China*
Email: jhong@aligos.com

Background and aims: Chronic hepatitis B (CHB) patients can achieve functional cure after monotherapy with antisense oligonucleotides (ASO) targeting hepatitis B virus (HBV) RNA, e.g. GSK-836 and AHB-137. This is a better outcome compared to many other new anti-HBV agents which showed no signs of HBV S antigen (HBsAg) loss. However, the reported rates of HBsAg loss at the end of ASO treatment were only moderate and the relapse rates during the off-treatment follow up period were high. Our goal is to develop a best-in-class HBV ASO that improves the rate of functional cure. We are targeting four areas for improvement compared with current clinical candidates: 1) significantly improved RNase H-mediated activity; 2) modestly improved human Toll-like receptor 8 (hTLR8) agonist activity; 3) less off target effects; and 4) improved ASO liver to kidney concentration ratio.

Method: In vitro and in vivo RNase H mediated-activity was analyzed with an HBsAg ELISA assay in the supernatant of HepG2.2.15 cell line or in the plasma of AAV-HBV mice. HEK-Blue hTLR8 and human peripheral blood mononuclear cell (PBMC) assays were used to monitor TLR8 activity. To validate ASO hTLR8 activity in vivo, hTLR8 knock-in (KI) mice were used as wild-type mice lack a functional TLR8 protein. Toxicity derived from ASO off-target effects was measured in a HepG2 Caspase3/7 assay and an ATP assay in InSphero 3-D liver cell spheroids. ASO concentrations in the liver and kidney were monitored in both mouse and monkey.

Results: To date, more than 1150 HBV ASO sequences incorporating novel chemistries have been designed, synthesized and tested. Utilizing stabilization chemistries, we have found in vitro RNase H-mediated activity could be improved ~10-fold (1 nM EC_{50}) in the HepG2.2.15 assay, compared with parental sequences with standard chemistries. Human TLR8 activities could be improved 10–100% over that of clinical stage compounds. In vitro Caspase 3/7 activities could be reduced 10–100% from those of clinical stage compounds. For individual ASOs, the overall improvements of all three aspects were evaluated and rank-ordered to select compounds for in vivo AAV-HBV mouse and hTLR8 KI mouse model studies. A lead compound, ALG-170961 has a better safety profile and improved hTLR8 activity than clinical stage ASOs. In AAV-HBV mice, HBsAg measured in mouse plasma, following 5 doses of ALG-170961 at 25 mg/kg, declined 2.89 $\log_{10}$ IU/mL from baseline to near lower limit of quantitation (LLOQ). When compared with clinical stage ASOs at the same dose level on Day 7, ALG-170961 showed 61% and 27% deeper HBsAg reduction than clinical stage compounds #1 and #2 respectively.

Conclusion: Applying novel chemistries could improve RNase H-mediated, hTLR8 and Caspase 3/7 profiles of HBV ASOs. Among several lead ASOs, ALG-170961 exhibited the most significantly improved in vivo efficacy when compared with current clinical stage compounds.

FRI-258

No evidence for viral escape mutations in immunodominant HCV-specific CD4 T cell epitopes

Jill Werner[1], Matthias Reinscheid[1], Lara Kelsch[1], Andreas Walker[2], Robert Thimme[1], Jörg Timm[2], Christoph Neumann-Haefelin[1], Maike Hofmann[1], Tobias Böttler[1]. *[1]University Hospital Freiburg, Internal Medicine 2, Freiburg, Germany; [2]University of Düsseldorf, Institute of Virology, Düsseldorf, Germany*
Email: jill.werner@uniklinik-freiburg.de

Background and aims: Hepatitis C virus (HCV) infection provides a valuable model for studying immune responses under viral persistence and clearance. Direct-acting antivirals (DAAs) clear HCV in about 95% of patients, but their impact on HCV-specific CD4 T cells remains incompletely understood. Previous studies identified an exhausted signature in HCV-specific CD8 T cells, particularly in those targeting conserved epitopes. Whether a similar signature exists in CD4 T cells and how immune escape mechanisms affect these cells is unclear. This study aimed to compare HCV-specific CD4 T cells in patients with chronic infection, after DAA therapy, and in individuals with spontaneous resolution on a single-cell level, while investigating CD4 immune escape mechanisms.

Method: HCV-specific CD4 T cells were analyzed in peripheral blood mononuclear cells (PBMCs) with MHC class II tetramers by flow cytometry and single-cell RNA sequencing (scRNAseq). Immunodominant viral epitopes were characterized through viral sequencing and mutation analysis in relation to HLA-DRB1 alleles

with Fisher's exact test. Epitope-specific CD4 T cell clones were tested for cytokine responses to mutated and non-mutated epitopes to assess mutation recognition by CD4 T cells. scRNAseq was performed on HCV-specific CD4 T cells from chronic patients (n = 4, 459 cells), post-DAA therapy (n = 2, 464 cells), and spontaneous resolvers (n = 3, 697 cells).
Results: HCV-specific CD4 T cell responses in chronic HCV patients (n = 153) were lower in frequency compared to individuals with spontaneous resolution (n = 6). HCV-specific CD4 T cells from post-DAA and spontaneously resolved patients clustered differently with higher CD127 expression and lower CD95 and PD-1 expression in spontaneous resolvers. scRNAseq revealed reduced expression of interferon-stimulated genes in HCV-specific CD4 T cells after DAA therapy compared to their chronic counterparts ($p < 0.001$). Circulating viral mutations were genotype-specific and were not associated with the corresponding HLA-DRB1 alleles. HCV-specific CD4T cell clones recognized both mutated and non-mutated epitopes equally, while artificially MHC class II anchor residue mutated epitopes were not recognized.
Conclusion: All circulating amino-acid substitutions within CD4 T cell epitopes were recognized by HCV-specific CD4 T cell clones targeting the wild-type sequence. Thus, loss of viral escape mutations of HCV-specific CD4 T cells does not appear to be a dominant mechanism of viral persistence. DAA-mediated HCV clearance is associated with a downregulation of interferon signatures on HCV-specific CD4 T cells, however, they still maintain phenotypic differences to those from spontaneous resolvers.

Phenotypic characterization of untreated chronic hepatitis B infected individuals in an ethiopian cohort using fixed whole blood samples
Julia MacLeod[1,2], Fikadu Girma Gudissa[3], Asgeir Johannessen[1,4], Nega Berhe[4,5], Hailemichael Desalegn[4,6], Asiya Jeylan[3], Lasse Rossvoll[1,4], Dag Henrik Reikvam[1,2], Niklas Björkström[7], Annika Niehrs[7]. *[1]Institute of Clinical Medicine, University of Oslo, Oslo, Norway; [2]Department of Infectious Diseases, Oslo University Hospital, Oslo, Norway; [3]Adama Comprehensive Specialized Hospital Medical College, Adama, Ethiopia; [4]Vestfold Hospital, Tønsberg, Norway; [5]Addis Ababa University, Addis Ababa, Ethiopia; [6]St Paul's Hospital Millenium Medical College, Addis Ababa, Ethiopia; [7]Karolinska Institutet, Centre for Infectious Medicine, Stockholm, Sweden*
Email: juliamacleod55@gmail.com

Background and aims: The immunophenotype of African patients with chronic hepatitis B virus (HBV) infection is rarely described despite the large burden of disease on the African continent. In this study we used a direct cryopreservation method and flow cytometry to investigate the immune cell phenotype of untreated, chronically HBV-infected Ethiopian patients across distinct clinical stages of infection.
Method: Untreated chronic HBV-infected patients were enrolled in Adama, Ethiopia. Patients were grouped into immune control, inflammation, cirrhosis, and grey zone based on structured medical history, clinical examination, ultrasound, elastography, ALT, HBV DNA quantification and APRI score. Whole blood samples were directly cryopreserved using Cytodelics whole blood stabiliser for deferred experimentation. Samples were thawed, stained using a 27-colour flow cytometry panel, and analysed to define immune cells including B cells, T cells, natural killer (NK) cells. Analysis was restricted to samples with more than 10,000 events in the $CD45^+$ immune cell gate (n = 302).
Results: Analysis of immune cell phenotypes within the distinct chronic HBV groups demonstrated differences in the immune cell frequencies. In detail, frequencies of CD3+ lymphocytes (defined as CD15-CD45+CD3+CD19-) were significantly lower in the cirrhosis group compared with the immune control ($p < 0.0001$), inflammation ($p = 0.01$), and the grey zone ($p = 0.01$) groups. Among T cells effector memory CD4 cells (CD45RA+CCR7-) were significantly lower in the cirrhosis group compared with both the inflammation ($p = 0.04$) and the grey zone ($p = 0.04$) groups. B cells were also notably altered in the cirrhosis population with memory B cells (IgD-CD27+) significantly lower in the cirrhosis group compared with the immune control ($p = 0.003$) and grey zone ($p = 0.009$) group. Furthermore, naïve B cells (IgD+CD27-) were significantly higher in the cirrhosis group compared to the immune control ($p = 0.014$) and grey zone ($p = 0.021$) group. In addition to changes in the adaptive immune cell compartment, we also observed changes in the distribution of innate immune cells within the distinct clinical groups with $CD56^{dim}$ NK cells (defined as CD15-CD45+CD3-CD19-$CD56^{dim}$) being significantly lower in the cirrhosis group compared to both the immune control ($p = 0.009$) and inflammation ($p = 0.01$) group.
Conclusion: Our findings indicate that untreated, chronic HBV-infected patients with cirrhosis in this Ethiopian cohort exhibit a unique immunophenotype compared to other clinical groups. They display a tendency towards a naïve rather than effector phenotype which could be contributing to ongoing tissue damage and failure to control infection. Additionally, our study underscores the effectiveness of Cytodelics as a reliable reagent for the cryopreservation of single cells from whole blood in resource-limited settings.

Background and aims: T cell-based therapies could play a key role in combination strategies directed towards functional cure of chronic hepatitis B (CHB). Successful drug development requires identification of viral epitopes that are prevalent in affected populations, conserved across genotypes, and abundantly expressed on hepatocytes through different disease stages. However, the database of validated HLA class I epitopes under-represents alleles in high CHB burden regions. Since human leukocyte antigen (HLA) -A*11:01 is highly prevalent (~50%) in China, we interrogated the hepatitis B virus (HBV) proteome for HLA-A*11:01-restricted epitopes using immunopeptidomics and bioinformatics, prioritizing HBV envelope (Env) due to the importance of hepatitis B surface antigen loss as a treatment goal.
Method: HLA-A*11:01-transduced PLC/PRF/5 cells containing integrated HBV DNA and HEK293 T cells transduced with both HLA-A*11:01 and HBV Env were both subjected to immunopeptidome analysis using HLA-A*11:01 immunopurification followed by liquid chromatography-tandem mass spectrometry. Predicted affinities of identified peptides for HLA-A*11:01 were determined using NetMHCpan-4.1. Variant frequencies were determined using publicly available HBV genotype B and C sequences.
Results: Five and six unique HLA-A*11:01-presented HBV Env peptides were identified from the PLC/PRF/5 and HEK293 T cells, respectively, with up to 5 variants (>5% frequency) associated with each of these peptides. Predicted affinities of these variants for HLA-A*11:01 ranged from ~5 nM to 23 µM, with 3 peptides predicted to have <500 nM affinity across genotypes B and C. Two of the three peptides were highly conserved length variants (10mer and 11mer) with a single sequence for each representing >90% of the sequences analysed. However, these peptides contain three consecutive cysteine residues which, due to complexities associated with disulphide bond formation, presents a challenge for drug development. The other peptide showed more acceptable biochemical properties for target selection despite greater genotypic variation (5 variants).

Conclusion: Our highly sensitive immunopeptidomic and bioinformatic strategy identified three HLA-A*11:01-binding HBV Env peptides as potential targets for T cell therapies. This work highlights the importance of evaluating prevalent HLA alleles in tandem with anticipated viral genotypic variation to ensure that drug development is tailored to people with CHB.

FRI-261

Persistent immune defects in innate-like CD8 T cells despite antiviral therapy in chronic hepatitis B

Lung Yi Loey Mak[1,2], Shue Xiong[1], Tizong Miao[1], Gerard Hernandez-Mir[1], Yu Lei[1], Anna Riddell[3], Apostolos Koffas[1], Patrick Kennedy[1], Upkar Gill[1]. *[1]Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [2]School of Clinical Medicine and State Key Laboratory of Liver Research, The University of Hong Kong, HK, Hong Kong; [3]Department of Virology, Barts Health NHS Trust, London, United Kingdom*
Email: loeymak@gmail.com

Background and aims: A novel population of CD8 T cells straddling the boundary between innate and adaptive immunity, has been identified. CD56+ CD8 T cells are distinguished from other CD8 T cell subpopulations, exhibiting high expression of NK receptors (NKR's) exerting NKR mediated effector functions in a TCR-independent manner, associated with global 'bystander' activation. Previous studies have recognised the role of bystander CD8 T cells correlating with liver inflammation. Evaluating this understudied cell population may provide insights into reasons for immunological failure of novel therapies for chronic hepatitis B (CHB) cure, where these cells may contribute to immunopathology.
Method: We studied the phenotypic and functional properties of global blood-circulating CD8 T cells from treated and untreated (treatment-naïve) CHB patients compared to healthy controls (HC). The proportion of activated CD8 T cells, expression of NKRs and functional profile of these cells was analysed by multi-parameter flow cytometry. Transcriptomic analysis of CD8 T cells was performed in a subset of patients.
Results: The proportion of activated (CD38+HLA-DR+) CD8 T cells expressing CD56 was significantly greater in CHB vs HC's, with a higher expression of NKRs (NKG2A, NKp30) on innate-like T cells (CD56+ CD8+). We noted the percentage of CD56+ CD8 T cells expressing NKRs were greater in subjects with 'immune active' disease (ALT >40, HBV DNA > 2,000) compared to immune control patients, reflecting their role in immunopathology. Contrarily, CHB subjects undergoing antiviral therapy (AVT), exhibited a reduced percentage of CD56+ CD8 T cells, however, NKR expression on global CD8 T cells remained significantly higher than in treatment-naïve patients. Undertaking transcriptomic analysis on sorted CD8 T cells, we observed mRNA expression of innate-like markers (KLRK1, NCR3) was higher in treated vs. untreated immune control patients indicating innate-like immune defects are not recovered by AVT. To determine cellular effector function, stimulation was undertaken with anti-CD3/CD28 (TCR-dependent) and IL-15 (TCR-independent). We noted IFNγ production was similar on CD56+ CD8 T cells with either stimulation method, but TNFα production was greater following IL-15 stimulation, indicating the capability of a differential functional profile in a TCR-independent manner.
Conclusion: We demonstrate the increased expression of a CD56+ CD8 T cells expressing NKR's in CHB patients, signalling via a TCR-independent manner, causing bystander innate immune defects. Further work is being undertaken for an in-depth evaluation of these cells to analyse the impact of AVT in the blood and liver of CHB patients, to further guide the development of therapeutic targets in the functional cure program.

Isogenic studies of basal-core promoter and precore mutations in hepatitis B genotype c

Leon Louis Seifert[1], Georgios Dangas[2], Yingpu Yu[3], Chenhui Zou[4], Catherine Freije[3], Xupeng Hong[3], Mengyin Zhang[3], Corrine Quirk[4], Yichen Zhou[5], Kosuke Ogata[6], Charles Rice[3], William Schneider[3], Eleftherios Michailidis[7], Ype De Jong[4]. *[1]The Rockefeller University Hospital, Laboratory of Virology and Infectious Disease, The Rockefeller University, New York, United States; [2]Emory University, Laboratory of Biochemical Pharmacology, Department of Pediatrics, Atlanta, GA, United States; [3]Laboratory of Virology and Infectious Disease, The Rockefeller University, New York, NY, United States; [4]Laboratory of Virology and Infectious Disease, The Rockefeller University, Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, NY, United States; [5]Laboratory of Virology and Infectious Disease, The Rockefeller University, Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, United States; [6]Department of Molecular Systems BioAnalysis, Kyoto University, Kyoto, Japan; [7]Laboratory of Biochemical Pharmacology, Department of Pediatrics, Emory University, Atlanta, GA, United States*
Email: lseifert@rockefeller.edu

Background and aims: In hepatitis B virus genotype C (HBV-C), the basal-core promoter mutation (A1762T/G1764A, BCPM) and precore mutation (G1896A, PCM) have been associated with increased risk of liver cirrhosis and liver carcinogenesis. However, the underlying mechanisms remain elusive. To facilitate study of isogenic infectious HBV mutations in human hepatocyte chimeric mice (huFNRGs), we developed a streamlined approach to launch HBV infection using direct intrahepatic injection (IHI) of synthetic, recombinant HBV covalently closed circular DNA (rcccDNA).
Method: To assess the efficiency of rcccDNA IHI, we engineered and validated silent mutant barcodes and mixed these with wild-type (WT) at ratios ranging from 1:10 to $1:10^4$ to produce infectious HBV stocks. Next, we generated isogenic virus stocks of HBV-C WT, BCPM and PCM and performed infection experiments in huFNRG mice. We also obtained human serum and liver biopsy samples from 34 patients infected with HBV-C (14 WT, 14 BCPM, 5 BCPM and PCM, 1 PCM).
Results: rcccDNA IHI is highly efficient, allowing the launch of at least 10^4 rcccDNA molecules per huFNRG mouse. rcccDNA IHI was successful across all HBV genotypes tested (A-F) with a success-rate of 89.6%. Comparative studies of HBV-C variants (WT, BCPM, PCM) revealed similar viral kinetics but distinct antigen secretion profiles. Mimicking findings in human patients, no HBe-Ag secretion was observed in PCM-infected mice, with a ~90% HBe-Ag reduction in BCPM-infected animals compared to WT. Pulse-SILAC proteomic analyses identified variant-specific changes in the hepatocyte proteome and differential responses to interferon treatment in cultured human hepatocytes. RNA-seq revealed unique variant-dependent transcriptomic profiles associated with these isogenic variants in huFNRG mice. Ongoing efforts include comparing these experimental findings with RNA-seq data from obtained patient liver biopsies.
Conclusion: We established and validated a robust IHI-based method for efficiently generating infectious HBV serum from rcccDNA in huFNRG mice, enabling detailed studies of isogenic mutants. Our investigations revealed variant-specific transcriptomic and proteomic differences in BCPM- and PCM-infected mice, with translational relevance being explored through RNA-seq comparisons with human liver biopsy samples.

FRI-263-YI

Viral N6-methyladenosine modifications regulate hepatitis E virus infections

Mara Klöhn[1], Pauline Wieczorek[1], Eike Steinmann[1]. [1]*Ruhr University Bochum, Bochum, Germany*
Email: mara.kloehn@rub.de

Background and aims: The Hepatitis E virus (HEV) is annually responsible for up to 3 million symptomatic cases and approximately 70,000 deaths worldwide, making it the leading cause of acute viral hepatitis. Current treatments, including ribavirin and, in select cases, pegylated interferon-alpha, are not universally effective and are linked to severe side effects such as anemia, organ rejection, and teratogenicity. Therefore, elucidating the HEV life cycle, particularly the virus-host interactions that facilitate viral replication, is key to developing novel antiviral strategies against HEV. Interestingly, recent studies have shown that N6-methyadenosine (m6A) modifications play a role in regulating the replication cycles of both RNA (e.g., hepatitis C virus) and DNA viruses (e.g., hepatitis B virus). This study aims to explore the roles of m6A writers, readers, and erasers in the context of HEV infection.
Method: To assess the impact of m6A RNA modifications on HEV infection, we administered the methyltransferase METTL3 inhibitor STM2457 to HEV-infected hepatoma and primary liver cells in a dose-dependent manner, with subsequent screening for virus-positive cells using fluorescence microscopy. Additionally, HEV replicon-transfected cells were treated with the inhibitor to evaluate effects on viral replication via luciferase assay. For validation, siRNA-mediated knockdown of key m6A-related proteins, including writers, was performed, followed by infection experiments. Knockout efficacy was confirmed by western blot analysis. Moreover, STM2457's antiviral activity was confirmed in primary human hepatocytes by fluorescence microscopy of infected cells, and the regulation of METTL3 expression by HEV was assessed through western blotting.
Results: Our findings indicate that inhibiting m6A methylation through the use of STM2457 disrupts infection with the human-derived HEV-3 strain Kernow-C1 p6 at an effective half-maximum concentration (EC50) of ~ 10 nM. However, viral replication remains unaffected when in vitro transcribed RNA is transfected by electroporation. Moreover, the antiviral efficacy of STM2457 was confirmed in primary human hepatocytes, demonstrating an 80% reduction in infection at a 10 µM drug concentration. These findings were further validated by siRNA knockdown experiments, which demonstrated that the depletion of the m6A writer METTL3 and METTL16 by siRNAs decreased HEV infections by 41% and 12%, respectively.
Conclusion: A comprehensive understanding of the HEV life cycle, including virus-host interactions that facilitate virus infection, is essential for developing novel antiviral strategies against HEV. Our study identified m6A methylation as a crucial component of HEV biology and suggests that it represents a promising target for future antiviral interventions.

FRI-264

Variability of the hepatitis delta virus and the role of the interferon I in a superinfected mice model

Email: mariafcortese@gmail.com

Background and aims: The hepatitis delta virus (HDV) is the most variable among the hepatitis viruses, mainly due to the loss of fidelity of the cellular RNA polymerase. The cellular enzyme ADAR1, whose expression is regulated by the intracellular interferon (IFN) pathway, enables the edition of the viral genome and the production of the large isoform of the delta antigen (HDAg). This study aimed to inspect the HDV genetic variability and the role of the type I IFN in an *in vivo* model of hepatitis B (HBV)- transgenic mice (HBVtg) super-infected with an adeno-associated vector carrying the HDV genome (AAV-HDV) and knocked-out for the IFNα/β receptor (HBVtgxIFNAR-KO).
Method: HBVtg and HBVtgxIFNAR-KO mice were injected with 5×10^{10} AAV-HDV or control vector (AAV-luciferase) viral genomes. The intrahepatic HDV RNA quasispecies (QS) was analyzed in the *HDAG* coding region (nucleotides- nt- 912–1298 in viral genome) through next-generation sequencing (MiSeq Illumina) at 7-, 21-, and 90-days post-injection (dpi). The QS composition was evaluated dividing it in fractions based on the variants' relative frequency (QFF), whereas the QS variability was studied by analyzing the nucleotide variations (SNVs) observed in at least two animals. The edition of the viral genome was calculated by considering the frequency of the variants with the A/G change in the edition site of the HDV genome.
Results: The composition of the *HDAG* QS was similar between the HBVtgxIFNAR-KO and WT mice at 7-dpi. Differently the proportion of emergent variants (frequency between 1% and the master) shows an upward trend in the next timepoints, especially in WT mice (19.6% and 30% at 21- and 90-dpi respectively, versus 12.8% and 19.8% in KO mice). In KO mice the edition of the viral genome was delayed related to the WT mice. At 7-dpi we observed the highest number of SNVs with a dominance of C/T transitions. Differently, at 21- and 90-dpi the changes were mainly A/G (changes that may be attributed to ADAR1) and T/C transitions. Among the observed SNVs, 10 were detected in all the timepoints, including the T431C (positions considering the *HDAG* ORF), whose frequency was higher and growing especially in WT mice ($5.6 \pm 4.6\%$, $13.4 \pm 5.2\%$ and $15.5 \pm 4.8\%$ at 7-, 21- and 90-dpi respectively versus $3.1 \pm 3.8\%$, $9.3 \pm 5\%$ and $8.8 \pm 3.6\%$ in KO). When considering the SNVs not-shared between the groups, at 21- and 90-dpi the WT mice presented a higher proportion of A/G and T/C changes than KO mice.
Conclusion: The different evolution of the composition of the viral QS between WT and KO mice suggests that the IFN may contribute to the intra-hepatic HDV variability. Most of the changes identified were A/G transitions, which are typically produced by ADAR1 enzyme. The common SNVs observed during the time might be indicative of the presence of hotspot of mutations in the HDV genome. Sydney, Australia
Email: mark.douglas@sydney.edu.au

Background and aims: Hepatitis B is the most common blood-borne virus infection and is incurable, requiring long-term suppressive antiviral therapy. Upon treatment cessation in selected HBeAg negative patients, 50–70% will relapse with risk of disease progression, ~30% will maintain virological control, and 0–20% will clear the infection (loss of HBsAg). These outcomes are difficult to predict from peripheral biomarkers alone as viral persistence is driven by intrahepatic covalently closed circular DNA (cccDNA) and integrated DNA (iDNA) which are challenging to quantify. We have developed novel assays that can detect cccDNA and iDNA in liver fine-needle aspirates (FNA) to predict relapse or cure (loss of HBsAg). We hypothesise that lower levels of cccDNA and iDNA predict viral clearance.
Method: We will recruit 130 patients who have been on long-term antiviral treatment with HBV DNA <20 IU/ml for ≥3 years, HBeAg negative, HBsAg <1000 IU/ml and are older than 18. Before stopping treatment, we will collect liver FNAs to measure intrahepatic cccDNA, iDNA and peripheral blood to measure biomarkers (HBV DNA, HBV RNA, HBsAg, HBcAg, HBeAg, ALT and peripheral blood mononuclear cells).
Results: To date we have obtained baseline FNAs from 30 patients and the procedure was well tolerated, with mild (45%) or moderate (55%) pain reported. Average recovery time was ~48 hours with minimal post-operative care. By staining cells with fluorescently-labelled myrcludex B (a hepatocyte-specific lipopeptide), we found an average of 3.3×10^5 hepatocytes per FNA. We have confirmed that our highly sensitive PCR-based assays can quantify cccDNA and iDNA in FNAs (requiring ~50 cells as minimum input). Patients have remained well past 6 months post treatment cessation with minimal flares overall. Some have cleared HBsAg and some have had to recommence treatment due to flares. Updated results will be presented.
Conclusion: We have developed highly sensitive and specific assays that can quantify HBV cccDNA and iDNA in minimally invasive liver FNAs. We will determine how well intrahepatic cccDNA and/or iDNA predict clinical outcomes after stopping antiviral therapy. We will also assess the correlation and performance of novel blood biomarkers as surrogate markers for HBV activity and host antiviral immune response. We aim to develop an integrated clinical algorithm to inform personalised treatment pathways, by identifying those who can safely stop treatment and achieve cure.

FRI-270

T helper 17 cell differentiation and the functional cure of chronic hepatitis B: insights from proteomic analysis and microRNA expression profiling of plasma-derived exosomes

Meng Zhao[1], Saisai Zhang[1], Danny Ka-Ho Wong[1], Judy Wai-Ping Yam[2], Cherlie Lot-Sum Yeung[2], Lung-Yi Mak[1,3], Rex Wan-Hin Hui[1], Man-Fung Yuen[1,3], Wai-Kay Seto[1,3]. [1]*Department of Medicine, School of Clinical Medicine, The University of Hong Kong, Hong Kong, China;* [2]*Department of Pathology, School of Clinical Medicine, The University of Hong Kong, Hong Kong, China;* [3]*State Key Laboratory of Liver Research, The University of Hong Kong, Hong Kong, China*
Email: mengz014@connect.hku.hk

Background and aims: Recent studies have shown that exosomes are involved in the disease process of chronic hepatitis B (CHB), but there is a lack of research on the role of exosomes in hepatitis B surface antigen (HBsAg) seroclearance. This study aims to use proteomics and microRNA (miRNA) high-throughput sequencing methods to compare the composition differences of plasma exosomes between HBsAg-positive hepatitis B e antigen (HBeAg)-negative CHB patients and CHB patients achieving HBsAg seroclearance, to provide new insights for discovering therapeutic targets in achieving a functional cure.
Method: Data-independent acquisition (DIA) mass spectrometry and small RNA sequencing were utilized to examine the dynamic profiles of exosome proteins and miRNAs in plasma exosomes extracted through ultracentrifugation (Optima XL-80 K, Beckman Coulter, United States) from treatment-naïve HBeAg-negative CHB patients (n = 10) and HBsAg seroclearance patients (n = 10). We employed three miRNA prediction tools: miRWalk (v3.0), mirDIP (v5.3.0.2), and TargetScan (v8.0) to identify the target genes of miRNAs. Bioinformatics and annotation analyses were studied using Geno ontology (GO) Enrichment Analysis, Kyoto Encyclopedia of Genes and Genomes (KEGG) Analysis and Gene set enrichment analysis (GSEA).
Results: A total of 104 differentially expressed proteins (DEPs) and 63 differentially expressed miRNAs (DE-miRNAs) were significantly altered when comparing patients achieving HBsAg seroclearance with HBsAg-positive HBeAg-negative patients, with absolute $\log_2$-(fold change) > 0.77 and > 1, respectively (all $p < 0.05$). The upregulated molecules in HBeAg-negative patients included liver-specific proteins, such as fructose-bisphosphate aldolase B (ALDOB), transcription factor (TF), and C-reactive protein (CRP), as well as miRNAs (miR-122, miR-192-5p, and miR-194-5p). GO analysis revealed a high enrichment of DEPs in multiple adaptive immune-related processes, while KEGG and GSEA analysis exhibited the involvement of the IL-17 signaling pathway ($p = 0.0002$ & 0.0004 respectively) and Th17 cell differentiation ($p = 0.003$ & 0.006 respectively). We identified several miRNAs from the let-7 family, notably let-7a-5p, which exhibited the highest expression abundance (Expr) (MeanExpr = 25825, $\log_2$(fold change) = − 1.9, $p < 0.05$) in all downregulated DE-miRNAs, with a target gene IL6R, identified to play a significant role in Th17 cell differentiation.
Conclusion: Our study for the first time described specific molecular pattern of plasma exosomes in CHB patients achieving HBsAg seroclearance. Exosomes can serve as a potential biomarker for assessing liver injury severity, with Th17 cell differentiation possibly playing an important role in HBsAg seroclearance, providing valuable diagnostic and therapeutic insights for advancing the pursuit of a functional cure.

FRI-271

Immune response patterns in HBeAg (-) chronic hepatitis B patients during NA treatment depends on the viral activity at baseline

Miriam Frisch[1], Anne Olbrich[1], Maria Pfefferkorn[1], Madlen Matz-Soja[1,2], Thomas Berg[1], Florian van Bömmel[1]. [1]*Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany;* [2]*Rudolf-Schönheimer-Institute for Biochemistry, Leipzig University, Leipzig, Germany*
Email: miriam.frisch@medizin.uni-leipzig.de

Background and aims: Chronic hepatitis B (CHB) persistence is linked to virus-specific adaptive immune dysregulation, mainly studied in HBeAg(+) patients. Immune reinvigoration involves reversing this exhaustion and restoring T cell function to improve immune control. However, immune responses during nucleos(t)ide analogue (NA) treatment in HBeAg(-) CHB patients remain under-explored. This study aims to analyze the T-cell response in HBeAg(-) CHB patients during NA treatment.
Method: We prospectively included 28 HBeAg(-) patients undergoing NA treatment. T-cell response was assessed by FACS on PBMCs stimulated with HBV-specific peptides, focusing on frequencies of CD3+, CD4+, CD8+, and (CD4/CD8+) IFN-γ+ T cells. Serum markers (HBV DNA, HBV RNA and HBsAg) were analyzed at baseline (BL), early therapy (≤6 months), and advanced therapy (>6 months), and correlated with T cell profiles. Based on HBV replication levels at BL patients were grouped in group A (HBV DNA >10,000 IU/ml, n = 15) and group B (HBV DNA <10,000 IU/ml, n = 13).
Results: At BL, patients in group A had significantly higher HBV RNA levels than patients in group B ($p = 0.006$), while median frequencies of CD3+, CD4+, and CD8+ T cells were similar between both groups. However, CD4+ IFN-γ+ T cells (1.0% vs. 0.43%, $p = 0.07$) and CD8+ IFN-γ + T cells (3.8% vs. 1.5%, $p = 0.08$) were higher in group A. During

treatment, CD4+ T cells increased (57.5% to 67.7%, p = 0.07), while CD8 + T cells decreased (39.5% to 28.0%, p = 0.09) from BL to early therapy in group A. Median frequencies of CD4+ IFN-γ+ and CD8+ IFN-γ+ T cells also decreased significantly from baseline (1.0% and 3.8%) to advanced therapy (0.3% and 1.0%), respectively (p = 0.001 and p = 0.005). In contrast, in group B, CD8+ IFN-γ+ T cells increased significantly from BL to early therapy (1.51% to 5.28%, p = 0.02), and a significant negative correlation was observed between CD8+ IFN-γ+ T cells and HBV DNA at BL (r = –0.712, p = 0.031).

Conclusion: Patients with lower HBV replication exhibited an increase in CD8+ IFN-γ+ T cells during NA treatment, suggesting a more robust immune response. Our findings suggest that HBV particles influence immune kinetics and treatment outcomes. Further research is needed to explore the long-term impact of these immune changes on treatment efficacy and response to NA treatment withdrawal.

FRI-272

On treatment modeling of ALT, HBVDNA and HBsAg in NUC-treated HBeAg-negative CHB patients helps to characterize the immune response and may predict clinical relapse after discontinuation

Piero Colombatto[1], Rachel Wen-Juei Jeng[2,3], Gabriele Ricco[1], Rong-Nan Chien[2,3], Daniela Cavallone[1], Yen-Chun Liu[2,3], Andrea Pinna[1], Francesco Damone[1], Barbara Coco[1], Ferruccio Bonino[4], Maurizia Brunetto[1,4,5]. *[1]Hepatology Unit, Pisa University Hospital, Pisa, Italy; [2]Department of Gastroenterology and hepatology, Chang Gung Memorial Hospital, Linkou Medical Center, Taoyuan, Taiwan; [3]College of Medicine, Chang Gung University, Taoyuan, Taiwan; [4]Institute of Biostructure and Bioimaging, National Research Council, Naples, Italy; [5]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy*
Email: maurizia.brunetto@unipi.it

Background and aims: Undetectable HBsAg and HBV DNA off-therapy (Functional Cure, FC) is the endpoint of chronic hepatitis (CHB) treatments. Nucleo(s)tide analogues (NUCs) have modest impact on HBsAg decline, but treatment discontinuation (DC) increases the chance of FC with limited risk of severe relapses in patients (pts) with low HBsAg at the end of therapy (EOT). We investigated by mathematical modeling the on-treatment kinetics of ALT, HBV DNA and HBsAg in HBeAg negative CHB before NUCs DC to gain insights on the mechanisms leading to FC.

Method: Model assumptions: 1) serum HBsAg is produced by cccDNA and integrated DNA (intDNA) in variable proportions, 2) cccDNA may have an intrinsic decay upon NUC blocking of HBV DNA production, 3) cccDNA is not transmitted to daughter cells by division, whereas intDNA is transmitted, 4) specific killing of HBV infected cells with cccDNA causes the release of ALT. Therefore, ALT levels at the start of treatment (SOT) provide the initial estimate of the Infected cells with cccDNA (Ic_0), and ALT decline in the first 3–6 months of therapy of their immune mediated clearance rate constant (δ_0), which tends to decrease by negative feedback according to the fraction of Ic overtime $(Ic_t/Ic_0)^k$, where k can range 0–1. NUCs antiviral effect is described by an initial block of HBV DNA production (ε) followed by a slower exponential decline, with time constant ϕ, and asymptotic value γ. Individual fitting of ALT, HBV DNA and HBsAg in 23 pts throughout treatment (19 ETV, 4 TDF) provided the final calculation of the model parameters.

Results: The model was applied in 14 pts (12 M, median age 45.5y, gt A:1, D:2, C:4, B:6) with clinical relapse (CR: ALT>2xULN and HBV DNA > 2000 IU/mL) and in 9 (8 M, median age 50.5y, gt C:3, B:6) without CR (noCR). Median NUCs duration was comparable in CR and noCR [2.8 (1.9–3.2) vs 2.1 (1.6–13.8)y, p = 0.734], same for the time of HBsAg clearance after NUCs DC [4.5 (2.2–5.5) vs 3.65 (0.3–5.6) y, p = 0.277]. Median ALT at SOT was similar in CR and noCR [167 (56–681) vs 151 (41–1563) U/L, p = 0.403], as well as Log HBV DNA [6.06 (5.04–6.74) vs 5.74 (3.42–8.05) p = 0.439], whereas Log HBsAg tended to be higher in CR [2.90 (2.20–3.95) vs 2.31 (0,89–4.42), p = 0.053]. Model computed parameters showed numerically higher Ic_0 in CR vs noCR [43.9 (10.1–62.8) vs 16.2 (4.2–94)%, p = 0.201], and longer Ic_0 half-lives [25.2 (17.9–73.6) vs 18.2 (8.9–64.50) days, p = 0.179]. The clearance rate of Ic slowed-down significantly more in CR than in noCR [k value: 0.65 (0.50–0.85) vs 0.49 (0.30–0.75), p = 0.023]. The estimated non-cytolitic decline of cccDNA was slower in CR vs noCR [0.001 (0.0001–0.005) vs 0.0001 (0–0.001) day^{-1}; p = 0.011]. The parameters describing direct antiviral effect (ε,ϕ,γ) were not significantly different.

Conclusion: Modeling the dynamics of HBV in pts with or without a clinical relapse after NUCs discontinuation, suggests that the better outcome depends on the persistence of a reactive immune response during therapy, with the contribution of non-cytolitic decline/inhibition of cccDNA.

FRI-273

Experimental HCV infection identifies ribosomal RNA 2′-O-methylation sites also affected across all etiologies and stages of chronic liver diseases

Pélagie Huchon[1,2], Frederic Catez[2], Fleur Bourdelais[2], Claire Verzeroli[1], Mélanie Roda[1], Marie-Laure Plissonnier[1], Karen Gammeltoft[3], Judith Gottwein[3], Armando Andres Roca Suarez[1], Xavier Grand[4], Romain Barnault[5], Virginie Marcel[2], Fabien Zoulim[1,6], Romain Parent[1,2]. *[1]INSERM UMR1350 PaThLiv, Lyon, France; [2]INSERM U1052 - CRCL, Lyon, France; [3]University of Copenhagen, Copenhagen, Denmark; [4]INSERM UMR1350 PathLiv, Lyon, France; [5]Inserm U1111 - CNRS UMR 5308 - UCBLI - ENS de Lyon, Lyon, France; [6]Hepatology and gastro-enterology service - Lyon University Hospital (HCL), Lyon, France*
Email: pelagie.huchon@inserm.fr

Background and aims: Ribosomes are mandatory factors for cell translation. They exhibit important heterogeneity when considering chemical modifications of ribosomal RNAs (rRNAs), events known to quantitatively and qualitatively alter translation. 2′-O-methylation (2′-O-Me) is their most abundant alteration, present in more than a hundred positions on all rRNA types. 2′-O-Me rates in defined rRNA positions have been identified as pivotal for acute myeloid leukemia or breast cancer progression. RNA viruses completely rely on cellular ribosomes for persistence, as they are unable to code for their own. Thus, oncogenic viruses are likely relevant models for the study of 2′-O-Me, especially if hepatotropic, as the liver is considered the organ with the most active protein synthesis. In this context, we considered the mutual impacts between 2′-O-Me and the hepatitis C virus (HCV), which remains a useful tool to study hepatic pathogenesis, and of which replication intensely relies on cellular translation due to its (+) RNA status.

Method: For better clinical relevance, *in vitro* infections of Huh7.5 cells were performed using the HCV genotype 1 strain TNcc-HI. 2′-O-Me scores were measured by RiboMeth-seq, a recognized quantitative method, in a variety of *in vitro* and clinical samples, obtained from one local (Lyon U. Hospital) and one national (French Liver Biobank) chronic liver disease (CLD) cohort, spanning all main etiologies and fibrosis stages (n = 90 cases), considering normal livers (n = 16) as references. RNAi depletion of the 2′-O-methyltransferase fibrillarin (FBL) was achieved to decrease the global rate of 2′-O-Me to study the implication of 2′-O-Me in HCV replication. Results were confirmed by specifically mutating the 2′-O-Me domain of FBL.

Results: *In vitro*, we demonstrated that 2′-O-Me was decreased on two rRNA positions in HCV-infected conditions compared to controls. While the global impairment of 2′-O-Me decreased by ≈50% intracellular HCV RNA levels, it triggered a near-total collapse of HCV proteins core and NS5A, demonstrating i) the importance of 2′-O-Me for viral replication, and ii) a potential new and likely decisive layer of regulation for HCV RNA translation. Of direct interest in the understanding of CLD pathogenesis, the virally induced 2′-O-Me profile persisted after viral clearance in the clinic. Strikingly, both HCV-impacted rRNA positions *in vitro* were seemingly regulated in

human liver biopsies derived from all main etiologies and fibrosis stages. Thus, as demonstrated in other pathologies, the regulation of 2′-O-Me could be of substantial importance in hepatic pathogenesis.
Conclusion: This work highlights the potential importance of ribosome chemistry regulation in hepatic pathogenesis. It also provides preliminary grounds for the identification of processes leading to these molecular alterations through viral infection.

FRI-274

Novel, high-sensitive immunoassays for phosphorylated and non-phosphorylated HBcAg detection

Rene Geissler[1], Kenn Forberg[1], Michael Berg[1], Gavin Cloherty. [1]*Abbott, Abbott Park, United States*
Email: rene.geissler@abbott.com

Background and aims: Current HBV guidelines for treatment eligibility are based on HBV DNA viral load levels. Specifically, for HBV infected patients with DNA levels ≥2,000 IU/ml (HBeAg-) or ≥20,000 IU/ml (HBeAg+), antiviral therapies are recommended. However, HBV molecular assays to monitor HBV DNA levels are often unavailable or unaffordable in low- and middle-income countries (LMIC). We previously developed two novel HBcAg immunoassays to specifically detect non-phosphorylated HBcAg as surrogate marker for HBV DNA-containing particles (referred as HBcAg) and phosphorylated HBcAg (referred as P-HBcAg), which represents non-HBV DNA-containing particles. HBcAg and P-HBcAg correlate best with HBV DNA as compared to HBV core-related antigen (HBcrAg). Here, we describe improved P-HBcAg/HBcAg assays with superior performance and higher sensitivity that should enable decisions to put patients on antiviral therapy.
Method: The improved P-HBcAg and HBcAg assays use specific monoclonal antibodies to capture and detect either non-phosphorylated or phosphorylated HBcAg that are secreted from HBV infected hepatocytes into the blood stream. P-HBcAg and HBcAg signals are measured as relative light units (RLUs) on an Abbott ARCHITECT. We analyzed single timepoint specimens from HBV infected patients with viral loads ranging from 10^2 to 10^8 HBV DNA IU/ml.
Results: Several factors were optimized, including new monoclonal antibodies, to increase the limit of quantification (LOQ) by ~20-fold for P-HBcAg and ~60-fold for HBcAg, respectively. Serial dilutions of specimens from HBV infected patients revealed that P-HBcAg could be detected at HBV DNA levels as low as 60 IU/ml. HBcAg, which represents infectious HBV DNA-containing particles and is the least abundant antigen, is still detectable at HBV DNA levels as low as 6,000 IU/ml.
Conclusion: The ability to specifically detect low abundant P-HBcAg/HBcAg levels at the lower limit of HBV DNA levels that qualify for treatment eligibility provides additional insights for disease staging. The assays have the potential to be made available at lower cost compared to molecular assays and are more easily deployable in low- and middle-income countries where HBV diagnosis and verification of response to therapies are most needed.

Email: robert.li10@gilead.com

Background and aims: The optimal therapeutic goal for chronic hepatitis B (CHB) is achieving functional cure (FC), defined as HBsAg loss with or without appearance of anti-HBs antibodies. However, the mechanism underlying HBsAg loss in patients with CHB is poorly understood. Here we characterize the HBV antigen specificity of T-cell response and neutralizing antibody responses in FC compared to the matched group of CHB patients.
Method: PBMCs from 19 FC and 22 CHB patients were analysed by ex vivo IFN-γ ELISpot assay with HBsAg, core, and polymerase (Pol) peptide pools. Greater than 45 background-subtracted IFN-γ SFC/million PBMC was considered a positive signal for each peptide pool. HBV neutralization activity was evaluated in primary human hepatocytes (PHH) infected with HBV GT A-D in the presence of serially-diluted plasma from 66 FC and 8 CHB patients. Neutralization titer for each plasma sample was defined as the fold-dilution that resulted in 50% inhibition of HBV infection. Samples from FC patients were collected at an estimated time ranging from 3 to 46 months after HBsAg loss.
Results: A higher percentage of individuals with HBsAg-specific T cell responses were observed in FC (9/19, 47%) as compared to CHB patients (3/22, 14%; $p < 0.05$, Fisher's exact test). The mean magnitude of HBsAg-specific T-cell response was higher in FC than in CHB (77 vs 21 SFC/million; $p < 0.05$, student t-test). The number of patients with T cell responses against at least one HBV antigen was also higher in FC (15/19, 79%) vs. CHB patients (12/22, 55%), as was the number of patients with T cell responses against more than one HBV antigen (7/19, 37% FC vs. 3/22, 14% CHB). HBV neutralization activity was detected in 25/66 FC (38%), with 5/66 (8%) exhibiting neutralization activity at a high titer of >500 against HBV GT A-D. No HBV neutralization activity was detected in CHB plasma (N = 8).
Conclusion: In this cohort of FC and CHB patients, FC was associated with a higher frequency of detectable peripheral HBsAg-specific T cell responses and T cell responses to more than one HBV antigen. In addition, FC is associated with the emergence of HBV-neutralizing antibodies in a subset of patients.

FRI-276-YI

Early kinetics of HBV and HDV serum and intrahepatic markers during and after liver transplantation: impact of HBIG and baseline HBsAg levels

Sara Battistella[1,2], Anna Pocurull Aparicio[1,2], Thais Leonel[1,2], Sergio Rodriguez-Tajes[1,2], Yilliam Fundora[3], Louis Shekhtman[4], Leeor Hershkovich[4], Scott Cotler[4], Harel Dahari[4], Gavin Cloherty, Tiffany Fortney[5], Mark Anderson, Sabela Lens[1,2], Sofía Pérez-del-Pulgar[1,2], Xavier Forns[1,2]. Email: sarabattistella93@gmail.com

Background and aims: Hepatitis B virus (HBV) remains a common indication for liver transplantation (LT), with graft reinfection being universal, despite the removal of the infected explant, and the use of hepatitis B immunoglobulin (HBIG) and nucleos(t)ide analogues (NUCs). The aim of this study was to investigate HBV and hepatitis D virus (HDV) kinetics in serum and liver samples during and immediately after LT to elucidate mechanisms of graft infection.
Method: Between 2020 and 2023, 12 HBV LT recipients (5 HDV-coinfected) were prospectively enrolled. Serial serum samples were collected every 15 minutes during LT and at regular intervals up to 12 months post-LT. HBsAg and HDV-RNA kinetics were analysed using piecewise linear fitting, stratified by HDV-coinfection and HBIG

administration. A plateau in HBsAg was defined as a slope not statistically different from zero. Liver tissue was obtained from explants and grafts (at reperfusion, 3, and 12 months post-LT) to assess intrahepatic viral markers (iHBV-DNA, cccDNA, iHDV-RNA) and antigens (HBsAg, HDAg).
Results: At LT, all patients were on NUCs, and only five patients had detectable HBV-DNA. After LT, serum HBV-DNA became undetectable within 48 hours in all patients. The 7 HBV-monoinfected patients all had baseline HBsAg $<10^4$ IU/mL. During anhepatic and reperfusion phases, HBV monoinfected patients who received HBIG had a rapid HBsAg loss (HBsAg clearance 5 days, t1/2 = 4.2 hours), whereas in those who did not receive HBIG, HBsAg slope plateaued, remaining near pre-treatment levels. In HDV-coinfected patients, all of whom received HBIG, HBsAg clearance during anhepatic and reperfusion phases was primarily influenced by baseline HBsAg levels. Patients with baseline HBsAg $< 10^4$ IU/mL (n = 2) cleared HBsAg within 6 hours (t1/2 = 6–9 hours), whereas those with baseline HBsAg $> 10^4$ IU/mL (n = 3) required up to 30 days to clear HBsAg (t1/2 = 4 days). HDV-RNA kinetics paralleled HBsAg, with rapid HDV declines in patients with lower baseline HBsAg (t1/2 = 2 minutes), but plateaued in those with higher baseline HBsAg, independent of baseline HDV-RNA levels.
Total iHBV-DNA was detected in all explanted livers, while cccDNA exclusively in HBV monoinfected patients. In contrast, in reperfusion and follow-up graft biopsies, intrahepatic viral markers (iHBV-DNA, cccDNA, iHDV-RNA) were absent, except in 1 HDV-coinfected patient with low levels of iHDV-RNA and HBsAg/HDAg staining at 3 months, despite negative serum markers.
Conclusion: HBIG administration accelerates HBsAg clearance in the immediate post-LT period only in patients with low baseline HBsAg levels. Circulating HBsAg early after LT may explain HBV and/or HDV entry into the graft, as a residual portion of HBsAg may harbour complete virions. However, the absence of intrahepatic HBV replication markers after LT suggests infection of very few hepatocytes and may explain the inability of HDV to complete its viral cycle.

Email: Schroeter.paulina@mh-hannover.de

Background and aims: Chronic HBV infection (CHB) remains a significant global health challenge, with the immunological mechanisms underlying functional cure still not fully understood. γδ T cells, a specialized subset of T cells abundant in the liver, are crucial for immune defense but remain poorly characterized in CHB. Our analysis identified a negative correlation between CD16-positive γδ T cells and HBcrAg, a marker of intrahepatic HBV replication, suggesting their potential role in viral control and antibody-dependent cellular cytotoxicity (ADCC); emphasizing the need for further research.
Method: Therefore, we analyzed γδ T cells in individuals with acute HBV infection (n = 13) and CHB (n = 57) using spectral flow cytometry and single-cell RNA sequencing, as well as HBV viral markers. To assess ADCC activity, isolated γδ T cells and NK cells from HBV patients (acute and chronic) or cord blood from healthy individuals were stimulated with polyclonal HBsAg-specific antibodies.".
Results: Our results revealed that $CD16^+$ γδ T cells, but not $CD16^+$ NK cells, negatively correlate with HBcrAg levels in CHB. These γδ T cells exhibited high expression of cytotoxic markers such as granzyme B, perforin, and NKG2D. Upon antibody stimulation with, they showed increased production of IFN-γ, TNF-α, and CD107a, emphasizing their ADCC functionality. *Ex vivo* staining further demonstrated that $CD16^+$ γδ T cells were strongly associated with ADCC activity in CHB and acute HBV cases. Conversely, γδ T cells from cord blood, with low CD16 expression, lacked ADCC functionality.
Conclusion: This study suggests a critical role of $CD16^+$ γδ T cells in controlling HBV through ADCC during CHB. The diminished presence or functionality of $CD16^+$ γδ T cells in cord blood may contribute to the high rates of CHB in vertical transmission, offering insights into potential therapeutic targets focused on γδ T cell-mediated ADCC.

FRI-278

Ubiquitinated hepatitis D antigen induced specific cytotoxic T lymphocyte responses inhibited HDV replication via JAK/STAT pathway in HDV infected liver organoids

Leer Shen[1], Luying Tian[2], Xiaohua Chen[2]. *[1]Shanghai Sixth People's Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, shanghai, China; [2]Shanghai Sixth People's Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China*
Email: shenleer1998@163.com

Background and aims: Hepatitis D virus (HDV) infection induces the most severe form of human viral hepatitis. Poor adaptive immune responses could result in persistent HDV infection, and virus-specific CD8+T cell response plays a significant role in the eradication of HDV. However, the impact of Ub-S-HDAg on CD8+T cells in HDV is unknown. Here, we aimed to investigate the anti-viral effect and mechanisms of Ub-S-HDAg in HDV infected liver organoids.
Method: Induced pluripotent stem cells were differentiated into hepatocyte-like cells (HLCs) and subsequently seeded onto inverted colloidal crystal (ICC) scaffolds. The HLC-ICC liver organoid system was co-infected with HBV and HDV particles. The ubiquitinated small Hepatitis D antigen (Ub-S-HDAg) recombinant lentiviral plasmid was constructed and transfected into human dendritic cells (DCs), which were then co-cultured with T cells. The levels of cytokine secretion by $CD8^+$ T cells and their antiviral efficacy were subsequently evaluated. Additionally, transcriptomic sequencing and bioinformatics analyses were conducted to elucidate the immune regulatory mechanisms of Ub-S-HDAg.
Results: In this study, we successfully established a model capable of stably expressing HDV. The results demonstrated that Ub-S-HDAg significantly promoted DC maturation, enhanced CD8+ T cell proliferation, and strengthened HDV-specific cytotoxic T lymphocyte (CTL) responses. Additionally, in the Ub-S-HDAg group, CD8+ T cells exhibited significantly elevated secretion of IFN-γ, IL-2, IL-12, and TNF-α, while HDV RNA viral load and HDAg levels were markedly reduced compared to other groups. Both KEGG pathway enrichment analysis and GSEA analysis suggested that DCs transfected with Ub-S-HDAg promote the activation of CD8+ T cells via the JAK/STAT pathway, exerting antiviral effects in liver organoids.
Conclusion: Overall, our findings indicate that Ub-S-HDAg induces DCs maturation, which in turn promotes CD8+ T cell differentiation and elicits a specific cellular immune response via the JAK/STAT pathway in HDV-infected liver organoids, thus providing a potential therapeutic approach for HDV eradication.

Email: smaranda.gliga@gmail.com

Background and aims: Cytomegalovirus (CMV) infection leads to expansion of adaptive natural killer (NK) cells, characterised by expression of NKG2C or FcepsilonRIgamma. CMV infection is often associated with chronic hepatitis B virus (HBV) and chronic HBV/hepatitis D virus (HDV) infections. The aim of this study was to investigate adaptive NK cell responses in CMV positive $^{(+)}$ versus CMV negative $^{(-)}$ healthy controls (HC), HBV and HBV/HDV infected patients.
Method: We investigated the phenotype and function of adaptive NK cells in a cohort of 44 HBV-positive patients: 16 (7 CMV$^-$, 9 CMV$^+$) with chronic infection (ciHBV), 24 (8 CMV$^-$, 16CMV$^+$) with chronic hepatitis (chHBV), 4 CMV+ with liver cirrhosis (lcHBV) and 12 CMV$^+$ patients with chronic (ch) HBV/HDV hepatitis and compared with 10 HC (3 CMV$^-$, 7 CMV$^+$). Chronic infection and chronic hepatitis were defined according to EASL guidelines. Follow-up samples after initiation of antiviral therapy (Tenofovir/Entecavir for HBV mono-infected, Hepcludex for HBV/HDV coinfected) were available for eight HBV and eight HBV/HDV coinfected patients.
Results: There is an increase in adaptive NK cells, particularly in the proportion of FcepsilonRIgamma-negative $^{(-)}$ CD56dim cells in CMV$^+$ ciHBV and chHBV patients ($p < 0.0001$) compared to their CMV$^-$ counterparts. More strikingly, this expansion was further increased in CMV$^+$ HBV and HBV/HDV patients with chronic hepatitis vs. CMV$^+$ HC ($p = 0.041$) and ciHBV ($p = 0.006$). FcepsilonRIgamma$^{(-)}$ CD56dim cells have higher expression of NKG2C, CD57, CD95, CD25, ILT2 and lower expression of Siglec-7, Ki67 and CD69 ($p < 0.0001$) compared to FcepsilonRIgamma$^{(+)}$ CD56dim non-adaptive NK cells. In addition, these adaptive NK cells have a higher production of Granzyme B and Eomes, but a lower production of T-bet. The frequency of FcepsilonRIgamma$^{(-)}$ CD56^{dim} cells directly correlates with viral replication in chHBV patients ($p = 0.014$). One year after initiation of therapy in patients with chronic hepatitis (HBV and HBV/HDV), the frequency of adaptive cells does not change significantly, but the expression of activation markers (CD25) decreases. After stimulation by antibody dependent cellular cytotoxicity (ADCC), adaptive NK cells show higher CD107a degranulation ($p < 0.0001$) and IFNgamma release ($p = 0.007$) compared to non-adaptive NK cells.
Conclusion: Chronic viral hepatitis B induces high level FcepsilonRIgamma$^{(-)}$ CD56^{dim} cell expansions in CMV$^+$ individuals and this does not change after initiation of therapy with nucleoside/nucleotide inhibitors. Adaptive NK cells have an activated profile and predominantly effector functions compared to non-adaptive NK cells. We hypothesise that the higher cytotoxic activity and high CD95 expression may be involved in the development of liver fibrosis.

FRI-280

Hepatitis delta virus infection hotspots in Ethiopia: a multicenter study

Email: teklucfan@gmail.com

Background and aims: Individuals co-infected with hepatitis B virus (HBV) and hepatitis D virus (HDV) are at high risk of developing a much faster progression of severe liver disease, including cirrhosis, hepatocellular carcinoma and liver decompensation as compared to those with HBV mono-infection. Ethiopia is endemic for HBV; however, little is known about the HDV prevalence outside the capital city. In the present study, we investigated the HDV burden in three regions of Ethiopia. The objective was to assess the prevalence of HDV specific antibodies (IgG) among HBsAg carriers in selected three regions of Ethiopia.
Method: A cross-sectional study was conducted among 1997 adult (18 years or older) patients with chronic HBV infection from May 2022 to April 2024. The study participants were recruited at four newly established hepatitis B treatment centers located in Adama, Jimma, Jigjiga and Dubti. Serum were investigated for HDV antibodies using a novel pan-genotype specific in-house competitive enzyme-linked immunosorbent assay (ELISA). Results were confirmed with a commercial ELISA method and anti-HDV positive samples were tested for HDV RNA using a commercial real-time PCR assay. HDV genotyping was determined for RNA-positive samples by Sanger method. Mann-Whitney U tests were used to compare laboratory results between anti-HDV positive and negative individuals.
Results: The median age was 30 years old (interquartile range (IQR) 25–38) and 53.0% (1059/1997) were men. The overall HDV seroprevalence was 5.3% (105/1997), but with profound geographical variations. Dubti (Afar region) had the highest HDV-specific antibodies seroprevalence with 16.9% (84/498), followed by Jimma (Oromia region) with 2.6% (13/500), Adama (Oromia region) with 1.4% (7/499), and Jigjiga (Somali region) with 0.2% (1/500). Of all anti-HDV positive samples, 63.8% (67/105) had detectable HDV RNA with a median viral load of 3.20 log10 IU/ml (IQR 1.6–5.3). All strains were HDV genotype 1. Anti-HDV positive patients had higher median values of Alanine aminotransferase 49 vs. 26 U/L ($p < 0.001$), Aspartate aminotransferase (AST) 45 vs. 26 U/L, ($p < 0.001$) and AST to platelet ratio index (APRI) score 0.5 vs. 0.3, ($p < 0.001$), and lower HBV DNA viral load 222 vs. 720 IU/ml, ($p = 0.008$) compared to anti-HDV negative patients.
Conclusion: The overall prevalence of HDV in Ethiopia is intermediate and with marked geographic variations. Of note, the Afar region seems to be a hotspot for HDV. Whereas the neighbouring Somali region has a negligible HDV prevalence, despite sharing cultural similarities with Afar. This discrepancy underscores the need for further research into risk factors influencing HDV transmission. Such studies are important to come up with effective prevention strategies and control the spread of the disease.

A novel quintuplex long-amplicon droplet digital PCR assay reveals greater quantities of hepatitis B virus splice variants in people with HBV/HIV co-infection compared to HBV mono-infection

Tanner Grudda[1], Chenkai Jiang[2], Nel Jason Haw[1], Steven Wolinsky[3], Kara Chew[4], Yue Chen[5], Jodie Dionne[6], Margaret Fischl[7], Igho Ofotokun[8], Nancie Archin[9], Eric Seaberg[10], Audrey French[11], Jennifer Price[12], Amanda Spence[13], Mark Kuniholm[14], Matthew Akiyama[15], Ashwin Balagopal[2], Chloe Thio[1,2]. *[1]Johns Hopkins University Bloomberg School of Public Health, Baltimore, United States; [2]Johns Hopkins University School of Medicine, Baltimore, United States; [3]Northwestern University Feinberg School of Medicine, Chicago, United States; [4]David Geffen School of Medicine at University of California Los Angeles, Los Angeles, United States; [5]University of Pittsburgh School of Medicine, Pittsburgh, United States; [6]University of Alabama at Birmingham School of Medicine, Birmingham, United States; [7]University of Miami Miller School of Medicine, Miami, United States; [8]Emory University School of Medicine, Atlanta, United States; [9]University of North Carolina School of Medicine, Chapel Hill, United States; [10]Johns Hopkins Bloomberg School of Public Health, Baltimore, United States; [11]Stroger Hospital of Cook County Health, Chicago, United States; [12]University of California San Francisco, San Francisco, United States; [13]Georgetown University, Washington, DC, United States; [14]University of Albany, State University of New York, Rensselaer, United States; [15]Montefiore Medical Center, Bronx, United States*
Email: tgrudda1@jhmi.edu

Background and aims: In people with chronic hepatitis B (CHB), HIV increases the risk of liver failure and liver cancer. HIV also increases HBV replication but decreases response to pegylated interferon (IFN) treatment. HBV splice variants (spHBV) derived from the genomic intermediate, pregenomic RNA (pgRNA), are also associated with increased replication and resistance to IFN. Thus, spHBV may partially explain certain adverse outcomes of HIV on CHB.
Method: We developed a high dimensional long amplicon droplet digital PCR to quantify the major spHBV RNAs in serum. We applied this assay in a cross-sectional study to people with HBV/HIV co-infection (PWHHB, n = 61) and people with HBV mono-infection (PWHB, n = 86) prior to treatment in the MACS/WIHS Combined Cohort Study, directly quantifying pgRNA, sp1, sp2, sp3, sp8, and sp9. In a subset with semiannual longitudinal samples, we tracked spHBV expression in stored samples from these groups (gp): 1) PWHHB before HBV-active antiretroviral therapy (ART, n = 19), 2) PWHHB during ART (n = 19), 3) PWHB (n = 12) and PWHHB (n = 2) who lose HBV DNA without treatment (HBV recovery), 4) PWHB not on treatment (n = 9). Comparisons were made with Kruskal-Wallis tests (cross-sectional study) and generalized estimating equation modeling using the Wald test (longitudinal).
Results: In the cross-sectional analysis, PWHHB had higher median HBV DNA log10 IU/mL than PWHB (8.1 vs 7.4, p = 0.01); among PWHHB, females (n = 17) had higher levels than males (n = 44, p = 0.02). After adding up the five major spHBVs in each individual, the median log10 copies/mL was higher in PWHHB compared to PWHB (4.1 vs 3.4, p = 0.07) and similar between female and male PWHHB (4.3 vs 3.9, p = 0.59). Of total spHBV RNA, PWHHB compared to PWHB had greater median proportions of sp2 (5.2% vs 3.0%, p = 0.01), sp3 (1.1% vs 0.6%, p = 0.006), sp8 (4.7% vs 3.6%, p = 0.04), and sp9 (0.7% vs 0.4%, p = 0.08) but not sp1 (79% vs 79%, p = 0.99). In the longitudinal analysis (median 2 years) those without treatment (gp1 and 4) had spHBV quantities and proportions of total HBV RNA (pgRNA + spHBV RNAs) that remained stable (all p > 0.2). Gp2 had a pre-ART median 4.6 log10 copies/mL of spHBV that declined – 0.23/year (p < 0.05). Gp3 had a baseline median 3.6 log10 copies/mL of spHBV that declined – 0.24/year (p < 0.05). Comparing spHBV expression dynamics during the observed window of follow-up time (median 2 years), people during HBV recovery were more likely to have spHBV declines compared to PWHHB taking ART (p < 0.001).
Conclusion: PWHHB have more spHBV than PWHB, which may contribute to differences in outcome. Further, PWHHB during ART and people with HBV recovery have decreasing quantities of spHBV over time in contrast to PWHHB and PWHB not taking treatment where no significant changes over time were observed. Interestingly, PWHHB during ART and people during HBV recovery had similar baseline spHBV quantities and rates of decline, although people during recovery were more likely to have spHBV declines.

Pre-mRNA Processing Factor 4B kinase is associated with hepatitis B virus replication

Wei-Lun Tsai[1], Wei-Chih Sun[2], Chia-Min Lu[3]. *[1]Division of general internal medicine,department of Internal Medicine, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; [2]Department of Gastroenterology and Hepatology, Kaohsiung Veterans General Hospital, Kaohiusng, Taiwan; [3]Department of Gastroenterology and Hepatology, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan*
Email: tsaiwl@yahoo.com.tw

Background and aims: There were still no effective therapy to cure HBV. Cellular kinases are important in the life cycle of HBV. Through a kinome siRNA library screening, we identified that Pre-mRNA Processing Factor 4B (PRPF4B) was an essential gene for HBV replication. The aim of the study is to investigate the molecular mechanism of PRPF4B on HBV replication.
Method: HBV infected HepG2-hNTCP-C4 will be used in the study. siRNA mediated knock-down of PRPF4B will be done. Quantification of supernatant HBsAg and HBV DNA and cellular cccDNA will be performed. Proteiomic studies and Bioinformatics analysis will also be performed.
Results: After siRNA mediated knockdown of PRPF4B in HBV infected HepG2-hNTCP-C4 cells, supernatant HBsAg and HBV DNA and cellular cccDNA were significantly decreased. From the TCGA database we also found that PRPF4B was significantly associated with overall survival in HBV related HCC (Adjusted hazard ratio (AHR) was 2.11, 95% confidence interval (CI) was 1.08–2.51 and p-value was 0.005). Via string data bases we found several PRPF4B related candidate proteins were associated with HBV or other viruses replication. After knock-down of RPF4B with siRNA in HBV infected NTCP-HepG2 cells, the levels of the candidate proteins including SART1, CDK2, CDK9, PRPF31 and EFTUD2 were increased. In proteiomic studies we also found several proteins related to HBV replications were up and down- regulated after knockdown of PRPF4B.
Conclusion: Inhibition of PRPF-4B significantly reduced HBsAg, HBV DNA secretion and cellular cccDNA in HBV infected HepG2-hNTCP-C4 cells. Proteiomic studies and Bioinformatics analysis gave us more information. Our data is promising and PRPF-4B may be a new therapeutic target for future anti-HBV treatment.

FRI-287

Epigenetic viral footprint of chronic HDV infection in HBV co-infected chimeric mice

Yogy Simanjuntak[1], Valerio Taverniti[1], Laura Meiss-Heydmann[1], Charlotte Bach[1], Eloi Verrier, Thomas Baumert[1,2,3], Joachim Lupberger[1]. *[1]University of Strasbourg, Institute of Translational Medicine and Liver Diseases (ITM), Inserm UMR_S1110, Strasbourg, France; [2]Gastroenterology and Hepatology Service, Strasbourg University Hospitals, Strasbourg, France; [3]Institut Universitaire de France, Paris, France*
Email:

Background and aims: Chronic infection with hepatitis D virus (HDV) causes the most severe form of viral hepatitis with accelerated progression of liver disease to hepatocellular carcinoma. Antiviral

therapy with bulevirtide reduces HDV load in patients with encouraging effects on liver disease parameters. However, effective chemopreventive strategies to attenuate liver disease progression and reliable biomarkers are urgently needed to improve disease management. Chronic diseases are often driven by epigenetic regulation, including histone modifications. Indeed, we have previously shown that chronic hepatitis C infection induces a pro-fibrotic transcriptional signature that is epigenetically regulated and partially persistent after antiviral therapy (Hamdane et al. Gastroenterology 2019; Juehling et al. Gut 2021). Here, we aim to determine the impact of chronic HDV infection on liver transcriptomics and epigenetics to identify molecular pathways of liver disease development and candidate biomarkers of liver disease progression.

Method: We infected human chimeric mice (FRG-NOD mice transplanted with human hepatocytes) with mock, HBV or HDV/HBV. Snap-frozen liver tissues were analyzed after 4 weeks post infection by bulk RNA-seq and ChIP-seq for histone marks associated with active transcriptional enhancers (H3K27ac and H3K4me1) and a mark for transcriptional repression (H3K27me3). In addition, we validated predicted biomarker candidates in the blood of infected chimeric mice and patients by ELISA.

Results: We identified 748 unique transcripts in the livers of HDV/HBV-infected mice compared to HBV mono- and mock-infected animals. Notably, most of these transcripts were highly upregulated by HDV infection and enriched for genes involved in HDV replication, inflammation, fibrosis, and cancer risk. Consistently, most of the genes encoding these transcripts are also associated with at least one histone mark associated with active enhancers, potentially representing a persistent viral footprint in the infected liver. Interestingly, 110 transcripts of this HDV signature potentially encode secretory proteins based on signal peptide prediction. The top candidate markers are positively correlated with transcript levels and are elevated in the blood of HDV-infected mice and patients.

Conclusion: We have uncovered an HDV-specific transcriptional signature that may be part of a persistent epigenetic viral footprint. Components of the signature are differentially secreted into the blood of infected animals and may therefore serve as risk markers for disease progression. Further work is underway to determine whether these proteins can serve as prognostic biomarkers for disease progression and/or therapeutic response, such as bulevirtide, and to predict and validate compounds capable of reversing risk-associated transcriptional signatures.

Synthetic interferon exhibits potent antiviral activity against HBV with the potential for an improved safety profile

Wade Blair[1], Yueh-Ming Loo[1], Marcus Bolton[1], Lynn Chen[1], Qingxiang Liu[1], Nate Sallada[1], Ruipeng Wang[1], Eunice Cho[1], Aracely Romero[1], Tao-Hsin Chang[1], Andrew Mercer[1], Cheyne Kurokawa[1]. [1]*IntegerBio, Gaithersburg, United States*
Email: wade.blair@Integer.bio

Background and aims: The type I interferon (IFN) system is a potent host innate immune defense mechanism against viral pathogens. Activation of this pathway occurs upon engagement of IFN with the host IFN alpha receptors 1 and 2 (IFNAR1/2) with subsequent signaling leading to the expression of >300 interferon stimulated genes (ISGs), many of which have direct antiviral activities. While type I IFNs and their derivatives have been utilized in patients as antiviral drugs, toxicity has limited widespread therapeutic use. Our goal is to develop synthetic interferons, SYNFERON™ molecules, that maintain the antiviral properties of type I IFN while reducing the inflammatory properties for an improved safety profile. SYNFERON molecules are bispecific antibody-derived domains comprised of one moiety that binds to IFNAR1 linked to a second moiety that binds to IFNAR2 that activate the IFN pathway with novel biological outcomes.

Method: Human PBMCs were treated with IFN or SYN1 and STAT1 phosphorylation was monitored by flow cytometry or ISG expression was measured using reverse transcription quantitative PCR (RT-qPCR). Primary human hepatocytes (PHH) were infected with HBV or co-infected with HBV and HDV and treated with IFN alpha (IFNα) or SYN1. HBsAg, HBV DNA and HDV RNA were measured. FRG liver-humanized mice were infected with HBV and treated with SYN1, pegylated IFNα or PBS. Serum HBV DNA levels, HBeAg and HBsAg levels were measured.

Results: We show that SYN1 activates IFNAR1/2 signaling as demonstrated by monitoring the phosphorylation of STAT transcription factors in cell lines and primary cells. In addition, we demonstrate that SYN1 shows reduced induction of pro-inflammatory and pro-apoptotic ISGs as compared to natural IFNs. SYN1-treated HBV-infected PHH showed dose-dependent and potent reduction of HBsAg, HBeAg and HBV DNA levels comparable to treatment with type I IFNs, with minimal impact on cell viability. Furthermore, SYN1 inhibited HDV replication in PHH co-infected with HBV and HDV. Importantly, SYN1 potently inhibited HBV replication in a mouse model of HBV infection. SYN1 also exhibited potent and broad antiviral activity against multiple virus families, including respiratory viruses, herpesviruses, and flaviviruses.

Conclusion: Our data demonstrate that SYN1 confers potent antiviral activity against HBV in vitro and in vivo with reduced inflammatory properties resulting in the potential for an improved tolerability and safety profile in the clinic.

FRI-289

Eliminating hepatitis B with a combination of the newly revised Entecavir and Birinapant

Wuu-Jyh Lin[1]. [1]*SeeCURE Taiwan Co., LTD., Kaohsiung, Taiwan*
Email: WJLin@seecurellc.com

Background and aims: Hepatitis B is a major global health issue, particularly in the Southeast Asia region. However, due to the heterogeneous nature of HBV infection, achieving a functional and chronic cure is challenging. Therefore, we designed a combination therapy using a newly revised Entecavir and Birinapant to test its effectiveness against HBV infection in mouse models. Both the revised Entecavir and Birinapant are liver-targeting compounds that selectively bind to the hepatocytes receptors while minimally affecting extrahepatic cells.

Method: We utilized hydrodynamic injection in an in vivo transfection mouse model to assess the efficacy of the revised drug, including SC-3001 (Entecavir analog) and SC-3002 (Birinapant analog), as well as their combination therapy. The control drugs included single uses of Entecavir or Birinapant and their combination therapy. We measured HBV DNA, HBs antigen (HBs Ag) and HBe antigen (HBe Ag) and anti-HBs antibody.

Results: SC-3001 significantly reduce the HBV DNA titer, demonstrating greater efficacy than Entecavir. SC-3002 significantly reduce the HBV DNA titer and HBe Ag level, showing superior efficacy compared to Birinapant. Although SC-3001 or SC-3002 did not significantly decrease the HBs Ag individually, their combined use resulted in significant elimination of HBV DNA and HBs Ag, increased production of anti-HBs antibodies and greater efficacy compared to the control drug (Entecavir + Birinapant). Furthermore, a notable side effect of the control drug is facial hair loss, which was not observed in the other groups.

Conclusion: The data indicated that the newly revised Entecavir and Birinapant can effectively eliminate HBV infection and induce the greater anti-HBs antibody production, achieving a functional cure. Therefore, their combined use may serve as a potential drug candidate for treating HBV infection.

Migliavacca" Center for Liver Disease, University of Milan, Department of Pathophysiology and Transplantation, Milan, Italy, Milan, Italy*
Email: yang.liu@gilead.com

Background and aims: Bulevirtide (BLV) is an entry inhibitor that binds to the HDV entry receptor, sodium taurocholate cotransporting polypeptide (NTCP). BLV has demonstrated potent antiviral efficacy in phase 2 and 3 studies and has been approved for the treatment of compensated chronic hepatitis D (CHD) in the EU and other non-EU countries. Recently a retrospective study reported a possible influence of the NTCP intronic polymorphism rs17556915 on baseline (BL) HDV RNA levels and early response to BLV in CHD patients receiving BLV 2 mg monotherapy. Here, we evaluated the impact of this polymorphism on BL HDV RNA levels and BLV treatment outcome in patients with CHD from a phase 3 study MYR301 (NCT03852719, BLV monotherapy) and a phase 2b study MYR204 (NCT03852433, BLV with or without peginterferon alfa-2a [PegIFN]).
Method: Whole genome sequencing (WGS) was performed on whole blood samples for a total of 290 of 324 (90%) patients in MYR301 (128 of 150, 85%) and MYR204 (162 of 174, 93%) at BL, with all patients from Europe. Viral response (VR), partial response (PR), and nonresponse (NR) were defined as achieved undetectable HDV RNA or ≥2 log10 HDV RNA decline from BL, achieved ≥1 but <2 log10 HDV RNA decline from BL, achieved <1 log10 HDV RNA decline from BL, respectively. Statistical analysis was conducted using One-way ANOVA or Fisher's exact test.
Results: All samples (n = 290) were performed for WGS and the rs17556915 polymorphism data was obtained from all the tested samples. The genotype distribution (CC: 194 of 290, 66.9%; TT: 6 of 290, 2.1%; CT: 90 of 290, 31.0%) was consistent with that of the European population and met Hardy-Weinberg Equilibrium expectations. The median BL HDV RNA levels from patients with genotypes CC, TT and CT were 5.38, 5.25, 5.33 log10 IU/mL, respectively, and had no significant difference across the 3 genotype groups (p = 0.3997). Patients with CC had similar VR, PR and NR rates compared to CT or TT groups during treatment at Weeks 24, 48, 96 and 144 in BLV 2 mg (n = 42), BLV 10 mg (n = 133) monotherapy, or BLV+PegIFN combination treatment (n = 92) groups. Additionally, patients with CC had similar decline rates in HDV RNA at each individual timepoints during treatment compared to CT or TT groups in BLV 2 mg, 10 mg monotherapy or BLV+PegIFN combination treatment groups.
Conclusion: The rs17556915 genotype distribution aligned with that of the European population. NTCP rs17556915 polymorphism had no impact on BL HDV RNA levels and BLV treatment outcomes in patients receiving BLV 2 mg or 10 mg monotherapy, or BLV+PegIFN combination therapy in MYR204 and MYR301 studies.

Email: yannick.brueggemann@rub.de

Background and aims: Viral infections are a major cause of disease, mortality and economic loss worldwide. In particular, RNA viruses cause a wide range of human diseases and represent a global health problem. To date, effective antiviral drugs are not available for a variety of clinically relevant viral pathogens, including the hepatitis E virus (HEV). Currently, therapeutic options for HEV are restricted to the off-label use of ribavirin (RBV), a broad-spectrum antiviral agent. The CRISPR/Cas13 system presents a promising approach for targeting RNA viruses. In this study, we explored the potential of the CRISPR/Cas13d system as an innovative therapeutic strategy against HEV.
Method: We developed a reporter assay to screen CRISPR RNAs (crRNAs) targeting conserved viral regions and identified functional crRNAs targeting HEV-3. Using a subgenomic replicon reporter and a robust HEV cell culture model, we investigated if the CRISPR/Cas13d system can be "programmed" to selectively target HEV replication/infection.
Results: Using our reporter assay we identified several functional crRNAs, which efficiently target different regions of the HEV-3 genome. We further demonstrate that the CRISPR/Cas13d system in combination with cRNAs targeting the ORF1 of HEV can effectively reduce HEV-3 replication and decrease the production of infectious particles in hepatoma cell lines. In addition, we show that the CRISPR/Cas13d system can be used to prevent HEV-3 infection in hepatoma cells. Using bioinformatic analysis, we further identified a minimal set of three crRNAs covering ~95% of HEV genomes with zero mismatches.
Conclusion: Overall, our findings highlight the potential of the CRISPR/Cas13d system as innovative antiviral strategy to simultaneously target different HEV variants and thereby combat viral infection.

FRI-292

Single-cell immune profiling of liver and blood reveals pretreatment signatures associated with treatment outcomes in young children with chronic hepatitis B

Chao Zhang[1], Cheng Zhen[1], Jing Li[1], Min Zhang[1], Fu-Sheng Wang. [1]*The Fifth Medical Center of Chinese PLA General Hospital, Beijing, China*
Email: zhangch302@163.com

Background and aims: Chronic hepatitis B virus (HBV) infection is more likely to become chronic in young children, but the cure rate following antiviral therapy is significantly higher in children compared to adults. The underlying immune mechanisms remain unclear. This study aims to explore the immune features associated with chronic HBV infection in children and adults, and how these relate to antiviral treatment outcomes in children.
Method: The study enrolled 19 untreated children aged 1–6 years with chronic HBV infection (9 of whom achieved HBsAg loss and 8 did not upon treatment), along with 11 untreated adults with chronic HBV infection. Immune characteristics of liver tissue and peripheral blood were analyzed using single-cell RNA sequencing and TCR/BCR sequencing. Differences between cured and non-cured children were assessed to identify immune features associated with treatment outcomes.
Results: Single-cell RNA sequencing revealed 8 major immune cell populations and 49 immune subpopulations in both liver tissue and peripheral blood. Children with chronic HBV (CHB) showed distinct immune characteristics compared to adults, notably with more naïve T cells and liver-resident NK cells, and fewer effector T cells and liver memory B cells. In children, the presence of CXCL13+ CD4 T cells in liver tissue and their role in germinal center B cell differentiation towards memory B cells was linked to the failure to achieve functional cure upon antiviral therapy.
Conclusion: This study provides a comprehensive analysis of the immune features in both adults and children with CHB, as well as in

cured and non-cured children. The differentiation of liver-resident memory B cells appears closely associated with the inability to achieve functional cure following antiviral therapy, providing insights into immune mechanisms that may influence treatment outcomes.

Peripheral helper CD4+ T cell functionality distinguishes between acute resolving and chronic hepatitis B

Peng Zhang[1], Xiaoyu Li[2], Junliang Fu[3], Fu-Sheng Wang, Chao Zhang[3].
[1]*The First Affiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, Hefei, China;* [2]*Basic Medical Sciences Division, Clinical Medical College, Anhui Medical University, Hefei, China;* [3]*Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, Beijing, China*
Email: zhangch302@163.com

Background and aims: $CD4^+$ T cells are crucial in mediating viral control and pathogenesis in HBV infection, but their phenotypical and functional characteristics remain incompletely understood in patients with both acute and chronic HBV infection.
Method: We utilized single-cell RNA sequencing (scRNA-seq), single-cell multiplex secretome analysis, and multicolor immunohistochemistry (mIHC) to analyze intrahepatic and blood $CD4^+$ T cells from HBV-infected patients at various disease phases, including immune tolerant (IT), immune activation (IA), acute resolving (AR), and chronic resolved (CR). Functional experiments were conducted to validate the phenotypes of peripheral helper $CD4^+$ T cells (Tph) and assess the impact of Ursodeoxycholic acid (UDCA) on Tph cell functionality.
Results: We identified ten distinct $CD4^+$ T cell subsets with different tissue preferences and functional profiles. Intrahepatic Tph cells were enriched in both AR and IA patients, but not in IT and CR patients. The frequency of Tph cells was positively correlated with liver inflammation. In IA, Tph cells predominantly produced TNF-α via ER stress and a BHLHE40-dependent mechanism, whereas in AR, they shifted toward producing IL-10 and IFN-γ. UDCA inhibited ER stress and corrected BHLHE40-dependent TNF-α polarization in Tph cells, enhancing IL-10 and IFN-γ production.
Conclusion: Our study indicates that Tph cell functionality differs between acute and symptomatic chronic HBV infections. UDCA treatment restores the function of Tph cells and may represent a therapeutic approach to the treatment of CHB.

Email: asisha.jane@gmail.com

Background and aims: Plasma exchange (PLEX) has recently shown to improve survival in acute liver failure (ALF); there is no study specifically analyzing its utility to treat Hepatitis A virus related acute liver failure (HAV-ALF). ALF patients who are not on inotropes tolerate PLEX better (PMID: 39001974). We aimed to assess efficacy of plasma exchange (PLEX) to treat HAV-ALF.
Method: We retrospectively studied consecutive HAV-ALF patients who underwent PLEX between 2018 and 2024 in 9 centres in India. The controls were HAV-ALF patients managed with standard medical treatment (SMT) between 2011–2024. Primary study outcome was in-hospital liver transplant (LT)-free survival with PLEX versus SMT. Poor outcome was defined as death or terminal discharge.
Results: Fifty HAV-ALF patients in PLEX group (males: 35; age: 21.5 (18–27 years, median, IQR; King's college criteria fulfilled (KCC): 12 (24%)) and 32 HAV-ALF in SMT group (males: 17; age: 20.5 (17–26.8) years; KCC fulfilled: 4(12.5%)) were studied. No patient underwent LT. PLEX group patients had 2 (1–3) PLEX sessions.Overall, patients in PLEX group tended to have more severe liver failure than SMT group [MELD: 32.5(26.8–38.3) versus 31 (24.3–35.8); SOFA: 10 (6–12) versus 6 (4.5–12.5); HAV-ALFSG score ≥2 factors fulfilled: 25 (52.1%) versus 10 (35.7%); ALFA score: −0.04 (−0.84 to 0.67) versus −0.64 (−1.4 to −0.08). In-hospital survival was 68.8% in the 32 HAV-ALF patients on SMT and 70% in the PLEX treated patients (P value = 1). Survival in patients not on inotropes was better in PLEX group (31/33; 94%) vis-à-vis SMT group (19/27; 70%), independent of MELD and ALFSG (≥2 poor prognostic factors fulfilled) with adjusted HR of 0.135 (95% CI 0.017–1.06, p value: 0.05). Similarly, in patients with ALFA score >−0.7, PLEX group had better survival (18/19; 95%) vis-à-vis SMT (6/9; 67%; p-value: 0.05).Overall PLEX patients on mechanical ventilation, inotropes, with high MELD or ALFA scores or those who fulfilled ≥2 poor prognostic ALFSG criteria had poor outcome (p value <0.01).
Conclusion: PLEX improves survival with native liver in HAV-ALF patients not on inotropes.

Email: drarunvalsan@gmail.com

Background and aims: Hepatitis A virus infection (HAV) is widely believed to be a mild self-limiting illness with fulminant presentation in less than one percent cases. Recently, a resurgence of HAV epidemic unfolded in Kerala, a state with high standards of sanitation and healthcare access comparable to developed nations. Many atypical findings were reported including early renal and pulmonary involvement, development of hemophagocytic lymphohistiocytosis (HLH) and acute liver injury/failure (ALI/F) prompting a detailed analysis of such cases.

Method: We conducted a multi-centric, hospital-based study at six tertiary care hospitals. Patients with IgM HAV positivity and atypical features (a-HAV) were included in the study arm and outpatients with usual symptoms (u-HAV) were used as comparator.
Results: Total of 269 patients (u-HAV-141, a-HAV-128) were included (mean age 33.27 ± 12.24, 67% males). a-HAV cases showed a significantly higher prevalence of metabolic co-morbidities and co-infection with dengue and leptospirosis (4.7% each) and scrub typhus (3.1%). a-HAV had significantly higher incidence of continuing fever (91% vs 13, evanescent rash(12% vs 4%), hepatomegaly(60% vs 38%), splenomegaly (24% vs 14%), prolonged cholestasis (16%), ascites (29% vs 10%), encephalopathy (21%), HLH(15%), higher mean levels of total leukocyte counts, bilirubin, AST, triglycerides, ferritin (4957 vs 1137 IU), LDH (818 vs 332 IU), presence of autoantibodies (16% vs 1.4%), AKI (16%), metabolic acidosis and lower levels of albumin and platelets. a-HAV was associated with significantly higher steroid use (33% vs 5.7%), plasma exchange (22%), continuous renal replacement (12%). Also, progression to ACLF (9.3%), hospital re-admission rates (12%), mortality (12%) was significantly higher in the a-HAV group. Genotyping revealed the strain to be genotype IIIA, a common variant in India in all 56 tested samples. Independent predictors of mortality in acute HAV infection were the presence of autoantibody (OR-5.6), encephalopathy (OR-25) and AKI (OR-1.6). Further, presence of autoantibodies was associated with disease progression or ALI/ALF in all patients with acute HAV infection (OR-13.6).
Conclusion: The study provides a strong indication regarding changing clinical presentation and virulence of hepatitis A infection. Unlike previous outbreaks, our cohort showed a significant number of patients with severe and atypical manifestations. Further genetic sequencing is planned for this cohort.

WED-262
Prolonged cholestasis following hepatitis A : what lies beneath
Souveek Mitra[1], Ranajoy Ghosh[1], Srijan Mazumder[1], Abhijit Chowdhury[1], Kishalaya Sharma[1], Dipankar Mondal[1]. [1]*Indian Institute of Liver and Digestive Sciences, Kolkata, India*
Email: souveek84@gmail.com

Background and aims: Hepatitis A virus is a common agent for acute viral hepatitis,particularly in the tropics. Prolonged cholestasis, manifested by jaundice and pruritus persisting for more than 4 weeks is encountered in a minority of HAV infection. Short course of steroids are often prescribed in prolonged cholestasis. With this background, we tried to describe the clinical course of prolonged cholestasis in HAV along with role of oral steroids in HAV cholestasis.
Method: All subjects having a serum total bilirubin more than five (5) mg /dl for a period of more than four (4)weeks, after being diagnosed of HAV related acute hepatitis,were followed up. Acute hepatitis A was diagnosed by typical symptoms of acute hepatitis, by the presence of serum IgM anti-HAV positivity, and by the exclusion of other etiologies of acute hepatitis. Liver function test and prothrombin time were done after 4 weeks of index diagnosis of HAV. Patients having florid features of cholestatic hepatitis on liver biopsies were given oral prednisolone at a dose of 0.5 mg/kg/day. Subjects who had bland cholestasis on liver biopsies were not given oral steroids and symptomatic management for pruritus was done. Follow up done for at least six months after stoppage of steroids.
Results: From January 2018 till January 2024, Sixty six (66) subjects having prolonged cholestasis of HAV were diagnosed. Males were predominant. Mean Age of the population 26 years (Range 14–48). None had underlying evidence of chronic liver disease. Mean value of peak total bilirubin 19.4 mg /dl (Range 13.3–56.8). Autoimmune markers were positive in 14 subjects. 63 subjects underwent percutaneous image guided liver biopsies. 4 subjects had bland cholestasis and were given supportive therapy for pruritus 0.18 subjects had features of autoimmune liver disease. 13 subjects diagnosed as autoimmune hepatitis, 4 subjets diagnosed as auto-immune hepatitis –primary biliary cholangitis overlap (AIH-PBC), and one subjects diagnosed as PBC. All of them were given standard medical care. Rest 41 showed features of cholestatic hepatitis. None had evidence of cirrhosis on histopathology. All, 41 subjects were given oral steroids at a starting dose of 0.5 mg/kg/day, weekly LFT and PT were monitored. Steroids were tapered at a dose of 5 mg/week if there was improvement of serum bilirubin in LFT or subjective improvement of pruritus. All of the subjects showed improvement of serum bilirubin after steroid administration. Mean time taken for normalization of serum bilirubin 42 days (range 14–63). 4 subjects who had bland cholestasis, mean time taken for normalization of serum bilirubin 98 days (range 56–140).
Conclusion: Prolonged cholestasis is not an uncommon complication of HAV infection. Short course of oral steroids offer an excellent therapy in a selected subset of patients and reduces morbidity. Underlying autoimmune liver disease can be present in them.

WED-263
Hepatitis E virus persistence in cerebrospinal fluid: a rare phenomenon observed in immunosuppressed patients beyond 18 months post-viremia clearance under Ribavirin therapy
Swetha Chalissery[1], Maria Mader[1], Matthias Gelderblom[1], Thorben Fruendt[1], Francis Ayuk[1], Ricardo Kosch[1], Katja Weisel[1], Annika Wolski[1], Jürgen Gallinat[1], Martin Lambert[1], Samuel Huber[1], Ansgar W. Lohse[1], Moritz Waldmann[1], Julian Schulze zur Wiesch[1], Sven Pischke[1]. [1]*University Medical Center Hamburg-Eppendorf, Hamburg, Germany*
Email: swethachalissery@gmail.com

Background and aims: This study aims to determine the duration of hepatitis E virus (HEV) persistence in the central nervous system (CNS) and to evaluate the prevalence of current HEV infections among neurological inpatients.
Method: Cerebrospinal fluid (CSF) samples were obtained from 326 patients undergoing lumbar puncture at the University Medical Center Hamburg-Eppendorf for various clinical indications. Additionally, 146 unselected neurological inpatients were included and compared to 1,000 healthy blood donors. HEV testing included PCR and detection of anti-HEV IgG and IgM antibodies.
Results: HEV was detected in the CSF of 1/326 patients (0.3%) but not in their blood samples. This individual, a stem cell transplant recipient, had cleared a chronic HEV infection more than 18 months prior following prolonged ribavirin therapy. Anti-HEV IgG antibodies were detected in 28.2% of CSF patients, 29.4% of neurological inpatients, and 16.8% of blood donors ($p = 0.002$ for both patient cohorts vs. blood donors). Anti-HEV IgG-positive patients were significantly older compared to anti-HEV IgG-negative patients (mean age 62 vs. mean age 68; $p = <0.001$) but did not differ significantly regarding the distribution of sex ($p = ns$). Anti-HEV IgM was detected in 1.2% of CSF patients, 2.7% of neurological inpatients, and 1% of blood donors ($p = ns$). Only one patient's anti-HEV IgM positivity was confirmed by immunoblot.
Conclusion: Although 92 patients undergoing CSF puncture showed evidence of previous HEV exposure, HEV persistence in CSF was identified in only one immunosuppressed patient, suggesting that CNS persistence beyond the blood-brain barrier is possible but uncommon. However, in cases of chronic HEV infection in immuno-suppressed individuals, HEV can persist in the CSF for more than a year despite the clearance of viremia. The higher anti-HEV IgG seroprevalence among neurological patients appears to be an age-related phenomenon, as these patients were older than the blood donors.

The impact of HBV genotypic diversity and temporal variations on hepatocellular carcinoma risk in chronic HBV infected patients

Ding-Lian Wang[1,2], Chih-Jen Huang[2], Mei-Hung Pan[2], Chien-Jen Chen[2], Hwai-I Yang[2]. [1]*Graduate Institute of Life Science, National Defense Medical Center, Taipei, Taiwan;* [2]*Genomics Research Center, Academia Sinica, Taipei, Taiwan*
Email: dl.wang19971224@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is a leading causes of cancer-related deaths worldwide. Chronic hepatitis B virus (HBV) infection is a major risk factor, with viral load, specific HBV genotypes, and mutants significantly associated with its progression. HBV, a diverse DNA virus with 10 genotypes (A to J), is predominantly represented by genotypes B and C in Asia, where co-infection with multiple HBV genotypes is common. While previous studies have focused on primary genotypes, most relied on single time-point analyses, leaving the impact of other genotypes and HBV diversity changes over time largely unexplored. This study investigated the relationship between HBV diversity proportions, their variation over time, and HCC risk using refined techniques for sub-genotype detection.
Method: Data from a longitudinal cohort of 439 chronic HBV carriers (REVEAL-HBV) in seven Taiwanese communities were analyzed. Full-length HBV DNA sequences, averaging ~5,000 reads per subject, were obtained using PacBio technology and compared with 35 NCBI reference sequences. Participants were classified into 3 categories based on primary genotype proportion: Class 1 (100%), Class 2 (100% > proportion ≥99.89%), and Class 3 (<99.89%). Class 1 and Class 2 formed the "Low HBV Diversity Group," while Class 3 comprised the "High HBV Diversity Group." Of the 439 participants, 250 underwent follow-up phase, and data from both phases were analyzed to evaluate changes over time. Cox and time-dependent Cox regression models assessed associations between HBV diversity and HCC risk, adjusted for gender, age, DNA levels, and primary genotypes.
Results: At baseline, over 80% of participants (n = 359) had more than two HBV genotypes, and approximately 50% (n = 216) were classified in the "High HBV Diversity Group." Individuals with primary genotype C2 had a higher HCC risk than those with genotype B2, based on baseline (HR = 3.40, 95% CI = 2.08–5.55) and follow-up data (HR = 2.77, 95% CI = 1.52–5.05). The "High HBV Diversity Group" exhibited higher HCC risk than the "Low HBV Diversity Group" in baseline data (HR = 1.78, 95% CI = 1.23–2.56), but this association was absent in follow-up data (HR = 1.15, 95% CI = 0.73–1.81). Time-dependent Cox regression revealed that a decrease in HBV class was linked to significantly elevated HCC risk (HR = 3.19, 95% CI = 1.78–5.72). All analyses adjusted for baseline HBV class, gender, age, DNA levels, and primary genotype.
Conclusion: This study underscores the predictive value of primary HBV genotypes for HCC risk, with genotype C2 conferring a higher risk than genotype B2, regardless of baseline or follow-up data. HBV diversity proportions reliably predict long-term HCC risk but are less effective in short-term. Patients co-infected with multiple HBV genotypes at baseline had higher HCC risk than those with singular infections; but this association diminished during follow-up. Changes in HBV class strongly predicted HCC risk, with a decrease linked to significantly elevated risk over time.

Clinicial ulility of novel HBV serological marker HBcrAg and immunological markers in the second trimester of pregnancy for predicting post-delivery ALT flares

Ivana Carey[1], James Lok[1], Zillah Cargill[1], Geoffrey Dusheiko[1], Kosh Agarwal. [1]*Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom*
Email: ivana.carey@nhs.net

Background and aims: Chronic Hepatitis B (CHB) changes in context of pregnancy - while pregnancy induces immune tolerance, post-delivery immune reconstitution manifests as ALT flares in 20% patients within 1 year post-partum. HBeAg+ status and high viral load were predictive of post-delivery flares. A novel marker of cccDNA transcriptional activity – hepatitis B core-related antigen (HBcrAg) is useful in predicting HBV mother-to-child-transmission (MTCT) risk, reflects HBeAg status and correlates with HBV DNA levels, but data on its utility to predict post-delivery ALT flares are lacking. Soluble markers of immune system activity chemokines CXCL10 (IP10) and soluble PD1 (sPD1) demonstrated ability to delineate CHB phases (infection vs hepatitis) and might be useful in predicting post-delivery flares. We aimed to assess ability of pregnancy (2nd trimester) plasma levels of immunological markers (CXCL10 and sPD1) and serological/virological markers (HBeAg status, HBV DNA, HBsAg and HBcrAg) to predict post-delivery ALT flares in single centre cohort.
Method: Plasma samples from the 2nd trimester (median gestation 23 wks) of 853 HBsAg+ pregnant patients with post-partum follow-up >1 year were collected between 1.1.2012–31.12.2022. We measured levels of HBV DNA by TaqMan PCR [IU/ml], HBeAg & HBsAg by Abbot Architect® [IU/ml], HBcrAg by CLEIA Fujirebio [log_{10}U/ml] and CXCL10 & sPD1 [both pg/ml] by ELISA (R&D Systems). The results were compared according to the presence/absence of ALT flares defined as (ALT > 38 IU/l and 2-fold increase from pregnancy level) within 1 year post-delivery (every 3 months follow-up) and according to treatment status.
Results: From enrolled 853 patients (median age 29 yrs): 668 (78%) patients were aware of HBV infection before pregnancy with 165 (19%) already treated with tenofovir and continued on therapy post-delivery vs 688 patients not on therapy. No case of MTCT was reported. Post-delivery ALT flares occurred in 170 (20%) patients and were more frequent in treated vs untreated patients (53 patients (32%) vs 117 patients (17%), $p < 0.05$). Untreated: All HBeAg negative, but patients with flares had higher levels for all tested markers when compared to non-flare patients (HBV DNA: 3450 vs 391 IU/ml, HBsAg: 8755 vs 4010 IU/ml, HBcrAg 3.8 vs 2.5 log_{10}U/ml, CXCL10: 215 vs 108 pg/ml and sPD1 189 vs 88 pg/ml, all medians, all $p < 0.05$). Treated: All patients had HBV DNA <10 IU/ml during pregnancy & post-delivery, 24 (14%) patients were HBeAg+ and had more frequent flares (75% HBeAg positive vs 25% HBeAg negative). While HBsAg levels were similar (9010 vs 8756 IU/ml), flare patients had higher levels of HBcrAg (4.9 vs 3.5 log_{10}U/ml), CXCL10 (273 vs 112 pg/ml) and sPD1 (205 vs 94 pg/ml).
Conclusion: The combination of levels of HBcrAg with immunological markers (CXCL10 & sPD-1) during pregnancy refined prediction of post-delivery ALT flares. Larger studies validating these markers to confirm their prognostic clinical significance are needed to enable personalised delivery of care post-partum.

Background and aims: The role of antiviral therapy (AVT) in immune tolerant (IT; HBeAg-positive chronic infection) chronic hepatitis B (CHB) patients remains controversial. Although current guidelines mostly recommend AVT once patients transition to immune active (IA) disease, there is a growing trend to expand treatment criteria. We studied the risk of transitioning to IA disease in strictly defined IT patients with CHB.
Method: This is a multi-centre international cohort study from the RADICAL-consortium, which includes data from a large cohort of mono-infected CHB patients from 12 sites in North America, Europe and Asia. Baseline refers to the first clinic visit at the investigational site. The IT-phase was strictly defined as persistently (1) HBeAg-positive, (2) ALT ≤40 U/L, and 3) HBV DNA ≥5 log IU/ml during the first year after baseline. Transition to IA disease was defined as ALT ≥60 U/L or ALT > 40 U/L at 2 consecutive visits or leading to AVT initiation.
Results: In total, 480 IT patients were included with a median age of 31 (IQR 24.5–39.4), 32% were male and 96% were of Asian ethnicity. Median ALT and HBV DNA at baseline were 25 (IQR 20–31) U/L and 8.36 (IQR 8.03–8.83) log IU/mL. Patients were followed for a median of 117 (IQR 77–182) months.
During follow-up, 219 (46%) patients developed IA disease, 42% defined by ALT > 40 at 2 consecutive visits, 39% ALT > 60 and 19% ALT > 40 at start of AVT. A total of 263 (55%) IT patients started on AVT during follow-up, of whom 64% after development of IA disease. The cumulative incidence of spontaneous HBeAg loss at 3-, 5- and 10-year was 3%, 7% and 19%. The 3-, 5-, 10- and 15-year cumulative incidences of transition from IT phase to IA disease were 17%, 34%, 63%, 76% in the overall population. Transition to IA disease was more likely in patients with a higher ALT (aHR 1.06, 95% CI 1.04–1.08, p < 0.001) at baseline. Age, sex and HBV DNA at baseline were not related to transition to IA disease. Also, no association was found when age categories were investigated (<30, 30–40, > 40). Notably, the 3-, 5-, and 10-year cumulative incidence of transition to IA disease was highest in patients with a baseline ALT > 30 (29%, 49%, 74%) compared to patients with an ALT > 20 and ≤30 (16%, 36%, 69%) and an ALT ≤20 (7%, 16%, 44%) at baseline (p < 0.001). Findings were consistent in multivariable analysis (aHR for ALT > 20 and ≤30: 2.21, 95% CI 1.49–3.29; aHR for ALT > 30: 3.10, 95% CI 2.02–4.75, p < 0.001). Similar results were found in patients with a persistent HBV DNA ≥7 log IU/ml during the first year after baseline.
Conclusion: One-third of the IT patients transition to IA disease within 5 years of follow-up. An ALT ≥30 at baseline was associated with significantly higher rates of transition which occurred in almost half of them. This suggests that these patients may be good candidates for strict monitoring or even pre-emptive AVT.

TOP-284
Accelerated HBsAg reduction rate and increased proportion of HBsAg <100 IU/mL through repeated finite Nuc therapy in HBeAg-negative chronic hepatitis B patients

Rachel Wen-Juei Jeng[1,2], Yen-Chun Liu[2,3], Rong-Nan Chien[2,3].
[1]Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou Medical Center, College of Medicine, Chang Gung University, Taoyuan, Taiwan; [2]College of Medicine, Chang Gung University, Taoyuan, Taiwan; [3]Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou Medical Center, Taoyuan, Taiwan
Email: rachel.jeng@gmail.com

Background and aims: Finite therapy is known to increase HBsAg loss rates, but its impact on HBsAg kinetics and reduction among HBeAg-negative chronic hepatitis B (CHB) patients who experience off-Nuc clinical relapse and are retreated with finite therapy remains unclear.
Method: This analysis included treatment-naïve HBeAg-negative CHB patients who underwent retreatment due to clinical relapse and received at least one additional course of finite Nuc therapy. Nuc cessation adhered to the APASL stopping rule, requiring at least one year of undetectable HBV DNA before stopping. Clinical relapse was defined as ALT > 2 times the upper limit of normal with HBV DNA > 2000 IU/mL. HBsAg levels were assessed at key time points: start (SOT) and end (EOT) of the 1st treatment, 2nd (1st retreatment: retx_SOT, retx_EOT), and 3rd (2nd retreatment: retx2_SOT, retx2_EOT) treatments, and the last follow-up, using the Elecsys HBsAg II Quantitative Assay (Roche). The annual HBsAg reduction velocity ($\log_{10}$ IU/mL/year) was calculated as HBsAg log reduction divided by treatment duration. The primary outcome was the proportion of patients achieving HBsAg <100 IU/mL by the end of follow-up.
Results: A total of 88 HBeAg-negative treatment naïve CHB patients were recruited. The mean age at the 1st treatment was 54.5 ± 9.1 years; 86.4% were male, and 34.1% were cirrhotic. During the first treatment, 70 patients used Entecavir, 8 used Tenofovir, and 10 used other Nucs (LAM, LdT). During the second treatment, 65 patients used Entecavir, and 35 used Tenofovir. The median follow-up duration was 13.4 (12.2–14.6) years. Sixty-six patients experienced relapse after the 1st retreatment, and 64 were retreated. Clinical relapse after repeat finite therapy was mostly observed in the first year and declined thereafter (1st, 2nd, 3rd, and 4th years from retx_EOT: 50.3%, 19%, 3.5%, and 2.6%, respectively). Median HBsAg levels (IU/mL) at SOT, EOT, retx_SOT, retx_EOT, retx2_SOT, retx2_EOT, and last follow-up were 1405, 507, 953, 224, 964, 144, and 76, respectively. Annual HBsAg reduction rates during the 1st, 2nd, and 3rd treatments were −0.091, −0.171, and −0.282 $\log_{10}$ IU/mL/year, respectively (P < 0.001). The proportion achieving HBsAg <100 IU/mL increased from 2.3% (SOT) to 5.7% (EOT), 11.4% (retx_SOT), 29.6% (retx_EOT), and 53.4% (last follow-up). Three patients (2 cirrhotic) developed HCC during follow-up, resulting in an annual HCC incidence of 0.33%. No liver-related mortality was observed.
Conclusion: Repeat finite therapy accelerates HBsAg reduction, significantly increases the proportion achieving HBsAg <100 IU/mL, with low HCC incidence, making it a considerable option for patients failing to achieve sustained response or functional cure after Nuc discontinuation.

SAT-243

Analysis of liver pathological characteristics and influencing factors in patients with an inactive HBsAg carrier status

Shan Ren[1], Xinyang Zhang[1], Sujun Zheng[1], Rongshan Fan[2], Faqing Ruan[3], Wenqi Huang[4], Haibing Gao[5], Xiulan Xue[6], Fang Yang[7], Xin-Yue Chen[1]. *[1]Beijing You'an Hospital, Capital Medical University, Beijing, China; [2]Shenzhen Hospital of Integrated Traditional Chinese and Western Medicine, Shenzhen, China; [3]Xiamen Hospital of Traditional Chinese Medicine, Xiamen, China; [4]Xiamen Humanity Hospital, Xiamen, China; [5]Mengchao Hepatobiliary Hospital Of Fujian Medical University, Fujian, China; [6]The First Affiliated Hospital of Xiamen University, Xiamen, China; [7]Shenyang Sixth People's Hospital, Shenyang, China*
Email: chenxydoc@163.com

Background and aims: The purpose of this study was to analyze the liver pathological characteristics and influencing factors in patients with an inactive hepatitis B surface antigen (HBsAg) carrier status (IHCs) and to explore the need for antiviral treatment in newly defined IHC patients according to liver tissue inflammation and fibrosis.
Method: This multicenter, retrospective and cross-sectional study included 231 IHC patients who underwent histopathological examination via liver biopsy at eight hospitals, including Beijing Youan Hospital Affiliated with Capital Medical University, from January 2018 to December 2023. Patient general information, biochemical indicators, HBV DNA and HBsAg levels, liver ultrasound findings, FibroScan results, and other examination results were collected. IHC patients were grouped on the basis of HBV DNA negativity. Differences in liver pathological inflammation activity (G) and liver fibrosis stage (S) of the patients in the two groups were analyzed. Factors affecting the degree of inflammation and fibrosis in the patients were identified with univariable and multivariable analyses, and the subsequently established multivariable prediction model was evaluated via receiver operating characteristic (ROC) curve analysis. The significance level was set to $\alpha = 0.05$.
Results: The median age of the 231 chronic hepatitis B patients was 43 years, among 95.2% (220/231) were aged ≥30 years, and men accounted for 95.2% (220/231). The median HBV DNA concentration was 94 IU/ml; a total of 35.9% (83) of the patients were negative for HBV DNA (<20 IU/ml). Patients with G≥2 accounted for 16.5% (38 patients) of the cohort, those with S≥2 accounted for 29% (67 patients), and those with evident hepatic injury (EHI), that is, those with G≥2 and/or S≥2, accounted for 35.9% (83 patients). In HBV DNA-negative IHC patients, the percentage of liver tissues with S≥2 was 42.2%, significantly greater than that in DNA-negative IHC patients (21.6%; $\chi^2 = 10.9$, $P < 0.001$). This significant difference occurred mainly in the population over 30 years of age (44.9% vs. 31%, $\chi^2 = 4.22$, $P = 0.04$). Multivariable analysis indicated that sex, HBV DNA, and the LSM were independent predictors of the liver tissue S value among IHC patients over 30 years of age. The area under the ROC curve (AUC) of the prediction model established from the independent factors was 0.855.
Conclusion: Despite presenting with HBV DNA negativity, 42.2% of patients exhibited significant liver fibrosis, and the percentage of patients with S ≥2 gradually increased with age. Male IHC patients over 30 years of age with negative HBV DNA should undergo comprehensive assessments including LSMs and platelet counts, as well as liver biopsy as appropriate. Selection of appropriate antiviral treatment can improve the chance of clinical cure and minimize the risk of long-term adverse outcomes.

M. and a. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milano, Italy*
Email: mariabutiferret@gmail.com

Background and aims: In a previous multicenter study in patients with chronic hepatitis D (CHD), we have shown that the levels of HDV RNA correlated with the development of clinical events (Palom A et al. J Hepatol 2023 #1810). In this study, we aim to validate the relationship between HDV RNA concentrations and the risk of developing clinical events in two independent cohorts of Italian patients with CHD.
Method: A multicenter retrospective study that includes three cohorts of untreated adults with detectable and quantified HDV RNA levels and a clinical follow-up of >1 year. In the previous analysis cohort (cohort A), HDV RNA was quantified using an in-house RT-PCR (LOD = 57.5 IU/mL). In the two Italian validation cohorts, Milano (cohort M) and multicenter one (cohort MU) HDV RNA was quantified by Robogene HDV Quantification Kit 2.0 (LOD = 6 IU/mL). Clinical endpoints (liver decompensation, HCC, liver transplant or liver-related death) were evaluated every 6 months during the follow-up.
Results: A total of 260 subjects were included and monitored during a median follow-up of 4.1 years (IQR 2–6). The analysis cohort (cohort A) included 98 patients: median age 44 (IQR 36–51) years, 59% male, 81% Caucasian, HDV RNA 5.3 (IQR 4.2–6.1) log IU/mL, ALT 71 (IQR 44–126) IU/mL, 30 (30.6%) cirrhosis and the median follow-up was 6 (IQR 3–9) years. Clinical events were observed in 12% (2/17), 22% (4/18), 18% (6/34) and 35% (10/29) of the patients according to the respective HDV RNA levels (6–6,000, >6,000–60,000, >60,000–600,000, >600,000 IU/mL) ($p = 0.103$). The two validation cohorts (cohort M: 100 patients, and cohort MU: 62 patients) were similar in gender ($p = 0.929$) and ALT levels ($p = 0.421$) but not in patient's age ($p < 0.001$), proportion of cirrhosis ($p < 0.001$) and qHDV RNA levels ($p = 0.013$). In the 119 non-cirrhotic patients, clinical events occurred in 0% (0/13), 15% (2/13), 9% (2/23), 21% (4/19) according to previous levels of viremia in the analysis cohort, and in a similar proportion in the validation cohorts: 0% (0/4), 0% (0/4), 0% (0/10), 9% (1/11) in cohort M

(p = 0.239), and 0% (0/6), 20% (1/5), 22% (2/9), 50% (1/2) in cohort MU (p = 0.164) (overall p = 0.166). In the 141 cirrhotic patients, clinical events occurred in 50% (2/4), 40% (2/5), 36% (4/11), 60% (6/10) in the analysis cohort and in a similar proportion in both validation cohorts: 41% (7/17), 25% (3/12), 40% (8/20), 50% (11/22) in cohort M (p = 0.415), and 50% (5/10), 40% (2/5), 53% (10/19), 0% (0/6) in cohort MU (p = 0.890) (overall p = 0.743).
Conclusion: In untreated patients with CHD, low levels of HDV RNA were associated with less clinical outcomes in patients without liver cirrhosis. These results were validated and confirmed in two external cohorts.

SAT-245
Treatment duration, adherence and persistence in patients with chronic hepatitis B virus infection treated with long-term nucleos (t)ide analogues in Germany
Verena Königer[1], Simon Hohenester[1], Vera Gielen[2], Seth Anderson[3], Tim Hartmann[1], Marlene Rohrmann[1], Tammo Viering[4], Svitlana Schnaidt[4], Shayon Salehi[2], Christian Jacob[4], Afisi Ismaila[3].

Email: afisi.s.ismaila@gsk.com

Background and aims: Chronic Hepatitis B virus (HBV) infection poses a significant threat to global health. Nucleos(t)ide analogs (NAs) are the current standard of care for chronic HBV infection. Adherence to long-term NA therapy is vital to maintain HBV-DNA suppression. Knowledge of NA treatment patterns in prevalent chronic HBV infection as well as the duration of treatment is important to understand adherence and persistence and to describe the real-world use of these therapies.
Method: We conducted a retrospective, observational claims data analysis, which examined and described the characteristics of treatment duration and adherence to single-drug formulation second-generation NAs in adult patients with chronic HBV infection in Germany. Data from the Institute for Applied Health Research Berlin GmbH (InGef) Research Database were used. Adult patients who initiated single-drug formulation second-generation NA treatment (entecavir, telbivudine, tenofovir disoproxil fumarate, and tenofovir alafenamide) between January 1, 2015–August 31, 2022, and had a recorded diagnosis for chronic HBV infection in the year prior to their initial NA prescription, were selected. Patients with co-infections such as HIV, Hepatitis delta-virus, and Hepatitis C virus were excluded.
Results: We identified 489 adult patients with chronic HBV infection who initiated single-drug formulation second-generation NA treatment in the study period (average age [SD] 53.0 [14.7] years, females 41.5%). During follow-up (average [SD] 3.3 [2.1] years), NA treatment discontinuation was observed in more than half of the patients (n = 273, 55.8%), with a median (95% CI) time to discontinuation of 743 (560, 1,107) days (24.4 [18.4, 36.4] months). A total of 216 (44.2%) patients continued treatment throughout follow-up and 128 (46.9%) patients who discontinued NA treatment eventually restarted their therapy. Less than 10% of patients switched NA treatment (n = 41, 8.4%). Adherence was significantly worse in females (HR = 1.31, p = 0.032) versus males and better in patients living in urban regions (HR = 0.73, p = 0.044) versus rural areas. Average adherence, defined as proportion of days covered, was 0.94 ± 0.09 at the end of follow-up, and remained constant for different follow-up lengths (0.94 after 12, 24 and 36 months; 0.93 at 48 and 60 months). Adherence was positively influenced by age (OR = 1.02, p = 0.041).
Conclusion: Treatment discontinuation remains a key challenge in the management of chronic HBV infection. This study highlights the unmet need for additional support to help patients persist with NA treatment. These results also underscore the critical need for alternative therapies for chronic HBV infection with shorter and finite treatment durations with a reduced need for rigid monitoring to mitigate the high discontinuation rate while ensuring optimal clinical outcomes.
Funding: GSK (Study 218717).

SAT-246
Long-term perspectives on treating or observing immune-tolerant chronic hepatitis B
Mai Kilany[1], Ahmed Elsheaita[1], David Wong[1], Scott K. Fung[1], Leila Amiri[1], Harry L.A. Janssen[2]. *[1]Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada; [2]Department of Gastroenterology and Hepatology, Erasmus University Medical Center, Rotterdam, The Netherlands, Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada, Rotterdam, Netherlands*
Email: mai.kilany@uhn.ca

Background and aims: The management of immune-tolerant (IT) chronic hepatitis B (HBV) remains debatable. While guidelines do not recommend treatment, expanding treatment to IT and "grey zone" patients is gaining support due to concerns about high viremia and liver disease risk. we aim to study the impact of treatment in IT and "grey zone" patients over the long term.
Method: This retrospective study included HBeAg-positive chronic hepatitis B patients (2000–2024) at the Toronto Centre for Liver Disease with HBV DNA > 6 log IU/mL, ALT <75 U/L, and minimal fibrosis (F0–1) assessed by biopsy or non-invasive methods. Patients treated during pregnancy for vertical transmission prevention were excluded. Groups included untreated IT (ALT <45 U/L), treated IT (ALT <45 U/L), and treated mildly active (MA) (ALT 45–75 U/L). Baseline was defined as the first clinic visit for untreated IT or treatment initiation for treated IT and MA groups. Data were analyzed using chi-squared, Kruskal-Wallis, and Kaplan-Meier methods (p < 0.05).
Results: The study included 161 patients: 107 untreated IT, 27 treated IT, and 27 treated MA. Treated IT patients most commonly received TDF (32.1%), ETV/IFN (28.6%), and TAF (21.4%), while treated MA patients primarily received TDF (53.6%) and IFN (17.9%). Of the total population, 63.5% (n = 102) were female, and 90% (n = 146) were Asian. The mean baseline age was 31 years in the untreated IT group, 35 years in the treated IT group, and 40 years in the treated MA group (P < 0.05). The mean follow-up duration was 9.6 years for the untreated IT group, 4.5 years for the treated IT group, and 8.3 years for the treated MA group. The mean ALT levels were 52 U/L in the treated MA group, 26 U/L in the untreated IT group, and 27 U/L in the treated IT group. Viral suppression (HBV DNA <10 IU/mL) was achieved in 44% of the treated IT group, 63% of the treated MA group, and 4% of the untreated group (P < 0.05). HBV DNA suppression probability reached 87% at 4 years and 100% at 10 years in the treated IT group, compared to 56% at 4 years and 95% at 10 years in the treated MA group (P < 0.05). However, 56% of treated IT and 37% of treated MA patients did not achieve suppression despite long-term therapy. HBeAg loss occurred in 11% of the treated IT group, 15% of the treated MA group, and 19% of the untreated group (P > 0.05), with 10-year probabilities of 55%, 21%, and 36%, respectively (P > 0.05). None of the patients developed cirrhosis or hepatocellular carcinoma (HCC) during the follow-up period.
Conclusion: Our findings suggest that HBeAg loss is uncommon among immune-tolerant and mildly active patients undergoing prolonged antiviral therapy. Antiviral treatment was safe, but achieving HBV DNA undetectability required extended durations of therapy for most patients. Notably, high HBV DNA in immune-tolerant patients was not associated with hepatocellular carcinoma (HCC) over a decade of follow-up.

Background and aims: HDV Describe is an observational study in which consecutive HBsAg-positive carriers with antibodies to HDV, referred to 32 Italian centers, were prospectively enrolled from August 2022 to July 2024. We aimed to conduct a phylogenetic analysis to identify the HDV genotypes (Gts) and subgenotypes (Sgts) in this study cohort.

Method: HDV Gts were determined by sequence analysis of a viral genome region spanning nucleotides 908–1265. After PCR amplification, Sanger-based sequencing (BMR-GENOMICS, Padova, Italy) was performed; obtained sequences were compared to reference sequences of the eight HDV Gts retrieved from GenBank, using Basic Local Alignment Search Tool (BLAST). The identification of Sgts was performed by phylogenetic analysis using MEGA11 software considering an intrasubgenotype percentage of difference <10%.

Results: Gts and Sgts were determined in 370 HDV RNA-positive patients. Overall, 366 patients were Gt-1 and 4 were Gt-5. All patients with HDV Gt-5 were migrants from Sub-Saharan Africa regions. Among patients carrying Gt-1, we identified the following Sgts: 3 (0.8%) Sgt-1a, 3 (0.8%) Sgt-1b, 153 (42%) Sgt-1c, 7 (1.9%) Sgt-1d, 194 (53%) Sgt-1e; it was not possible to assign the Sgt in 6 (1.6%) patients. Among native Italians (n = 221), the prevalent Sgt was 1e (145/221; 65.6%), while foreign-born (n = 149) were mostly infected with HDV Sgt-1c (88/149; 59.1%) ($p < 0.001$). Most foreign-born patients were from East Europe (135/149; 90.6%); Sgt-1c was prevalent in patients from Eastern European Countries (Moldova, Albania, Ukraine, Georgia, and Russia), except those from Romania where the prevalence of Sgt-1c and 1e was equal (both 49.2%). Considering the Italian patients' sequences, the overall mean genetic distance was

0.076 ± 0.01. Among patients successfully genotyped for HBV (n = 57), most of them (47/57; 82.5%) were infected with HBV Gt-D; in such patients, HDV Sgt-1e and 1c were equally distributed (23/47, 48.9% vs. 21/47, 44.7%). Finally, Sgt-1e was associated with lower HBsAg (3.55, IQR 2.45–3.96 Log IU/mL vs 3.73, IQR 2.91–4.09 Log IU/mL; p < 0.037) and HBcrAg levels (3.30, IQR 2.6–4.3 Log U/mL vs 3.70, IQR 2.8–4.6 Log UI/ml; p < 0.020) compared to patients infected with other HDV Sgts. No further associations were found with available clinical, biochemical, and virological parameters.

Conclusion: In Italy, the most frequently observed HDV Sgts are 1c and 1e. The former is prevalent among foreign-born patients while the latter is prevalent among native Italians. The association between HDV Sgt-1e and lower levels of HBV antigens may reflect a peculiar interplay between these two viruses.

This research was supported by Gilead Sciences, Inc (study ID: IN-IT-980–6382).

Email: arno.furquimdalmeida@uantwerpen.be

Background and aims: Nucleos(t)ide analogue (NUC) withdrawal in chronic hepatitis B has been proposed as a strategy to increase functional cure rates, but the possibility of severe flares necessitates close off-treatment monitoring. Baseline predictors to identify patients at risk for such flares would improve the safety. We thus investigated several biomarkers for the prediction of flares within 24 weeks after NUC cessation in a multicenter prospective clinical trial (COIN-B, NCT04779970).

Method: End of treatment (EOT) samples of 85 start of treatment HBeAg negative, non-cirrhotic (<F3), long-term (>3 years) NUC suppressed chronic HBV patients were analyzed. Patients were monitored every 2–4 weeks. Hepatitis B surface antigen (HBsAg) (Limit of Detection (LOD) 0.05 IU/mL) and HBV RNA (LOD 3 cp/mL; Limit of Quantification (LOQ) 10 cp/mL) were analyzed on the Cobas (Roche) analyzer. Hepatitis B core related antigen (HBcrAg) (LOD 2 logU/mL; LOQ 3 logU/mL) and hepatitis B core IgG antibodies (anti-HBc IgG) (LOD 0.5 IU/mL; LOQ 0.8 IU/mL) were analyzed on the Lumipulse (Fujirebio) G600 platform.

Results: Majority of patients were male (72.9%) with a median (IQR) age of 47 (13) years. 63/85 (74.1%) were treated with tenofovir and the median (IQR) duration of last NUC treatment was 7.2 (4.8) years. Severe virological (SVF) (HBV DNA >5 log IU/mL) and severe biochemical flares (SBF) (ALT > 10×ULN) were observed in 34 (40.0%) and 19 (22.4%) patients respectively. There is an increased odd for having a viral flare (HBV DNA > 2000 IU/mL, n = 77/85) per log increase of HBsAg at EOT (OR 2.41, 95% CI 1.22–5.36, p = 0.01). 25 (30.1%) patients had HBV RNA > LOD at baseline, 13 (52.0%) of those were > LOQ. HBV RNA > LOD is not associated with any type of flare. HBcrAg was >LOD in 51 patients (60.0%), of which 29 (56.9%) were >LOQ. SVF (p = 0.006) and SBF (p = 0.03) were more frequently observed in patients with HBcrAg >LOD at baseline. Patients with HBcrAg >LOD had an OR 4.34 (95% CI 1.67–12.48, p = 0.004) and OR 4.72 (95% CI 1.41–21.70, p = 0.02) for a SVF and SBF respectively. The respective negative predictive value (NPV) to identify SVF and SBF based on HBcrAg >LOD are 79.4% and 91.1%. There is a significant decrease in the odds for having a SVF (OR 0.46, 95% CI 0.21–0.93, p = 0.04) and SBF (OR 0.20, 95% CI 0.07–0.50, p = 0.001) per log increase of anti-HBc IgG. An EOT anti-HBc IgG of ≤475 IU/mL allowed the identification of SVF and SBF with a NPV of 74.3% and 97.1% respectively. Multivariate logistic regression including HBcrAg and anti-HBc IgG pointed towards HBcrAg >LOD as an independent predictor for SVF (aOR 4.57, 95% CI 1.66–14.17, p = 0.005) and SBF (aOR 6.18, 95% CI 1.46–43.14, p = 0.03) and lower anti-HBc IgG for SBF (aOR 0.21, 95% CI 0.06–0.55, p = 0.004).

Conclusion: EOT serum anti-HBc IgG and HBcrAg but not HBV RNA nor HBsAg are associated with severe flares after NUC cessation in a multicenter prospective trial. Anti-HBc IgG and HBcrAg show promise to identify the patients at highest risk for adverse outcomes and may guide future treatment cessation strategies.

SAT-253

DM type 2 is a significant risk factor for HCC and decompensation of liver disease in HBV s Ag positive patients

Assaf Issachar[1,2], Michal Cohen-Naftaly[1,2], Marius Brown[1,2], Iftah Akai[1,2], Ran Tur-Kaspa[1,2], Orly Sneh Arbib[1,3,4]. *[1]Liver institute, Rabin Medical Center, Beilinson hospital, Petah Tikva, Israel; [2]Faculty of medicine, Tel aviv university, Tel Aviv, Israel; [3]Gastroenterology and Liver clinic, Clalit Health Service, Jerusalem, Israel; [4]Faculty of Medicine Hebrew University, Jerusalem, Israel*

Email: assafissa@gmail.com

Background and aims: Hepatitis B virus (HBV) infection is a significant cause of liver disease, liver transplantation, and hepatocellular carcinoma (HCC). Various factors contribute to liver outcomes and mortality in HBV patients. However, there is limited data on the influence of metabolic factors, such as type 2 diabetes mellitus (T2DM), which is closely associated with the development of metabolic-associated steatotic liver disease (MASLD), on liver outcomes in patients with HBV.

This study aim to analyze the factors influencing liver outcomes and mortality in HBsAg-positive patients in Israel

Method: Clalit Health Services (CHS), the largest Health Maintenance Organization (HMO) in Israel, serves over 4.5 million people. We conducted a retrospective big data study analyzing all patients who

tested positive for HBsAg from January 1, 2000, to June 1, 2022. Data collection included demographics, medical history, liver outcome diagnoses (cirrhosis, ascites, esophageal varices, portal hypertension, encephalopathy, and HCC), liver transplantation (LT), and mortality. Multinomial logistic regression analysis was performed to identify factors related to outcomes. Data was extracted from CHS using Clalit's data-sharing platform powered by MDClone (https://www.mdclone.com).

Results: From January 1, 2000, to June 1, 2022, 1,749,414 patients underwent HBsAg testing, with 25,013 positive results (1.4%). After excluding 783 patients with HBV core IgM antibodies, 24,230 patients were included in the analysis. Demographic and clinical data showed that 57.6% were males, the mean age at diagnosis was 42.6 years, 47.3% had low socio-economic status, 2.4% were positive for HDV antibodies, 2.9% for HCV antibodies, and 11.4% had T2DM. Significant factors for cirrhosis complications, HCC, LT, and mortality included no antiviral treatment (OR: 7.26, 7.29, 30.4, and 3.25, respectively), platelet count <120 K (OR: 9.49, 3.77, 10.32, and 3.25, respectively), and T2DM (OR: 3.13, 2.29, 3.01, and 1.95, respectively). Smoking, co-infection with HCV, and co-infection with HDV were also significant. Female gender had a significant influence on cirrhosis complications, HCC, and mortality but not on LT.

Conclusion: In addition to factors related to viral infection and co-infection with HDV and HCV, T2DM strongly influences liver outcomes, HCC, and mortality in HBsAg-positive patients, underscoring the importance of metabolic factors in disease progression.

SAT-254

Healthcare resource utilisation and costs associated with hepatitis delta virus infection compared with hepatitis B virus monoinfection prior to death among adults in Spain

Maria Buti[1], Marvin Rock[2], Mertixell Ascanio[3], Josep Darba[4], Chong Kim[2]. [1]*Liver Unit, Hospital Universitario Valle Hebron, Barcelona, Spain;* [2]*HEOR–Global Value & Access, Gilead Sciences, Inc., Foster City, United States;* [3]*BCN Health Economics & Outcomes Research SL, Barcelona, Spain;* [4]*Department of Economics, University of Barcelona, Barcelona, Spain*
Email: chong.kim9@gilead.com

Background and aims: Concurrent hepatitis delta virus (HDV) and hepatitis B virus (HBV) infection results in higher morbidity and mortality than HBV monoinfection (HBV only). This retrospective study compared healthcare resource utilisation (HCRU) and costs for patients with HDV vs HBV only in the 12 months before death among adults in Spain.

Method: The Spanish National Health System's Hospital Discharge Records Database (Conjunto Mínimo Básico de Datos) was screened for patients aged ≥18 years with ≥1 *International Classification of Diseases, Ninth or Tenth Revision, Clinical Modification* diagnosis code for HDV or HBV between 01/2000–12/2019 (study period). Patients with an initial HDV or HBV only diagnosis in the identification period (01/2001–12/2018) and continuous enrolment for ≥12 months before and after first diagnosis were selected; patients with HBV only had no HDV claim in the study period. Baseline characteristics and clinical comorbidities were recorded from the year before first diagnosis. The mean per-patient all-cause and disease-specific HCRU and costs between patients with HDV vs HBV only who died in the study period were evaluated in the 12 months before death. All p values were calculated using McNemar chi-square tests and generalised linear models with gamma distribution (log link).

Results: Of 10,994 patients diagnosed with HDV or HBV only during the identification period, 159 with HDV and 2,920 with HBV only were included. Patients with HDV vs HBV only had a mean age of 47 and 52 years, respectively, and were mostly male (73% and 73%, respectively). In the 12 months before death, all-cause HCRU and costs were significantly higher for patients with HDV (n = 64) vs HBV only (n = 1,168). Among patients with HDV vs HBV only, the all-cause mean number of inpatient (2.9 vs 1.9) and outpatient (2.7 vs 1.6) visits, length of inpatient stay (38.2 vs 31.7 days), number of pharmacy claims (3.5 vs 2.8), and per-patient total cost (€ 12,823 vs € 9,746), inpatient cost (€ 4,668 vs € 3,294), and outpatient cost (€ 4,796 vs € 3,148) in the 12 months before death were higher for patients with HDV ($p < 0.05$ each). These differences were also observed for disease-specific HCRU and costs (HDV, n = 54; HBV only, n = 992): in the 12 months before death, the disease-specific mean number of inpatient (3.1 vs 2.1) and outpatient visits (2.9 vs 1.8), length of inpatient stay (39.5 vs 30.8 days), number of pharmacy claims (3.6 vs 3.0), and per-patient total cost (€ 14,139 vs € 11,289), inpatient cost (€ 5,146 vs € 3,812) and outpatient cost (€ 5,288 vs € 3,649) were higher for patients with HDV ($p < 0.05$ each).

Conclusion: For adult patients in Spain, inpatient length of stay, HCRU and costs from liver-related morbidities were significantly greater in the 12 months prior to death for patients with HDV vs HBV only. These findings underscore the need to reduce the costs and disease burden associated with HDV infection in Spain.

SAT-255

Performance evaluation of the Elecsys anti-HBc II quant assay

Tanja Schneider[1], Ariadna Rando-Segura[2], Sarah Guttmann[3], Sofía Pérez-del-Pulgar[2], Kristin Maria Meyer-Schlinkmann[3], Johannes Polz[1], Christian Voitenleitner[4], Francisco Rodríguez-Frías[2]. [1]*Roche Diagnostics GmbH, Penzberg, Germany;* [2]*Clinical Biochemistry Department, Vall d'Hebron Institut of Research (VHIR), Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain;* [3]*MVZ Labor Krone eGbR, Bad Salzuflen, Germany;* [4]*Roche Diagnostics International AG, Rotkreuz, Switzerland*
Email: christian.voitenleitner@roche.com

Background and aims: Anti-hepatitis core antibodies (anti-HBc) correlate well with the phases of hepatitis B virus (HBV) infection; therefore, anti-HBc provide an indication of past and present HBV infection and disease progression. The Elecsys Anti-HBc II quant immunoassay enables *in vitro* quantification of anti-HBc in human serum and plasma. The aim of this study was to evaluate the assay's clinical performance in terms of diagnostic sensitivity and specificity at the Medical Decision Point (MDP).

Method: Leftover anonymised serum and plasma samples from HBV-infected people, collected from two external sites, were used for diagnostic sensitivity and specificity at MDP analyses. Sensitivity was assessed in samples from participants with present acute or chronic HBV infection (with or without necroinflammatory activity), while specificity was assessed in samples from participants with past HBV infection (recovered). The MDP to distinguish between present and past infection was 180 IU/mL (based on established Roche internal MDP). Seroconversion sensitivity was compared against the qualitative Elecsys® Anti-HBc II [Roche] test across eight anti-HBc seroconversion panels. Correlative analysis between nominal anti-HBc titers of a serial dilution (0–50 IU/L) of the anti-HBc World Health Organization (WHO) Standard (95/522) and Elecsys Anti-HBc II quant-measured titers was also conducted.

Results: In the overall sensitivity analysis cohort (n = 518), 484 samples had an anti-HBc titer ≥180 IU/mL yielding a sensitivity at MDP of 93.44% (95% confidence interval [CI]: 90.95–95.41). In the overall specificity analysis cohort (n = 393), 377 samples had an anti-HBc titer <180 IU/mL yielding a specificity at MDP of 95.93% (95% CI: 93.47–97.66). Furthermore, the assay significantly differentiated past and present infection samples based on mean anti-HBc titers (44.9 vs. 6002.1 IU/mL, respectively; Wilcoxon test, $p < 0.0001$). Similar seroconversion sensitivity was achieved compared with the Elecsys Anti-HBc II test. The Elecsys Anti-HBc II quant showed good linearity ($r^2 = 0.9$), with low deviation from nominal titer (0 to 11%), over the anti-HBc WHO Standard (95/522) quantification range.

Conclusion: The Elecsys Anti-HBc II quant assay demonstrated good overall diagnostic sensitivity (>93%) and specificity (>95%) at MDP for distinguishing past and present hepatitis B infections. Seroconversion sensitivity was broadly similar compared with the

Elecsys Anti-HBc II qualitative assay. Good linearity and accuracy was also shown against the anti-HBc WHO Standard (95/522).

SAT-256

Role of HBV RNA in predicting nucleos(t)ide analogues initiation and risk of relapse after cessation

Chen-Ta Chi[1], I-Cheng Lee[2], Pei-Chang Lee[2], Chieh-Ju Lee[1], Yi-Hsiang Huang[3]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan, Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan, Taipei, Taiwan; [2]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan, Taipei, Taiwan; [3]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan, Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan, Healthcare and Services Center, Taipei Veterans General Hospital, Taipei, Taiwan, Taipei, Taiwan*
Email: yhhuang@vghtpe.gov.tw

Background and aims: The safe cessation of nucleos(t)ide analogues (NUCs) remains challenging in patients with chronic hepatitis B (CHB). We aimed to investigate the potential role of novel biomarkers in predicting risk of NUCs initiation and off-therapy relapse.
Method: From November 2020 to September 2023, we prospectively enrolled 133 CHB patients who did not receive NUCs as cohort 1, and 45 CHB patients who received NUCs and met cessation criteria as cohort 2. The correlation of novel biomarkers including quantitative hepatitis B surface antigen (qHBsAg), hepatitis B core-related antigen (HBcrAg) and hepatitis B virus RNA (HBV-RNA) was studied. Risk factors associated with suitability for National Health Insurance (NHI)-indicated antiviral therapy (cohort 1) and off-NUCs relapse (cohort 2) were also analyzed.
Results: The mean ages of cohort 1 and 2 were 53.4 and 58.9 years, respectively. 132 of 133 (99.2%) CHB patients were HBeAg-negative in cohort 1, and 13 of 45 (28.9%) CHB patients were HBeAg-positive in cohort 2. Hepatitis B virus DNA (HBV-DNA) and HBV-RNA were highly correlated ($r = 0.795$, $p < 0.001$), while qHBsAg and HBV-RNA were moderately correlated ($r = 0.485$, $p < 0.001$) in patients without antiviral therapy. During a median follow-up period of 37.8 months, 18 (13.6%) HBeAg-negative CHB patients in cohort 1 were eligible for NHI antiviral therapy. Baseline HBV-RNA ≥3 log (copies/mL) was associated with the risk of further antiviral therapy (HR = 2.910, $p = 0.047$). During a median follow-up of 21.2 months, 36 (80%) patients experienced virological relapse, and 31 (68.9%) patients experienced clinical relapse after discontinuation of NUCs in cohort 2. HBV-RNA ≥3 log at end of treatment (EOT) (HR = 2.258, $p = 0.025$) and off-treatment month 3 (HR = 2.227, $p = 0.021$), and HBcrAg ≥4 log (U/mL) at month 3 (HR = 2.558, $p = 0.009$) were associated with virological relapse. In contrast, HBcrAg ≥4 log at EOT (HR = 4.494, $p < 0.001$) and month 3 (HR = 9.349, $p < 0.001$) were factors associated with clinical relapse. The combination of HBV-RNA and HBcrAg levels significantly differentiated the risk of relapse after treatment, and the prognostic power of the prediction model at month 3 was better than that at EOT. Lastly, we found that kinetics changes in novel biomarkers after cessation of NUCs differed significantly between patients with or without off-treatment relapse.
Conclusion: HBV-RNA levels predict risk of NUCs initiation or relapse after treatment. The combination of HBV-RNA and HBcrAg can be used to identify patients who can safely discontinue NUCs therapy.

SAT-257

The correlation of P62 expression in predicting outcomes of HBV-related HCC after surgical resection

Chien-Wei Su[1], Chih-Li Chen[2], Jenny Yuh-Jin Liang[3], Jaw-Ching Wu[3]. *[1]Division of General Medicine, Department of Medicine, Taipei Veterans General Hospital, Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, School of Medicine, College of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan; [2]School of Medicine, College of Medicine, Fu Jen Catholic University, New Taipei, Taiwan; [3]Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, Division of Translation Research, Department of Medical Research, Taipei Veterans General Hospital, Taipei, Taiwan*
Email: jcwu@vghtpe.gov.tw

Background and aims: P62, an autophagy adaptor and signaling hub, plays a critical role in hepatic carcinogenesis in patients with chronic hepatitis B virus (HBV) infection. However, its prognostic significance in HBV-related hepatocellular carcinoma (HCC) remains unclear. This study aimed to assess the impact of P62 expression levels on outcomes, including overall survival (OS) and recurrence-free survival (RFS), in patients undergoing surgical resection for HBV-related HCC.
Method: This retrospective study included 150 patients with HBV-related HCC who underwent surgical resection, collected from the Taiwan Liver Cancer Network (TLCN). Baseline demographics, serum biochemistry and pathological data from hepatectomy specimens were analyzed. P62 expression levels were determined using immunohistochemistry (IHC) staining, with a cutoff of 40% cytoplasmic staining. Prognostic factors for OS and RFS were identified using Cox proportional hazards models, and Kaplan-Meier survival analyses were employed for group comparisons.
Results: Among the 61 patients with high P62 expression, liver cirrhosis in non-tumor specimens was significantly more prevalent compared to those with low P62 expression (45.9% vs. 25.8%, $P = 0.011$). After a median follow-up of 123.5 months (interquartile range: 64–150 months), 65 patients had died, and 92 experienced HCC recurrence. The 5-year OS rates were 91.9% for patients with low P62 expression versus 77.3% for those with high P62 expression ($P < 0.001$), confirmed by multivariate analysis (hazard ratio HR 4.191, 95% confidence interval CI: 1.737–10.115, $P = 0.001$). Similarly, the 5-year RFS rates were 65.8% for low P62 expression and 28.8% for high P62 expression ($P = 0.002$). Multivariate analysis identified high P62 expression as an independent predictor of recurrence (HR 2.717, 95% CI: 1.688–4.372, $P < 0.001$).
Conclusion: In HBV-related HCC patients, high P62 expression is associated with poorer outcomes, significantly impacting both OS and RFS following surgical resection. P62 may serve as a valuable prognostic biomarker for this patient population.

Efficacy and safety of Tenofovir Amibufenamide and Tenofovir Alafenamide in patients with hepatitis B cirrhosis: a retro-prospective observational study

Jun Chen[1], Xueyao Yang[1], Lihua Duan[1], Xuexuan Li[1], Shang Gao[1], Zebing Huang[1], Yan Huang[1]. *[1]Xiangya Hospital Central South University, Changsha, China*
Email: drhyan@csu.edu.cn

Background and aims: Tenofovir amibufenamide (TMF) has shown potent antiviral efficacy in randomized clinical studies for chronic hepatits B (CHB). However, its efficacy and safety profile in patients with hepatitis B virus (HBV)-related cirrhosis is not well-established. This study aimed to assess the effectiveness and safety of TMF in the real world and compared compare its outcomes with those of tenofovir alafenamide (TAF).
Method: In this retro-prospective study, TMF-treated patients with hepatitis B cirrhosis were divided into treatment-naive (TN) and treatment experienced (TE) groups with low-level viremia. Using the propensity score matching method (PSM), TAF-treated patients were enrolled. A total of 606 subjects meeting the inclusion criteria were divided into two groups: TMF group (n = 304) and TAF group (n = 302). The virologic response (VR, HBV DNA < 10 IU/mL) rate, alanine transaminase (ALT) normalization rate, liver stiffness measurement (LSM), renal function parameters and blood lipid profiles during 48 weeks of treatment were evaluated. The fibrosis 4 score was also calculated in both groups.

Results: At week 24 and week 48, the VR rates in the TMF group were 63.2% and 85.7% respectively, compared to 59.3% and 82.4% in the TAF group ($P > 0.05$). Similar VR rates were observed in both groups among TN and TE patients with low-level viremia. ALT normalization rates were 86.8% (264/304) in the TMF group and 84.1% (254/302) in the TAF group ($P = 0.26$). In the TAF group, total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels showed a slight increase ($P = 0.15$), which was not observed in the TMF group. Renal function parameters, including serum creatinine and estimated glomerular filtration rate, were no significant changes from baseline to week 48 in the two groups. LSM and fibrosis 4 score reduced significantly in both groups.
Conclusion: Both TMF and TAF have profound antiviral effectiveness and improvement of liver fibrosis among patients with hepatitis B cirrhosis. The effects on blood lipids are mild and regular monitoring of blood lipid profiles is recommended.

SAT-259

Long-term outcomes of 'Grey Zone' (GZ) individuals living with HBeAg-negative chronic hepatitis B in a tertiary UK centre

Evangelos Chalatsis[1], Apostolos Koffas[1,2], Almuthana Mohamed[1], Anna Riddell[3], Upkar Gill[1], Patrick Kennedy[1]. *[1]Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, QMUL, London, United Kingdom; [2]Centre for Digestive Diseases, Barts Health NHS Trust, London, United Kingdom; [3]Department of Virology, Barts Health NHS Trust, London, United Kingdom*
Email: e.chalatsis@nhs.net

Background and aims: Hepatitis B 'e' antigen (HBeAg) negative chronic infection is a well-defined hepatitis B disease phase. However, owing to the dynamic nature of chronic hepatitis B (CHB), the natural history of individuals considered to be in the 'Grey Zone' (GZ) is less clear. Given the recent changes in international (WHO and Chinese) treatment guidelines, we aimed to evaluate baseline characteristics and long-term outcomes in people living with hepatitis B (PLWHB) designated to be in the GZ and excluded from treatment based on historical guidelines (EASL 2017). We report our findings from a Tertiary UK Centre.
Method: All PLWHB with HBeAg-negative CHB who first visited our Centre between 2010 and 2019 were included, if they either had baseline HBV DNA between 2,000 IU/mL and 20,000 IU/ml, or >20,000 and ALT ≤2×ULN. Individuals with co-infection, hepatocellular carcinoma (HCC) at baseline, alcohol misuse, on immunosuppression, or only one clinic visit were excluded. GZ individuals were defined by baseline HBV DNA ≥2,000 IU/ml and ALT > ULN, or HBV DNA >20,000 IU/mL and ALT ≤2×ULN. Treatment was initiated as per 2017 EASL criteria: a) ALT>×2ULN ± HBV DNA >20,000 IU/mL, b) presence of advanced fibrosis or cirrhosis, or c) Age>30 and persistently high HBV DNA levels.
Results: Out of 4,233 PLWHB, 1,635 were HBeAg-negative treatment-naïve at baseline, of whom 172 (10.5%) were designated GZ. The median follow-up for GZ individuals was 4.3 years (1.8–6.8). They were predominantly female (54.1%), mainly of White (39%), Black (31%) or Asian (21%) ethnicity and an average age of 43 ± 8 (NB 164 with Age > 30). During the follow-up period, 28 (16.3%) were initiated on treatment due to cirrhosis (n = 7), advanced fibrosis (n = 2), ALT > ×2ULN and HBV DNA > 20,000 (n = 6) or persistently high HBV DNA (n = 13). GZ individuals who required treatment were older than their peers (48 vs 41 years, p < 0.0001), predominantly male (60.3% vs 42.4%) and primarily of White origin or ethnicity (43% vs 35%). They also had higher baseline ALT (32.75 vs 26.9 u/L, p = 0.03) and liver stiffness measurement (7.3 vs 5.6 kPa, p = 0.002). Their HBV DNA level was also higher at baseline, but did not reach statistical significance (10,500 vs 5099 IU/mL, p = 0.39).
Conclusion: Some PLWHB designated as GZ are at risk of disease progression and are likely to require treatment. They share some distinguishing demographic and laboratory characteristics. These individuals can benefit from earlier treatment initiation to mitigate the risk of liver-related complications. Further prospective studies are deemed necessary to confirm these findings.

Background and aims: Chronic liver disease induced by hepatitis D virus (HDV) infection is associated with autoimmune manifestations. We aimed to investigate the prevalence of autoantibodies (auto-ab) and their association with clinical and virologic features in patients with chronic HDV infection.
Method: We studied 494 patients with chronic HDV infection from the HDV Describe study cohort. Non-organ-specific auto-ab (e.g., anti-nuclear auto-ab [ANA], anti-smooth muscle auto-ab [ASMA], anti-mitochondrial auto-ab [AMA], and anti-liver-kidney microsomal auto-ab [LKM]) were tested in diluted serum samples (1:80) by indirect immunofluorescence (IIF) on rat kidney/stomach/liver tissue slides (Euroimmun, Germany). Selected serum samples were analysed by immunoblot (IB) (Euroimmun, Germany) to detect antigen-specific auto-ab.
Results: The prevalence of ANA, ASMA, AMA, and LKM by IIF was 9.9% (n = 49), 12.3% (n = 61), 2.0% (n = 10), and 1.8% (n = 9), respectively. Among LKM+ patients, only one patient was LKM-1+ at IB. A high proportion of patients had anti-brush border auto-ab (n = 99; 20.0%); 9 patients were anti-parietal cells auto-ab+, 1 was anti-reticulin auto-ab+, and 1 was anti-lysosome auto-ab+. Patients who underwent previous interferon-based treatment showed a higher prevalence of ANA+ (14.6% vs. 8.3%; p = 0.046). ASMA+ was associated with liver cirrhosis (OR = 2.00, 1.08–3.70) and HDV RNA > 3 Log IU/mL (OR = 1.91, 1.03–3.52), whereas no association was observed between ASMA + and ALT > 40 U/L (OR = 1.12, 0.65–1.93). At multivariate analysis, ASMA+ results were significantly associated with liver cirrhosis (OR = 1.89, 1.01–3.51) independently from HDV RNA (OR = 1.57, 1.01–2.42) and ALT (OR = 1.22, 0.79–1.87).
Conclusion: In patients with chronic HDV infection, non-organ-specific auto-abs are often detected as epiphenomena of chronic viral infection. The assessment of circulating auto-ab might help to identify patients with high HDV replication and advanced liver disease. This research was supported by Gilead Sciences, Inc (study ID: IN-IT-980-6382).

Field evaluation of a novel hepatitis B core-related antigen rapid test (HBcrAg-RDT) for the identification of highly viremic pregnant women, the Gambia: preliminary results from a prospective diagnostic accuracy study

Erwan Vo Quang[1], Gibril Ndow[1], Sainabou Drammeh[1], Bakary Dibba[1], Alice N. Guingané[2], Lauren Perieres[3], Yasuhito Tanaka[4], Sylvie Boyer[5], Dramane Kania[6], Maud Lemoine[1], Yusuke Shimakawa[7]. *[1]Medical Research Council Unit The Gambia, London School of Hygiene & Tropical Medicine, Banjul, Gambia; [2]Hepato-Gastroenterology Department, Bogodogo University Hospital Center, Ouagadougou, Burkina Faso; [3]Aix Marseille Univ, INSERM, IRD, SESSTIM, Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale, Marseille, France; [4]Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan; [5]a, Marseille, France; [6]Programme de Recherche sur les Maladies Infectieuses, Centre Muraz, Institut National de Santé Publique, Bobo-Dioulasso, Burkina Faso; [7]Unité d'Épidémiologie des Maladies Émergentes, Institut Pasteur, Paris, France*
Email: erwan.voquang@gmail.com

Background and aims: Mother-to-child transmission (MTCT) represents the main route of transmission of hepatitis B virus (HBV) and identification of highly viremic pregnant women (HBV DNA level ≥200,000 IU/mL) for peripartum antiviral prophylaxis remains challenging in sub-Saharan Africa (SSA). We evaluated the performance of a novel RDT for hepatitis B core-related antigen (HBcrAg-RDT) using capillary blood and plasma to identify HBsAg-positive pregnant women with high viral loads in The Gambia.
Method: We prospectively recruited pregnant women at four health facilities in The Gambia during their first antenatal visit. We tested a total of 116 HBsAg-positive pregnant for the index serological tests (HBcrAg-RDT using capillary blood and plasma) and the reference molecular test (PCR, Xpert HBV Viral Load, Cepheid, using plasma). Our primary outcomes were the sensitivity and specificity of the HBcrAg-RDT using either capillary blood or using plasma at the laboratory to detect pregnant women with viral loads ≥200,000 IU/mL, quantified by RT-PCR (Xpert) as a reference.
Results: From March 18, 2024, to October 21, 2024, 116 treatment-naive HBV-infected pregnant women were enrolled in this study. Participants had a median age of 30 years (IQR 25–34), median HBV DNA of 100 IU/mL (10–1,445), 8/116 (6.9%) of participants with a high viral load. The sensitivity and specificity of the HBcrAg RDT using capillary blood and plasma were 0.88 (95% CI: 0.53–0.98) & 0.99 (0.94–1.00), and 0.88 (0.53–0.98) & 0.97 (0.92–0.99), respectively.
Conclusion: The HBcrAg RDT showed high diagnostic performance to identify pregnant women at risk of HBV MTCT who should receive peripartum antiviral prophylaxis. This could be a valuable tool for identifying high-risk pregnant women in decentralized antenatal care settings in resource-limited countries.

The asymmetry of the liver and spleen stiffness measures between patients with chronic hepatitis B and D reflects clinic-pathologic differences

Francesco Damone[1], Piero Colombatto[1], Andrea Pinna[1], Gabriele Ricco[1], Daniela Cavallone[1], Giovanni Petralli[1], Barbara Coco[1], Lidia Surace, Veronica Romagnoli[1], Filippo Oliveri, Ferruccio Bonino[2],

Maurizia Brunetto[1,2,3]. [1]*Hepatology Unit, Pisa University Hospital, Pisa, Italy;* [2]*Institute of Biostructure and Bioimagin, National Research Council, Naples, Italy;* [3]*Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy*
Email: maurizia.brunetto@unipi.it

Background and aims: Chronic Hepatits D (CHD) infection causes an additional pathologic burden in patients (pts) with chronic Hepatitis B Virus (CHB) infection that accounts worsening clinical outcome. We studied the relative differences in liver (LSM) and spleen stiffness measurements (SSM) in pts with CHB and CHD, in order to point out potential added values of the SSM in this clinical setting.
Method: We studied 119 HBsAg+ pts, 71 CHB and 48 CHD undergoing regular follow-up at the Hepatology Unit of Pisa University Hospital. Physical examination, ultrasound scan, LSM and SSM (FibroScan®, Echosens,France) were performed on the same day, liver biochemistry and virological assays within one week.
Results: CHD pts were younger (median age: 47.8 vs 58.9 years, $p < 0.001$), with higher prevalence of female gender (43.8% vs 23.9%, $p = 0.038$) and mostly non-italian native (62.5% vs 26.8%, $p < 0.001$). Cirrhosis prevalence was similar between CHB and CHD pts [30 (42.3%) vs 27 (56.3%), $p = 0.189$]. CHD pts showed higher median HBsAg serum levels (3.65 vs 2.61 log UI/ml, $p < 0.001$), AST (28 vs 24 U/L, $p = 0.014$) and ALT (27 VS 19 U/L, $p = 0.001$). Median LSM was lower in CHB than in CHD pts [6.2 (2.8–71) vs 8.1 (2.8–33.1) kPa ($p = 0.004$)], whereas SSM was similar [25.6 (9.3–87.6) vs 26.8 (4.8–100) kPa, ($p = 0.569$)]; accordingly, median SSM/LSM-ratio was lower in CHD than in CHB [2.98 (1.00–9.64) vs 3.88 (1.09–16.25), $p = 0.003$). Median spleen diameter (SD) was 11.0 (7.0–18.0) cm in CHB and 12.0 (6.5–23.0) cm in CHD ($p = 0.079$). CHD showed a significantly lower SD/LSM ratio [1.33 (0.36–3.89) vs 1.78 (0.21–4.08), $p = 0.007$], but similar SD/SSM ratio [0.44 (0.14–2.06) vs 0.43 (0.14–1.07), $p = 0.688$]. Also in cirrhotic pts, median LSM was significantly lower in CHB than in CHD [9.7 (3.7–71) vs 13.3 (5.6–33.1) kPa, $p = 0.022$], whereas SSM was similar [34.0 (9.9–87.6) vs 33.3 (14.5–100) kPa, $p = 0.842$]. The SD/LSM ratio showed a trend to be lower in cirrhotic CHD [0.92 (0.36–2.09) vs 1.20 (0.21–2.89); $p = 0.054$]. In CHD, as compared to CHB pts, SSM correlated better with LSM, overall ($\rho = 0.761$ vs $\rho = 0.465$) and in cirrhotics ($\rho = 0.799$ vs $\rho = 0.432$); with SD overall ($\rho = 0.643$ vs $\rho = 0.489$) and in cirrhotics ($\rho = 0.647$ vs $\rho = 0.524$) and with platelets count overall ($\rho = -0.617$ vs $\rho = -0.498$) and in cirrhotics ($\rho = -0.726$ vs $\rho = -0.638$).
Conclusion: Combining LSM and SMM provides a useful differential clinic pathologic characterization of liver disease in patients with CHB and CHD. The significantly lower SD/LSM ratio found in CHD pts, suggests the specific role of HDV induced necro-inflammation as a driver of disease progression with splenomegaly and platelet count reduction. Longer follow up in CHD treated patients are needed to define the curative impact of the current antivirals.

Background and aims: Hepatitis delta virus (HDV) is responsible for the most severe form of chronic viral hepatitis due to its rapid progression to liver fibrosis, cirrhosis, and hepatocellular carcinoma. The Delta Double Reflex (DDR) Spain study seeks to implement a double reflex diagnostic strategy for HDV, evaluate the seroprevalence and prevalence of chronic HDV infection, and characterize the virological, clinical, and demographic features of HDV in Spain.
Method: This multicenter, national study follows an ambispective and observational design, comprising a retrospective evaluation of DDR implementation during 2022–2023 and a prospective phase starting in 2024 to examine the virological, clinical, and demographic characteristics of diagnosed patients. The study examined the diagnostic cascade, from identifying HBsAg-positive individuals to confirming HDV-RNA positivity
Results: The cohort included 41,449 HBsAg-positive patients from 69 centers across 16 of 17 Autonomous Communities (ACs) of Spain. Reflex testing rates increased significantly from 55.1% in 2022 (participation range: 4.2%–98.7%) to 64.8% in 2023 (25%–100%; $p < 0.0001$). The anti-HDV seroprevalence declined from 5.6% (95%CI 5.2–6.1) in 2022 to 4.9% (95%CI 4.6–5.3) in 2023, with significant inter-regional variability. Testing for HDV-RNA among anti-HDV-positive individuals improved from 72.6% in 2022 to 90.8% in 2023 ($p < 0.0001$). The prevalence of chronic active HDV infection decreased from 40.2% (95%CI 35.5–45.1) in 2022 to 31.6% (95%CI 28.0–35.3) in 2023. Starting in the third quarter of 2024, the prospective phase had enrolled 87 anti-HDV-positive patients with a median age of 53 years (IQR 42–58), 59% being male and 54% of Spanish origin. Co-infection rates included 20% for HIV and 21% for HCV (2 with active hepatitis C). Elevated fibrosis markers were observed in 22% of patients with FIB-4 > 2.67, and 16.9% presented APRI > 1.5. Active HDV-RNA was detected in 37% (n = 32) of cases, with a median viral load of 4.17 log IU/mL (IQR 3.18–5.10).
Conclusion: This study, the largest of its kind in Spain, underscores significant disparities in HDV diagnostic practices across ACs. These findings highlight the urgent need for nationwide efforts to standardize diagnostic protocols, enhance professional education, and promote awareness to ensure equitable care and better outcomes for HDV patients.

New strategies to enhance molecular diagnosis of hepatitis Delta

Marta Illescas-López[1,2], Lucía Pérez-Rodríguez[1,2], Ana Alberola Romano[1], Adolfo de Salazar[1,2,3], Federico García[1,2,3].
[1]Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Instituto de Investigación Biosanitaria Ibs.Granada, Granada, Spain; [3]Centro de Investigación Biomédica en Red en Enfermedades Infecciosas (CIBERINFEC), ISCIII, Madrid, Spain
Email: martaille96@gmail.com

Background and aims: Hepatitis delta virus (HDV) aggravates chronic hepatitis B virus (HBV) infection, accelerating progression to liver failure, cirrhosis or hepatocarcinoma. While 5–10% of HBV patients are estimated to have HDV co-infection, the true prevalence is likely underestimated. Accurate detection and quantification of ribonucleic acid (RNA) of HDV are crucial for the effective management of chronic HDV hepatitis. However, variability of commercial assays or viral genotype may affect the accuracy of results. Unlike other RNA viruses, HDV RNA exhibits unique folding and supercoiling characteristics. The aim of our study was to assess the impact of pre-heating on RNA elution for the detection of HDV.
Method: We conducted a retrospective study for HDV RNA detection and quantification. Genetic material was extracted from 300 microlitres of serum using the TANBead Maelstrom 4800 system, with a final elution volume of 60 microlitres. A 10 microlitres aliquot of the eluate underwent thermal-shock, consisting of heating at 95°C for 10 minutes followed by freezing at −20°C for another 10 minutes, as per the manufacturer's instructions. Both heat-treated and untreated aliquots were analysed in parallel using the Hepatitis Delta Realtime PCR kit (Vircell SL, Granada) on a BioRad CFX96 thermal cycler.
Results: We analysed 118 serum samples, 49 were negative and 69 positive, with a 97.5 % qualitative agreement between results obtained with and without pre-treatment. Pre-heating enabled detection of viraemias above the detection limit (24 international units per mililitre [IU/ml], 43 UI/ml and 118 IU/ml) in three samples initially reported as negative. Among positive samples, pre-heating increased viraemia by at least one logarithm in 74 % (51/69) of cases. Changes by log level, compared to quantification without pre-heating, were as follows: a) Log 6: 2/5 increased by one log a) Log 5: 5/7 increases by one log; b) Log 4: 9/18 increased by one log, 4/18 by two logs; c) Log 3: 7/16 increased by one log, 4/16 by two logs; d) Log 2: 6/14 increased by one log, 5/14 by two logs; e) Log 1: 2/3 increased by one log. Notably, only five positive samples showed no log increase after pre-heating.
Conclusion: Our findings demonstrate that pre-heating enhances HDV-RNA detection and quantification. This strategy could improve the diagnosis and monitoring of patients co-infected with HDV and HBV.

Background and aims: Currently, eight distinct genotypes of HDV have been identified, each encompassing multiple subgenotypes. Genotype 1 (G1) is the most widely distributed worldwide, with genotype 5 (G5) following in prevalence. Investigating the molecular epidemiology of HDV is crucial for understanding its pathogenic potential, implications for treatment strategies, and diagnostic challenges, as RNA detection methods may vary in their effectiveness across genotypes. This research focused on examining the molecular epidemiology of HDV in Spain through whole-genome sequencing (WGS).

Method: A retrospective observational study was carried out between August 2019 and November 2024, focusing on patients with confirmed HDV RNA positivity. Genotyping was performed using WGS, employing overlapping primers and Illumina's tagmentation-indexing protocol on a NextSeq 1000 platform. Sequence assembly was performed using the CLC Genomics Workbench, referencing the HDVdb database for genotype determination. Phylogenetic relationships were inferred using the Neighbor-Joining method in the MEGA software. Sequences with > 90% coverage were included in the analysis alongside reference sequences representing all eight recognized genotypes and their subgenotypes. Potential recombination events were assessed using the RDP5.63 software.

Results: A total of 122 patients were analyzed, of whom 66 (54.1%) were of Spanish origin. The median HDV RNA level was Log 4.91 (IQR: 3.74–6.17). Genotyping was successful in 112 cases (91.8%) with an average sequence coverage of 98% (range: 70%–100%). G1 was the most frequent (101 cases, 90.2%), followed by G5 (10 cases, 8.9%), exclusively identified in patients of West African origin. One case (0.9%) belonged to genotype 7. Genotyping failed in 10 samples due to either non-amplification (3 cases) or insufficient coverage (7 cases). Phylogenetic analysis was performed on 110 sequences with >90% coverage. Within G1, subgenotype 1d represented 87.1% of cases, while subgenotype 5b accounted for 60% of G5 cases. None of the 112 sequences displayed evidence of recombination.

Conclusion: HDV genotyping provides critical insights into its molecular epidemiology within Spain. Consistent with previous studies, G1 is the most prevalent among Spanish patients, while G5 is exclusively linked to individuals of West African descent. These findings offer valuable data on the distribution of HDV genotypes and their regional variability.

Email: gianpaolo.caviglia@unito.it

Background and aims: Migratory flows are reconstituting the hepatitis D virus (HDV) reservoir in Italy, displacing the infection in Italians. We aimed to compare the features of contemporary Chronic Hepatitis D (CHD) in native Italians and foreign-born patients.
Method: Consecutive hepatitis B surface antigen (HBsAg) carriers positive for antibodies to HDV (anti-HDV) referred to 32 Italian Centres, were prospectively enrolled from 08/2022 to 07/2024. Sera were centralized in Torino for virologic assessment.
Results: Overall, 432 of 515 (83.9%) patients were HDV-RNA-positive (4.39, IQR 1.30–5.82 Log IU/mL; 99.0% HDV genotype-1). HDV-RNA levels correlated with ALT (rs = 0.58, 0.51–0.63) and liver stiffness (rs = 0.28, 0.19–0.37). The 317 native Italians (61%) were older than the 198 foreign-born patients (39%) (median age 60, IQR 55–65 vs 46, IQR 39–54 years; $p < 0.001$), most likely males (68.1% vs 49.5%; $p < 0.001$), and exhibited a higher prevalence of liver cirrhosis (70.3% vs. 50.5%; $p < 0.001$) and hepatocellular carcinoma (14.8% vs. 0.5%; $p < 0.001$). Most (70.3%) of the ageing native Italians had liver cirrhosis acquired long ago. However, 29.7% (94/317) had no cirrhosis: their features denoted an active and viremic CHD in 44.7% (42/94) and an inactive/minimal disease with low viremia (<3 Log) in 55.3% (52/94), presumably acquired as a slow infection decades before. Despite the younger age, foreign-born patients already exhibited a 50.5% rate (100/198) of symptom-free compensated cirrhosis (median albumin: 4.1, IQR 3.8–4.4 g/dL); in the other 45.5% (98/198), 50 (51.0%) had an active CHD and 48 (49.0%) an inactive/mild infection with low viremia (<3 Log).
Conclusion: In Italy, the current scenario of chronic HDV infection is more heterogeneous than expected, changing the perspective of CHD as a most severe disease; about a quarter of native Italians and foreign-born patients had a lingering less virulent CHD, and half of foreign-born patients presented with recently acquired liver cirrhosis, which was compatible with a stable clinical condition. This research was supported by Gilead Sciences, Inc (study ID: IN-IT-980-6382).

SAT-271

Impact of drugs for hepatocellular carcinoma development in chronic hepatitis B patients who treated with entecavir and tenofovir disoproxil as initial therapy: population-based study

Tae Hyung Kim[1], Hyung Joon Yim[2], Seong Hee Kang[2], Sun Young Yim[1], Young-Sun Lee[3], Young Kul Jung[2], Yeon Seok Seo[1], Ji Hoon Kim[3], Jong Eun Yeon[3], Kwan Soo Byun[3]. *[1]Korea University Anam Hospital, Seoul, Korea, Rep. of South; [2]Korea University Ansan Hospital, Ansan-si, Korea, Rep. of South; [3]Korea University Guro Hospital, Seoul, Korea, Rep. of South*
Email: gudwns21@korea.ac.kr

Background and aims: Entecavir (ETV) and Tenofovir disoproxil fumarate (TDF) have been used as the first-line antiviral agents for patients with treatment-naive chronic hepatitis B (CHB), resulting in successful decline of hepatocellular carcinoma (HCC) development and mortality. However, there has been controversy about the equivalence of long-term efficacies between ETV and TDF. In addition to antiviral agents, other drugs including aspirin, statin, and H1-antihistamines had protective effects on HCC development in several studies. Thus, we aimed to compare these effects of diverse drugs in a unified population-based cohort.
Method: Using the Korean National Health Insurance Service database, we extracted a nationwide population cohort of patients with CHB who initiated ETV or TDF between January 2012 and December 2020. Then, a 15,569 pair propensity score-matched cohort was constructed. We compared cumulative incidence rates of HCC and mortality one year after starting treatment according to the drug prescription and dosage, using competing risk analyses.

Results: The incidence of HCC was 51.0 and 41.5 per 1000 person-years in the ETV and TDF groups of a total cohort. In the matched cohort, HCC development was significantly lower in the TDF group than ETV group (subdistribution hazard ratio [SHR], 0.91). In addition, the use of statin and H1-antihistamines was significantly associated with a low risk of HCC development (SHR, 0.57 and 0.69, respectively). Even after applying antiviral groups, the low risks of statin and H1-antihistamines independently remained (SHR, 0.58 and 0.69, respectively). Furthermore, H1-antihistamines use had a dose-response relationship with the risk of HCC. The SHR of the H1-antihistamines use of 28–90, 90–180, and > 180 cumulative defined daily doses were 0.48, 0.31, and 0.29, respectively, relative to no H1-antihistamines use.
Conclusion: In this study, TDF showed a more protective effect on HCC development compared to ETV. In addition, the use of statin and H1-antihistamines was independently associated with a lower risk of HCC development relative to no use of each drug. The effects of various drugs on the development of HCC were confirmed, and further research is needed on these mechanisms.

Comparing Tenofovir Alafenamide and Tenofovir Disoproxil Fumarate in reducing hepatocellular carcinoma risk in chronic hepatitis B: a propensity score matching study

Seong Hee Kang[1], Hyung Joon Yim[1], Young Kul Jung[2], Sun Young Yim[1], Young-Sun Lee[1], Yeon Seok Seo[1], Ji Hoon Kim[1], Jong Eun Yeon[3]. [1]*Korea University College of Medicine, Seoul, Korea, Rep. of South;* [2]*Korea University College of MEdicine, Seoul, Korea, Rep. of South;* [3]*Korea University College of Medicine, Seoul, Korea, Rep. of South*
Email: gudwns21@korea.ac.kr

Background and aims: Tenofovir alafenamide (TAF) and tenofovir disoproxil fumarate (TDF) are both recommended as first-line treatments for antiviral-naïve patients with chronic hepatitis B (CHB). However, it remains controversial which drug is more effective in preventing hepatocellular carcinoma (HCC). We aimed to compare the effects of TAF and TDF on HCC risk.
Method: We included 1,628 treatment-naïve CHB patients who underwent antiviral therapy with either a TAF-based regimen (TAF group: n = 335) or TDF only (TDF group: n = 1,293) between 2007 and 2021. The TAF group consisted of patients who received TAF as a first-line treatment and those who switched from TDF to TAF. Propensity score (PS) matching was used to reduce the effects of confounding factors.
Results: After PS matching, we analyzed data from 334 patients in the TAF group (mean age: 48.0 ± 11.7 years; 192 men [57.5%]) and 573 patients in the TDF group (mean age: 47.4 ± 11.6 years; 326 men [56.9%]). During a 60-month follow-up, 8 patients in the TAF group (2.4%) and 46 patients in the TDF group (8.0%) developed HCC. TAF treatment was associated with a significantly lower risk of HCC compared to TDF (hazard ratio [HR], 0.34; 95% confidence interval [CI], 0.16–0.72; P < 0.001). In multivariate analysis, factors independently associated with HCC development included age (adjusted HR [aHR], 1.07; P < 0.001), liver cirrhosis (aHR, 2.02; P = 0.045), diabetes (aHR, 4.78; P < 0.001), alcohol use (aHR, 3.07; P = 0.002), and TAF treatment (aHR, 0.22; P < 0.001).
Conclusion: TAF treatment was associated with a 66% lower risk of HCC compared to TDF treatment. Further studies with larger sample sizes and longer follow-up periods are needed to confirm these findings.

SAT-273

Characteristics and predictors for elevated alanine transferase in 3,399 treatment-naïve HBV/HDV co-infected patients, with comparison to propensity score-matched mono-HBV infected patients

Habiba Kamal[1], Ganbolor Jargalsaikhan[2], Sanjaasuren Enkhtaivan[3], Karin Lindahl[4], Daniel Bruce[5], Hannes Hagström[4], Michael Ingre[4], Naranjargal Dashdorj[6], Soo Aleman[4]. [1]*Karolinksa Institutet, Stockholm, Sweden;* [2]*Liver Center Mongolia, ULaanbaatar, Mongolia;* [3]*Liver Center Mongolia, Ulaanbaatar, Mongolia;* [4]*Karolinska Institutet, Stockholm, Sweden;* [5]*Cytel Stockholm, Stockholm, Sweden;* [6]*Liver Center Mongolia, ULaanbattar, Mongolia*
Email: habiba.khodir@ki.se

Background and aims: Chronic HDV infection causes the most severe form of viral hepatitis. However, knowledge regarding the characteristics and predictors of elevated alanine aminotransferase (ALT) in treatment-naïve patients with HBV/HDV co-infection is limited, and data on young adults are lacking. This large cohort study aimed to (1) characterize ALT levels, virological, and fibrosis parameters in treatment-naïve patients with HBV/HDV co-infection (2) identify predictors of elevated ALT, and (3) compare these parameters in propensity score-matched pairs of HBV/HDV co-infected and mono-HBV infected patients, to elucidate the impact of HDV.
Method: We analyzed 51,113 individuals who underwent HBsAg testing at the Liver Center, Mongolia, between 2015–2023, using data from an electronical database. Persons with prior hepatocellular carcinoma, HCV or HIV co-infection, or previous anti-HDV/HBV therapy were excluded. HBsAg+ patients were categorized into two cohorts based on virological parameters: 1) HDV infection, if serum HDV RNA level ≥50 IU/mL (n = 3,399), and 2) mono-HBV infection, if negative anti-HDV or HDV RNA test, and no record of anti-HDV or HDV RNA positivity (n = 2,556). Pairwise comparisons were conducted using Spearman correlation coefficient (rho). Univariable and multivariable logistic regression analyses were conducted to identify predictors for elevated ALT. Propensity score matching for sex, age and HBsAg test date resulted in 2,231 matched pairs of HBV/HDV co-infected and mono-HBV infected patients, with odds ratio (OR, 95% CI) calculated for risk of ALT elevation.
Results: Among 3,399 patients with HDV infection, elevation of ALT levels was seen in 78.5% of patients, with the highest frequency in the 18–29 years age group (n = 340, 84%). This age group displayed 4.80-odds for elevated ALT, 2.76-odds of elevated GGT, and 5.08-odds of cirrhosis, compared to matched mono-HBV infected patients (all p < 0.05). The proportion of elevated ALT increased with higher fibrosis stages, with 93% displaying elevated ALT among those with liver stiffness measurements (LSM) ≥ 15.2 kPa. ALT levels correlated weakly with HDV RNA (rho = 0,23; p < 0.001) and LSM levels (rho = 0,37, p < 0.001), moderately with GGT levels (rho = 0.48, p < 0.001), while no correlation with HBV DNA or HBsAg levels in HBV/HDV co-patients. In multivariable analysis, significant predictors of elevated ALT were age <30 years, elevated GGT level and HDV RNA ≥100,000 IU/mL.
Conclusion: In this large cohort of patients with HDV infection, hepatic necro-inflammatory process, as indicated by elevated ALT and GGT levels, was significantly more frequent and severe already in patients under 30 years compared to matched mono-HBV infected patients. These findings underscore the urgent need for early antiviral intervention in HDV infection to prevent severe disease progression and reduce the risk of hepatocellular carcinoma.

SAT-274

Enhanced 2- and 3-Year recurrence-free survival rates with switching from Entecavir to Tenofovir post-radiofrequency ablation treatment in HBV-HCC patients

Jing Liang[1], Xue Zhang[1], Baiguo Xu[1]. [1]*Tianjin Third Central Hospital, Tianjin, China*
Email: haolele77@sina.com

Background and aims: Antiviral therapy for hepatitis B virus (HBV) is crucial for reducing the recurrence rate following curative treatment of HBV-related hepatocellular carcinoma (HCC). There remains controversy regarding whether nucleoside analogs (NAs) and nucleotide analogs (NtAs) differ in their efficacy in preventing HCC recurrence after radiofrequency ablation (RFA). This retrospective

study aimed to compare the 3-year recurrence-free survival (RFS) rates among HBV-related HCC patients who switched from entecavir (ETV) to tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF) after RFA with those who continued long-term ETV therapy.
Method: This study consecutively enrolled patients with hepatitis B cirrhosis and newly diagnosed HCC at Tianjin Third Central Hospital between August 2018 and December 2020. All patients had received more than one year of ETV treatment before the diagnosis of HCC. We observed the 3-year HCC recurrence rate in patients who switched to NtAs (TDF or TAF) post-RFA and compared it with those who remained on long-term ETV therapy. Propensity score matching (PSM) was used to balance confounding variables, including age, sex, tumor stage, Child-Pugh classification, and alanine transaminase (ALT) levels, and 3-year survival curves were plotted.
Results: A total of 270 patients with initially diagnosed HBV-related HCC were included in this study. Among them, 203 patients who underwent RFA for HCC were divided into two groups based on the type of oral antiviral medication post-RFA: the ETV group (n = 152) and the switch therapy group (from ETV to TDF or TAF, n = 47). The 1-, 2-, and 3-year RFS rates were 71.05% vs 85.11% (P = 0.054), 44.08% vs 80.85% (P < 0.01), and 39.47% vs 72.34% (P < 0.01) for the ETV and switch therapy groups, respectively. After propensity score matching, the switch therapy group showed significantly lower HCC recurrence rates at 2 years (hazard ratio [HR] 0.298, 95% confidence interval [CI] 0.140–0.635, P = 0.003) and 3 years (HR 0.366, 95% CI 0.182–0.735, P = 0.006) compared to the ETV group, although no significant difference was observed at 1 year.
Conclusion: In HBV-HCC patients after RFA treatment, switching from ETV to NtAs (TDF or TAF) results in higher 2- and 3-year RFS rates compared to continuous NA therapy, indicating that NtAs may be superior to NAs in reducing the recurrence rate following curative treatment of HBV-related HCC.

SAT-275-YI
Likelihood level of a functional HBV-specific CD8 cell response upon discontinuation of eAg(-) chronic hepatitis B treatment correlates with long-term clinical outcome
Henar Calvo Sánchez[1,2,3], Raquel Encijo[1], Julia Peña Asensio[1], Rocío López[1,4], Alberto Delgado[1], Joaquín Míquel[1,2], Alejandro González Praetorius, Miguel Torralba[1,3,5], Juan Ramón Larrubia[1,2,3]. *[1]Translational Research Group on Cellular Immunology (GITIC), IDISCAM., Guadalajara, Spain; [2]Department of Gastroenterology, University Hospital of Guadalajara, Guadalajara, Spain; [3]Department of Medicine and Medical Specialties, University of Alcalá, Alcalá de Henares, Spain; [4]Immunology Unit, University Hospital of Guadalajara., Guadalajara, Spain; [5]Department of Internal Medicine, University Hospital of Guadalajara, Guadalajara, Spain*
Email: juan.larrubia@uah.es

Background and aims: There are not clear predictors of HBV control after nucleos(t)ide analogue (NA) withdrawal in e-antigen negative chronic hepatitis B (CHBe(-)). A logistic regression model (LRM) predicting the likelihood of functional HBV-specific CD8 cell response upon NA stop (Peña-Asensio, Aliment Pharm Therap 2022) could help select cases able to control HBV off-treatment. The aim of this study was to test the validity of this LRM regarding to this issue.
Method: 27 Caucasian CHBe(-) patients (64% male, Age 47 ± 11 years) with liver fibrosis <F3 were chosen to stop NA at Guadalajara University Hospital (Spain). Patients were followed for 60 months or until retreatment or functional cure. Treatment was restarted if patient developed virologic flare (ALT > 5 upper limit of normal plus HBsAg level increase) or HBV DNA > 10000 IU/ml on 3 occasions or if HBV DNA was between 2000 and 10000 IU/ml plus age >50 years and/or transient elastography >9 kPa. Patients were followed monthly for first six months and every three months thereafter. ALT, HBV DNA and HBsAg levels were tested at each appointment. Patients were split into two groups according to LRM probability (P < 0.7 & P ≥ 0.7) based on the following predictors: treatment duration, age at treatment start, HBsAg level, patient age. Repeated measures ANOVA was used to compare HBsAg decline between both cohorts. Generalized linear regression with Poisson distribution was used to compare HBV DNA events >10000 IU/ml between both groups. Kaplan-Meier curves were used to compare retreatment-free survival between both cohorts. Speed of HBsAg change was calculated by the tangent of the slope angle of HBsAg curve. In 13 HLA-A2+ cases, at treatment stop, HBV-specific CD8 cell expansion was tested after 10day HBV-core/HBV-polymerase (pol) peptide in-vitro challenge. Functional cure rate was compared between groups.
Results: HBsAg level decline was 7-fold faster in P ≥ 0.7 group (p < 0.001). HBV DNA > 10000 IU/ml incidence rate ratio was 66% lower in P ≥ 0.07 group (p = 0.034). 1/13 patients in P ≥ 0.7 group and 7/14 in P < 0.7 cohort received retreatment with significantly different Kaplan-Meier survival curves, with a 50% increase in retreatment-free survival in P ≥ 0.7 group (p = 0.019). Functional cure was achieved in 4 cases in P ≥ 0.07 group and no case in P < 0.07 cohort (p = 0.027). No patient experienced liver failure, and all retreated patients achieved negative HBV DNA after NA restart. 100% of P ≥ 0.07 and 28% of P < 0.07 HLA-A2+ patients had expanding HBV-specific CD8 cells after HBVcore/HBVpol stimulation at treatment stop (p = 0.011).
Conclusion: In CHBe(-), a high probability of functional HBV-specific CD8 cell response at the time of NA withdrawal correlates with faster HBsAg decline, lower incidence of HBV DNA > 10.000 IU/ml, low risk of retreatment, presence of a reactive HBV-specific CD8 response and higher rate of functional cure after 60-month follow-up.

SAT-276
Investigation the persistent effects following HBsAg clearance in chronic hepatitis B patients treated with Interferon therapy
Huiling Xiang[1], Qing Ye[1], Tao Wang[1], Fei Tang[1], Fei Yan[2], Jing Chen[2]. *[1]Department of Gastroenterology and Hepatology, Tianjin Third Central Hospital, Tianjin, China; [2]The Third Central Clinical College of Tianjin Medical University, Tianjin, China*
Email: huilingxiang@163.com

Background and aims: The clinical cure regimen for chronic hepatitis B (CHB) based on interferon therapy is increasingly attracting the attention of clinicians; however, there are few studies on the sustained response of HBsAg after achieving HBsAg clearence. This study investigates the persistent effects following HBsAg clearance in CHB patients treated with Peg-IFNα-2b treatment, aim to explore the sustained viral response after HBsAg clearance.
Method: CHB patients who received Peg-IFNα-2b alone or in combination with nucleos(t)ide analogues (NAs) and achieved HBsAg clearance at Tianjin Third Central Hospital from January 2018 to May 2024 were collected. Regular follow-ups were conducted to observe the dynamic changes of HBsAg. The time of HBsAg recurrence (HBsAg > 0.05 IU/mL) was recorded, the pattern of HBsAg recurrence was analyzed, and the optimal timing for sustained HBsAg clearance was explored.
Results: A total of 173 patients with chronic hepatitis B or compensated cirrhosis were included. The average age was 41.5 ± 9.0 years, with 16.28% with compensatory cirrhosis. The median follow-up duration was 89.3 weeks, with HBsAg recurrence in 26 patients, yielding a recurrence rate of 15.03% (26/173). Of the 26 patients who recurred, 50% (13/26) occurred within 24 weeks, and 80.77% within 48 weeks, with a gradual decrease in recurrence after 48 weeks. The sustained viral response (SVR) rate at 48 weeks was 95.45%, and it stabilized at 100% at 120 weeks and beyond. For patients with regular re-examinations, no recurrence was observed after 72 weeks. At the time of HBsAg recurrence detection, ALT, AST, and TBiL were normal in all 26 patients, with a median HBsAg level of 0.70 IU/mL (0.05 IU/mL–8.13 IU/mL), and only one case was accompanied by low-level positivity for HBV-DNA (117 IU/ml). No adverse events such as liver failure, decompensated cirrhosis, or hepatocellular carcinoma occurred during the follow-up period

Conclusion: CHB patients have good durability after achieving HBsAg clearance with Peg-IFNα-2b treatment, but there is still a risk of HBsAg recurrence after treatment discontinuation. Most HBsAg recurrences occur within 48 weeks after treatment cessation. SVR48 is a necessary follow-up time period for CHB patients after HBsAg clearance, SVR72 may be an ideal follow-up time point, and SVR120 can be considered as an extended follow-up time point.

SAT-277

Accurate prediction of long-term hepatitis B surface antigen seroclearance with machine learning: prognostic and management implications

Rex Wan-Hin Hui[1], Victor Chun-Lam Wong[2], Karen Cheuk-Ying Ho[1], Trevor Kwan-Hung Wu[1], Ryan Hin-Man Leung[1], Lung Yi Loey Mak[1], Danny Ka-Ho Wong[1], James Fung[1], Wai-Kay Seto[1], Man-Fung Yuen[1]. *[1]The University of Hong Kong, Hong Kong, Hong Kong; [2]OncoSeek Limited, Hong Kong, Hong Kong*
Email: huirex@connect.hku.hk

Background and aims: Hepatitis B surface antigen (HBsAg) seroclearance is a favourable yet uncommon outcome in chronic hepatitis B (CHB). With the emergence of novel hepatitis B virus (HBV) antivirals, accurate prediction of HBsAg seroclearance may influence management decisions. We utilized machine learning approaches on routinely available clinical data for predicting HBsAg seroclearance.

Method: We included CHB patients with longitudinal quantitative HBsAg (qHBsAg) data up till 15 May 2024 from Queen Mary Hospital, Hong Kong. Patients were randomly divided in an 8:2 ratio into training and internal validation cohorts. Baseline clinical variables (Age, sex, alanine aminotransferase [ALT], antiviral treatment status, hepatitis B e antigen [HBeAg] status, HBV DNA) were utilized to develop a baseline random forest model. A gated recurrent unit (GRU) model was also developed using longitudinal qHBsAg data. We subsequently merged the baseline and longitudinal models to develop a combined model for predicting HBsAg seroclearance. Model performance was evaluated through area-under-curve (AUC), positive and negative predictive values (PPV/ NPV), specificity, and sensitivity.

Results: This analysis included 4,287 patients (62.5% male; mean baseline age 48.0 ± 12.8. years; median baseline ALT 28.0 [20.0–42.0] U/L; 24.9% baseline HBeAg positive; 45.2% on antivirals at baseline for an average of 5.5 [3.6–8.1] years; baseline median qHBsAg 630.8 [117.1–1875.5] IU/ml). After follow-up for 7.0 [6.1–15.6] years, 526 patients (12.3%) developed HBsAg seroclearance at a median time of 4.2 [3.0–9.3] years from baseline. In the validation cohort, the baseline random forest model achieved AUC 0.74 (PPV 0.62, NPV 0.89, specificity 0.97, sensitivity 0.28), whereas the longitudinal GRU model achieved AUC 0.88 (PPV 0.69, NPV 0.94, specificity 0.96, sensitivity 0.61) for predicting HBsAg seroclearance. The diagnostic performance improved with combination of both baseline and longitudinal models, and our combination model achieved AUC 0.91 (PPV 0.75, NPV 0.93, specificity 0.97, sensitivity 0.53). The performance of the model remained robust after stratification by age, sex, antiviral treatment status, and fibrosis level respectively.

Conclusion: Using routinely available data, we developed and validated a highly accurate machine learning model for predicting HBsAg seroclearance. With high specificity of 97%, the model can identify patients who are unlikely to achieve HBsAg seroclearance, and these patients may attain the greatest benefits from novel HBV antivirals.

SAT-278

A marker of cccDNA transcription - hepatitis B core-related antigen (HBcrAg) - mimics HBV RNA decline during antiviral therapy with bulevirtide in chronic hepatitis delta (HDV) patients

Zillah Cargill[1], Sital Shah[2], James Lok[1], Geoffrey Dusheiko[1], Kosh Agarwal[2], Ivana Carey[1]. *[1]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom; [2]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom*
Email: ivana.carey@nhs.net

Background and aims: HBsAg mediates viral entry via NTCP receptor attachment and is critical to propagation of hepatitis delta virus (HDV). HBsAg originates from both cccDNA and integrated DNA. Hepatitis B core-related antigen (HBcrAg) and pre-genomic HBV RNA (pgRNA) reflect cccDNA transcriptional activity. Bulevirtide (BLV) mimics a pre-S1 HBsAg protein and blocks viral entry to hepatocyte by inhibitory competition. While total HBsAg concentrations did not change during BLV therapy, there no data comparing changes in HBcrAg, pgRNA and pre-S1 during BLV therapy. We aimed to compare levels of HBV markers (HBV DNA, HBsAg, HBcrAg, pgRNA, pre-S1) in sequential samples one year before therapy vs during BLV therapy and assess changes in relation to therapy response (HDV RNA decline).

Method: Plasma samples from 14 patients with HBV/HDV co-infection (all HDV RNA+, median age 45 yrs, 8 males, 79% compensated cirrhosis) treated with BLV were collected sequentially one year before therapy start, at therapy start, week 24 & 48 and levels of following markers were measured: HBsAg by Abbott Architect® [IU/ml], HBcrAg by CLEIA Fujirebio [log_{10}U/ml], pgRNA by Abbott Diagnostics dual-target real-time-PCR assay, LLoQ = 0.49 log_{10}U/ml, pre-S1 by Abbkine ELISA [IU/ml] and HDV RNA by in-house real-time PCR (LLoQ 640 IU/ml) at same time-points. The levels of HBV DNA, HBsAg, HBcrAg, pgRNA, pre-S1, HDV RNA and ALT were compared between time-points (pre-therapy vs on-therapy) and according to HDV RNA decline from start vs week 24 & 48.

Results: Therapy start levels of HBsAg, HBcrAg, pgRNA, pre-S1, HDV RNA & ALT were not predictive of HDV RNA decline >2 log_{10} at week 24 and 48. Levels of all markers 1 year before start of therapy vs at therapy start were similar. *Week 24 vs therapy start*: From 12 patients who completed week 24: 5 (42%) patients had >2 log_{10} HDV RNA decline, 5 (42%) patients had HDV RNA drop 1–2 log_{10} and 2 (16%) patients decline <1 log_{10}. There were significant changes in levels of ALT (−46 IU/L), HDV RNA (−1.72 log_{10}IU/ml) and HBcrAg (−1.42 log_{10}U/ml), all $p < 0.01$ and increase in pre-S1 levels (66 IU/ml, $p = 0.05$), but HBsAg (9082 vs 9389 IU/ml, $p = 0.67$), HBV DNA (0 vs 0 IU/ml, $p = 1$) and pgRNA (1.5 vs 1.58 log_{10}U/ml, $p = 0.58$) levels were similar. *Week 48 vs therapy start*: From 10 patients who completed week 48: 5 (50%) patients had >2 log_{10} HDV RNA decline, 4 (40%) patients had HDV RNA drop 1–2 log_{10} & 1 (10%) patient had decline <1 log_{10}. There were significant changes in levels of ALT (−53 IU/L), HDV RNA (−2.13 log_{10}IU/ml) and HBcrAg (−1.78 log_{10} U/ml) and decline in pre-S1 levels (−77 IU/ml), all $p < 0.01$, but HBsAg (9082 vs 8829 IU/ml, $p = 0.33$), HBV DNA (0 vs 0 IU/ml, $p = 1$) and pgRNA (1.5 vs 1.45 log_{10}U/ml, $p = 0.28$) levels did not differ. These were similar irrespective of BLV therapy responses for weeks 24 & 48.

Conclusion: Of several novel HBV biomarkers only HBcrAg levels mirrored HDV RNA decline during antiviral therapy with BLV, in contrast to no changes in levels of HBsAg and pgRNA. Larger studies assessing the role of HBcrAg during HDV therapy would be beneficial.

SAT-279

Infants with chronic hepatitis B can achieve functional cure through a definite duration of antiviral treatment

Jing Li[1], Peiyao Fan[2], Junliang Fu[1], Chao Zhang[1], Min Zhang[1], Shishu Zhu[1], Fu-Sheng Wang[1]. *[1]Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, National Clinical Research Center for Infectious Diseases, Beijing, China, Beijing, China; [2]Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, National Clinical Research Center for Infectious Diseases, Beijing, China, Peking University 302 Clinical Medical School, Beijing, China, Beijing, China*
Email: fswang302@163.com

Background and aims: This study aims to investigate whether and how antiviral treatment can achieve a functional cure for infants with chronic hepatitis B (CHB).
Method: This real-world study enrolled 28 infants (13 boys and 15 girls) with HBeAg-positive CHB who were perinatally infected with HBV via mother-to-child transmission (MTCT). The median baseline age was 9 months. Five infants received lamivudine monotherapy. The other 23 cases started LAM monotherapy at first, and then interferon-α treatment was added when they were more than 12 months old. The virological responses, functional cure and treatment safety were analyzed for 36 months (treatment plus follow-up visit duration).
Results: All 28 infants with CHB (baseline median HBV DNA was 7.50 log10 IU/ml) had full viral suppression after antiviral treatment and the median time taken for undetectable HBV DNA was 6 months (range: 1–19 months). Correspondingly, the median time taken for HBeAg seroconversion was 7 months (range: 3–18 months) for 27 infants, and one case didn't obtain HBeAg seroconversion; 25 of the 28 infants achieved a functional cure through a median time of 9 months (range: 3–28 months) since baseline. Three infants didn't achieve functional cure at the 36-month endpoint, but they achieved undetectable HBV DNA, and two of them had HBeAg seroconversion. Flu-like symptoms associated with IFN-α treatment were the common side effects, however, no serious adverse events were observed. In discussion section, we analyzed the natural history and related characteristics of infants with HBV infection.
Conclusion: Our findings indicate that under one-year-old infants with CHB can achieve a significantly high probability of a functional cure when they receive a definite duration of antiviral treatment using available agents.

SAT-280

SE London emergency department (ED) testing for BBV demonstrates a high HBV prevalence: an effective public health intervention to address inequalities for people living with HBV

Kate Childs[1], Mia Olsen[2], Kartikeya Khanna[3], Oliver Mizzi[4], Laura Hunter[5], Angela Hart[6], Nina VanZyl[7], Sharon Hall[8], Kosh Agarwal[9], Bo Wang[3], Laura Blackmore[10]. *[1]Institute of Liver Studies, King's College Hospital, London, United Kingdom; [2]Institute of Liver Studies, London, United Kingdom; [3]Guys and St Thomases NHS Trust, London, United Kingdom; [4]King's College Hospital, London, United Kingdom; [5]Guys and St Thomases Hospital, London, United Kingdom; [6]Queen Elizabeth Hospital Woolwich, London, United Kingdom; [7]SE London Integrated Care Board, London, United Kingdom; [8]Lewisham @ Greenwich NHS Trust, London, United Kingdom; [9]King's College Hospital NHS Trust, London, United Kingdom; [10]Lewisham & Greenwich NHS Trust, London, United Kingdom*
Email: kate.childs@nhs.net

Background and aims: From April 2022, in areas of high (>5/1000) HIV prevalence, NHS England launched 'opt out' testing for blood borne viruses BBV (HIV, HBV and HCV) in 34 Emergency Departments (EDs) with integrated linkage to clinical care. SE London is an area of high deprivation and high diversity with 38% of the population born outside the UK (ONS). We aim to report the results of the first 18 months of BBV testing in all EDs in SE London.
Method: We report on ED testing at three SE London trusts. Due to staggered initiation there was 18 months of data Nov 2022-May 2024 from two trusts and May 23–May 24 for the third trust. Screen positivity and demographics including deprivation index for people newly diagnosed with HBV were reported.
Results: Between November 2022 and May 2024 in SE London, 565,289 people attended ED. After exclusion of duplicate testing, 282,363 had blood tests and were eligible for BBV testing. Of these, 223044 (79%) underwent HBV testing. We found 1885 individuals screen positive for HBsAg, giving a SE London HBV prevalence rate of 1885/223044 = 0.85%. This compares to 2704 positive HIV tests out of 247,699 HIV tests performed giving an HIV prevalence of 1.09%. Out of the 1885 positive tests, 756/1885 (40%) were confirmed new diagnoses. Demographics of the 756 people newly diagnosed with HBV are as follows: 482 (64%) male, 272 (36%) female. Median age 49 yrs, IQR (39, 59). 344 (45%) Black ethnicity (271 (78%) of whom are black African), 25 (3.3%) White British, 75 (9.8%) White other Europe, 46 (6.1%) Chinese or SE Asian, 146 (19%) not known. Where 1 is the most deprived and 10 the least deprived; 392 (52%) live in IMD decile 1–3, 218 (29%) decile 4–6, 106 (14%) decile 7–10.
Conclusion: ED testing has been a success in SE London, with 79% of eligible persons being tested. SE London has the highest prevalence of HIV in the UK and these results show a similar high prevalence of Hepatitis B infection. 40% of the patients with positive HBV were confirmed new diagnoses. ED testing is reaching a group of patients with undiagnosed HBV, the majority of whom are of black African ethnicity and living in the most deprived areas. The fact that they have reached a median age of 49 yrs without knowing the diagnosis suggests that they have not had the opportunity to be tested previously and would not be tested in other settings. This represents a health inequality, as in a proportion of patients, the lack of access to testing will eventually result in decompensated cirrhosis or liver cancer. ED testing helps address this inequality and in an area of high HBV prevalence is an important public health tool to prevent future morbidity and HBV transmission.

SAT-285-YI

Performance of the PAGE-B score for the prediction of hepatocellular carcinoma in chronic hepatitis B patients with metabolic dysfunction

Lesley Patmore[1], Ivana Carey[2], Jordan J. Feld[3], Willem Pieter Brouwer[1], Keyur Patel[3], Maria Buti[4,4], Pieter Honkoop[5], Douwe Postma[6], Hans Blokzijl[6], Ozgur Koc[7], Kosh Agarwal[8], Marc van der Valk[9], Faydra Lieveld[10], Mai Kilany[11], Matthijs Kramer[7], Joep de Bruijne[10], Mark Claassen[12], Bettina E. Hansen[1], Robert A. de Man[1], Harry L.A. Janssen[1,11], R. Bart Takkenberg[13], Milan J. Sonneveld[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]King's College Hospital, Londen, United Kingdom; [3]Toronto Centre for Liver Disease, Toronto General Hospital, Toronto, Canada; [4]Liver Unit, Hospital University Valle d'Hebron, Barcelona, Spain; [5]Albert Schweitzer Hospital, Dordrecht, Netherlands; [6]University Medical Center Groningen, Groningen, Netherlands; [7]Maastricht University Medical Center+, Maastricht, Netherlands; [8]King's college Hospital, Londen, United Kingdom; [9]Hiv Monitoring Foundation, Amsterdam, Netherlands; [10]Utrecht University Medical Center, Utrecht, Netherlands; [11]Toronto Centre for Liver Disease, Toronto General Hospital, Toronto, Netherlands; [12]Rijnstate Hospital, Arhnem, Netherlands; [13]Amsterdam UMC, Amsterdam, Netherlands*
Email: l.patmore@erasmusmc.nl

Background and aim: The presence of metabolic comorbidities and metabolic dysfunction-associated steatotic liver disease (MASLD) are associated with an increased risk of hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB). The PAGE-B score, which includes age, sex, and platelet count, stratifies the risk of HCC in patients with HBV mono-infection, but whether this score can be applied in CHB patients co-affected by metabolic dysfunction is unclear.
Method: Our study cohort included patients with CHB mono-infection from 9 centers in Europe and Canada, who had at least one metabolic comorbidity (overweight, diabetes mellitus type 2 [DM2], hypertension or dyslipidemia). The PAGE-B score was calculated patients were stratified as at low, intermediate or high risk of HCC. Presence of steatosis was assessed by ultrasound or CT, controlled attenuation parameter or liver histology. HCC incidence was assessed in the overall cohort and in the CHB-MASLD cohort stratified by PAGE-B risk groups.
Results: We included 1968 CHB patients with metabolic dysfunction. The median age was 42 years (IQR 34–51), the majority was male (64.5%), 239 (12.1%) had cirrhosis and 1077 (54.7%) received antiviral therapy. 1770 patients (89.8%) had overweight, 450 (22.8%)

hypertension, 259 (13.1%) dyslipidemia, 234 (11.9%) DM2 and 758 (38.5%) MASLD. During a median follow-up of 7.9 years, 87 patients developed HCC. The 5-year cumulative incidence of HCC was 2.3% in the overall cohort. HCC risk was significantly higher in those with cirrhosis at baseline (14.9% vs 0.6% at 5 years, p < 0.001), but was similar for those with and without MASLD (2.8% vs 2.1%, p = 0.972). In the overall cohort, the 5-year risk of HCC was 0.1% in those with a low PAGE-B scores (n = 873, 45.4% of cohort), compared to 2.0% and 12.4% in patients with intermediate (n = 831, 43.2% of cohort) and high PAGE-B scores (n = 219, 11.4% of cohort, p < 0.001). PAGE-B effectively stratified HCC risk in those without cirrhosis (5-year HCC risk: 0% vs. 1.2% and 1.8%, p < 0.001). Amongst those with cirrhosis, 5-year HCC risk was 4.2% for patients with low PAGE-B score, compared to 6.9% and 27.3% for intermediate and high scores. In the subset of patients with MASLD the 5-year HCC risk was 0%, 2.8%, 11.1 for low, intermediate and high risk score patients (p < 0.001). Excluding patients not on antiviral therapy did not change the results.

Conclusion: CHB patients with metabolic dysfunction are at significant risk of HCC. In patients without cirrhosis, low PAGE-B scores, even in patients with MASLD, was associated with a negligible 5-year risk of HCC. Conversely, a significant residual risk of HCC was observed amongst CHB patients with metabolic dysfunction and cirrhosis despite low PAGE-B scores, highlighting the need for continued HCC surveillance in this subgroup of patients.

SAT-286

Risk of hepatocellular carcinoma and other liver-related events in chronic hepatitis B patients with or without hepatitis D virus co-infection

Lesley Patmore[1], Michelle Spaan[1], Kosh Agarwal[2], Özgür Koc[3], Hans Blokzijl[4], Samantha Brouwer[5], Hanneke van Soest[6], Astrid van Hulzen[7], Harry L.A. Janssen[1], Annemiek Van der Eijk[1], Jolanda Lammers[8], Louis Jansen[9], Mark Claassen[10], Robert A. de Man[1], R. Bart Takkenberg[11], Remco van Dijk[12], Dirk Posthouwer[13], Jurriën Reijnders[1], Ivana Carey[14], Milan J. Sonneveld[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]King's college Hospital, London, United Kingdom; [3]Maastricht University Medical Center+, Maastricht, Netherlands; [4]Groningen University Medical Center, Groningen, Netherlands; [5]Haga ziekenhuis, Den Haag, Netherlands; [6]Haaglanden Medisch Centrum, Den Haag, Netherlands; [7]Isala, Zwolle, Netherlands; [8]Isala, Rotterdam, Netherlands; [9]OLVG, Amsterdam, Netherlands; [10]Rijnstate Hospital, Arnhem, Netherlands; [11]Amsterdam UMC, Amsterdam, Netherlands; [12]Leiden University Medical Center, Rotterdam, Netherlands; [13]Maastricht University Medical Center+, Maastricht, Netherlands; [14]King's college hospital, Londen, Netherlands*
Email: l.patmore@erasmusmc.nl

Background and aims: Previous studies suggest that HDV co-infection (chronic hepatitis delta, CHD) is associated with an excess risk of HCC and other adverse liver-related outcomes compared to HBV mono-infection (CHB). Whether this excess risks persists in patients with established cirrhosis remains uncertain. We aimed to compare the clinical outcomes of patients with CHD to those with CHB, stratified by the presence or absence of cirrhosis.

Method: We analysed all consecutive patients with CHD (HDV RNA positive) managed at 10 sites in the Netherlands and the United Kingdom and compared clinical outcomes to all consecutive CHB patients managed at one academic site in the Netherlands. We studied the cumulative incidence of HCC and liver-related events (LRE; defined as the first of a composite of HCC, liver transplantation and liver-related mortality), in the overall study population, and stratified for presence of cirrhosis (defined by biopsy showing METAVIR F4, liver stiffness measurement ≥12 or signs or cirrhosis on imaging).

Results: We analysed 1468 patients, 144 CHD patients with a median age of 38 (IQR 33–47) and 1324 CHB patients with a median age of 40 years (IQR 32–50, p = 0.252). Patients with CHD were more likely to have cirrhosis (50.0% vs. 7.8%, p < 0.001), had lower HBV DNA levels (1.6 vs. 3.0 log UI/mL, p < 0.001) and higher ALT (84 vs. 33 U/L, p < 0.001). During a median follow-up of 8.0 years (IQR 4.6–12.4), 57 first events (30 HCC, 22 liver transplantations, 5 liver-related deaths) were recorded. The 5-year cumulative HCC incidence for CHD patients was 6.0%, compared to 0.8% for CHB patients (p < 0.001) and the 5-year cumulative incidence of LRE was 20.9% for CHD patients, compared to 0.8% for CHB patients (p < 0.001). Among patients with cirrhosis (n = 175), of which 158 (90.3%) were on NUC therapy, the 5-year cumulative HCC incidence for patients with CHD was 12.4%, compared to 4.1% for CHB patients (p = 0.002). Findings for LRE were consistent (41.9% vs. 4.1%, p < 0.001). In multivariable analysis adjusted for age, platelet count, HBV DNA log10 and cirrhosis at baseline, the presence of CHD was significantly associated with an increased risk of HCC (aHR 5.6, 95% CI 2.0–15.9, p = 0.003) and LRE (aHR 7.7, 95% CI 3.8–15.8, p < 0.001).

Conclusion: Patients with CHD are at increased risk for the development of HCC and other liver-related events compared to patients with CHB. The excess risk persisted amongst patients with cirrhosis, underscoring the need for diagnosis and treatment of HDV infection even in patients who already progressed to cirrhosis.

SAT-287

Metabolic comorbidities are risk factors for adverse liver-related events in individuals with HIV-HBV on tenofovir-based antiretroviral therapy

Lesley Patmore[1], Anders Boyd[2], Colette Smit[2], Mark Claassen[3], Katalin Pogány[4], Dirk Posthouwer[5], Theodora de Vries-Sluijs[1], Berend van Welzen[6], Marc van der Valk[2], Milan J. Sonneveld[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]Hiv Monitoring Foundation, Amsterdam, Netherlands; [3]Rijnstate Hospital, Arhnem, Netherlands; [4]Maasstad Hospital, Rotterdam, Netherlands; [5]Maastricht University Medical Center+, Maastricht, Netherlands; [6]Utrecht University Medical Center, Utrecht, Netherlands*
Email: l.patmore@erasmusmc.nl

Background and aims: Individuals with HIV have an increased risk to develop diabetes mellitus (DM), hypertension (HT) and dyslipidemia (DL). These metabolic comorbidities (MC) are risk factors for the hepatocellular carcinoma (HCC) and liver-related mortality in individuals with HBV mono-infection. We aimed to study the association between MC and liver-related events in individuals with HIV-HBV on tenofovir-based antiretroviral therapy (ART).

Method: We analysed data from the ongoing nationwide AIDS Therapy Evaluation in the Netherlands (ATHENA) cohort. We included all individuals with HIV-HBV who commenced tenofovir-based (ART) and studied the association between baseline metabolic comorbidities and liver-related events (composite endpoint of HCC, liver transplantation and liver-related mortality) using Cox proportional hazards regression in the overall cohort and in the subset of patients at highest risk (i.e. those with cirrhosis and/or intermediate-high PAGE-B score).

Results: We analyzed 1205 individuals, the majority of whom were male (85.5%) and born in Europe (49.6%). At baseline, median age was 45 years, 737 (61.1%) had intermediate-high PAGE-B scores and 71 (5.9%) had cirrhosis. Median nadir CD4+ was 280 cell/mm^3 (IQR 134–450) and 21.5% had previous exposure to thymidine analogues (d-drugs). In total, 417 (34.6%) individuals had one or more metabolic comorbidities (7.1% DM, 26.9% HT and 13.3% DL). During a median follow-up of 10.2 (IQR 5.2–14.7) years, a total of 28 liver-related events occurred (17 HCC, 1 liver transplantation and 10 liver-related deaths). In univariable analysis, DM (HR 4.7, p = 0.002) and HT (HR 3.6, p < 0.001) were associated with liver-related events, but DL (HR 1.3, p = 0.622) was not. The highest risk of liver-related events was observed in individuals with both DM and HT (1 MC: HR 3.0; 2 MC: HR 12.5, p < 0.001). Findings were consistent in multivariable analyses adjusting for age, platelet count, nadir CD4+ T-cell count and previous exposure to D-drugs (diabetes aHR 3.4, p = 0.024 and hypertension aHR 2.8, p = 0.016). Presence of DM and HT was also

associated with an increased risk of liver-related events amongst individuals with intermediate-high PAGE-B scores and in the subset of individuals with cirrhosis.
Conclusion: Metabolic comorbidities are prevalent in individuals with HIV-HBV on tenofovir-based ART. Presence of DM or HT was independently associated with an increased risk of liver-related events. These findings underscore the need for metabolic assessment for thorough risk stratification in patients with HIV-HBV.

SAT-288

Predictive performances of PAGED-B and reREACH-B models in non-cirrhotic, treatment-naive patients with chronic hepatitis B

Ho Soo Chun[1,2], Minjong Lee[1,2], Hye Ah Lee[3], Tae Hun Kim[1,2], Seung Up Kim[4]. *[1]Department of Internal Medicine, Ewha Womans University College of Medicine, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Ewha Womans University Medical Center, Seoul, Korea, Rep. of South; [3]Clinical Trial Center, Ewha Womans University Seoul Hospital, Seoul, Korea, Rep. of South; [4]Department of Internal Medicine, Institute of Gastroenterology, Yonsei University College of Medicine, Seoul, Korea, Rep. of South*
Email: minjonglee2@naver.com

Background and aims: PAGED-B and reREACH-B models, consisting of fibrotic burden and moderate hepatitis B virus (HBV) DNA levels, were recently proposed to predict development of hepatocellular carcinoma (HCC) in non-cirrhotic patients with chronic hepatitis B (CHB). We validated their predictive performances in non-cirrhotic, treatment-naive patients with CHB.
Method: Between 2007 and 2023, this multicenter retrospective cohort study recruited 4,190 non-cirrhotic, treatment-naïve, adult patients with CHB from 3 medical centers in South Korea. The index date was defined as the date of the first test for serum HBV DNA levels and the primary outcome was HCC development. The discrimination performance of the PAGED-B and reREACH-B models was assessed using time-dependent area under the receiver operating characteristics (AUROC), and the calibration performance of the two models was also assessed. In addition, the models were compared to the two default strategies "Treat All" and "Treat None" using decision curve analysis (DCA).
Results: The mean age was 47.3 years, and hepatitis B e antigen was positive in 797 (19.0%) patients. During a median follow-up period of 6.8 years (interquartile range, 3.6–10.3 years), 32 (0.8%) patients developed HCC (0.11 per 100 person-years) and 672 (16.0%) patients started antiviral therapy (AVT). The HCC development was significantly higher in CHB patients who started AVT (n = 17, 2.5%) than in those who did not (n = 15, 0.4%; $p < 0.001$). The 5-year time-dependent AUROC of the PAGED-B model (0.850) was higher than that of the reREACH-B model (0.825). Calibration performance of the PAGED-B model was better than that of the reREACH-B model which overestimates the HCC risk (Integrated calibration index; PAGED-B: 0.001 vs. reREACH-B: 0.023). DCA also showed that the clinical utility of the PAGED-B model (0.002) was superior to that of the reREACH-B model (-0.001) at a threshold probability of 1% for 5-year HCC risk. When the predictive performances of the two models were compared at the time of starting AVT, the PAGED-B model (0.858) had significantly higher 5-year time-dependent AUROC than reREACH-B model (0.578), with better calibration performance and higher net benefit by DCA.
Conclusion: The predictive performances of the PAGED-B model was comprehensively better than those of the reREACH-B model in non-cirrhotic, treatment-naive patients with CHB. The PAGED-B model may also be more useful than the reREACH-B model even in CHB patients who start AVT in a natural course, which is a high-risk group for HCC development.

SAT-289-YI

Scaling up treatment of chronic hepatitis B in Africa: 1-year results from a simplified public-sector treatment program in Ethiopia

Lasse Rossvoll[1], Hailemichael Desalegn[2], Fikadu Girma Gudissa[3], Dawit Brhane[4], Ahmed Hussen[5], Waqtola Cheneke[6], Asiya Jeylan[3], Esayas Gudina[6], Nega Berhe[7], Asgeir Johannessen[1]. *[1]Vestfold Hospital Trust, Tønsberg, Norway; [2]St. Paul's Hospital Millenium Medical College, Addis Ababa, Ethiopia; [3]Adama Comprehensive Specialized Hospital Medical College, Adama, Ethiopia; [4]Dubti General Hospital, Dubti, Ethiopia; [5]Jigjiga University Sheikh Hassen Yabare Comprehensive Specialized Hospital, Jigjiga, Ethiopia; [6]Jimma University, Jimma, Ethiopia; [7]Addis Ababa University, Addis Ababa, Ethiopia*
Email: lasse.rossvoll@gmail.com

Background and aims: In the global efforts to combat chronic hepatitis B (CHB), the African continent is falling behind with only 0.2% of an estimated 65 million CHB patients receiving antiviral therapy. The new WHO guidelines advocate for simplified treatment criteria to reach a larger proportion of CHB patients in low- and middle-income countries, but it is unclear how this simplified approach works in real-life. In this study, we present 1-year results from a large, simplified CHB treatment program in Ethiopia, where a modified version of the new WHO guidelines has been used for several years.
Method: In 2021/22, CHB treatment clinics were established at four regional hospitals in Ethiopia (Adama, Dubti, Jigjiga and Jimma). Adult HIV-negative CHB patients were enrolled and assessed with blood samples, including liver enzymes and viral markers. The treatment eligibility criteria were: i) clinically diagnosed cirrhosis, ii), AST to platelet ratio index (APRI) ≥0.7, iii) ALT > 40 U/L and HBV DNA > 2000 IU/ml, and iv) HCC in first-degree relative and HBV DNA > 2000 IU/ml. Patients who met the criteria were given Tenofovir disoproxil fumarate (TDF) free of charge, and appointed for follow-up after three, six and twelve months. Changes in ALT and APRI were analyzed with Wilcoxon signed-rank test, while logistic regression models were used to identify predictors for virological failure (HBV DNA > 10 IU/ml) after 12 months.
Results: A total of 4,356 patients were enrolled between December 2021 and June 2023, of whom 1,135 treatment-naïve patients fulfilled the treatment criteria and started TDF before July 01, 2023. Of the patients starting treatment, the median age was 30 years (interquartile range 25–39 years) and 827 (72.9%) were men. In total, 531 (46.8%) patients completed one year of treatment, while 508 (44.8%) were lost to follow-up, 56 (4.9%) died, 23 (2.0%) withdrew, 10 (0.9%) started due to pregnancy and stopped postpartum, and 7 (0.6%) were transferred out. Of the 56 patients who died within the first year, 51 (91.1%) died from complications related to advanced chronic liver disease. Of the patients who completed one year of treatment, the median ALT and APRI declined from 48 to 32 U/L ($p < 0.001$) and 0.72 to 0.48 ($p < 0.001$), respectively, and 78.3% had suppressed HBV DNA (<10 IU/ml). HBV DNA > 10^6 IU/ml (adjusted odds ratio (AOR) 5.24; 95% CI 3.18–8.73) and decompensated cirrhosis (AOR 2.29; 95% CI 1.03–4.98) were independent predictors of virological failure at 12 months.
Conclusion: About half of the patients who initiated antiviral therapy completed one year of treatment, with evidence of biochemical and virological treatment response. However, roughly 45% were lost to follow-up after one year, highlighting the need for improved understanding of sociocultural barriers to long-term CHB care in Africa.

SAT-290

Staging liver fibrosis using non-invasive tests in people with chronic hepatitis B (CHB) to inform WHO 2024 guidelines: a systematic review and meta-analysis

Antonio Liguori[1,2], Mirko Zoncapè[1,3], Giovanni Casazza[4,5], Philippa Easterbrook[6], Emmanuel Tsochatzis[1]. *[1]University College London (UCL) Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom; [2]Departement of Medical and Surgery Sciences, Fondazione Policlinico Universitario A. Gemelli, IRCCS, Rome, Italy; [3]Liver Unit, Department of Internal Medicine, University of Verona and Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy; [4]Department of Clinical Sciences and Community Health, Università degli Studi di Milano, Milan, Italy; [5]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [6]Department of Global HIV, Hepatitis and STI Programmes, World Health Organization, Geneva, Switzerland*

Email: lig.antonio91@gmail.com

Background and aims: Non-invasive tests (AST-to-platelet ratio index (APRI) and transient elastography (TE)) were recommended in the 2015 World Health Organization (WHO) guidelines to guide treatment decisions in people with chronic hepatitis B (CHB). Those guidelines were based on a systematic review that included 69 studies. We undertook an updated systematic review and meta-analysis to inform new cut-offs for NITs for diagnosis of significant fibrosis and cirrhosis for the 2024 WHO global guidelines for care and treatment of persons with CHB infection.

Method: We conducted an updated systematic review and meta-analysis of studies comparing the diagnostic accuracy of APRI, FIB4, and TE against liver biopsy in diagnosing ≥F2 and ≥F4 liver fibrosis. We searched PubMed, Embase and Science Citation Index Expanded for studies published between January 2014 until February 2023 and combined the data with those from the 2014 meta-analysis. We performed meta-analyses using the bivariate random-effects model. We report on the results of this review and how it was used to inform the 2024 WHO treatment recommendations.

Results: We included 264 studies, of which 211 with 61665 patients were used in the meta-analysis. For ≥F2 the summary sensitivity and specificity were: 73% and 65% for APRI low cut-off (>0.5); 30% and 92% for APRI high cut-off (>1.5), 75% and 79% for TE >7.0 kPa, respectively. For cirrhosis (F4) the summary sensitivity and specificity were: 59% and 74% for APRI low-cut-off (>1.0), 30% and 88% for APRI high cut-off (>1.5), 83% and 89% for TE >12.5 kPa. Using an APRI cut-off of >0.5 for unselected CHB patients with an assumed ≥F2 prevalence of 25%, 26% of treated patients would be false positives, while only 6.8% would be false negatives. This approach prioritises minimising false negatives over false positives, aligning with the goal of expanding access to antiviral treatment in resource-limited settings.

Conclusion: An APRI score >0.5 or a TE value of >7.0 kPa was shown to identify most adults with ≥F2 and an APRI score of >1.0 or a TE value of >12.5 kPa to identify most adults with cirrhosis. The findings informed decisions on new thresholds of APRI and TE for diagnosis of ≥F2 and ≥F4 in the 2024 WHO guidelines on CHB. These findings offer a robust evidence base for expanding treatment eligibility in resource-limited settings, enabling earlier intervention and improved outcomes for CHB patients globally.

SAT-291

Characterizing serum HBcAg and phosphorylated HBcAg in the natural history of chronic hepatitis B infection

Lung Yi Loey Mak[1], Mark Anderson, Rene Geissler[2], Megha Patel[2], Danny Ka-Ho Wong[1], Rex Wan-Hin Hui[3], Wai-Kay Seto[1], Gavin Cloherty, Man-Fung Yuen[1]. *[1]The University of Hong Kong, State Key Laboratory of Liver Research, Hong Kong, China; [2]Abbott Laboratories, Illinois, United States; [3]The University of Hong Kong, Hong Kong, China*

Email: loeymak@gmail.com

Background and aims: Serum hepatitis B virus core antigen (HBcAg) and its phosphorylated form (P-HBcAg) are novel biomarkers in chronic hepatitis B infection (CHB). We aimed to describe the profile of HBcAg and P-HBcAg in the various disease phases of CHB infection.

Method: In this cross-sectional study, patients with CHB at different disease phases according to the EASL classification who were never on antiviral treatment with retrievable serum samples were included for analysis. HBcAg and P-HBcAg are detected with a fully automated high throughput assay, with S/CO ≥1 considered to be positive. Hepatitis B virus (HBV) pre-genomic RNA (pgRNA) was measured by Research Use Only RealTime HBV RNA v2.0 (0.2 mL) (Abbott Diagnostics) which has lower limit of detection (LLOD) of 0.8 log U/mL. HBcrAg was measured by the Lumipulse G HBcrAg chemiluminescence Enzyme Immunoassay (Fujirebio, Tokyo, Japan), with LLOD of 100 U/mL. Values were log transformed.

Results: A total of 156 patients (32 hepatitis B e antigen [HBeAg]-positive chronic infection, 59 HBeAg-positive chronic hepatitis, 21 HBeAg-negative chronic infection, 33 HBeAg-negative chronic hepatitis, 11 [hepatitis B surface antigen] HBsAg seroclearance) were recruited, with median age 41.9 years old, 54.5% male, and 53.2% genotype C infection (the rest were genotype B). The median serum HBV DNA, pgRNA, HBcAg, P-HBcAg, HBsAg and HBcrAg were 4.66 log IU/mL, 4.58 log U/mL, 0.39 log S/CO, 2.49 log S/CO, 6.63 log mIU/mL and 6.99 log U/mL, respectively. The profile of HBcAg and P-HBcAg mirrors the trend of HBV DNA, HBV pgRNA and HBcrAg across disease phases. Serum HBcAg demonstrates excellent correlation with P-HBcAg ($r = 0.936$), HBV DNA ($r = 0.840$), HBV pgRNA ($r = 0.823$) and HBcrAg ($r = 0.706$); all $p < 0.001$, whereas serum P-HBcAg demonstrates strong correlation with HBV pgRNA ($r = 0.886$), HBV DNA ($r = 0.796$) and HBcrAg ($r = 0.827$); all $p < 0.001$. Patients infected with genotype C HBV had lower HBcAg (0.00 vs 1.26 log S/CO, $p = 0.023$) and P-HBcAg (1.58 vs 4.23 log S/CO, $p = 0.019$) compared to patients infected with genotype B HBV. HBeAg negative patients were more likely to have undetectable HBcAg (81.7% vs 23.1%) and P-HBcAg (61.1% vs 1.1%) compared to HBeAg positive patients; both $p < 0.001$. Both markers were not detectable in patients with HBsAg seroclearance. In patients with undetectable HBcAg, HBV DNA and pgRNA were 14.7% and 29.3% undetectable, respectively. In patients with undetectable P-HBcAg, HBV DNA and pgRNA were 21.6% and 45.9% undetectable, respectively.

Conclusion: HBcAg and P-HBcAg showed excellent correlation with other HBV biomarkers in the natural history of CHB and change dynamically with disease phases, thus representing as promising markers for assessing transcriptional silencing of covalently closed circular DNA.

SAT-292-YI

In HDV sub-genotypes 1, the high degree of genetic variability can drive the selection of divergent genetic pathways modulating HDV replicative potential and cytolytic activity

Email: lorenzo.piermatteo@uniroma2.it

Background and aims: So far, paucity of information is available on the extent of HDV genetic diversification in HDAg domains and CTL epitopes across the different sub-genotypes 1 and their correlation with virological and biochemical parameters.
Method: 103 individuals with chronic HDV infection (CHD) were included. Full-length HDV genome sequences were obtained by Illumina (median [IQR] reads/seq: 62045[30460–91899]). Sub-genotypes 1 were defined by phylogenetic analysis. Amino acid (aa) residues were defined conserved if not mutated in 95% of sequences. HDAg domains and cytotoxic T lymphocytes (CTL) epitopes (N = 18) were defined according to Pascarella 2010 and Kohsar 2021.
Results: CHD were mostly males with a median age of 54 (44–60) years coming mainly from Eastern Europe (51%) and Italy (44.8%). Serum HDV-RNA and ALT were 5.6 (4.9–6.2) logIU/ml and 94 (65–152) U/L. Sub-genotypes 1c and 1e were the most prevalent (47.1% and 45.2%), followed by 1a (4.8%), 1b (1.9%) and 1d (1%). Sub-genotype 1c predominated in CHD from Eastern Europe (77.6% vs 22.4%, P < 0.001) while 1e in Italians (77.5% vs 22.5%, P < 0.001). Overall, the number of conserved aa in HDAg was only 33.2% (71/214) ranging from 38.5% in RNA binding domain (RDB)1 to 36.4% in RBD2, 27.3% in coiled coil sequence (CCS), 25% in virus assembly signal (VAS), 19.1% in nuclear localization sequence (NLS) and 18.2% in RBD3, indicative of high genetic diversification. Similarly, the degree of genetic conservation ranges from 0% in CTL epitope 81–90 to 33.3% in CTL epitopes 105–112 and 194–202. Notably, a lower degree of genetic conservation was noted in CTL epitope 170–179 from CHD with HDV-RNA > 5 logIU/ml (70% of conserved aa with vs 20% without HDV-RNA <5 logIU/ml, P = 0.025), suggesting that an enrichment of mutations in this CTL epitope can enhance viral replication. Finally, despite a comparable degree of genetic conservation between sub-genotypes 1e and 1c, they were characterized by divergent genetic pathways. In particular, sub-genotype 1c was significantly associated with the selection of 7 specific mutations (I16T/V, N22S, D47E, R112K, T180A, A202S, prevalence ranging from 26.5% to 44.9% vs 0% in 1e, P < 0.001). Conversely, sub-genotype 1e was significantly associated with the selection of 6 specific mutations (D29E, D46E, K113R, R131K, M171L, I188V prevalence ranging from 23.9% to 43.5% vs 0% in 1c, P < 0.009). Notably, in sub-genotype 1c, the co-presence of I16V/T+D47E+A202S correlated with ALT > 3ULN (100% vs 27.5%, P = 0.001).
Conclusion: Sub-genotypes 1 are characterized by a conspicuous degree of genetic diversification that has led to the selection of divergent genetic signatures. The enrichment of mutations in specific CTL epitopes could hamper HDV recognition by immune response and in turn enhancing viral replication. Overall, the role of the high degree of genetic variability in affecting the proper HDV detection by the currently available diagnostic assays deserves further investigation.

SAT-293
High FIB-4 index predicts liver decompensation in chronic hepatitis B patients who develop clinical relapse after antiviral therapy cessation

Chun-Hsun Liao[1], Tung-Hung Su[1,2], Chun-Jen Liu[1,2], Hung-Chih Yang[1,2], Jyh-Ming Liou[1], Chun-Ming Hong[3], Tai-Chung Tseng[1,2,4], Chen-Hua Liu[1,2], Jia-Horng Kao[1,2,4]. *[1]Division of Gastroenterology and Hepatology, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; [2]Hepatitis Research Center, National Taiwan University Hospital, Taipei, Taiwan; [3]Division of Hospital Medicine, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; [4]Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan*
Email: love890101@gmail.com

Background and aims: Finite nucleos(t)ide analogues (NA) therapy may facilitate HBsAg seroclearance to achieve a functional cure. However, clinical relapse (CR, HBV DNA > 2000 IU/mL and ALT > 2-fold elevation) developed in more than 30% of patients who discontinued NA therapy, and liver decompensation may occur. Our aim was to identify risk predictors for liver decompensation after discontinuation of NA therapy.
Method: We conducted a prospective study to consecutively enroll 320 noncirrhotic patients with chronic hepatitis B (CHB) who discontinued NA therapy in a tertiary medical center since 2012. They were monitored at 1st and 3rd month off therapy, and every 3 months afterwards. Patients who developed a CR were included, and they were traced for liver decompensation, or censored at time of retreatment, or last follow-up. Clinical parameters and the fibrosis-4 (FIB-4) index were collected for statistical analysis. To validate our findings, we conducted a retrospective cohort study using electronic medical records (EMRs) from the Integrated Medical Database of the National Taiwan University Hospital (NTUH-iMD) and subsequently investigated their outcomes.
Results: Overall, 320 patients were included in the prospective study, of whom 144 (45%) developed CR. These patients received entecavir (56%) and tenofovir (31%) for a median of 37 months before NA cessation. Of 144 patients, 98 (68%) fulfilled the APASL stopping rule, and 124 (86%) received retreatment. Liver decompensation developed in 12 patients (3.8%) who had comparable pretreatment HBeAg status, HBV DNA, ALT, NA regimens, end-of-therapy (EOT) HBsAg level, and fulfillment of stopping rule compared to those without decompensation. Decompensated patients had a longer consolidation duration (31.5 vs. 16.5 months, p = 0.026) and higher EOT FIB-4 index (1.79 vs. 1.10, p < 0.001). Multivariable Cox regression analysis showed that EOT FIB-4 index > 1.5 (vs. ≤1.5) increased subsequent liver decompensation risk (adjusted HR: 31, 95%CI: 4–242, p = 0.001). Moreover, higher ALT level and FIB-4 index >4.4 (vs. ≤4.4) at CR significantly increased the risk of liver decompensation (adjusted HR: 10, 95%CI: 2–51, p = 0.005). In our validation study, we retrospectively assessed 1214 patients using identical inclusion and exclusion criteria as the original cohort. Of these, 317 patients who experienced CR were included in the final analysis, with 7 patients developing liver decompensation. Previous findings were corroborated in the retrospective cohort.
Conclusion: An EOT FIB-4 index of >1.5 can help identify patients at a high risk of developing liver decompensation following CR. These patients should be closely monitored after NA discontinuation. Moreover, patients with a FIB-4 index >4.4 at CR indicate an even greater risk and should receive prompt retreatment.

SAT-294
Should EASL expand its 2017 treatment criteria for chronic hepatitis B virus infection to ineligible people: analysis from a UK-based cohort

Monika Prabhaker-Kaushal[1], Alexander Cole[1], Yusuke Shimakawa[2], Erwan Vo Quang[3], Ameet Dhar[4], Belinda Smith[4], Zebib Habtemariam[4], Shevanthi Nayagam[4], Ashley Brown[4], Maud Lemoine[1]. *[1]Imperial College, London, United Kingdom; [2]Institut Pasteur, Paris, France; [3]APHP, Paris, France; [4]Imperial College Healthcare NHS Trust, London, United Kingdom*
Email: m.prabhaker@imperial.ac.uk

Background and aims: Expansion of treatment criteria to CHB people who are ineligible to current criteria is increasingly debated as proposed in the revised WHO guidelines despite limited evidence. From a cohort study of patients with chronic hepatitis B virus infection (CHB) in London, we assessed i. the liver-related mortality and ii. the rate of liver disease progression and HBsAg loss, in patients with e-antigen negative CHB who are ineligible for antiretroviral therapy (AVT) according to the 2017 EASL criteria

Method: Between January 2016 and December 2018, we implemented a cohort study of patients with CHB who were ineligible for AVT according to the 2017 EASL treatment criteria, and had follow-up liver assessment. All patients were recruited at Imperial College NHS Healthcare Trust in London, UK across 2 hospital sites. We excluded patients coinfected with HIV, HCV or HDV and patients with HCC or cirrhosis at enrolment. Liver disease progression was defined as becoming newly eligible for treatment and/or increasing liver fibrosis stage using Fibroscan and/or developing hepatocellular carcinoma (HCC).
Results: Out of 493 patients with CHB, 381 treatment-naïve, ineligible, eAg-negative CHB patients were enrolled, 39 (10.2%) were lost to follow-up, leaving 342 patients for this analysis (52% female, baseline median age 42 years (IQR: 35–49 years), median HBV DNA 337 IU/mL (IQR 69–1,482 IU/mL), median ALT 28 IU/L (IQR 21–37 IU/L), median LSM 4.6 kPa (IQR 3.9–5.5 kPa), 60% were in the eAg-negative chronic HBV infection phase, median BMI 27 kg/m^2 (IQR 23–30 kg/m^2), 19.7% were obese, 7.9% had liver steatosis and 2.9% reported excessive alcohol intake. Median follow-up time between enrolment and last reassessment was 5.04 years (IQR 4.73–5.32). Out of 342 patients, 4 (1.2%) died from non-liver-related causes with no liver-related deaths reported. Over the study period, only 1 patient (0.3%) developed HCC, 2 (0.6%) had hepatic flares, 16 (4.7%) spontaneously lost HBsAg and 13 (3.8%) experienced liver disease progression; no patient progressed to cirrhosis. Univariate analysis identified only HBV viral load ≥2,000 IU/mL and elevated ALT (>ULN) as associated factors for liver disease progression. When applying the 2024 revised WHO guidelines, the proportion of patients newly eligible for AVT increased significantly with 53 patients (15.5%, 95%CI: 12.0–19.0%) becoming eligible at year 5. However, out of the 13 patients who had liver progression, only 4 of these patients would have been captured by the recently expanded WHO treatment criteria.
Conclusion: Due to the very low risk of liver-related events observed in this UK-based study, there is little evidence to support expansion of AVT to eAg-negative CHB people who are currently ineligible to treatment according to the 2017 EASL guidelines.

SAT-295

Functional cure of chronic HBV: natural history, determinants, and outcomes: a real-world experience from a tertiary liver center

Mai Kilany[1], Ahmed Elsheaita[1], Leila Amiri[1], Scott K. Fung[1], David Wong[1]. [1]*Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada*
Email: mai.kilany@uhn.ca

Background and aims: Functional cure, defined as sustained HBsAg loss after chronic HBV infection, is rare. Recent studies report it occurs in 3–5% of non-Asian patients after prolonged NA therapy. Toronto is a multi-ethnic city where >53% of residents are foreign born. Our clinic has been testing HBsAg annually in all patients with chronic HBV infection since 2010. This study evaluates the prevalence of functional cure and its associated long-term outcomes.
Method: Retrospective study analyzed 1,846 chronic HBV patients who were seen in clinic from June 2022 to November 2024. The SlicerDicer module of Epic EMR was used to identify cases of chronic HBV (ICD-10 B18.19, B18.1, B18.10) or functional cure (ICD-10 Z09.9). Chart review confirmed functional cure, treatment history and liver disease outcomes.
Results: Of the 1,846 patients, 148 (8.0%) achieved functional cure, 101 (68%) were male. Functional cure occurred in 27/180 (15%) of Caucasian patients, 12/117 (10.2%) Black patients and in 108/1021 (10.5%) Asian patients. The mean age at HBsAg loss was 59 years (95% CI: 57.46–60.48) with median follow-up duration of 4 years (range: 0.2–21) after achieving HBsAg loss. The majority were treatment naive N = 90 (61%). Treated patients (N = 58) received TDF (35%), LAM (28%), or Entecavir (19%), and the mean therapy duration was 5.2 years (95% CI: 4.48–5.9). Only 16 (28%) achieved HBsAg loss during therapy while 42 (72%) achieved HBsAg loss after stopping therapy (P > 0.05), with a median interval of 6 years (range: 1–23) from stopping therapy to HBsAg loss. In those who stopped therapy, the median HBsAg at end of treatment was 208 IU/ml (0.19–2043). N = 10 (24%) experienced ALT flares (ALT > 200 U/L) within 6 months, median ALT was 334 U/L (range: 205–1274), all resolved without retreatment and the median time from stopping therapy to HBsAg loss was 5.5 years (range: 1–19). 18 (43%) had ALT (≤40 U/L) and 14 (33%) had ALT levels >40–<200 U/L and the median time from stopping therapy to HBsAg loss was 5.7 years (range: 1.5–22), and 6.5 years (range: 2–23) respectively. Hepatocellular carcinoma (HCC) occurred in 11 (7.4%) of those with functional cure, mostly in males (81.8%) and those with cirrhosis (72.7%) or advanced fibrosis (36.4%). Half of the patients developed HCC after HBsAg loss, median time was 0.6 years (range: 0–5) from HBsAg loss to diagnosis. Occult HBV DNA was detected in 4.73% (n = 7), none developed HCC. No patients underwent liver transplantation, 3 deaths (2%) occurred, none related to liver disease.
Conclusion: Functional cure was observed in 8.0% of the cohort, a prevalence higher than that previously reported in the literature. This might be due to routine annual HBsAg testing for all patients. Most with functional cure were treatment-naïve. Most treated patients (72%) achieved HBsAg loss after stopping antiviral therapy. Despite favorable outcomes, HCC occurred in 7.4%, primarily in those with cirrhosis or advanced fibrosis, underscoring the need for ongoing HCC surveillance and tailored follow-up for high-risk patients.

SAT-296

High rates of advanced chronic liver disease in patients with chronic hepatitis D virus infection in Uzbekistan

Malika Khodjaeva[1], Aziza Khikmatullaeva[1], Petra Huber[2], Michael Gebel[2], Heiner Wedemeyer[2,3,4,5], Erkin Musabaev[6], Lisa Sandmann[2,3,4,5]. [1]*The Research Institute of Virology of the Republican specialized scientific practical medical center of epidemiology, microbiology, infections and parasitics diseases., Tashkent, Uzbekistan;* [2]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany;* [3]*D-SOLVE consortium, an EU Horizon Europe funded project (No 101057917), Hannover, Germany;* [4]*Excellence Cluster RESIST, Excellence Initiative Hannover Medical School, Hannover, Germany;* [5]*German Center for Infection Research (DZIF), Hannover/Braunschweig, Germany;* [6]*The Research Institute of Virology of the Republican specialized scientific practical medical center of epidemiology, microbiology, infections, and parasitic diseases, Tashkent, Uzbekistan*
Email: malika.muskh@gmail.com

Background and aims: Chronic hepatitis B virus (HBV) infection is endemic in Uzbekistan. Previous data showed a high prevalence of anti-hepatitis D virus (HDV) antibodies in HBsAg-positive individuals. Limited data are available on disease severity, treatment availability and uptake, and hepatocellular carcinoma (HCC) prevalence in patients with chronic HDV infection in Uzbekistan.
Method: The Scientific Research Institute of Virology (SRIoV) is the leading medical and scientific reference center for viral hepatitis in Uzbekistan. Patients diagnosed with viral hepatitis are referred to the SRIoV by hepatology centers throughout the country for further diagnostics and treatment. In this cross-sectional, retrospective study, epidemiological, clinical, and laboratory data were collected and analyzed from all anti-HDV-positive patients presenting to the SRIoV between June 2023 and May 2024. Data from HBV-mono-infected patients presenting during the same period were collected for comparison.
Results: A total of 1030 HBsAg-positive, anti-HDV-positive individual patients presented to the SRIoV during the study period. The majority were male (52%, n = 532/1030) with a median age of 41.9 years (IQR 37.3–48.7). HDV RNA was detectable in 79% (812/1023; median HDV RNA 5.11 $\log_{10}$ IU/ml [IQR 3.99–5.85]) of patients. Liver cirrhosis was present in the majority of patients (78.4%, n = 808/1030), of whom 30.4%, 57.2%, and 11.4% were classified as Child-Pugh Score A, B, and C,

respectively. Signs of portal hypertension (spleen size >13.5 cm and platelets <150,000/µl, or ascites) were detected in 76.9% of patients with liver cirrhosis. There was no significant difference in nucleos(t)ide analogue (NA) treatment between patients with and without cirrhosis (72% vs. 65%, p = 0.063), while only a minority had ever received interferon treatment (0.4%, n = 4/1030). The proportion of patients with HBV monoinfection in the study period was lower (26.1%, [n = 363/1393] vs. 73.9% [n = 1030/1393]). They were significantly older (p < 0.001), had a lower prevalence of liver cirrhosis (43.9 % vs. 78.4 %, p < 0.001), and were more likely to be diagnosed in the same year as the presentation to the SRIoV (16.8 % vs. 12.3 %, p = 0.032) compared to HDV co-infected patients. The HCC detection rate was low in both patient groups (HBV: n = 11/363, HDV: n = 7/1030).
Conclusion: Chronic HDV infection exceeds chronic HBV infection in terms of number of cases and severity of disease. HDV-infected patients presenting to the SRIoV have advanced liver disease with high rates of decompensated liver disease and currently no access to HDV-directed treatment. These results emphasize the need to strengthen preventive and diagnostic measures, including screening programs for HDV detection and HCC surveillance, as well as access to HDV-directed antiviral treatment.

SAT-300

The effect of antiviral therapy on the outcomes of baseline grey-zone (GZ) patients with HBeAg-negative chronic hepatitis B virus infection (CHBVe-)

Margarita Papatheodoridi[1], Sofia Paraskevopoulou[1], Panagiota Ioannidou[1], Paraskevi Fytili[1], Dimitrios Karagiannakis[1], Evangelos Cholongitas[1], Ioannis Vlachogiannakos[1], George Papatheodoridis[1]. *[1]1st Academic Department of Gastroenterology, General Hospital of Athens "Laiko", Medical School of National & Kapodistrian University of Athens, Athens, Greece*
Email: gepapath@med.uoa.gr

Background and aims: The optimal management of GZ CHBVe- patients (pts) remains controversial, but a proportion of them starts nucleos(t)ide analogue (NA) therapy, although the effect of therapy has not been clarified. In this retrospective cohort study, we assessed the potential effect of NA initiation on HBsAg loss and hepatocellular carcinoma (HCC) development in GZ CHBVe- pts.
Method: All GZ CHBVe- pts with ≥1 visit between 2010–2019 were included. GZ was defined at baseline as ULN < ALT ≤2×ULN, or HBV DNA 2000–20,000, or HBV DNA ≥20,000 and ALT ≤ULN, or ALT > 2×ULN and HBV DNA < 2000 IU/ml. Patients with HCV/HDV/HIV coinfection, immunosuppression, decompensation, HCC or other liver injury were excluded. Epidemiological, clinical and laboratory parameters based on a predefined CRF were collected. Typical treatment indications (TTI) included a) HBV DNA > 20,000 and ALT > 2×ULN, b) HBV DNA > 2000 and advanced fibrosis [Ishak's stage 3–4 or liver stiffness (LS) 9.1–12/12.1–15 kPa in case of ALT ≤/> ULN] or c) detectable HBV DNA and cirrhosis (Ishak's stage 5–6 or LS > 12/>15 kPa in case of ALT ≤/>ULN). NA initiation was decided by the treating physicians. Cumulative incidence rates were derived from Kaplan-Meier curves, whereas Cox regression analyses including time varying covariates were used for assessment of the effects of TTI and therapy on outcomes.
Results: At baseline, 811 of 2012 chronic HBV pts (40%) (age:45 ± 14 yrs, 64% males, born in Greece 58%, BMI 26 ± 4 kg/m^2, follow-up 6.8 ± 5.4 yrs) fulfilled the criteria for GZ CHBVe- cases. TTI were present at baseline by LS ± histology in 165 (20%) pts and developed during follow-up in another 115 (14%) pts resulting in 3-, 5- and 10-yr cumulative rates of 33%, 35% and 38%. NA was initiated in 523 (65%) pts resulting in 1-, 5- and 10-yr cumulative rates of 49%, 68% and 77%. NA was initiated in 277/280 (99%) pts who developed TTI and 246/531 (46%) pts remaining in GZ (p < 0.001). Patients with vs without NA initiation were more frequently males (69% vs 56%, p < 0.001) and had older mean age (47 vs 41 yrs, p < 0.001) and lower baseline platelets (206 vs 223 × 10^3/mm^3, p < 0.001). HBsAg loss was observed in 19 (2.3%) pts with 1-, 5- and 10-yr cumulative rates of 0.1%, 1.0% and 4.2%. HBsAg loss was not associated with any baseline characteristic, development of TTI or NA initiation. HCC developed in 32 (4%) pts with 1-, 5- and 10-yr cumulative rates of 1%, 3% and 5%. HCC development was independently associated with older age [HR/yr:1.09 (1.05–1.14), p < 0.001], male gender [HR: 2.86 (1.15–7.12), p = 0.024] and lower baseline platelets [HR/10^3/mm^3: 0.98 (0.97–0.99), p < 0.001], but not with development of TTI or NA initiation or HBsAg loss, although it developed in no pt with HBsAg loss.
Conclusion: The probability of HBsAg loss and HCC development does not seem to be affected by NA therapy in treated GZ CHBVe-pts, who however are at higher baseline HCC risk compared to such pts remaining untreated.

SAT-301

Prevalence and burden of hepatitis delta virus infection in a large cohort of hepatitis B- infected individuals in the Brazilian Amazon

Wornei Braga, Michael Berg[1], Mary Rodgers[2], Antonio da Costa[3], Francisco Averhoff[2], Noely Ferreira[3], Cássia Silveira[3], Esper Kallas[3], Marcia Castilho[4], Yanka Rodrigues[4], Michele Gouvea[3], Leidiane Ribeiro[3], Matheus Thomazella[3], Layla Honorato[3], Tania Mendoza[3], Steven Witkin[5], Gavin Cloherty[2], Maria Cassia Mendes-Correa. *[1]Infectious Diseases Research, Abbott Diagnostics, Chicago, Brazil; [2]Infectious Diseases Research, Abbott Diagnostics, Chicago, United States; [3]Sao Paulo University Medical School, Sao Paulo, Brazil; [4]Fundação de Medicina Tropical Dr. Heitor Vieira Dourado, Manaus, Brazil; [5]Department of Obstetrics and Gynecology, Weill Cornell Medicine, New York, United States*
Email: wornei.braga@hotmail.com

Background and aims: HBV-HDV co-infections result in the most severe form of viral hepatitis. Despite the severity of HDV, there is scarce recent data on its prevalence and clinical burden in the Brazilian Amazon. This study evaluated the prevalence and clinical characteristics of HDV-infected individuals in a large HBV-infected cohort from the Brazilian Amazon.
Method: This was a prospective study performed on HBV-infected individuals (HBsAg +) followed at two Viral Hepatitis Referral Units in the state of Amazonas, Brazil from October 2022 until February 2024. Clinical and laboratory information was taken from medical records. Blood samples were evaluated for the presence of HBV, HDV, HIV and hepatitis C virus (HCV) serological markers. Commercial kits (Architect i1000TM, Abbott Diagnostics, Brazil and DiaSorin®, Italy) were used to detect HBsAg, anti-HBc, anti-HBs, HBeAg, anti-HCV, anti-HIV and anti-HDV. HBV DNA and HDV RNA were identified by commercial kits (Abbott RealTime HBV Viral Load Assay and Altona Diagnostic RealStar® HDV RT-PCR kit). For statistical analysis, the Student t-test, Mann–Whitney U-test or Fisher's exact test were applied when applicable to evaluate differences between variables. Bivariate logistic regression was used for each variable to estimate an odds ratio (OR) with 95% confidence intervals for anti-HDV reactivity. All tests were performed at a 5% significance level.
Results: Among 356 individuals included, 75.6% (n = 269) were mono-infected with HBV, while 24.4% (n = 87) were also co-infected with HDV. Among the anti-HDV positive patients mean age was 42.6 (±9.4) years, 57.5% were male,43 (49.4%) were HDV-RNA-positive, 85 (98%) presented with an HBV DNA viral load below 2,000 IU/mL, 3 (3.4%) were HBeAg positive, one individual (1.2%) was anti-HIV positive, and none were anti-HCV positive. Univariate logistic regression analysis revealed that younger age (p = 0.009), indigenous racial origin (p = 0.001), signs or symptoms of advanced liver disease (p = 0.002), low leukocyte count (p = 0.001), low or undetectable HBV DNA viral load (p = 0.001), low platelet count, and an AST or ALT level five times the upper limit of normal (p < 0.05) were associated with anti-VHD reactivity. A stepwise multivariate logistic regression analysis revealed that low platelet count (p = 0.002), an AST/ALT> five times the upper limit of normal (p = 0.024) and an HBV DNA viral

load under the limit of detection were independently associated with HDV infection.
Conclusion: Our data confirm a high prevalence of anti-HDV /RNA positive individuals among HBV-infected patients in the Brazilian Amazon and its association with laboratory markers suggestive of active liver disease. An undetectable or low HBV viral load, in conjunction with elevated liver enzymes, are predictive of HDV infection among HBV-infected individuals in this region.

SAT-302

Dynamics of HBsAg isoforms during up to 9 years in treated and untreated HBeAg-negative chronic hepatitis B patients

Background and aims: Recent findings suggest that lower isoforms of hepatitis B virus (HBV) surface antigen large (LHBs) and medium (MHBs) to be associated with HBeAg-negative stages of HBV infections and HBsAg loss. A decrease of intrahepatic viral activity has been associated with silenced cccDNA activity in patients with HBeAg-negative HBV infection (ENI) or HBeAg-negative chronic hepatitis B (CHB). In our study we have investigated the dynamics of HBsAg isoforms during long-term courses of treatment with tenofovir disoproxil fumarate (TDF) or natural course of the disease.
Method: Two cohorts with either ENI (n = 38) or CHB (n = 96) patients were retrospectively enrolled. In the HBeAg negative CHB cohort, patients received first (n = 24) or second line (n = 72) treatment with TDF for up to 8 years. In the ENI cohort, untreated patients either with (n = 19) or without (n = 19) subsequent HBsAg loss were analysed over a duration of 9 years. HBsAg components and other viral markers were quantified at baseline (BL) and during up to 9 years of TDF treatment on a 1–3 yearly basis.
Results: In the CHB cohort, median HBsAg levels (log ng/mL) declined slightly over time from 3.5 at BL to 3.0 after 8 years in groups (p = n.s). The ratios of LHBs declined from 9.4 (3–18)% at BL to 4.2 (1–14)% (p = 0.005) after 3 years and remained unchanged during up to 6 years of consecutive TDF treatment. Mean MHBs (%) strongly declined over time from 12.9 (1–26)% at BL to 3.3 (0–10)% after 8 years of TDF treatment in both groups. In the ENI cohort, patients with and without subsequent HBsAg loss showed significantly lower levels of total HBsAg (2.9 vs. 3.5 log ng/mL, p < 0.001) and ratios of LHBs (3.6% vs. 9.4%, p < 0.001) and MHBs (1.3% vs. 12.9%, p < 0.001) at BL compared to the CHB-cohort. However, after 8 years of TDF treatment, the CHB cohort showed similar ratios of LHBs (4.1%, p = ns), but not MHBs (3.3%, p = 0.02) compared to ENI (at BL). In ENI patients with HBsAg loss, MHBs (%) decreased from 1.2 (0–7.2)% at BL to 0.5 (0–5.0)% after 4–6 years (p = 0.05). In contrast, in ENI patients without HBsAg loss, MHBs (%) increased from 1.3% at BL to 3.3% at 4–6 years.
Conclusion: During long-term TDF treatment in HBeAg-negative CHB patients, LHBs and MHBs initially decrease but later approximate the levels observed in ENI patients without HBsAg loss. However, ENI patients who experience HBsAg loss show a consistent decline in LHBs and MHBs. Our findings indicate that LHBs and MHBs may be subject to different transcriptional regulation depending on the clinical context. LHBs and HMBs could potentially serve as predictive markers for HBsAg loss.

Email: mariastellafranze@gmail.com

Background and aims: Chronic hepatitis B virus (HBV) infection progresses through distinct clinical phases, with some patients falling into a "gray zone" (GZ). This study aimed to characterize the intrahepatic immune microenvironment and the gene expression profiles across the gray zone and other well-defined clinical phases in a large cohort of untreated HBV patients.
Method: Three hundred forty-nine HBV patients who underwent liver biopsy between 2005 and 2020 at Henri Mondor University Hospital (Créteil, France) were evaluated and classified according to the EASL criteria into four phases [chronic infection (CI)/chronic hepatitis B (CHB), HBeAg±]. Those not fitting into these phases were categorized as GZ-1 (HBeAg+) and GZ-2 (HBeAg–). RNA sequencing was performed to assess gene expression profiles, and supervised clustering was applied. Immune liver infiltrates were estimated by the MCP counter. Statistical analyses were performed with R version 4.2.0.
Results: One-hundred twenty-four HBV patients [93 males, median age 39 years (32–50)] were included in the analysis: 28 HBeAg+ (4 CI, 11 CHB, 13 GZ-1), 96 HBeAg- (15 CI, 53 CHB, 28 GZ-2). In the HBeAg+ phases, gene-expression analysis revealed 277 differently expressed genes (DEGs) in CI *vs.* GZ-1, 91 in CHB *vs.* GZ-1, and 301 in CHB *vs.* CI. *Up*-regulated genes were related to inflammatory processes and immune response modulators in GZ-1 *vs.* CI, the formation/regulation of extracellular matrix in CHB vs. GZ-1, and both in CHB *vs.* CI. At enrichment analysis, GZ-1 *vs.* CI showed *over*-expression of adaptive immune-activation gene-set pathways, CHB *vs.* GZ-1 *over*-expression of gene pathways related to liver tissue regeneration, but CHB *vs.* CI *over*-expression of gene pathways related to immune activation/cytokine-signaling and liver cells (stellate/Kupffer cells). GZ-1 microenvironment (*vs.* CI) was richer in cytotoxic lymphocytes (p = 0.003) and B/T-cells (p = 0.01; p = 0.045); no significant differences were observed in GZ-1 *vs.* CHB. In the HBeAg- phases, 74 DEGs were found in GZ-2 *vs.* CI, 254 in CHB *vs.* GZ-2, and 231 in CHB *vs.* CI. *Up*-regulated genes were related to the immune response in GZ-2 *vs.* CI, the formation of extracellular matrix/inflammation in CHB *vs.* GZ-2, and cytokines/receptors involved in inflammatory processes and

tissue remodeling/extracellular matrix structure in CHB *vs*. CI. At enrichment analysis, GZ-2 *vs*. CI showed *over*-expressed immune response related-gene pathways, CHB *vs*. GZ-2 *under*-expressed metabolism/hepatocyte processes gene pathways, and CHB *vs*. CI *over*-expression of gene set pathways related to immune response/liver tissue regeneration. The liver microenvironment was enriched with fibroblast (p = 0.008) and B-cells (p = 0.034) in CHB *vs*. CI and fibroblast (p = 0.029) in CHB *vs*. GZ-2.
Conclusion: GZ profiles, like CHB, showed significant immune activation, warranting closer monitoring and potentially early antiviral therapy.

SAT-304
Insufficient implementation of pretherapeutic hepatitis B and C screening guidelines in academic and general belgian hospitals
Marie Coessens[1,2], Jolien De Graeve[3], Wim Verlinden[1,2], Anja Geerts[3], Thomas Vanwolleghem[2,4], Christophe Van Steenkiste[2,4,5], Jeoffrey Schouten[1]. *[1]Vitaz, Department of Gastroenterology and Hepatology, Sint-Niklaas, Belgium; [2]Laboratory of Experimental Medicine and Pediatrics (LEMP), University of Antwerp, Wilrijk, Belgium; [3]Ghent University Hospital, Department of Gastroenterology and Hepatology, Ghent, Belgium; [4]Antwerp University Hospital, Department of Gastroenterology and Hepatology, Edegem, Belgium; [5]AZ Maria Middelares, Department of Gastroenterology and Hepatology, Ghent, Belgium*
Email: jeoffrey.schouten@vitaz.be

Background and aims: Hepatitis B virus reactivation (HBVr) still occurs in patients receiving immunosuppressive therapies (IT). This study aims to assess pretherapeutic HBV screening rates in haematological (H), oncological (O), inflammatory bowel disease (IBD), rheumatological (R), and dermatological patients (D) according to EASL guidelines and pretherapeutic HCV screening rates in haematological patients according to ECIL-5 guidelines. Real life data on this topic are scarce.
Method: Between 2023 and 2024, a retrospective patient file analysis was done in the above-mentioned departments in two academic and two general hospitals in Belgium (AH1, AH2, GH1, GH2). All patients that had at least two documented administrations of any systemic chemotherapy or immunomodulating/immunosuppressive therapy regimen were included. HBV (and HCV) screening was considered correct if both HBsAg and HBcAb (and HCVAb in haematology patients) were performed prior to the initiation of therapy. In addition, demographics were documented and class of IT regimen according to risk of HBV reactivation. B-cell depleting agents, anthracyclines, and TNF inhibitors were considered high risk (HR) molecules. In addition, screening rates were re-evaluated after an information session at an haemato-oncology department in one general hospital.
Results: In total, pretherapeutic HBV screening rates were assessed in 2437 patients (H 410; O 1180; IBD 482; R 259; D 106) in 4 hospitals (AH1 22.9%, AH2: 29.3%; GH1: 22.6%; GH2: 25.2%). Overall, correct pretherapeutic HBV screening rates are low (H 62.5%; O 20,4%; IBD: 61.2%; R: 29.7%; D: 34.0%), as well as pretherapeutic HCV screening rates in haematological patients (66.5%). Haematological and IBD patients were most often on HR IT (H 49.3%; O 20.6%; IBD 65.8%; R 32.0%; D 13.2%). Pretherapeutic HBV screening was significantly better performed in academic hospitals (AH 50.3% vs GH 24.8%, p < 0.001). Overall, HBV screening rates are higher when only HBsAg is considered (H 64.6%; O 31.1%; IBD: 74.5%; R: 38.2%; D: 45.3%), instead of HBsAg and HBcAb as recommended by 2009 EASL guidelines. Patients on HR IT are often not screened at all (H 28,3%; O 68,4%; IBD 28.1%; R 47.0%; D 57.1%). HBV and HCV screening rates in haemato-oncologists improved after the information session [H: 49.2% up to 58.1% p < 0.001; O: 25.7% up to 59.1%; p < 0.001].
Conclusion: In this large and multicentric study we demonstrate that HBV and HCV screening prior to administration of chemotherapy and immunosuppressive therapy regimens is performed suboptimal. Despite general beliefs, pretherapeutic screening rates are low in both an academic and general hospital setting, particularly in oncology, rheumatology and dermatology departments. Low HBV screening in patients on high-risk therapy regimens is worrisome. Encouragingly, one single awareness session already significantly improved screening adherence.

SAT-305
Qualitative interviews to explore multicultural appropriateness and content validity of the hepatitis B quality of life (HBQOL) among highly impacted populations (chinese and vietnamese) with chronic hepatitis B (CHB) in the US
Naveen Gara[1], Marvin Rock[2], Caroline Burk[3], Larissa Stassek[4], Sonya Stanczyk[4], Alireza Farabi[5], Cainan Foltz[6], Tuan T. Nguyen[7]. *[1]Gastroentertology and Liver Institute, Escondido, CA, United States; [2]Gilead, Foster City, CA, United States; [3]HEOR Consultant, Laguna Beach, CA, United States; [4]Evidera, Wilmington, NC, United States; [5]Las Vegas Research Center, LLC., Las Vegas, NV, United States; [6]Medical Associates Research Group, Inc., San Diego, CA, United States; [7]Research and Education, Inc, San Diego, CA, United States*
Email: giandliverinstitute@gmail.com

Background and aims: Chronic hepatitis B (CHB) has a negative impact on patients' health-related quality of life (HRQoL),[1–5] particularly among people from high HBV prevalence regions, such as China or Vietnam.[6] Patient-reported outcome (PRO) measures like the Hepatitis B Quality of Life (HBQOL) assess symptoms and impacts of CHB from patients' perspectives; however, there may be gaps in culturally important concepts for these highly impacted populations. Qualitative interviews were conducted in the US to explore CHB experiences among native Mandarin and Vietnamese speakers and English-speaking adults to assess content validity of the HBQOL.
Method: Virtual concept elicitation (CE) interviews were conducted in English, Mandarin, or Vietnamese with adults with CHB recruited from US clinical sites. Participants first described their CHB experiences spontaneously then were probed for other known CHB symptoms and impacts.
Results: Twenty-three interviews were completed, including eight in Vietnamese and four in Mandarin. The 11 English-speaking participants self-reported being Asian (n = 5), White (n = 3), Black (n = 1), and Other (n = 2). Fewer than 5% of symptoms and impacts were first reported in the final interviews, indicating that saturation of concept was reached. The three symptoms in the HBQOL (tiredness, memory problems, muscle aches) were among the most frequently reported symptoms in the total sample. Other frequently reported symptoms not currently in the HBQOL were itching (n = 16/23, 69.6%) and joint pain and decreased energy (n = 10/23 each, 42.5%). Notably, all Mandarin-speaking participants (n = 4/4, 100%) reported "decreased energy," in contrast to a smaller proportion of English (n = 2/11, 18.2%) and Vietnamese-speaking participants (n = 4/8, 50.0%). The impacts of CHB reported by over half of the participants included concerns about developing liver cancer in the future (n = 16/23, 69.6%), disrupted sleep (n = 14/23, 60.9%), and feelings of shame and sadness (n = 12/23 each, 52.2%). Among English-speaking participants, other impacts frequently reported were feelings of stigmatization (n = 7/11, 63.6%), difficulties with work or school and difficulties with sexual activities (n = 6/11 each, 54.5%). Most of the Mandarin-speaking participants (n = 3/4, 75.0%) reported social difficulties due to CHB. Participant's reported impacts largely matched those in the HBQOL, but additional impacts such as disrupted sleep (n = 14/23, 60.9%) and caution with alcohol consumption (n = 4/23, 17.4%) were also identified.
Conclusion: These interviews provided insights into the content validity and multicultural appropriateness of the HBQOL. The next step will be to modify the HBQOL based on these results and administer the modified version during cognitive debriefing interviews. This study may also be replicated in communities with persons born in other regions with high reported HBV prevalence.

SAT-306

Assessment of hepatocarcinogenesis risk using CAMP-B and PAGE-B in patients with chronic hepatitis B

Masatsugu Ohara[1], Goki Suda[1], Takatsugu Tanaka[1], Shoichi Kitano[1], Naohiro Yasuura[1], Akimitsu Meno[1], Risako Kohya[1], Takashi Sasaki[1], Takashi Kitagataya[1], Masato Nakai[1], Takuya Sho[1], Naoya Sakamoto[1]. [1]*Department of Gastroenterology and Hepatology, Hokkaido University Hospital, Sapporo, Japan*
Email: masamasama_zu@yahoo.co.jp

Background and aims: The suppressive effect of nucleos(t)ide analogs on hepatocarcinogenesis in patients with chronic hepatitis B (CHB) remains inconclusive. Risk-based stratification is essential for identifying high-risk patients, emphasizing the need for effective hepatocarcinogenesis risk evaluation methods. While PAGE-B has been widely used, the recently proposed CAMP-B scoring system offers another approach to risk stratification. This study aimed to evaluate the utility of CAMP-B in stratifying hepatocarcinogenesis risk and to characterize its performance compared to PAGE-B in CHB patients.
Method: Among 866 HBV-infected patients regularly attending our institution, 230 CHB patients without prior hepatocellular carcinoma (HCC) and with baseline clinical data at the initiation of antiviral therapy were included. Risk scores were calculated using PAGE-B (low risk: ≤9, intermediate risk: 10–17, high risk: ≥18) and CAMP-B (low risk: ≤3, intermediate risk: 4–6, high risk: ≥7; maximum score limited to 6 for non-cirrhotic cases).
Results: The cohort comprised 230 patients, with a median age of 47 years and 126 males (54.5%). Over a median follow-up of 7.8 years, the 10-year cumulative incidence of HCC was 4.7%. Based on CAMP-B, 150 patients were classified as low risk and 80 as intermediate risk, with cumulative incidences of 2.7% and 8.8%, respectively (HR 3.61, 95%CI: 1.01–13.0, $P < 0.05$). According to PAGE-B, 75, 126, and 29 patients were categorized into low (4.2%), intermediate (1.6%), and high-risk groups (19.4%), respectively, with a significantly elevated risk in the high-risk group (HR 9.14, 95%CI: 1.72–48.5, $P < 0.01$).
Conclusion: Patients classified as high-risk by PAGE-B require rigorous surveillance due to their substantially increased risk of HCC. Furthermore, the presence of HCC cases across all risk groups in both CAMP-B and PAGE-B highlights the importance of regular surveillance in all CHB patients.

SAT-307

Transient liver stiffening and mechanosignaling activation promote IFN-mediated anti-HBV response

Fahong Li[1], Jianyu Ye[2], Tiantian Hu[1], Jinyu Wang[1], Yide Kong[1], Weien Yu[1], Zhongliang Shen[1], Jieliang Chen[2], Jiming Zhang[1]. [1]*National Medical Center for Infectious Diseases, Huashan Hospital, Fudan University, Shanghai, China;* [2]*Key Laboratory of Medical Molecular Virology, Shanghai Medical College Fudan University, Shanghai, China*
Email: minelihong@163.com

Background and aims: Elevated liver stiffness measurement (LSM) values have been reported to correlate with adverse outcomes in patients with liver disease. A transient increase in LSM value has been observed in some chronic hepatitis B patients undergoing interferon therapy, yet the correlation between this fluctuation and clinical outcomes remains unclear.
Method: This study included 291 HBeAg-negative patients with normal ALT levels and HBV DNA levels below 2000 IU/mL who received 48 weeks of PegIFNα therapy. The training set comprised 183 patients, while the validation set included 108 patients. HBsAg, ALT level, and LSM were assessed every 12 weeks. The correlations between HBsAg loss and LSM during therapy were analyzed. LSM was also measured in C57BL/6 mice receiving IFN treatment.
Results: In the training set, patients with HBsAg clearance exhibited significantly higher elevated LSM values compared to those without HBsAg clearance (4 vs 1 kPa, $P < 0.0001$). Notably, 88.9% of patients with an increased LSM value above 8 kPa achieved HBsAg clearance. In contrast, no patients without LSM elevation during treatment achieved HBsAg clearance. ALT elevation was not significantly correlated with HBsAg clearance, but with HBsAg decline at week 48. Both baseline HBsAg levels and elevated LSM values demonstrated significant diagnostic value for predicting HBsAg clearance, with AUROC of 0.823 ($P < 0.001$) and 0.776 ($P < 0.001$), respectively. The combination of baseline HBsAg level <2.35 log IU/mL and LSM elevation >2 kPa predicted HBsAg clearance with high specificity (88.9%). Additionally, patients with a ≥1 $\log_{10}$ IU/mL decline in HBsAg levels at week 48 had significantly higher elevated LSM values during treatment. In the validation set, similar results were observed. In C57BL/6 mice, LSM values were also significantly elevated following IFNα treatment.
Conclusion: A transient increase in LSM value during IFN therapy may indicate a high likelihood of HBsAg clearance or reduction in HBeAg-negative patients.

SAT-308

Anti-HDV prevalence in HBsAg positive patients and virological characterization of HBV/HDV co-infected individuals at the diagnostic laboratory of the university medical center Hamburg-Eppendorf between 2008 and 2024

Lisa Sophie Pflüger[1], Katja Giersch[1], Susanne Polywka[1], Sven Pischke[1], Maura Dandri[1], Martin Aepfelbacher[1], Julian Schulze zur Wiesch[1], Marc Luetgehmann[1]. [1]*University Medical Center Hamburg-Eppendorf, Hamburg, Germany*
Email: mluetgeh@uke.de

Background and aims: Hepatitis B and D virus (HBV/HDV) coinfection represents the most severe form of viral hepatitis. However, epidemiological studies and real-world data on prevalence are scarce. Therefore, we aimed to analyze i) the anti-HDV prevalence between 2008 and 2024 and ii) the virological characteristics of HBV/HDV co-infected patients in the diagnostic laboratory of the University Medical Center of Hamburg-Eppendorf.
Method: Patients who yielded a reactive test result for hepatitis B virus surface antigen (HBsAg) for the first time during the study-period (2008–2024) were retrospectively included in the study and analyzed for anti-HDV, HBV DNA and HDV RNA. HDV genotyping was performed either by Sanger sequencing of the R1 or R0 region or by next-generation sequencing (NGS) utilizing the iSeq100 system.
Results: Overall, 7,378 HBsAg positive individuals were newly diagnosed of which 62% (n = 4,249) were screened for anti-HDV. The screening rate varied from 30.4%–70.5% per year. In total, 5.5% were anti-HDV positive with positivity rates ranging from 3.9–8.2% per year. Although overall anti-HDV testing increased over the observation period, anti-HDV prevalence remained unchanged. The majority of the HBsAg and anti-HDV positive individuals (n = 234) were male (63%) and had a median age of 42 years (range 19–76). The median HBsAg level was 4,365 IU/ml (n = 176; range 0.05–1 × 10^5 IU/ml). HBV DNA was detectable in 70% with a median viral load of 570 IU/ml (range 2–9 × 10^8 IU/ml) and, consistent with low viral activity, only 9% of the patients were HBeAg positive. HDV RNA was tested in 66% (156/234) of which 43% had detectable HDV RNA with a median HDV RNA titer of 15,000 copies/ml (n = 52; range 20–2 × 10^8) or 165,070 IU/ml (n = 16; range 86–1 × 10^7). HDV genotyping was successfully performed in 64/68 HDV RNA positive patients and revealed 86% GT1 (n = 55), 11% GT5 (n = 7) and 3% GT8 (n = 2).
Conclusion: This mono-center study shows an anti-HDV prevalence of 5.5% in HBsAg positive patients in Germany, confirming previous studies. Interestingly, increased adherence to HDV screening guidelines among newly diagnosed HBsAg-positive patients did not result in a decrease of anti-HDV prevalence, but showed an overall lower rate of HDV RNA-positive patients. Finally, HDV genotyping revealed that an unexpected 10% of patients within the cohort were infected with non-GT1 HDV.

SAT-309

Hepatitis B surface antigen loss after nucleot(s)ide analogue cessation in patients living with chronic hepatitis B: a model-based meta-analysis of published studies

Myriam Drysdale[1], Matthew L. Zierhut[2], Nathan Hanan[3], Robert Elston[4], Ruth Tarzi[4], Dickens Theodore[5]. *[1]GSK, London, United Kingdom; [2]Certara, San Diego, CA, United States; [3]GSK, Collegeville, PA, United States; [4]GSK, Stevenage, United Kingdom; [5]GSK, Durham, NC, United States*
Email: myriam.g.drysdale@gsk.com

Background and aims: Hepatitis B virus (HBV) infection is a major global health issue (estimated prevalence in 2022 of 256 million). Nucleot(s)ide analogues (NAs) are commonly used to treat chronic hepatitis B (CHB) infection. Indefinite treatment is often required to prevent virological and clinical relapse, but functional cure (sustained loss of hepatitis B surface antigen (HBsAg) with both undetectable hepatitis B e-antigen [HBeAg] and HBV DNA ≥24 weeks after treatment cessation) is rarely achieved. The need for lifelong NA therapy has been questioned. We conducted a systematic literature review in patients with CHB infection, the results of which were used to perform Model-Based Meta-Analysis (MBMA) to estimate the proportion of patients achieving HBsAg loss after NA cessation.
Method: We searched Medical Literature Analysis, MEDLINE and Embase over the period from inception to Aug 2023. Results were screened versus predefined criteria to identify observational studies and clinical trials of patients with CHB who discontinued NA therapy. Most studies were conducted in Asia-Pacific (~72%) in HBeAg-negative patients. The MBMA population included HBsAg-positive patients enrolled in NA treatment arms before cessation. Longitudinal data were utilised, with time of NA cessation considered as the index date. Multiple variables were explored as potentially influential covariates of HBsAg loss, including time, baseline demographic and disease characteristics (e.g. HBsAg levels, cirrhosis status), HBeAg status, and average NA treatment duration prior to cessation; impact of other variables will be analyzed.
Results: The final MBMA dataset consisted of summary-level HBsAg loss results from 41 studies, 11 of which were stratified by baseline HBsAg levels. Study sample size ranged from 8 to 1,368 patients, and study duration ranged from 24–521 weeks. Longitudinal data was reported in 24 studies, ranging from 2–16 timepoints. Model-estimated HBsAg loss in a population with mean baseline HBsAg of 3.04 log10 IU/mL ([1105 IU/mL] geometric mean of a uniform distribution between 1 and 3000 IU/mL) was 1.08% (95% confidence interval [CI]: 0.86, 1.37) after 6 months of NA cessation, and 1.67% (1.33, 2.14) after 1 year. The main factors driving between- and within-study variability (applied in the logit domain) were time (exponential rate constant [k] 0.0142 wk−1; 95% CI: 0.0105, 0.0195), and baseline HBsAg level, both as an additive effect per log10 IU/mL (−0.69 [95% CI: −1.1, −0.3]) and as a proportional effect on k (per unit log10 IU/mL; 0.36 [95% CI: 0.29, 0.44]).
Conclusion: HBsAg loss occurs infrequently after NA cessation in populations with a mean HBsAg level of ~3 log10 IU/mL, particularly in the first year after cessation. This indicates a need for alternative therapies for patients with CHB that have a finite treatment duration and potential to achieve functional cure.
Funding: GSK (Study 222039).

SAT-310

Immune profiling of peripheral and intrahepatic B cells in chronic hepatitis B

Anna Pocurull Aparicio[1], Maria Saez-Palma[1], Thais Leonel[1], Sara Battistella[1], Maëlle Locatelli[1], Ángela Sanzo-Machuca[2], Simon Fletcher[3], Mala Maini[4], Xavier Forns[1], Sabela Lens[1]. *[1]Hospital Clínic de Barcelona, Fundació de Recerca Clínic Barcelona-Institut d'Investigacions Biomèdiques August Pi i Sunyer, Universitat de Barcelona, CiberEHD., Barcelona, Spain; [2]Inflammatory Bowel Disease Unit, Hospital Clinic, IDIBAPS, CIBEREHD, Barcelona, Spain; [3]Gilead Sciences, Foster city, California, United States; [4]Division of Infection and Immunity, University College of London, London, United Kingdom*
Email: slens@clinic.cat

Background and aims: The host immune response plays a fundamental role in the control of hepatitis B virus (HBV) infection. However, there is limited knowledge regarding the characteristics of B cells in peripheral blood and the intrahepatic compartment, primarily due to their low frequency. This study aimed to compare the frequency and gene expression profiles of global and HBV-specific B-cell populations in circulation and liver tissue in patients with chronic hepatitis B (CHB).
Method: Intrahepatic samples were obtained through fine-needle aspiration, while peripheral blood lymphocytes (PBMC) were isolated via density gradient centrifugation. Global B-cell subsets, HBV core antigen-specific memory B cells (HBcAg-MBC), and follicular helper T cells (Tfh) were analyzed using spectral flow cytometry (Aurora, Cytek) (n = 16). Single-cell RNA sequencing was employed in patients with paired peripheral and intrahepatic samples to assess gene expression (n = 11).
Results: Sixteen untreated HBV patients (88% male, median age 42 years) were included, of whom 75% had HBeAg-negative CHB. Median ALT was 65 U/L (IQR 50–177), qHBsAg 1879 IU/mL (598–5301), and HBV DNA 6.02 log IU/mL (3.43–7.56), with 88% testing positive for HBcrAg. The frequency of peripheral B cells was higher than that intrahepatic B cells (5.8% vs. 3.1%, $p < 0.01$). However, intrahepatic B cells predominantly exhibited activated (CD21+CD27+) and atypical memory (CD21-CD27-) phenotypes compared to circulating B cells (6.3 vs 5.0% and 7.2 vs 4.5%; respectively; $p < 0.05$). Pathway enrichment analysis showed differential gene expression between intrahepatic and circulating B cells. Especially, B cell activation pathways were upregulated in all B cell subtypes in the intrahepatic compartment compared to the periphery. Intrahepatic B cells also showed upregulation of innate immune signaling and metabolic pathways. Although at low frequencies, virus-specific HBcAg-MBC were detected in 94% of peripheral blood samples and 75% of liver samples (0.42 vs. 0.64% of total MBC, n.s). A positive correlation between HBcAg-MBC percentages in blood and liver was observed ($r = 0.85$, $p < 0.05$), independent of HBV viral replication. Tfh proportions were similar in both compartments, but circulating Tfh expressed higher levels of CD40L (4.5% vs. 1.9%, $p = 0.02$), a key marker for B-Tfh interactions.
Conclusion: In CHB, the frequency of intrahepatic B cells is lower than in circulation, however, these cells exhibit distinct gene expression profiles and signs of a more activated state likely reflecting increased antigen exposure within the liver. Elevated CD40L expression in circulating Tfh cells suggests enhanced interactions with B cells, potentially promoting their activation and migration to the liver.

SAT-311

Prevention of HBV mother to child transmission using HBV three dose and selective use of HBV BD and treatment of high viral load pregnant women in Uganda

Ponsiano Ocama[1], Samantha Hall[2], Julius Kiwanuka[1], Brian Lwanga[1], Joan Mutyoba[3], Viola Kasone[4], Rachel Beyagira[5], Alexis Voeller[6], Homie Razavi[7]. *[1]Makerere University College of Health Sciences, Kampala, Uganda; [2]Center for Disease analysis foundation, Denver, United States; [3]Makerere University College of Helath Sciences, Kampala, Uganda; [4]Central Public Health Laboratories, Kampala, Uganda; [5]Ministry of Health, Kampala, Uganda; [6]Center for Disease Analysis Foundation, Denver, United States; [7]Center for Diease Analysis Foundation, Denver, United States*
Email: ponsiano.ocama@gmail.com

Background and aims: In Uganda ≥80% of all infants have received three doses (3D) of pentavalent vaccines since 2004 and ≥90% since 2013. Hepatitis B virus (HBV) universal birth dose (BD) vaccination of infants started in 2023. However, access to the BD vaccination

remains limited and sometimes intermittent outside of the large cities. Approximately 58% of annual 1.7 million births occur at home, posing a challenge to the complete rollout of universal BD vaccination. We aimed to evaluate the impact of combining universal 3D infant vaccination, targeted BD vaccination, and antiviral treatment of mothers on HBV prevalence among infants.

Method: This study was conducted over 18 months in 5 regional maternity hospitals. All pregnant HIV- women attending the hospitals were screened for HBsAg using rapid diagnostic tests. Among the 661 women who tested HBsAg+, HBV DNA viral load testing was performed to stratify them into three groups: high viral load (HVL, ≥20,000 IU/mL), low viral load (LVL, <20,000 IU/mL), and LVL currently on antiviral treatment. HVL women were prescribed 3 months of TDF/ 3TC during their third trimester.

Infants born to HBsAg+ mothers received a BD vaccine within 24 hours of birth, followed by the pentavalent 3D vaccination series. Infants born to HBsAg negative mothers (n = 662) adhered to the national pentavalent 3D vaccination schedule. All infants were tested for HBsAg at 9 months.

Results: Among the 661 HBsAg+ mothers, 83 women (12.6%, 95% Confidence interval: 10.0–15.1%) had HVL, 538 women (81.4% (78.4–84.4%)) had LVL, and 11 women (1.7% (0.7–2.6%)) with LVL were already on antiviral treatment. Of the HVL mothers, 95.2% (n = 76, 90.6–99.8%) initiated antiviral treatment during their last trimester. This group delivered 80 infants, of whom 88.8% (n = 71, 81.8–95.7%) received the BD vaccination, and 81.3% (n = 65, 72.2–89.8%) completed the 3D vaccination series. None of the infants in this group tested HBsAg+ at nine months. Low viral load mothers gave birth to 425 infants, 90.1% (n = 383, 87.3–93.0%) of whom received the BD vaccination. Among these, 82.1% (n = 349, 78.5–85.8%) completed the 3D vaccination. Three infants tested HBsAg+ at nine months and all three had completed 3D vaccination series. The 11 mothers with low viral loads who were on antiviral treatment delivered 11 infants. All these infants received the HBV BD, and 90.9% (n = 10, 73.9–100%) completed the 3D vaccination schedule. None of these infants tested HBsAg+ at nine months. Among the 662 HBsAg negative women, 99.5% (n = 659, 99.0–100%) of their infants completed the 3D vaccination series and none of the infants tested HBsAg+ at nine months.

Conclusion: Implementing these strategies in countries with a high number of home births can effectively minimize HBV MTCT. By applying these findings to a national program, Uganda can achieve its target of reducing HBV prevalence among infants to less than 0.1% before 2030

SAT-312-YI

Distinct circulatory and intrahepatic mono-mac and CD8 T cell clusters associated with fibrosis in patients with low levels of hepatitis B surface antigen

Ravinder Singh[1], Pramod Gautam[1], Gayatri Ramakrishna[1], Archana Rastogi[1], Shiv Kumar Sarin[1], Nirupma Trehanpati[1]. [1]*Institute of Liver and Biliary Sciences, Delhi, India*
Email: ravinchaudhary0001@gmail.com

Background and aims: Chronic hepatitis B virus (HBV) infection can lead to liver fibrosis, a precursor to cirrhosis and hepatocellular carcinoma. Hepatitis B surface antigen (HBsAg) levels are commonly used to monitor disease progression. However, the relationship between HBsAg levels, immune cell profiles, and fibrosis severity remains unclear.

Method: Liver infiltrated immune cells and peripheral blood mononuclear cells (PBMCs) from six chronic HBV patients with low (<2000 IU/mL) and high HBsAg (>2000 IU/mL) were subjected to single-cell sequencing. Validation of soluble factors CXCL8, CXCL11, CXCL12 and histopathological analysis were performed in 36 naïve chronic HBV patients with low and high HBsAg levels.

Results: Chronic Hepatitis B patients with low HBsAg levels had significantly high fibrosis score than patients with high HBsAg levels. Single-cell sequencing of PBMCs and liver biopsies revealed that mono mac population was expanded and differentiated into unique and distinct clusters in HBsAg low patients. Out of 15 distinct monocyte clusters (M_c0–c14) in PBMCs, M_c1 and M_c6 clusters were only appeared in HBsAg low with high expression of CXCL8, CCL3 CXCL2, CCL4, CCL3L1, CCL20, IL1B, CROCC, TNFAIP6, TEX14, EREG, SELL, FOS, PRIM1, CREB1, AL592429.2, ZFP36 associated with chemotaxis, cell recruitment and inflammation. Similarly, intrahepatic mono-mac populations also showed high expression of CXCL8, CXCL2, CCL20, IL1B, TNFAIP, RHOB, S100A9, and TEX14 in HBsAg low patients. Levels of CXCL8, CXCL12, CXCL11 and IL1B were also increased in plasma of HBsAg low patients compared to HBsAg high. Additionally, a distinct peripheral $CD8^+$ T cell cluster expressing GNLY, GZMH, GZMB, GZMA, ITGB1, CX3CR1, ADGRG1, CCL4, and TGFBR3 were identified in patients with low HBsAg levels, contributing to cell adhesion, activation, cytotoxicity, and fibrosis.

Conclusion: Despite low HBsAg levels, naïve CHBV patients had increased fibrosis score. Single-cell sequencing data revealed appearance of distinct mono-mac and CD8 T cell clusters only in $HbsAg^{lo}$ patients with high expression of chemotactic, inflammation and apoptosis genes associated with fibrosis.

SAT-313

Hepatitis B virus screening, antiviral prophylaxis, and reactivation in Rituximab-treated patients: insights from a large retrospective cohort study

Fadi Abu Baker[1], Tarek Saadi[2], Mifleh Tatour[3], Rawi Hazzan[3]. [1]*Hillel Yaffe medical center, Hadera, Israel;* [2]*Rambam Health Care Campus, Haifa, Israel;* [3]*Haemek medical center, Afula, Israel*
Email: Fa_fd@hotmail.com

Background and aims: Hepatitis B virus (HBV) reactivation is a well-documented complication of rituximab, an anti-CD20 monoclonal antibody used to treat autoimmune diseases and hematologic malignancies. Screening and prophylactic antiviral therapy are essential strategies to mitigate this risk, but adherence to guidelines has historically been suboptimal. This study aimed to evaluate trends in HBV screening, antiviral prophylaxis, and reactivation rates in a large cohort of rituximab-treated patients.

Method: A retrospective cross-sectional analysis was conducted using data from Clalit Health Services (CHS), Israel's largest health maintenance organization. Adult patients who received rituximab between 2000 and 2022 were included. Data were collected on HBV serologic tests (HBsAg, anti-HBc), HBV DNA, liver function tests, and prescriptions for antiviral therapy. Screening was categorized as full (both HBsAg and anti-HBc) or partial (one test only) and considered timely if performed within 90 days before rituximab initiation. Temporal trends were analyzed, and HBV reactivation was defined based on standardized virologic criteria.

Results: Among 1,857 rituximab-treated patients (mean age: 60.5 years; 50.4% male), hematologic malignancies were the predominant indication for therapy. HBV screening rates improved significantly over the study period, with timely full screening increasing from <40% in 2000–2005 to >80% after 2014 ($p < 0.0001$). Of the cohort, 10.9% had positive HBV serology (8.6% anti-HBc+; 2.3% HBsAg+), and 122 of 188 screened-positive patients received prophylactic antiviral therapy. Prophylaxis rates rose from <40% in the early years to >80% after 2017 ($p < 0.0001$). Six cases of HBV reactivation were identified, all in hemato-oncologic patients; no significant liver enzyme elevations or reactivations were documented in non-hemato-oncologic settings.

Conclusion: Advances in HBV screening and prophylactic antiviral therapy among rituximab-treated patients, particularly through multidisciplinary collaboration, have significantly reduced reactivation rates. The notably low reactivation in non-hemato-oncologic settings underscores the need to integrate this observation into risk-based treatment and follow-up strategies, ensuring optimized and patient-specific HBV management.

SAT-314

HBV RNA ultra-deep sequencing as a tool for HBV genotyping and resistance monitoring in virologically-suppressed individuals with chronic hepatitis B infection

Emma Bell[1], Maria Teresa Catanese[1], Jean-Christophe Hoflack[1], Sunny Shen[2], Marc Sultan[1], Matteo Metruccio[1], Anna Maria Geretti[1,3], Rémi Kazma[1]. *[1]F. Hoffmann-La Roche Ltd, Basel, Switzerland; [2]Roche R&D Center (China) Ltd, Shanghai, China; [3]University of Rome Tor Vergata, Rome, Italy*
Email: remi.kazma@roche.com

Background and aims: In routine practice, the assessment of the HBV genotype and drug resistance mutations uses sequencing of plasma HBV DNA. However, in the context of the development of novel treatment regimens to achieve functional cure in virologically suppressed individuals with chronic HBV infection, an alternative to investigate HBV genotype and drug resistance is needed. As HBV RNA is detected in the plasma of a fraction of virologically suppressed individuals, our aim was to develop an ultra-deep sequencing assay targeting the viral Pol/RT domain to determine HBV genotype and monitor pre-existing and treatment-induced resistance in clinical trials recruiting virologically suppressed participants.
Method: HBV RNA was extracted from plasma samples obtained from a cross-sectional cohort of 60 adults with chronic HBV infection whose origin was mainly from Europe, Asia, and Africa. The median (IQR) HBV DNA level was 3.3 (1.4–4.5) $\log_{10}$ IU/mL; overall, 25% (15/60) were virologically suppressed on antiviral therapy (HBV DNA < 10 IU/mL). The HBV RNA level was assessed using qPCR. For HBV RNA sequencing, reverse transcription of HBV RNA followed by nested PCR amplification of the Pol/RT domain were performed. Libraries of the PCR products were prepared and then sequenced to a depth of 5000x using Illumina short-read sequencing. The HBV genotype was determined by phylogenetic analysis with reference sequences. In addition, 22 samples had sufficient volume to perform HBV DNA sequencing of the whole HBV genome.
Results: Of the 60 plasma samples tested, 45 had detectable plasma HBV RNA with a median (IQR) level of 3.4 (1.2–6.0) $\log_{10}$ copies/mL. HBV RNA sequencing was successful in 43 samples to which an HBV genotype was assigned: A = 4, B = 11, C = 20, D = 5, and E = 3. The median (IQR) HBV RNA level of samples successfully sequenced was 4.9 (2.9–6.6) $\log_{10}$ copies/mL with 2 samples that succeeded sequencing despite having undetectable HBV RNA levels. HBV DNA sequencing succeeded in 14 of 22 samples. The concordance rate between the HBV genotype assigned by RNA and DNA sequencing was 100% (A = 1, B = 4, C = 8, and D = 1). All 14 successful sample pairs showed a nearly identical sequence match between the RNA and DNA sequencing (99.3–100%). Using sequencing of *in vitro* transcribed HBV RNA at 3 concentration levels, the total error rate of the assay was estimated at 3.4%. Therefore, the use of a conservative cutoff threshold at 5% for variant calling offers a reliable option to monitor HBV RNA minor variants. The evaluation of the use of HBV RNA sequencing for resistance monitoring is underway.
Conclusion: HBV RNA sequencing is a sensitive method to determine genotype in samples from virologically suppressed individuals. The assay also reliably detects HBV RNA minor variants above a threshold of 5%, offering insights into the evolution of viral RNA species and resistance mechanisms. This method holds promise for supporting the development of new therapies targeting HBsAg aimed at HBV functional cure.

SAT-315

Establishment and application of a new method for dual detection of HDV RNA and HBV DNA based on CRISPR technology

Feng Ren[1], Yuan Tian[2], Zihao Fan[2], Ling Xu[2]. *[1]Beijing institute of Hepatology/Beijing Youan Hospital, Beijing, China; [2]Beijing Institute of Hepatology/Beijing Youan Hospital, Beijing, China*
Email: renfeng7512@hotmail.com

Background and aims: Hepatitis D virus (HDV) is a defective virus that is dependent on hepatitis B virus (HBV) for infection and replication, and co-infection with HDV and HBV exacerbates the development of viral hepatitis. In this study, we used the clustered regularly interspaced short palindromic repeats-CRISPR-associated proteins (CRISPR-Cas) system to establish a method for the detection of HDV RNA and HBV DNA, as well as dual detection.
Method: We constructed HDV and HBV plasmids by comparing conserved sequence regions; and we designed and screened RT-RAA primer pairs to amplify the HDV plasmid and RAA primers to amplify the HBV plasmid, as well as corresponding crRNAs (CRISPR-derived RNAs), respectively; the conditions of the assay were optimized, leading to the establishment of a new CRISPR-Cas13a/Cas12a-based assay. Then the sensitivity and specificity of the new method was evaluated by fluorescence and lateral flow test strip method of the "line elimination method". The established new assay was validated by collecting HDV- and HBV-related clinical samples in comparison with RT-qPCR and RT-ddPCR methods.
Results: RT-RAA-CRISPR-Cas13a/RAA-CRISPR-Cas12a fluorescence and "line elimination" lateral flow test strip assays were established for HDV RNA detection and HBV DNA detection, respectively. The sensitivities of RT-RAA-CRISPR-Cas13a for detecting HDV plasmids and positive samples were both 10 copies/μL, and the sensitivities of RAA-CRISPR-Cas12a for detecting HBV plasmids and positive samples were both 1 copy/μL. Moreover, we established a RT-RAA-CRISPR-Cas13a/Cas12a dual fluorescence and "line elimination" lateral flow test strip assays for HDV RNA and HBV DNA. The sensitivity for detecting HDV and HBV plasmids and positive samples was 10 copies/μL, and there was no cross-reactivity between the detection of HDV and HBV and other related viruses; the RT-RAA-CRISPR-Cas13a/Cas12a dual fluorescence and lateral flow test strip assays showed a detection rate of 70% and 65.7% for HDV RNA and HBV DNA, respectively.
Conclusion: We developed a novel CRISPR-Cas13a/Cas12a-based assay for accurate, convenient, highly sensitive and specific detection of HDV RNA and HBV DNA, providing a more effective alternative for early detection and treatment of HDV and HBV infections, as well as for the guidance of medication administration and the evaluation of clinical therapeutic effects.

Sustained HBsAg loss in HIV/HBV-coinfected patients is not a rare event under HBV-active ART even if a residual risk of viral reactivation and liver disease progression still persists over time

Email: rsalpini@yahoo.it

Background and aims: To date, HBsAg loss is considered the best surrogate marker for HBV functional cure. Here, we investigate the still controversial rates of HBsAg loss in the setting of HBV/HIV coinfection, its clinical determinants and long-term outcomes.
Method: This study included HBV-chronically infected people with HIV (PWH) from the Italian Icona cohort who started an antiretroviral regimen (ART) with ≥1 HBV active drug (TDF/TAF and/or FTC or 3TC). HBsAg loss was defined as HBsAg negativity in 2 consecutive time-points or 1 HBsAg negative and HBsAb turned positive. Kaplan-Meier curve was used to estimate the probability of HBsAg loss. Cox regression models adjusted for age, CD4 count and calendar year of baseline, when appropriate, were used to assess baseline clinical factors associated with HBsAg loss. The rate of HBV-reactivation and the clinical progression to liver disease (FIB4 > 3.25) was investigated by Kaplan-Meier curve in PWH experiencing HBsAg loss.
Results: 344 PWH included, mostly males (84.6%), Italian (74.4%), infected by heterosexual (39.5%) and MSM transmission (35.2%), with a median age of 40 (IQR: 34–48) years. At the time of starting HBV-active ART, median CD4+ cell count and HIV-RNA were 272 (136–450) cells/mm^3 and 4.7 (4.1–5.2) log copies/ml. In a median follow-up of 7.5 (4.2–12.1) years, HBsAg loss occurred in 34 PWH (10%). Probabilities of HBsAg loss at 5 and 10 years were 8.6% [95%CI 5.6–13.2%] and 15.1% [10.3–21.9%], respectively; notably, 59.7% also seroconverted to antiHBs. Older age (aHR for 10 years older: 1.44, 95%CI 1.01–2.06) and MSM (aHR: 2.66, 95%CI 1.15–6.13) were the only factors associated with HBsAg loss. No other clinical parameters were associated with HBsAg loss, including the other hepatitis co-infections and baseline HIV viro-immunological status.After achieving HBsAg loss, in a median follow-up of 5.0 [3.2–7.4] years, 2 PWH, both anti-HBs negative, experienced HBV reactivation with HBsAg positivity and HBV-DNA reuptake (2.9 and 4.8 log IU/ml) despite still on TDF/FTC treatment, with a probability of HBV reactivation of 5.5% [0.8–33.4%] at 2-year and 16.0% [3.9–53.2%] at 5-years. Among PWH with FIB-4 <3.25 at HBsAg loss (N = 24), 2 (8.3%) PWH had liver disease progression (FIB4 > 3.25), after 3 and 6 years, while HBsAg negative (1 was HCV-RNA positive).
Conclusion: A substantial proportion of PWH with chronic HBV infection achieves HBsAg loss during HBV-active ART with a probability of 15% by 10-years. HBsAg loss was maintained even if reactivation occurred with a 5.5% probability at 5-years. This highlights the need to better understand viro-immunological features underlying HBsAg loss and the risk to develop HBV reactivation and liver disease progression. This can have relevant implications for the success of incoming antiviral strategies aimed at achieving HBV functional cure in the setting of HIV coinfection.

SAT-317
HCC risk in intermediate PAGE-B patients: implications for surveillance strategies

Sara Battistella[1,2], Jose Rios[3,4], Anna Pocurull Aparicio[1,2], Zoe Mariño[1,2], Marco Sanduzzi Zamparelli[1,2,5], Alejandro Forner[1,2,5], María Reig[1,2,5], Xavier Forns[1,2], Sabela Lens[1,2]. *[1]Liver Unit, Hospital Clínic, IDIBAPS, University of Barcelona, Spain, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Barcelona, Spain; [3]Biostatistics Unit, Medical School, Universitat Autònoma de Barcelona, Campus, Cerdanyola, 08193, Barcelona, Spain; [4]Department of Clinical Pharmacology, Hospital Clinic and Medical Statistics Core Facility, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS)., Barcelona, Spain; [5]Barcelona Clinic Liver Cancer (BCLC), IDIBAPS, University of Barcelona, Spain, Barcelona, Spain*
Email: sarabattistella93@gmail.com

Background and aims: Hepatitis B virus (HBV) is a leading global cause of hepatocellular carcinoma (HCC). PAGE-B score is widely used to predict HCC risk. Currently, International Guidelines recommend surveillance for patients with advanced fibrosis or those with high risk according to PAGE-B score (score > 17). However, the clinical utility of HCC surveillance in intermediate risk patients (PAGE-B 10–17) remains unclear. This study aimed to (1) assess the risk of HCC in patients with PAGE-B 10–17 and (2) identify additional baseline factors associated with HCC development.
Method: We included all chronic HBV patients with at least one PAGE-B score between 10 and 17 during their follow-up at the Liver Unit of Hospital Clinic, Barcelona. Patients with follow-up duration <12 months, HCC within 6 months of enrolment, or HDV, HCV, or HIV coinfections were excluded. Patients were stratified into low-risk (LR, ≤9), intermediate-risk (IR, 10–17), and high-risk (HR, ≥18) based on PAGE-B score and by baseline cirrhosis status. Demographic, clinical, and biochemical variables were collected at baseline and updated every 6–12 months.
Results: Among 654 patients (20.5% female, median age 50 years [41–59]), 56.7% were Caucasian, and 56% were diagnosed as HBeAg-negative chronic infection. Nearly half (48.3%) were under nucleos(t)ide analogues (NUCs), and 13.8% had baseline cirrhosis. Patients were categorized by PAGE-B scores as follows: LR (18.1%), IR (63.7%), and HR (18.1%). HR and IR groups showed significantly higher APRI, FIB-4, liver stiffness values, and cirrhosis rates compared to LR group. Additionally, the use of NUCs was more frequent in HR and IR than LR patients (61% vs. 46% vs. 39%, p = 0.008). Over a median follow-up of 6.5 years (2–11), 13 patients (2%) developed HCC. The cumulative incidence of HCC at 3, 5, and 10 years across the entire cohort was 1.1%, 1.4%, and 2.8%, respectively. At 10 years, HCC incidence was 1.6% for LR, 2% for IR and 6.7% for HR patients. Non-cirrhotic patients had a 10-year HCC incidence of 0.7% compared to 15% for cirrhotic patient. Interestingly, although Chinese patients comprised only 11.3% of the cohort, they accounted for 31% of HCC cases, underscoring ethnic disparities in the HCC risk.
Patients who developed HCC were more likely to have baseline cirrhosis and elevated ALT and GGT levels. Notably, PAGE-B categories did not significantly differ between patients who did or did not develop HCC (p = 0.370).
Conclusion: In this large cohort with extended follow-up, the incidence of HCC was low and mainly driven by baseline cirrhosis. Patients with intermediate-risk PAGE-B score demonstrated a very low risk of HCC, irrespective of antiviral therapy, raising the question if HCC surveillance in this subpopulation is required. More nuanced risk stratification tools are urgently needed, ensuring cost-effectiveness and competing risks for death while addressing the heterogeneity of HBV-related HCC risk.

SAT-318-YI
Treatment coverage of the WHO 2024 hepatitis B guidelines in patients with chronic hepatitis B

Shaoqiu Zhang[1], Jian Wang[1,2], Chao Jiang[3], Ye Xiong[4], Tao Fan[4], Shengxia Yin[1], Jie Li, Chuanwu Zhu[5], Rui Huang[1,2,3,4], Chao Wu[1,2,4]. *[1]Department of Infectious Diseases, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China; [2]Institute of Viruses and Infectious Diseases, Nanjing University, Nanjing, China; [3]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Jiangsu University, Nanjing, China; [4]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine, Nanjing, China; [5]Department of Infectious Diseases, The Affiliated Infectious Diseases Hospital of Soochow University, Suzhou, China*
Email: dr.wu@nju.edu.cn

Background and aims: Antiviral treatment can improve prognosis for patients with chronic hepatitis (CHB). The WHO 2024 hepatitis B guidelines expanded treatment criteria to increase treatment eligibility. This study assessed treatment coverage under the updated WHO guidelines and compared treatment coverage with 2015 WHO guidelines in a large cohort of CHB patients.
Method: A total of 6,925 treatment-naïve CHB patients were included from three medical centers. Treatment eligibility was determined by four treatment options of the WHO 2024 hepatitis B guidelines: option 1, APRI > 0.5 or transient elastography value > 7 kPa or

evidence of cirrhosis; option 2, HBV DNA > 2000 IU/mL and ALT > 1 × ULN; option 3, presence of co-infections, a family history of liver cancer or cirrhosis, immune suppression, co-morbidities, or extra-hepatic manifestations; the option 4 of persistently abnormal ALT is a conditional recommendation for settings where HBV DNA testing is unavailable and other treatment criteria have not been met.
Results: Among 6,925 patients (60.2% male, median age 38 years), 63.8% met treatment criteria according to options 1–3. The proportions of patients who met option 1, option 2, and option 3 were 37.7%, 39.2%, and 23.4%, respectively. Treatment eligibility was higher in patients aged >30 years (64.5% vs. 61.9%, P = 0.047), males (67.6% vs. 58.0%, P < 0.001), and HBeAg-positive patients (91.5% vs. 53.3%, P < 0.001). When considering 4 options, the overall treatment eligibility rate achieved 61.6% which was significantly higher than the rate of 36.2% by the criteria of WHO 2015 hepatitis B guidelines (P < 0.001).
Conclusion: The WHO 2024 guidelines significantly increase treatment eligibility in CHB patients using expanded and simplified criteria. Even in resource-limited settings without HBV DNA testing, treatment coverage remains as high as 61.6%. These updated WHO 2024 guidelines may contribute to accelerating the achievement of WHO's goal for eliminating HBV by 2030.

High GALAD scores predict hepatocellular carcinoma in hepatitis B-related cirrhosis patients who received antiviral therapy

Tung-Hung Su[1], Chun-Jen Liu[1], Hung-Chih Yang[1], Tai-Chung Tseng[1], Shang-Chin Huang[1], Shih-Jer Hsu[1], Chun-Ming Hong[1], Chen-Hua Liu[1], Pei-Jer Chen[1], Jia-Horng Kao[1]. *[1]National Taiwan University Hospital, Taipei, Taiwan*
Email: kaojh@ntu.edu.tw

Background and aims: In hepatitis B-related cirrhosis patients on long-term antiviral therapy, hepatocellular carcinoma (HCC) risk persists, motivating the need for risk prediction. The GALAD score, encompassing gender, age, alpha-fetoprotein L3, alpha-fetoprotein, and des-gamma carboxyprothrombin (DCP) measurements, is designed for HCC detection. This study investigates the role of the GALAD score in HCC prediction in CHB-related cirrhosis patients on antiviral therapy.
Method: We conducted a retrospective cohort study to include HBV-related cirrhotic patients undergoing long-term antiviral therapy with regular HCC surveillance. The serum samples were retrieved for alpha-fetoprotein-L3, alpha-fetoprotein, and DCP measurements to calculate the GALAD score. Cox proportional hazard regression analysis identified risk predictors for HCC.
Results: A total of 252 patients were included, with a median follow-up of 6.1 years. HCC developed in 64 patients with an annual incidence of 4%. The GALAD scores were measured before therapy in 213 patients and after a median of 2.6 years of antiviral therapy in 39 patients, with a median GALAD score of −2.84 and −3.76, respectively (p = 0.012). Overall, the pre-treatment GALAD score classifies the risks of 1-year HCC significantly better than alpha-fetoprotein-L3, alpha-fetoprotein, and DCP, with an AUROC of 0.857. Higher GALAD scores significantly increased the risk of HCC before antiviral therapy (per 1 GALAD score increase, adjusted hazard ratio [aHR] 1.20, 95% confidence interval [CI]: 1.06–1.35), and during antiviral therapy (aHR: 1.72, 95% CI: 1.10–2.70). The pretreatment GALAD score ≥−1.35 (vs. <−1.35) or on-treatment GALAD score ≥−3.38 (vs. <−3.38) increased 1.83-folds and 3.85-folds risks of HCC, respectively.
Conclusion: High pre-treatment or on-treatment GALAD scores significantly stratified a greater risk of HCC. The GALAD score may be measured during routine HCC surveillance.

Email: qning@vip.sina.com

Background and aims: Functional cure is considered the advanced treatment goal for patients with chronic hepatitis B (CHB). We aimed to evaluate hepatitis B surface antigen (HBsAg) loss rates after combination treatment of entecavir (ETV), peginterferon alfa-2b (Peg-IFN) with or without granulocyte-macrophage colony stimulating factor (GM-CSF).
Method: In this multicenter randomized controlled trial, 257 virally-suppressed patients undergoing nucleos(t)ide analogues treatment who had HBsAg <3000 IU/mL were randomized (1:1:1) to receive either ETV for 96 weeks (E group), or 48 weeks of Peg-IFN+ETV, followed by 48-week Peg-IFN alone (EP group), or 48 weeks of Peg-IFN+ETV+GM-CSF, followed by 48-week Peg-IFN alone (EPG group). The primary outcome is HBsAg loss at week 96.
Results: Among 249 patients (81 in E group, 83 in EP group and 85 in EPG group) receiving at least one dose of the study drug, EP group (30.12%, 35.53%) and EPG group (22.35%, 34.67%) achieved significantly higher HBsAg loss and hepatitis B surface antibody (HBsAb) positivity rates than E group (0.00%, 0.00%; p < 0.0001, p < 0.0001) at week 96. Multivariate analysis showed that age, HBsAg level at baseline and HBsAg decline at week 24 correlated with HBsAg loss or HBsAb positivity at the end of Peg-IFN-based treatment. HBV RNA decline at week 24 correlated with HBsAg loss. The HBsAg longitudinal trajectory could predict HBsAg loss with an AUROC of 0.944. More patients in EP group and EPG group experienced adverse events than E group. Peg-IFN-based therapy was generally well tolerated.
Conclusion: In virally-suppressed patients with CHB, combination of ETV and Peg-IFN with or without GM-CSF improved the rates of HBsAg loss and HBsAb positivity. HBsAg trajectory may accurately predict HBsAg loss under Peg-IFN-based therapy.

SAT-321

Immunological correlates of rapid HBsAg decline in chronic HBV hepatitis patients undergoing Tenofovir Amibufenamide treatment

Shu Xiong[1], Hang Jia[1], Xu Quan[1], Bo Liang[1], Si Lu[1], Yi Cheng[1], Hua Wang[1], Han Li[1], Ling Xu[1], Su Li[1], Tong Wang[1], Yi Shu[1], Jia Yu[1], Jia Liu[1,2], Xin Zheng[1,2]. *[1]Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China; [2]Joint International Laboratory of Infection and Immunity, Huazhong University of Science and Technology, Wuhan, China*
Email: xiong2015un@163.com

Background and aims: While most chronic viral hepatitis B (CHB) patients undergoing Tenofovir amibufenamide (TMF) antiviral therapy experience a rapid decline in HBV DNA levels, the same is not observed for HBsAg decline in all patients, highlighting unclear immunological mechanisms. This study aims to prospectively and dynamically observe immunological changes during the initial stage of TMF antiviral treatment.
Method: A total of 37 CHB patients who will initiate antiviral treatment with TMF were enrolled, comprising 18 HBeAg positive and 19 HBeAg negative individuals. Clinical assessment was performed over 48 weeks post-TMF treatment. The phenotypes of B cells, dendritic cells (DCs), monocytes, T cells, and HBV-specific T cell functions were longitudinally assessed using freshly isolated peripheral blood mononuclear cells (PBMCs).
Results: The study revealed a rapid decrease in HBV DNA and RNA levels following TMF antiviral treatment among all CHB patients. Notably, the HBeAg positive group exhibited a significant decline in HBsAg levels, characterized by abnormal ALT levels at baseline. Immunological marker monitoring revealed elevated frequencies of B cells and CD8 T cells in HBeAg positive group, while a significant decrease in T cells was observed in the HBeAg negative group, primarily due to a reduction in CD4 T cells. In general, both groups exhibited a transient upregulation in the expression of CD80, CD86, and CD72 on B cells following 8 weeks of TMF treatment. The HBeAg negative group showed a significant increase in the expression of CD80 and PD-L1 on B cells and PD-L1 on monocytes, while demonstrating a decrease in CD72 on B cells expression compared to baseline levels. Furthermore, they also manifested a more robust HBcAg-specific T cell response. Moreover, among those who exhibited a reduction in HBsAg above 0.5log within 12 weeks of treatment in HBeAg positive group, elevated levels of CD80 and CD72 expression were observed on B cells, along with increased expressions of CD86, CD80, and PDL-1 on monocytes. The expressions of both CD25 on CD4 T cells and HLA-DR on CD8 T cells remained consistently elevated throughout the entire follow-up period but showed a declining trend. However, these patients still did not exhibit a robust HBV-specific T cell response.
Conclusion: TMF antiviral treatment leads to a more pronounced HBsAg reduction in HBeAg positive naïve patients accompanied by consistent activation of B cells and monocytes, as well as a gradual decline in T cell activation. Only the HBeAg negative group exhibits a stronger HBV-specific T cell response. Our findings suggest potential differential immunological mechanisms underlying TMF's antiviral effect between HBeAg negative and positive patients, along with significant reduction of HBsAg during the early stage of TMF treatment.

SAT-322

Nucleos(t)ide analogue cessation outcomes in non-cirrhotic patients with HBeAg-negative chronic hepatitis B

Zeynep Melekoğlu Ellik[1], Fatma Tuğçe Şah Ünal[2], Özge Koç[1], Serkan Duman[3], Sevinç Tuğçe Güvenir[1], Volkan Yılmaz[1], Mesut Gümüşsoy[4], Abdullah Mübin Özercan[5], Emin Bodakçi[4], Ramazan Erdem Er[1], Hale Gokcan[1], Ramazan Idilman[1]. *[1]Ankara University School of Medicine, Department of Gastroenterology, Ankara, Türkiye; [2]Ankara University School of Medicine, Department of Endocrinology and Metabolism Diseases, Ankara, Türkiye; [3]Toros State Hospital, Mersin, Türkiye; [4]Gaziantep City Hospital, Department of Gastroenterology, Gaziantep, Türkiye; [5]Fırat University School of Medicine, Department of Gastroenterology, Elazığ, Türkiye*
Email: zeynepmelekoglu33@hotmail.com

Background and aims: Since a functional cure is rare during nucleos (t)ide analog (NAs) therapy, this treatment is typically lifelong for patients with chronic hepatitis B (CHB). We aimed to determine the outcomes of discontinuing NA treatment after the cessation of NA therapy in a large cohort of patients with HBeAg-negative CHB at a single center.
Method: This HBeAg-negative CHB court study included 140 non-cirrhotic patients who had virally suppressed and stopped NA therapy. Seventy patients (male/female ratio: 39/31, median age: 53.0 years) discontinued their NA treatment, while 70 age- and gender-matched patients who continued long-term NA treatment for at least 60 months were randomized in a 1:1 ratio. NA treatment was discontinued in selected non-cirrhotic patients who received long-term (>5 years) antiviral treatment and had achieved at least 3 years of virological suppression under NA treatment. HBV reactivation (virological and biochemical relapse) was defined as a single elevation of HBV DNA >2000 IU/mL and a single elevation of serum ALT >2× upper limit of normal (ULN) level during the off-treatment follow-up period. The primary outcome was sustained HBsAg loss for up to week 96, and the secondary outcome was HBV relapse after NA cessation.
Results: The median off-treatment follow-up duration was 45.5 months. Four patients in the antiviral treatment discontinuation group experienced HBsAg loss, while none in the NA treatment group experienced HBsAg loss ($p = 0.042$). Sustained remission was achieved by 43 patients (61.4%, 43/70), while overall, HBV relapse occurred in 27 patients during the off-treatment follow-up period. HBV reactivation was most commonly observed within three months after the cessation of NA treatment (n = 21, 77.8%). Re-treatment with NAs was initiated in these 27 patients. A decrease in serum HBV DNA to undetectable levels and normalization of serum ALT was achieved in all patients undergoing NA treatment. No serious adverse events related to antiviral treatment cessation occurred.
Conclusion: The cessation of NA treatment in non-cirrhotic CHB patients was associated with a significant loss of HBsAg and was effective in achieving treatment endpoints.

Background and aims: Peg-interferon (peg-IFN) plays an increasingly important role in HBV cure strategies, either in combination with novel antivirals or as a lead-in treatment to reduce viral antigen burden before novel antivirals are introduced. Robust estimates of HBsAg decline and clearance that can be achieved with peg-IFN addition to nucleo(s)tide analogue (NA) therapy are therefore urgently needed.
Method: We performed a post-hoc meta-analyses of individual participant data from 7 international prospective clinical trials involving CHB patients on NA therapy who received peg-IFN add-on treatment for 24 to 48 weeks. The primary endpoint of our analyses was HBsAg loss at end of follow-up (EOF, 6 to 12 months after end of peg-IFN therapy). Secondary analyses focused on on-treatment HBsAg decline to <1,000 IU/mL.
Results: We included 531 patients, 431 (81%) were male, 370 (70%) were Asian, mean age was 44 (±11) years. At start of peg-IFN therapy (SOT), 205 (39%) were HBeAg positive, mean HBsAg level was 3.02 (±0.96) log10 IU/mL (HBsAg <100 IU/mL: 66 (13%); 100–1,000 IU/mL: 152 (29%); >1,000 IU/mL: 306 (58%)), median HBV DNA was TND [IQR: TND-TND] and median ALT was 0.77 [IQR: 0.59–1.07]×ULN. Peg-IFN add-on was planned for 48 weeks in 446 patients (84%). At EOF, 49 (9.2%) patients achieved HBsAg loss. HBsAg loss rates varied with SOT HBsAg levels; HBsAg loss was achieved in 40.9/11.2/1.6% of patients with SOT HBsAg <100/100–1,000/>1,000 IU/mL ($p < 0.001$). Findings were also consistent across ethnicities (Caucasian: 30.0/8.7/3.6%, $p = 0.007$; Asian: 41.5/10.8/1.0%, $p < 0.001$). HBsAg loss was achieved in 20.2% amongst patients with SOT HBsAg <1,000 IU/mL, and in 13.2% amongst patients with SOT HBsAg <3,000 IU/mL. HBeAg status was not associated with HBsAg loss when adjusted for baseline HBsAg levels ($p = 0.39$). Mean HBsAg decline after 24 and 48 weeks of peg-IFN add-on was −0.61 (±0.96) and −0.96 (±1.19) log10 IU/mL. Amongst patients with HBsAg >1,000 at SOT, HBsAg <1,000 IU/mL was achieved in 28% at week 24 and in 45% at week 48. In pairwise analysis, 48 weeks of treatment was superior to 24 weeks in achieving levels <1000 IU/mL for patients with SOT HBsAg 1,000–2,000 IU/mL (79.4% vs. 68.3%, $p = 0.016$), 2,000–3,000 IU/mL (44.2% vs. 25.0%, $p = 0.013$), and >3,000 IU/mL (26.7% vs. 14.3%, $p = 0.004$).
Conclusion: Addition of peg-IFN to NA-therapy results in HBsAg loss in 20% of patients with SOT HBsAg <1,000 IU/mL, and in 41% of those with SOT HBsAg <100 IU/mL. Amongst patients with higher HBsAg levels, peg-IFN can be used to reduce HBsAg to below thresholds associated with response to novel antivirals, although 48 weeks of therapy seems required to optimize response rates. These findings can be used as a reference for the design of trials aiming for HBV cure.

Email: lisabetta.degasperi@policlinico.mi.it

Background and aims: Bulevirtide (BLV) monotherapy up to 144 weeks was safe and effective in patients with chronic hepatitis D virus (HDV) infection in the MYR-301 trial, however real-life data in large cohorts of patients with cirrhosis are lacking.
Method: Consecutive HDV patients with cirrhosis reaching week 144 of BLV 2 mg/day sc monotherapy in the retrospective multicenter real-life European study (SAVE-D) were included. Virological (HDV-RNA undetectable or ≥2-log decline *vs.* baseline), biochemical (ALT <40 U/L), combined response (biochemical + virological), adverse events and liver-related events (LREs) were assessed. HDV RNA was tested locally.
Results: 48 patients treated with BLV monotherapy for 144 weeks were enrolled: age 51 (IQR 41–58) years, 65% men, ALT 106 (66–144) U/L, liver stiffness measurement (LSM) 20.8 (14.6–27.5) kPa, platelets 76 (54–113) × 10^3/mm^3, 98% CPT score A, 52% with varices, 2% HIV-positive, 8% with a history of previous decompensation, 4% with active HCC, 100% on NUC. Baseline HBsAg levels and HDV-RNA were 3.8 (3.6–4.1) log IU/mL and 5.4 (4.4–6.3) log IU/mL, respectively, median HBcrAg (positive in 90% of available samples) 3.8 (3.5–4.4) $\log_{10}$ U/mL. Following 144 weeks of BLV monotherapy, 75% of patients achieved a virological response, 67% a biochemical response, 56% a combined response, 35% HDV RNA undetectability. 5 (10%) patients had <1 Log HDV RNA decline *vs.* baseline (non-virological response), whereas 7 (15%) had achieved at >1 but <2 Log HDV RNA decline (partial virological response). 42 (51%) of patients with a suboptimal response (non- or partial virological response) had at least a 50% ALT decrease compared to baseline. During long-term BLV monotherapy, AST, GGT, IgG and AFP levels significantly declined while albumin levels increased ($p < 0.001$ compared to baseline). Mean HBsAg levels declined (Bas → W144: 3.7 → 3.5 Log_{10}IU/mL, $p = 0.02$), as well as mean HBcrAg values (4.1 → 3.7 $\log_{10}$ U/mL, $p = 0.01$), LSM values (24.2 → 17.4 kPa, $p = 0.001$) and serological non-invasive tests of fibrosis (FIB-4, APRI score). At variance, no significant reduction in spleen

stiffness values was observed. No baseline predictors of HDV RNA undetectability at week 144 (baseline ALT, HBsAg levels HDV RNA levels, bile acids) were identified. Bile acids levels increased, 25% of patients reported mild and transient pruritus, independently of bile acid levels. During 144 weeks of BLV treatment, de-novo ascites occurred in 3 patients, no patients died or underwent liver transplantation.
Conclusion: BLV monotherapy 2 mg/day for 144 weeks confirmed safety and effectiveness in patients with HDV-related cirrhosis also in real-life setting. Liver-related events were rare.

Background and aims: Bulevirtide (BLV) has been available in Italy since May 2023 for patients with chronic hepatitis Delta (CHD), but no studies have addressed features of patients treated with BLV and their responses to treatment yet.
Method: CHD patients starting BLV 2 mg/day as monotherapy were included in a multicenter prospective real-life Italian study (D-SHIELD). Patients' characteristics and treatment responses were assessed at baseline and trimonthly afterwards in patients with or without cirrhosis. The primary endpoint was the achievement of a virological response, defined as a reduction in HDV RNA >2 Log IU/mL compared to baseline or HDV RNA undetectable.
Results: 404 patients from 38 centers were enrolled in this ongoing study: 303 (75%) cirrhotics and, 101 non-cirrhotics (25%). At baseline, median HDV RNA was 5.1 (1.5–8.2) *vs.* 5.7 (2.3–7.4) Log IU/ml (p = 0.005), ALT 75 (12–1,074) *vs.* 75 (19–513) U/L (p = 0.20). Median age 55 (24–82) *vs.* 55 (26–76), 55% *vs.* 55% men, 97% *vs.* 93% on NA therapy; 94% *vs.* 94% European origin. Among cirrhotics, 40% had varices, 10% previous history of HCC, 10% previous history of ascites, 3% of varices hemorrhage, 6% were decompensated. As of the end of November 2024, 340 patients (257 cirrhotics and 83 non-cirrhotics) completed 24 weeks and 203 (160 cirrhotics, 43 non-cirrhotics) patients have completed 48 weeks of treatment. ALT declined in both groups at week 24 (median ALT levels 35 *vs.* 35 U/L, p = 0.60) and at week 48 (31 *vs.* 31 U/L, p = 0.90). HDV RNA decline was more pronounced in non-cirrhotics at week 24 (3.5 *vs.* 3.8 Log IU/mL, p = 0.04), but not at week 48 (2.9 *vs.* 3.2 Log IU/mL, p = 0.06). Virological, biochemical and combined responses were achieved by 47% *vs.* 42% (p = 0.60), 64% *vs.* 69% (p = 0.51), and 34% *vs.* 32% (p = 0.89) of patients at week 24; 68% *vs.* 50% (p = 0.04), 69% *vs.* 68% (p = 0.87), and 49% *vs.* 34% (p = 0.06) of patients at week 32, and by 66% *vs.* 65% (p = 1), 73% *vs.* 55% (p = 0.06), and 54% *vs.* 33% (p = 0.05), of patients at week 48 in cirrhotics *vs.* non-cirrhotics, respectively. At the same time points HDV RNA undetectability (defined as target not detected or <lower limit of detection or quantification) was achieved by 13% *vs.* 10% (p = 0.69), 22% *vs.* 14% (p = 0.53) and 24% *vs.* 20% (p = 0.68) of cirrhotics *vs.* non-cirrhotics, respectively. Among non-virological responders at week 24, a partial virological response (HDV RNA decline >1 Log IU/mL but <2 log IU/mL compared to baseline), was achieved by 24% *vs.* 23% (p = 1), and 20% *vs.* 14% (p = 0.76) of cirrhotics *vs.* non cirrhotics

patients at week 32 and 48, respectively and a virological response by 44% *vs.* 26% (p = 0.09) and 53% *vs.* 48% (p = 0.81), respectively.
Conclusion: D-SHIELD is the largest single country study on BLV treatment for CHD in Europe. Virological, biochemical and combined responses through week 48 were overall similar between patients with and without cirrhosis.

WED-286
Comparative renal safety of besifovir dipivoxil maleate and tenofovir disoproxil fumarate in chronic hepatitis B patients: insights from a nationwide cohort study
Hyun Bin Choi[1], Jae-Young Kim[2], Jeong-Ju Yoo[3], Sang Gyune Kim[3], Young Seok Kim[3]. *[1]Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South; [2]Department of Internal Medicine, Soonchunhyang University School of Medicine, Bucheon, Korea, Rep. of South; [3]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South*
Email: 123123mike@naver.com

Background and aims: Besifovir dipivoxil maleate (BSV) is a novel antiviral agent approved in Korea for chronic hepatitis B (CHB) treatment. While previous comparative studies between BSV and tenofovir disoproxil fumarate (TDF) suggested lower renal toxicity with BSV, these findings were limited by small sample sizes. This study aimed to comprehensively assess the incidence of chronic kidney disease (CKD) in CHB patients treated with BSV versus TDF using a nationwide cohort.
Method: In this retrospective cohort study, we analyzed treatment-naïve CHB patients who initiated BSV or TDF therapy between January 2018 and December 2022. Using South Korean national health database, we created balanced cohorts of 25,849 patients each through inverse probability of treatment weighting (IPTW). The primary outcome measure was CKD incidence.
Results: The incidence rate (IR) of CKD was significantly lower in the BSV group compared to the TDF group (3.11 vs. 4.75 per 1,000 person-years; incidence rate ratio [IRR] 1.53, 95% CI 1.28–1.82, p < 0.001). Using BSV as the reference, the adjusted hazard ratio (HR) for CKD in the TDF group was 1.26 (95% CI 1.05–1.52, p = 0.014). In patients aged 60 years and older, TDF showed a markedly higher incidence and risk of CKD (IR 3.93 vs. 10.18 per 1,000 person-years; IRR 2.59, 95% CI 1.87–3.59, p < 0.001; HR 2.45, 95% CI 1.74–3.47, p < 0.001).
Conclusion: BSV is linked to a lower incidence of CKD compared to TDF, particularly in patients aged 60 and older, suggesting it may be a safer treatment option for CHB, especially in elderly patients at higher risk of renal impairment.

WED-287
High levels of hepatitis B virus deoxyribonucleic acid integration by high-throughput viral integration detection method predict non-responsiveness of antiviral treatment
Misi Gu[1], Wenyu Wu[1], Jie You[1], Qianjun Wu[1], Fei Huang[1], Yixuan Zhang[1], Peng Wang[1], Dong Xi[1], Weiming Yan[1], Xiaojing Wang[1], Tao Chen[1], Di Wu[1], Qin Ning[1], Meifang Han[1]. *[1]The Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Huazhong University of Science and Technology, Wuhan, China*
Email: mfhan@foxmail.com

Background and aims: Hepatitis B virus (HBV) integration influences antiviral response. We aimed to analyse the features of HBV integration in chronic hepatitis B(CHB) patients and identify integration parameters predicting antiviral response.
Method: A total of 257 nucleos(t)ide analogues (NUCs) experienced CHB patients were recruited in Anchor study, then were randomized (1:1:1) into ETV monotherapy group (Group I), pegylated interferon alpha-2b (Peg-IFN) & ETV combination therapy group (Group II), and Peg-IFN & ETV & Granulocyte-macrophage Colony Stimulating Factor (GM-CSF) combination therapy group (Group III), and 249 participants completed the entire 96-week antiviral treatment regimen. The patients who obtained HBsAg loss at week 96 were named as responders, otherwise named as non-responders. Respectively, 13 and 17 cases were randomly selected from responders and non-responders in the Peg-IFN & ETV group (Group II), as well as additional 15 cases from the ETV monotherapy group (Group I) for high-throughput Viral Integration Detection (HIVID) with pairs of liver samples (at baseline and week 48).
Results: At baseline, the levels of integration were much higher in patients with a family history of CHB compared to those without and were positively correlated with the duration of CHB, and the levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST), but not with the levels of HBsAg, HBcrAg, HBV RNA and HBV cccDNA quantification. After 48 weeks of antiviral treatment in either Group I or Group II, the levels of HBV integration were essentially comparable with those at baseline. Totally, the non-responders of antiviral therapy demonstrated greater elevated numbers of break-point types of integration at both baseline and week 48 when compared to responders. Especially, the non-responders in Group II displayed much higher numbers of recurrent integrations and clonal integrations than responders at week 48. A baseline number of breakpoint types exceeding 28 might serve as an indicator for predicting non-response at week 96 of antiviral therapy totally.
Conclusion: Duration of CHB, ALT and AST levels were associated with the integration levels of virally-suppressed CHB patients. The higher numbers of recurrent integrations and clonal integrations contributed to the non-responsiveness of Peg-IFN treatment and the number of breakpoint types might predict non-responsiveness of antiviral therapy totally.

HBV reactivation in HBV/HDV coinfected patients during bulevirtide monotreatment
Alexander Killer[1], Paul Park[1], Smaranda Gliga[1], Nadine Lübke[2], Andreas Walker[2], Jörg Timm[2], Tom Luedde[1], Hans H. Bock[1].
[1]Department for Gastroenterology, Hepatology and Infectious Diseases, Medical Faculty and University Hospital Düsseldorf, Heinrich Heine University Düsseldorf, Düsseldorf, Germany; [2]Institute of Virology, Medical Faculty and University Hospital Düsseldorf, Heinrich Heine University Düsseldorf, Germany, Düsseldorf, Germany
Email: Alexander.Killer@med.uni-duesseldorf.de

Background and aims: In 2020 bulevirtide (BLV) was conditionally approved in the EU for the treatment of chronic hepatitis D (CHD) as combination treatment with nucleos(t)ide analogues (NA) or as monotreatment. BLV leads to normalization of transaminases and decrease of HDV viral load in most patients by blocking viral entry of HBV/HDV. We report three cases of HBV reactivation in patients with BLV monotreatment who had undetectable HBV DNA at start of treatment.
Method: Real life data collected in clinical routine. Serum CXCL-10 was measured by Quantikine[c] ELISA Human CXCL10/IP-10 Immunoassay. All patients provided written informed consent.
Results: Of 20 patients treated with BLV in our outpatient clinic, three had no detectable HBV-DNA and were therefore initially treated with BLV monotherapy. In patient A HBV-DNA was detectable in month (mo) 4 after BLV start and reached a peak of 25,800 IU/ml in mo. eight, while ALT rose from 91 U/l at start of flare to a maximum of 204 U/l. After starting treatment with tenofovir disoproxil fumarate (TDF) ALT normalized and HBV-DNA was undetectable again. For patient B HBV first became detectable after 30 months of BLV monotreatment, HBV-DNA rose to 2,000 IU/ml in mo. 36, and ALT increased from 29 U/l to 63 U/l. NA led to ALT-normalization and HBV suppression. Six months after the HBV reactivation HDV RNA became undetectable. In patient C, HBV was first detected six months after BLV start. Although HBV-DNA was only 10 IU/ml and ALT remained normal, we started NA-treatment, because the patient had a compensated liver cirrhosis. Reactivation led to an increase of the ISG (interferon-stimulated

gene) CXCL-10 in the sera of patients A (29 → 32 pg/ml) and B (22→34 pg/ml), which decreased after initiating NA treatment (median 32.4 →22.2 pg/ml, six months after NA start). In comparison the CXCL-10 levels of three HBV/HDV patients initially treated with a combination of NA+BLV and therefore without HBV reactivation showed a steady decline of CXCL-10 after starting with BLV before BLV: (median 40.2 pg/ml→ 23.7 pg/ml, 9 months after BLV).
Conclusion: All 3 CHD patients with undetectable HBV-DNA became HBV-DNA positive after initiation of BLV monotreatment. These patients need to be monitored by regular measurement of HBV-DNA, or receive combination treatment. The mechanism of HBV reactivation and profile of inflammatory markers in those cases needs to be further analyzed, because it could unveil interactions between HBV and HDV infection.

WED-289
Patient centered-outcomes in HDV-treated patients with Bulevirtide

Email: francescopaolo.russo@unipd.it

Background and aims: Chronic Hepatitis Delta (CHD) is recognized as the most severe type of viral hepatitis. Bulevirtide, recently approved for treatment, has demonstrated potential in lowering viral loads and improving liver function. However, there is limited real-world evidence regarding its effectiveness, treatment adherence, and patient-reported outcomes (PROs). This study aimed to assess the virological and biochemical responses to bulevirtide, alongside evaluating the impact of a pharmacist-led educational initiative (EXPLAIN) on therapy adherence, quality of life (QoL), and reported adverse effects.
Method: A total of 31 CHD patients undergoing bulevirtide treatment were prospectively monitored at Padua University Hospital. The pharmacist-led educational program aimed to improve patient understanding of the therapy. Primary outcomes measured included virologic response, QoL (assessed using the EQ-5D-5L questionnaire), and adherence (measured via the Proportion of Days Covered, PDC).
Results: At both 24 and 48 weeks, bulevirtide therapy resulted in significant reductions in HDV RNA levels and improved liver function tests. At 24 weeks, 90.3% of patients achieved optimal adherence (PDC ≥90%). QoL scores showed marked improvements during follow-up, particularly in pain and anxiety domains. The safety profile was consistent with prior clinical trials, with commonly reported adverse events including injection-site reactions and fatigue.
Conclusion: The EXPLAIN program facilitated excellent adherence rates and notable QoL improvements, underscoring the critical role of clinical pharmacists in managing CHD antiviral therapy. These findings highlight the value of pharmacist-led education programs in enhancing patient outcomes in real-world clinical settings.

Email: e.ogawa.a65@m.kyushu-u.ac.jp

Background and aims: Chronic hepatitis B (CHB) treatment requires long-term nucleos(t)ide analogue (NUC) therapy, making renal safety evaluation crucial. Tenofovir alafenamide (TAF) has shown favorable viral suppression and renal safety profiles in international clinical trials; however, long-term outcomes, particularly for patients switching to TAF and for those with chronic kidney disease (CKD) remain insufficiently characterized. This study examines the five-year virological efficacy and renal function of CHB patients undergoing sequential TAF therapy.
Method: This real-world, multicenter retrospective study included 414 CHB patients aged 18 and older switched from an NUC to TAF who were followed-up for at least five years. The primary endpoints included five-year virological efficacy (HBV DNA <10 IU/mL and HBsAg reduction), biochemical response (ALT normalization), and renal function (eGFR). Sensitivity analysis assessed patients with CKD (eGFR <60) at the time of TAF switch.
Results: The mean age in the TAF switch group was 57.5 ± 12.6 years, 254 were men (61.4%), 301 (72.7%) had normal ALT levels, and 54 (13.0%) had cirrhosis. Prior treatments included entecavir (ETV) for 177 patients, tenofovir disoproxil fumarate (TDF) for 122, and combination therapy for 115: 52 patients (12.6%) remained HBV DNA positive. After five years of TAF therapy, HBV DNA suppression was achieved by 99.3% of the patients ($P < 0.001$), and the percentage with undetectable HBV DNA (target not detected: TND) significantly improved from 70.5% to 91.7% ($P < 0.001$). No cases of HBV DNA breakthrough due to NUC resistance were observed, including among those previously on combination therapy. The ALT normalization rate increased from 72.7% to 85.8% over the five years ($P < 0.001$). HBsAg

reduction over five years averaged 0.39 ± 0.63 logIU/mL (annual rate: 0.077 logIU/mL), while eGFR decreased by −3.60 ± 7.47 mL/min/1.73 m^2. In the prior ETV group, the eGFR change was −4.51 ± 7.85, compared to −3.27 ± 7.21 in the TDF and combination groups (P < 0.01). Among the 100 patients (23.8%) with CKD at TAF initiation, the five-year HBV DNA suppression rate was 100%, the TND rate was 93.0%, and the ALT normalization rate was 91.0%, indicating robust therapeutic efficacy. The reduction of HBsAg at five years for these CKD patients was 0.36 ± 0.72 logIU/mL, similar to that of patients with normal renal function. Additionally, the eGFR change after five years of TAF therapy remained within the physiological range, at −2.50 ± 6.53.

Conclusion: This five-year follow-up of CHB patients who had been switched to TAF found sustained high virological and biochemical efficacy. Treatment efficacy and renal safety for patients with CKD were comparable to that of non-CKD patients.

WED-291

Long risk of decompensation and HCC in patients with HDV-related compensated cirrhosis treated with Bulevirtide monotherapy for up to 144 weeks: the retrospective multicenter european study (Save-D)

Email: elisabetta.degasperi@policlinico.mi.it

Background and aims: Bulevirtide (BLV) has been approved by EMA for treatment of compensated chronic hepatitis D virus (HDV) infection, however data about liver-related outcomes in HDV cirrhotics treated with BLV are limited.

Method: Patients with HDV-related cirrhosis treated with BLV 2 mg/day sc were included in a retrospective multicenter real-life European

study involving 49 centers (SAVE-D). Virological (HDV-RNA undetectable or ≥2-log decline *vs.* baseline), biochemical (ALT<40 U/L), combined response (biochemical+virological) and liver-related events (LREs) were assessed. Clinically significant portal hypertension (CSPH) was defined according to Baveno VII criteria.
Results: 344 patients treated with BLV monotherapy up to 144 weeks were included: age 50 (IQR 40–58) years, 62% men, ALT 81 (54–130) U/L, liver stiffness measurement (LSM) 16.5 (12.6–25.5) kPa, platelets 100 (68–149) × 10^3/mm^3, 95% CPT score A, 47% with varices, 8% HIV-positive, 13% with previous decompensation, 5% with HCC, 90% on NUC. Baseline HDV-RNA and HBsAg levels were 5.4 (4.1–6.4) log IU/mL and 3.7 (3.2–4.1) log IU/mL, respectively. During treatment, 74%, 41% and 59% of patients achieved a virological, biochemical and combined response, respectively, while 41% HDV RNA undetectability. 21 patients developed a de-novo LRE: 13 HCC and 8 decompensations (ascites in 4, bleeding in 4). Overall, the 3-year cumulative incidence of de-novo LREs was 10.4% (95% CI 7–15%): 6.2% for HCC (95% CI 3–9%) and 3.3% for decompensation (95% CI 1–6%). Median time to HCC was 13 (10–23) months; 11 (85%) patients had early HCC (BCLC 0-A), 11 (75%) had CPT A and 10 (77%) CSPH at baseline. At HCC, 8 (62%) had achieved a virological response to BLV. Median time to decompensation was 14 (6–18) months: 6 (75%) patients had achieved a virological response to BLV, 75% had baseline CPT score A6, with a triggering event identified in 4 cases. In patients with or without baseline CSPH, the 3-year cumulative incidence of HCC was 8.1% (95% CI 3–12%) *vs.* 4.3% (95%CI 1–7%) ($p = 0.18$) and of decompensation 7.6% (95%CI 3–12%) *vs.* 0%, respectively ($p < 0.001$). At Cox regression univariate analysis, higher baseline BMI, spleen size, lower albumin values and CSPH at baseline were associated with LREs. At multivariate analysis, only lower albumin values independently predicted LREs (HR 0.28; 95% CI 0.11–0.71, $p = 0.01$). The 3-year liver transplantation (LT)/ death-free survival was 89.4% (95% CI 85–93%): 18 patients underwent LT (15 HCC, 3 decompensation) and 9 patients died, 4 of liver-related events.
Conclusion: In patients with HDV-related cirrhosis treated with BLV 2 mg/day monotherapy up to 144 weeks, the 3-year incidence of LREs remained low and was associated with lower baseline albumin values. Liver decompensation occurred only in compensated cirrhotics with baseline CSPH.

WED-292

A cross-sectional, intrahepatic analysis of HBV and HDV markers in liver trasplants of untreated and Bulevirtide-treated patients with chronic hepatitis Delta

Elisabetta Degasperi[1], Clara Dibenedetto[1], Marco Maggioni[2], Dana Sambarino[1], Enrico Sguazzini[1], Floriana Facchetti[1], Maria Paola Anolli[1], Michele Sagasta[1], Sara Monico[1], Pierluigi Toniutto[3], Caroline Zöllner[4], Frank Tacke[5], Nasser Semmo[6], Maria Francesca Donato[1], Pietro Lampertico[1,7,8]. *[1]Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]Division of Pathology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [3]Hepatology and Liver Transplantation Unit, University of Udine, Udine, Italy; [4]Department of Hepatology and Gastroenterology, Charité Universitätsmedizin Berlin, Berlin, Germany; [5]Department of Hepatology and Gastroenterology, Charité Universitätsmedizin Berlin, Berli, Germany; [6]Department of Visceral Surgery and Medicine, Inselspital, Bern University, Bern, Switzerland; [7]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy; [8]D-SOLVE consortium, an EU Horizon Europe funded project (No 101057917), Milan, Italy*
Email: elisabetta.degasperi@policlinico.mi.it

Background and aims: Bulevirtide (BLV) was approved by EMA for CHD treatment, however no data exists about intrahepatic features of BLV-treated patients who underwent liver transplantation (LT). Aim of the study was to compare intrahepatic and clinical features of untreated and BLV-treated CHD patients who received LT.
Method: BLV-treated (SAVE-D study) and untreated CHD patients who underwent LT were compared. Clinical and virological features were collected at LT; HDV RNA was quantified with Robogene® 2.0. Intrahepatic (i) HDAg, HBsAg, and HBcAg staining were performed by immune-histochemistry (Ventana Benchmark Ultra System).
Results: 45 LT were studied, 35 untreated patients and 10 patients treated with BLV monotherapy for 14 (5–18) months before LT. BLV-treated and untreated patients were similar in terms of age at LT (56 *vs.* 49 years), male gender (60% *vs.* 49%), indication for LT (HCC 70% *vs.* 49%), HBsAg levels (3.6 *vs.* 3.6 LogIU/mL), NUC therapy (100%) and undetectable HBV DNA (90% *vs.* 80%). By contrast, BLV-treated patients had lower MELD (11 *vs.* 17, $p = 0.01$), lower ALT (41 *vs.* 56, $p < 0.01$) and lower HDV RNA levels (3.0 vs 4.9 LogIU/mL, $p = 0.11$). At histology, iHBcAg stained negative in all patients, while iHBsAg stained negative in 3 (7%) patients, <10% positive in 12 (27%), 10–30% in 13 (29%), >30% in 17 (38%), without significant differences between groups. iHBsAg levels correlated with serum HBsAg ($p = 0.01$), but not with serum HDV RNA. iHDAg stained negative in 13 patients (29%), 1–5% positive in 16 (36%), 10–50% in 12 (27%) and >50% in 4 (9%), without significant differences between groups. Diffuse (42%) and focal (27%) were the most prevalent iHDAg patterns. iHDAg correlated with serum HDV RNA ($p = 0.04$), but not with serum HBsAg or iHBsAg.
Conclusion: In CHD patients undergoing LT, iHBsAg was positive in most patients and correlated with serum HBsAg; on the other hand, iHDAg staining correlated with serum HDV RNA levels but resulted negative or low positive in most patients, independently of BLV-treatment.

WED-293

Comparative performance of hightly sensitive HBcrAg and HBsAg assays in predicting clinical flares and HBsAg loss after nucleos(t)ide analgoues withdrawal in patients with chronic hepatitis B

Yao-Chun (Holden) Hsu[1], Ying-Nan Tsai[2], Jia-Ling Wu[3], Cheng-Hao Tseng[2], Tzu-Haw Chen[4], Jaw-Town Lin[4], Mindie Nguyen[5], Yasuhito Tanaka[6]. *[1]E-Da Hospital, I-Shou University, Kaohsiung, Taiwan; [2]E-Da Cancer Hospital, Kaohsiung, Taiwan; [3]National Cheng Kung University, Tainan, Taiwan; [4]E-Da Hospital, Kaohsiung, Taiwan; [5]Stanford University, Stanford, United States; [6]Kumamoto University, Kumamoto, Japan*
Email: holdenhsu@gmail.com

Background and aims: Finite nucleos(t)ide analogue (NA) therapy has recently been proposed as a potential strategy to facilitate seroclearance of hepatitis B surface antigen (HBsAg). However, NA withdrawal can lead to hepatitis flares with risks of liver failure and death. Monitoring serum levels of HBsAg and hepatitis B core-related antigen (HBcrAg) was reported to aid in predicting off-NA outcomes, but prior studies were limited by the insensitivity of older assays. Furthermore, the comparative performance of these two biomarkers remains incompletely understood.
This study aimed to compare the predictive performance of highly sensitive (iTACT) HBsAg and HBcrAg assays for clinical flares and HBsAg loss after NA cessation.
Method: We conducted a retrospective cohort study involving adults with chronic hepatitis B (CHB) who did not have cirrhosis or hepatocellular carcinoma and who discontinued entecavir or tenofovir after at least 3 years of therapy. Eligible participants had negative hepatitis B e-antigen (HBeAg) and undetectable HBV DNA for at least 12 months prior to treatment cessation. Clinical flare was defined as serum ALT >5 times the upper limit of normal (ULN) following the recurrence of viremia. Serum HBsAg and HBcrAg levels were

quantified using iTACT assays at the end of treatment and every 6 months thereafter for up to 3 years or until antiviral therapy was resumed, whichever occurred first. Time-dependent models were used to evaluate the associations between HBsAg and HBcrAg dynamics and the occurrence of subsequent hepatitis flares or HBsAg loss.

Results: The study enrolled 206 patients (median age, 50.0 years; 78.6% male) who discontinued NA after a median of 37.6 months of treatment (47.6% entecavir, 52.4% tenofovir). During post-NA discontinuation follow-up (median 36.1 months for hepatitis flares and 70.3 months for HBsAg loss), 67 patients experienced hepatitis flares, and 30 achieved HBsAg loss, yielding 8-year cumulative incidence of 38.9% (95% CI, 31.3–47.6%) for hepatitis flares and 16.0% (95% CI, 10.3–22.7%) for HBsAg loss. HBcrAg significantly outperformed HBsAg in predicting hepatitis flares with greater areas under the time-dependent receiver operating characteristic curves (0.71–0.73 vs. 0.58–0.64). Multivariable time-varying analyses confirmed that higher HBcrAg level (vs. HBsAg) was a stronger risk factor for hepatitis flares (adjusted HR, 1.61 per log U/mL; 95% CI, 1.37–1.89), while higher HBsAg level (vs. HBcrAg) was a stronger predictor for lack of HBsAg loss (adjusted SHR, 0.33 per log IU/mL; 95% CI, 0.23–0.47).

Conclusion: Using highly sensitive HBsAg and HBcrAg assays, we found that dynamic HBcrAg levels significantly outperformed HBsAg in predicting post-NA withdrawal hepatitis flares, while HBsAg dynamics were more effective predictors of HBsAg loss. These findings highlight the complementary roles of these two biomarkers in guiding the management of CHB patients discontinuing NA therapy.

WED-294

Virological response and safety of combination treatment with bulevirtide and pegylated interferon in chronic hepatitis D patients with advanced fibrosis/cirrhosis: 48 weeks interim results from SEE-D trial

Karin Lindahl[1], Habiba Kamal[2], Katarina Århem[1], Susanne Cederberg[3], Annika Olsson[3], Niklas Björkström[4], Soo Aleman[5]. [1]*Dept of Infectious Diseases, Karolinska University Hospital/Karolinska Institutet, Stockholm, Sweden;* [2]*Dept of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden;* [3]*Dept of Infectious Diseases, Karolinska University Hospital, Stockholm, Sweden;* [4]*Dept of Clinical Microbiology, Karolinska University Hospital/Karolinska Institutet, Stockholm, Sweden;* [5]*Dept of Infectious Diseases, Karolinska University Hospital/Karolinska Institutet, Stockholm, Sweden*
Email: soo.aleman@ki.se

Background and aims: The Phase 2b MYR204 trial demonstrated that combination therapy with bulevirtide (BLV) and pegylated interferon alfa-2a (48 weeks) achieved higher virological response rates than mono-BLV therapy in patients with chronic hepatitis D (CHD). Clinical trial data on the efficacy and safety of extended combination treatment are lacking. We aimed therefore to evaluate the efficacy and safety of BLV 2 mg and peg-IFN (administered for 96 weeks:180 µg for first 48 weeks, then 135 µg for 48 weeks) therapy in SEE-D study. We present here interim results up to week 48 (w48).

Method: In total, 31 patients with advanced fibrosis/compensated cirrhosis and CHD were treated with BLV, peg-IFN and nucleos(t)ide analogues and assessed in SEE-D, an observational clinical trial conducted at Karolinska University Hospital, Sweden (EU nr 2023-504414-29-00). HDV RNA levels were measured using RoboGene HDV RNA Quantification Kit 2.0, with a lower limit of quantification (LLOQ) and a detection limit (LLOD) of 50 IU/ml and 6 IU/ml, respectively. Adverse events of special interest, serious adverse events (SAE) and SUSAR (suspected unexpected serious adverse reaction) were collected.

Results: At baseline (BL), mean age (±SD) was 44.6 (8.6) years, 58.1% were men, 87.1% Asian, 64.5% IFN-experienced, and median (IQR) liver stiffness measurement was 12.1 (4.2) kPa. Median (IQR) log 10 HDV RNA and HBsAg levels were 5.1 (1.4) and 3.9 (0.5) IU/ml, respectively at BL. At w24 and w48, all patients achieved >2 log HDV RNA reduction, among those who have reached these time points (n = 29 and n = 19, respectively). HDV RNA levels <LLOQ were seen in 75.9% at w24 and 89.5% at w48, while <LLOD was achieved in 34.5% and 78.9%, respectively. While no HBsAg loss occurred, HBsAg reduction of either >2 log decrease or to <200 IU/ml was achieved in 16% of patients (minimum level: 5.3 IU/ml). No significant predictors for HbsAg <200 IU/ml were identified. The proportion of patients with elevated ALT levels decreased from 80.6% at BL to 54.8% at w24 and 63.2% at w48. Bile acids increased from median (IQR) 9.0 (13.0) at BL, to 42.0 (51.8) at w24 and 36.0 (34.0) µmol/L at w48. Cytopenia (≥grade 3) occurred in 61.3%, and 9.7% developed grade 2 thyroid disorders. Peg-IFN dose reduction occurred in 48%. None discontinued BLV, while one discontinued peg-IFN due to exacerbation of inactive psoriasis, with resolved symptoms during follow-up. Three SAEs (9.7%), appendicitis, pyelonephritis, and suspected hepatocellular carcinoma, were reported, and none were classified as SUSAR. Updated data will be reported at the conference.

Conclusion: In this trial study, combination therapy with BLV and peg-IFN resulted in high rates of undetectable HDV RNA by w48, exceeding those reported in previous trials. Significant HBsAg reductions were observed in a subset of patients, with potential for HBsAg loss with extended peg-IFN therapy. These findings highlight the potential of this combination therapy, with need of further studies to define optimal finite therapy strategies.

WED-295

Comparative efficacy and safety of tenofovir amibufenamide vs tenofovir alafenamide and entecavir in the hepatitis B virus related acute-on-chronic liver failure patients: a single-centre retrospective study

Xiaochuan Diao[1], Qianjun Wu[1], Misi Gu[1], Fei Huang[1], Yue Chen[1], Yixuan Zhang[1], Qin Ning[1], Meifang Han[1]. [1]*The Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Huazhong University of Science and Technology, Wuhan, China*
Email: mfhan@foxmail.com

Background and aims: There is a scarcity of clinical studies on the use of tenofovir amibufenamide (TMF) for Hepatitis B Virus-Associated Acute-on-Chronic Liver Failure (HBV-ACLF) patients. The aim of this research is to investigate the efficacy and safety between entecavir (ETV), tenofovir alafenamide fumarate (TAF), and TMF in the treatment of HBV-ACLF.

Method: We selected patients diagnosed with HBV-ACLF, in accordance with the APASL 2019 guidelines. Admitted between May 2022 and January 2024 to the department of infectious diseases ward were the aforementioned patients, from whom we collected multiple clinical indicators and outcomes at the time of their admission and after two weeks and 60 days of their treatment. We then analyzed the differences in clinical indicators between and within ETV, TAF, and TMF. Concurrently, we conducted a survival analysis to assess the efficacy and safety profiles of these three medications. The research was approved by the Ethics Committee of Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology.

Results: A total of 235 patients were included in the study: 41 in the TMF group, 60 in the TAF group, and 117 in the ETV group. The 60-day overall survival rates for three groups were 71.11%, 73.77%, and 73.65%, respectively ($p > 0.05$). After two weeks of treatment, all the three groups of patients showed significant improvements in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels ($p < 0.05$), and there were no significant differences between the three groups in above indicators. None of the groups experienced worsening deteriation of renal function after treatment, and the estimated glomerular filtration rate (eGFR) levels at two weeks post-treatment were significantly improved in the TAF and TMF groups

compared to the ETV group ($p < 0.05$). There were no significant changes in total cholesterol levels in any of the groups compared to baseline.

Conclusion: TMF, TAF, and ETV exhibited no differences in the 60 -day overall survival rate among patients with HBV-ACLF. However, TMF and TAF showed a greater improvement in renal function compared to ETV.

WED-296

Impact of long-term tenofovir-based treatment on hepatocellular carcinoma risk in patients with chronic hepatitis B using the reREACH-B score

Young-Suk Lim[1], Harry L.A. Janssen[2,3], Grace Lai-Hung Wong[4], Frida Abramov[5], Dana Tedesco[5], Hongyuan Wang[5], Leland J. Yee[5], Wai-Kay Seto[6], Kosh Agarwal[7], Jinlin Hou[8], Seng Gee Lim[9], Jia-Horng Kao[10], Maria Buti[11,12]. *[1]Asan Medical Centre, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [2]Toronto Centre for Liver Disease, Toronto General Hospital Research Institute, University Health Network, Toronto, Canada; [3]Department of Gastroenterology and Hepatology, Erasmus University Medical Center, Rotterdam, Netherlands; [4]The Chinese University of Hong Kong, Hong Kong, China; [5]Gilead Sciences, Inc., Foster City, United States; [6]Department of Medicine, School of Clinical Medicine, the University of Hong Kong, Pok Fu Lam, Hong Kong, China; [7]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom; [8]Department of Infectious Diseases, State Key Laboratory of Organ Failure Research, Nanfang Hospital, Southern Medical University, Guangzhou, China; [9]National University Hospital (NUH), Singapore, Singapore; [10]Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; [11]Hospital Universitario Vall d'Hebron, Barcelona, Spain; [12]CIBEREHD del Instituto Carlos III, Madrid, Spain*
Email: frida.abramov@gilead.com

Background and aims: Chronic hepatitis B (CHB) is a leading cause of hepatocellular carcinoma (HCC), and oral antivirals can reduce HCC risk. Nomograms, such as the Risk Estimation for HCC in CHB (REACH-B) score, have been useful in assessing patient risk for HCC. Reports indicate that the relationship between hepatitis B virus (HBV) DNA level and HCC risk follows a nonlinear, parabolic pattern; thus, the REACH-B score was updated to incorporate age, gender, platelet count, and HBV DNA, alanine aminotransferase (ALT), and hepatitis B e antigen (HBeAg) status. We used the updated reREACH-B score to assess the impact of therapy on HCC risk among patients enrolled in tenofovir-based clinical trials.

Method: In 2 Phase 3 studies evaluating tenofovir alafenamide (TAF), HBeAg-positive (n = 1039) and -negative (n = 593) patients were randomised (2:1) to receive either once-daily TAF 25 mg or tenofovir disoproxil fumarate (TDF) 300 mg for up to 3 years (Y), followed by open-label TAF through Y8. ReREACH-B scores at baseline (BL) and over 8Y (384 weeks [W]) were generated. Patients with evidence of HCC at screening were excluded, and HCC was assessed every 6 months using hepatic ultrasonography, which was introduced after W96 and used throughout. Patients were stratified into low (<0.01) and high (≥0.01) HCC risk categories based on reREACH-B scores, reflecting an annual incidence rate of 0.2%, the cost-effectiveness threshold for HCC surveillance.

Results: Through 8Y of follow-up, HCC occurred in 26 of 1632 (1.6%) patients (TAF, 14/1093 [1.3%]; TDF, 12/539 [2.2%]). Of 26 cases of HCC, 9 patients (35%) had cirrhosis at BL. Patients who developed HCC were older (median age 52Y vs 39Y; $p < 0.0001$), more likely to be male (89% vs 65%; $p = 0.0119$), and more likely to have cirrhosis at BL (FibroTest score ≥0.75; 35% vs 9%; $p < 0.0001$). At BL, among 1632 patients, 547 were categorised as low risk and 1084 as high risk. Compared with patients at low risk, those at high risk were more likely to be older (median age 43Y vs 32Y) and male (74% vs 47%), and less likely to be HBeAg positive (57% vs 77%); had lower platelet counts (median 174 vs 233×10^3/μL); had lower HBV DNA (median 6.7 vs 8.2 $\log_{10}$ IU/mL) and higher BL ALT levels (median 89 vs 70 U/L). Among individuals characterised as high or low risk at BL, 24 of 1084 (2.2%) and 2 of 547 (0.4%) developed HCC over 8Y. At Y8, mean (range) change from BL in reREACH-B score was −0.1 (−1.0 to 0.1). Notably, 58% and 52% of patients deemed high risk at BL with available data at Y5 and Y8 transitioned to low risk; only 5% and 8% of patients shifted from low to high risk at Y5 and Y8.

Conclusion: Using data from studies of patients receiving tenofovir-based therapy, we highlight the importance of treatment to reduce HCC risk. Application of reREACH-B risk scores supports that few patients at low risk for HCC at treatment initiation developed HCC, while many high-risk patients improved to a lower risk after long-term treatment.

WED-300

Impact of long-term oral antiviral treatment on hepatocellular carcinoma risk in patients with chronic hepatitis B who are hepatitis B e antigen positive using the PAGED-B score

Background and aims: Chronic hepatitis B (CHB) is a leading cause of hepatocellular carcinoma (HCC) worldwide, and while oral antivirals lower the risk of HCC, they do not eliminate it. Recent studies indicate that moderate hepatitis B virus (HBV) DNA levels may be strongly linked to HCC risk in hepatitis B e antigen (HBeAg)-positive people with CHB. The recently validated PAGED-B (platelets, age, gender, diabetes, and HBV DNA) score, which incorporates HBV DNA, can be used to stratify HCC risk in this population. We used the PAGED-B score to assess HCC risk in HBeAg-positive patients with CHB enrolled in a trial of tenofovir-based therapy.

Method: In a Phase 3 multicentre study (GS-US-320-0110), patients who were HBeAg positive with HBV DNA ≥20,000 IU/mL and alanine aminotransferase >60 U/L (males) or >38 U/L (females) were randomised to receive tenofovir alafenamide (TAF) 25 mg or tenofovir disoproxil fumarate (TDF) 300 mg once daily for up to 3 years. Thereafter, patients received open-label TAF through year 8 (week 384). PAGED-B scores at baseline (BL) and over 384 weeks were generated. Shifts in risk categories (low risk [0 to <7] and high risk [≥7]) were evaluated.

Results: Among 1052 (TAF, n = 703; TDF, n = 349) HBeAg-positive patients (66% male, 85% Asian [n = 893]/Pacific Islander [n = 4], 98% HBeAg positive [2% transitioned to HBeAg-negative status between screening and BL visits]), mean (range) BL PAGED-B score was 4.3 (0–

11); 885 (84%) and 167 (16%) were low and high risk, respectively. At weeks 240 and 384, mean (range) changes from BL in PAGED-B scores were −0.8 (−4 to 4) and −0.7 (−4 to 2), respectively. Among those in the low-risk category at BL with available data at week 384, the majority remained unchanged; only 6 (1%) shifted to high risk, primarily driven by age and platelet changes. In the high-risk group, most patients improved to low risk (69%), and only 31% remained at high risk. Overall, 12 HCC cases developed over 8 years (0.3%, BL low-risk group; 5.4%, BL high-risk group).
Conclusion: The application of the PAGED-B risk score demonstrates that among HBeAg-positive patients, most (69%) high-risk patients experienced a decrease in risk with long-term treatment, whereas shifts from low risk of HCC at the start of treatment to a higher risk category were rare (1%).

WED-301
Predictive value of baseline HBsAg, HBV RNA, and HBcrAg levels for HBsAg clearance in NAs-suppressed HBeAg-Negative chronic hepatitis B patients treated with pegylated interferon-alpha
Mengya Liu[1,2], Jiayi Wang[1,2], Huan Liu[1,2], Juan Liao[1,2], Libo Yan[1,2], Hong Li[1,2], Linyao Du[1,2], Lang Bai[1,2], Ming He[1,2], Xing Cheng[1,2], Hong Tang[1,2]. *[1]Center of infectious diseases, West China Hospital of Sichuan University, chengdu, China; [2]Laboratory of infectious and liver diseases, Institution of infectious diseases, West China Hospital of Sichuan University, chengdu, China*
Email: liumy00123@outlook.com

Background and aims: Predicting HBsAg clearance is essential for optimizing the management of chronic hepatitis B (CHB) patients receiving pegylated interferon-alpha therapy. Serum HBV RNA and HBV core-related antigen (HBcrAg) have emerged as promising markers of hepatitis B virus (HBV) infection. However, in HBeAg-negative patients, it remains uncertain whether HBV RNA and HBcrAg outperform other HBV markers in predicting HBsAg clearance. This study aimed to assess the predictive value of HBsAg, HBV RNA, and HBcrAg for HBsAg clearance in NAs-suppressed HBeAg-negative CHB patients undergoing pegylated interferon-alpha therapy.
Method: This retrospective study included 153 HBeAg-negative CHB patients who achieved HBV DNA suppression (HBV DNA <100 IU/mL) and HBsAg level ≤1500 IU/mL following more than 1 year of nucleos (t)ide analog (NAs) treatment. Patients were categorized into two groups based on their treatment outcomes at 48 weeks of pegylated interferon-alpha therapy: the Response group, comprising those who achieved HBsAg clearance (HBsAg <0.05 IU/mL), and the Non-Response group, consisting of those who did not. A comprehensive analysis was conducted on the baseline levels of various indicators, including blood cell counts,biochemical markers (ALT and AST), and serum virological markers (HBsAg, HBV RNA, and HBcrAg). Logistic regression analysis was conducted to identify independent predictors of HBsAg clearance at. The area under the curve (AUROC) was used to evaluate the predictive accuracy of these independent predictors for HBsAg clearance. p values of <0.05 were considered significant.
Results: Among 153 patients, 33.3% (51/153) achieved HBsAg clearance after 48 weeks of pegylated interferon-alpha therapy. The baseline HBsAg level [1.8 (0.7–2.2) vs. 2.5 (2.1–2.8) $\log_{10}$ IU/mL, $p < 0.001$], HBV RNA [2.0 (2.0–2.3) vs. 2.3 (2.0–2.7) $\log_{10}$ copies/mL, $p < 0.001$] and HBcrAg [3.1 (3.0–3.4) vs. 3.6 (3.0–4.3) $\log_{10}$ U/mL, $p < 0.001$] were significantly lower in the Response group compared to the Non-Response group. Logistic regression analysis indentified baseline HBsAg (OR = 4.29 [2.71–8.61], $p < 0.001$), HBV RNA (OR = 5.05 [1.80–14.19], $p = 0.002$) and HBcrAg (OR = 3.91 [1.96–7.81], $p < 0.001$) as independent predictors of HBsAg clearance at week 48. Among the biomarkers, baseline HBsAg showed the highest AUROC and was significantly superior to HBV RNA and HBcrAg ($p < 0.05$ for all comparisons). Combination analysis revealed that integrating HBsAg, HBV RNA and HBcrAg yielded superior predictive accuracy for HBsAg clearance compared to HBsAg alone [AUROC: 0.850 (0.787–0.912), $p < 0.05$].
Conclusion: A combined predictive strategy using baseline HBsAg, HBV RNA, and HBcrAg enhances the prediction of HBsAg clearance in HBeAg-negative CHB patients undergoing pegylated interferon-alpha therapy. Background and aims: Low-level viremia (LLV) is usually defined as a detectable but lower than 2000 IU/mL hepatitis B virus (HBV) DNA level after 12 months or longer duration of first-line antiviral therapy in chronic hepatitis B (CHB) patients. We aimed to investigate the optimal therapeutic strategies related to LLV.
Method: From October 2021 to October 2024, this multicenter, prospective, observational study enrolled CHB patients who had been treated with first-line nucleoside analogues (NAs) for ≥12 months at 44 sites. CHB patients were grouped into 2 categories, LLV group and CVR group (complete virological response, hepatitis B virus DNA <10 IU/mL). For CVR and LLV patients, two therapeutic options are available, continuing NA(s) therapy or adding on peginterferon α-2b therapy for 96 weeks.
Results: A total of 1614 patients were included in the study (LLV group, n = 1264; CVR group, n = 350), and there was no difference in

gender or age between LLV group and CVR group. Compared with NAs therapy, adding on peginterferon α-2b showed a higher rate of HBV DNA undetectable in patients with LLV after 24 weeks [47.3% (107/226) *Vs.* 37.3% (157/421), *P* = 0.023], 48 weeks [63.5% (113/178) *Vs.* 40.8% (130/319), *P* = 0.000], 72 weeks [69.0% (80/116) *Vs.* 51.9% (95/183), *P* = 0.004] and 96 weeks [76.3% (45/59)*Vs.*59.4% (60/101), *P* = 0.03] weeks of treatment. According to the HBV DNA level at baseline, LLV group was divided into three subgroups (10–100 IU/mL, 100–500 IU/mL and 500–2000 IU/mL). In patients with baseline HBV DNA levels of 100–500 IU/mL, adding on peginterferon α-2b had higher rates of HBV DNA undetectable at 24, 48, 72 and 96 weeks. 81.33% (1028/1264) of LLV patients were HBeAg-positive and they got lower rates of HBV DNA undetectable at 12 [36.1% (60/166) *Vs.* 56.4% (22/39), *P* = 0.020], 24 [34.7% (118/340) *Vs.* 58.3% (35/60), *P* = 0.001] and 48 [37.3% (98/263) *Vs.* 62% (31/50), *P* = 0.001] weeks compared to HBeAg-negative patients. Interestingly, HBeAg-positive LLV patients still achieved higher rates of HBV DNA undetectable by adding on peginterferon α-2b compared with NAs treatment after 24 [61.4% (89/145) *Vs.* 37.3% (98/263), *P* = 0.000] and 72 [65.3% (66/101) *Vs.* 50.7% (76/150), *P* = 0.021] weeks of treatment. Furthermore, the HBsAg clearance rates were much lower in LLV patients comparing with CVR patients at 24 [1.5% (4/266) *Vs.* 9% (13/144), *P* = 0.000], 48 [3.1% (7/225) *Vs.* 11.9% (14/118), *P* = 0.001], 72 [0.7% (1/140) *Vs.* 18% (9/50), *P* = 0.000], and 96 [2.7% (2/73) *Vs.* 25% (6/24), *P* = 0.003] weeks.

Conclusion: Adding on peginterferon α-2b might be a better option for HBV DNA clearance in LLV patients. Compared with CVR patients, LLV status seriously affected the clearance of HBsAg.

Background and aims: Hepatitis D virus (HDV) infection remains a significant global health challenge due to its severity and high risk of progression to cirrhosis and hepatocellular carcinoma (HCC). This study evaluated the efficacy and safety of bulevirtide in reducing HDV RNA levels and improving liver function in a real-life cohort of Italian patients with HDV infection.

Method: This multicenter prospective trial enrolled 85 consecutive patients with chronic HDV infection, from June 2023 to June 2024, who received 2 mg/day of bulevirtide as monotherapy or in combination with a nucleoside/nucleotide analogue for hepatitis B virus (HBV) infection. Patients with any stage of liver fibrosis or compensated cirrhosis were included.

Results: The virological response was achieved in 55.7% of patients (n = 47), with 32 demonstrating undetectable HDV RNA levels. Among responders, ALT levels decreased significantly from 66.0 U/mL (IQR 46.5–120.0) to 31.5 U/mL (IQR 25.0–37.0, $p < 0.001$), and AST levels from 71.0 U/mL (IQR 48.5–94.5) to 31.0 U/mL (IQR 27.0–38.5, $p = 0.021$). Median HDV RNA dropped from 16,410 IU/mL (IQR 2,530–339,400) to 0 IU/mL (IQR 0–84,000, $p < 0.001$). No significant predictors of response emerged. Mild adverse events, including pruritus (7.1%) and injection-site reactions (2.4%), were reported, with no treatment discontinuation.

Conclusion: Bulevirtide effectively reduces HDV RNA levels and improves liver function with a favorable safety profile, offering a promising therapeutic option for chronic hepatitis D.

WED-304

HERACLIS_BLV_D: Increasing response rates during 2-year bulevirtide real-life therapy in chronic hepatitis D

Email: gepapath@med.uoa.gr

Background and aims: Bulevirtide (BLV) was approved by the European Medicine Agency for the treatment of compensated chronic hepatitis D (CHD) and started to be used in European countries including Greece a few years ago, but there are limited real-life data to date. The aim of this study is to assess the efficacy and safety of up to 2-year BLV therapy in CHD patients treated at Greek liver centers.

Method: All adult (>16 years old) patients with CHD followed at any of the participating centers who started BLV before the approvals (05–11/2023) of the HERACLIS_BLV_D study (NCT05928000) were included. All patients were treated with daily BLV subcutaneous injections of 2 mg, with or without concomitant use of a nucleos(t)ide analogue (NA). Patients' monitoring was based on standard clinical practice according to the current recommendations for treatment of CHD. A predefined case report form was used for data collection. Serum HDV RNA during the study was determined by a polymerase chain reaction assay at a central lab (sensitivity: ≤100 IU/

ml). Virological response (VR) was defined as HDV RNA undetectable (complete VR) or decline >2 log_{10} compared to baseline levels. Biochemical response (BR) was defined as normal ALT (≤40 IU/L).
Results: In total, 76 patients were included; mean age: 50 ± 12 years, males: 37 (49%), born in Greece: 21 (28%), mean BMI: 25.4 ± 3.9 kg/m^2, mean liver stiffness (LS): 15.9 ± 9.5 kPa, cirrhosis: 45 (59%) (decompensated cirrhosis: 6/45), (peg-)interferon (IFN) in the past: 32 (42%) cases. No patient received combination of BLV with pegIFN; BLV alone was given in 9 (12%) and BLV plus a NA in 67 (88%) patients (ETV: 29, TDF: 35, TAF: 3). In 72, 70, 54 and 46 patients assessed at 6, 12, 18 and 24 months, rates of VR were 67%, 73%, 87% and 93%, of complete VR 38%, 57%, 70.4% and 80.4%, of BR 66%, 71%, 74% and 74% and of combined response (VR+BR) 49%, 51%, 62% and 74%, respectively. VR response at 24 months was not associated with any baseline characteristic, while 24-month complete VR was independently associated with lower baseline HDV RNA (OR per log IU/ml: 0.44, 95%CI: 0.22–0.88, p = 0.019) and platelets (OR per 10^3/mm^3: 0.986, 95%CI: 0.97–1.00, p = 0.045). Both 24-month BR and combined responses were independently associated with lower baseline GGT (OR per 10 IU/L: 0.85, 95%CI: 0.76–0.95, p = 0.004) and hemoglobin levels (OR per g/dl: 0.16, 95%CI: 0.05–0.59, p = 0.006). There was no drug-related serious adverse event (AE) and no patient discontinued BLV due to AE.
Conclusion: BLV therapy, with or without NA, is safe and effective for the treatment of CHD patients followed at Greek tertiary liver centers offering increasing rates of VR, complete VR and BR or combined response exceeding 90%, 80% and 70%, respectively, at 2 years of therapy.

Email: maria.anolli@unimi.it

Background and aims: Accurate quantification of HDV-RNA is essential for diagnosing and managing chronic hepatitis Delta (CHD), but there is considerable variability between different assays. In this study, we compared three methods for HDV-RNA quantification in both untreated and Bulevirtide (BLV)-treated CHD patients.
Method: Frozen plasma samples from untreated and BLV–treated CHD patients were tested in a single-center retrospective study by 3 different assays: Robogene HDV-RNA Quantification Kit 2.0 [Roboscreen GmbH; Lower Limit of Detection (LOD) <6 IU/mL, Lower Limit of Quantification (LOQ) 60 IU/mL on 7500 Fast Real-Time PCR System (Applied Byosystem)], AltoStar HDV RT-PCR RUO Kit 1.5 (Altona Diagnostics, estimated LOD <10 IU/mL estimated LOQ 20 UI/mL on AltoStar®AM16) and EurobioPlex HDV PCR quantitative EBX071 [Eurobio Scientific, LOD <20 UI/mL, LOQ 50 UI/mL on CFX96™ real-time PCR detection system (Bio-Rad)].
Results: 112 plasma samples collected from 79 CHD (10 untreated and 69 BLV-treated) patients were studied by 3 different assays (total 336 tests): median age 55 (32–76), 54% men, 76% cirrhotics, 100% GT 1 (available in 70 patients), 90% HBeAg negative. Median ALT were 34 (8–273) U/L, median HBsAg 3.5 (0.3–4.9) Log IU/mL. Overall, HDV RNA levels were 3.05 (−0.04–6.69) Log IU/mL with Robogene 2.0, 3.22 (−0.31–7.03) IU/mL with AltoStar, and 3.78 (−0.83–7.78) IU/mL with EurobioPlex EBX071 (Robogene *vs.* AltoStar p < 0.0001; Robogene *vs.* EurobioPlex p = 0.005; EurobioPlex *vs.* AltoStar p = 0.50; overall p < 0.0001). Compared to Robogene 2.0, AltoStar reported different (±>0.5 Log IU/mL difference) HDV RNA levels in 18% of positive samples. By contrast, EurobioPlex EBX071 reported different (±>0.5 Log IU/mL difference) HDV RNA levels in 45% samples. Overall, HDV RNA during therapy was TND in 13%, 9% and 21% of the samples tested with the 3 assays, respectively (p < 0.001). Rates of HDV RNA undetectability (TND or <LLOQ or <LOD) during BLV therapy differed at week 24 (33% *vs.* 15% *vs.* 33%; overall p = 0.02; Robogene *vs.* AltoStar p = 0.01; Robogene *vs.* EurobioPlex p = ns; AltoStar *vs.* EurobioPlex p = 0.01) and at week 48 (19% *vs.* 8% *vs.* 31%; overall p = 0.01; Robogene *vs.* AltoStar p = ns; Robogene *vs.* EurobioPlex p = 0.08; AltoStar *vs.* EurobioPlex p = 0.01) but not at week 96 (36% *vs.* 25% *vs.* 36%,; overall p = 0.10; Robogene *vs.* AltoStar p = 0.08; Robogene *vs.* EurobioPlex p = ns; AltoStar *vs.* EurobioPlex p = 0.08).
Conclusion: Quantification of HDV-RNA levels in untreated and BLV-treated patients significantly differed according to the commercial assay used. The proportion of patients achieving HDV RNA TND at different time points during BLV monotherapy differed as well.

WED-306
The kinetic of HBsAg isoforms predicts response to BLV and pegylated interferon alfa2a in patients with chronic hepatitis delta

Email: Maria.pfefferkorn@medizin.uni-leipzig.de

Background and aims: Chronic hepatitis D (CHD) can be treated with the entry inhibitor bulevirtide (BLV) or the immune modulator PEG-IFNα-2a. However, prediction of treatment response is not established. The composition of HBsAg (large [L], middle [M], and small [S] HBs) has been shown to be associated with HBsAg loss in HBV mono-infection. Our study aims at evaluating the association of HBsAg composition with response to different treatments in CHD.
Method: A real-world cohort of 106 CHD patients, treated with either 180 mg/week PEG-IFNα-2a (n = 56) or 2 mg/day BLV (n = 50), was followed for a median duration of 26 (6–156) months. HDV RNA (Robogene 2.0) and HBsAg isoforms were measured at baseline (BL) and in available samples at 6, 12, 18, 24, and 36 months. LHBs, MHBs

and SHBs were quantified by ELISA and ratios confirmed by western blot. Patients were categorized as non-responders (NR, n = 53), those with HDV RNA decrease >2 log IU/mL (n = 17), undetectable HDV RNA (n = 26), or HBsAg loss (n = 7) based on response after 12 months of treatment.

Results: Baseline HBsAg isoform levels significantly correlated with HDV RNA levels (LHBs: r = 0.340, p = 0.004; MHBs: r = 0.402, p = 0.001; SHBs: r = –0.380, p = 0.005). Interestingly, baseline ratios of LHBs and MHBs were lower in patients who subsequently achieved >2 log IU/mL HDV RNA decrease (7.9 and 6.0%), undetectable HDV RNA (6.5 and 5.0%), or HBsAg loss (8.5 and 3.4%) compared to NR (7.6 and 6.5%), regardless of treatment. Moreover, patients with a percentage of LHBs <4.8% at BL had a significantly higher likelihood of subsequently achieving response (HDV RNA decrease >2 log IU/mL and undetectable HDV RNA) to either PEG-IFNα-2a or BLV compared to patients with >4.8% LHBs at BL (83% vs. 16%, p < 0.001). In available samples taken during treatment from 86/106 patients we found that after 12 months of treatment HBsAg levels, MHBs%, and LHBs% did not change in NR receiving either PEG-IFNα-2a or BLV (p = ns). However, patients achieving undetectable HDV RNA exhibited a decrease in MHBs ratios from BL to month 12. This association was found in the PEG-IFNα-2a group (n = 5) who showed a decrease from 9.5% (2.9–19.3%) to 2.1% (0–3.1%) as well as in the BLV group (n = 14) with a decrease from 6.4% (2.3–13.3%) to 3.9% (0.9–9.9%) (p = 0.016). In addition, after 18 months of BLV treatment, patients with undetectable HDV RNA had significantly lower LHBs ratios compared to NR (2.0 vs. 2.8 log ng/mL, p = 0.05) and lower MHBs (2.1 vs. 2.9 log ng/mL; p = 0.05) levels, as well as lower ratios of LHBs (6.0 vs. 9.2%) and MHBs (6.0 vs. 7.4%; p = ns).

Conclusion: HBsAg isoforms have a high potential to become an efficacy marker during PEG-IFNα-2a or BLV treatments in HBV/HDV-coinfection.

WED-307

Good flare or bad flare? ALT variability predicts outcome after stopping nucleos(t)ide analogue therapy in HBeAg-negative chronic hepatitis B

Marte Holmberg[1,2], Olav Dalgard[2,3], Soo Aleman[4], Nega Berhe[1,5,6], Hailemichael Desalegn[5,7], Nina Weis[8,9], Lars Heggelund[10,11], Lars Normann Karlsen[12], Pascal Brugger-Synnes[13], Hans Erling Simonsen[14], Dag Henrik Reikvam[2,6], Asgeir Johannessen[1,2,6]. *[1]Vestfold Hospital, Tønsberg, Norway; [2]University of Oslo, Oslo, Norway; [3]Akershus University Hospital, Lørenskog, Norway; [4]Karolinska University Hospital, Stockholm, Sweden; [5]Addis Ababa University, Addis Ababa, Ethiopia; [6]Oslo University Hospital, Oslo, Norway; [7]St. Paul's Hospital Millennium Medical College, Addis Ababa, Ethiopia; [8]Copenhagen University Hospital, Hvidovre, Denmark; [9]University of Copenhagen, Copenhagen, Denmark; [10]Vestre Viken Hospital, Drammen, Norway; [11]University of Bergen, Bergen, Norway; [12]Stavanger University Hospital, Stavanger, Norway; [13]Ålesund Hospital, Ålesund, Norway; [14]Nordland Hospital, Bodø, Norway*
Email: marte.holmberg@online.no

Background and aims: Flares are common after discontinuing nucleos(t)ide analogue (NA) treatment in patients with HBeAg-negative chronic hepatitis B (CHB). Whether these flares represent a beneficial immune response leading to HBsAg decline ("good flare") or are detrimental leading to hepatic necroinflammation and fibrosis progression ("bad flare"), is difficult to discern. We hypothesized that it is the variability in ALT levels after NA cessation that determines outcomes following a flare, rather than the magnitude of the ALT flare. Therefore, we aimed to investigate whether differences in ALT variability following a flare can predict outcomes in patients enrolled in an NA stop trial.

Method: This study was nested in the prospective Nuc-Stop Study, in which 127 HBeAg-negative CHB patients discontinued NA treatment and were followed for 36 months. Of these, all 38 patients who experienced a flare and did not restart treatment were included in the present analysis. Flares were defined as an ALT >2× the upper limit of normal (ULN) or >2× the baseline value. Good flares were defined as flares occurring in patients who achieved HBsAg loss, HBsAg decline >1 log10 IU/mL within 36 months, or sustained off-therapy virological control (HBV DNA <2000 IU/mL) at all study visits during year three of follow-up. Bad flares were defined as flares in patients with no HBsAg decline (<0.5 log10 IU/mL) and absence of off-therapy virological control, as defined above. Study visits were conducted at baseline, weeks four, eight, and 12, and every third month thereafter until the end of the study. The first flare was defined as the first occurrence of ALT > 2× ULN or >2× the baseline value. ALT values recorded at or before the first flare, as well as ALT values after HBsAg loss, were excluded from the analyses. Levene's test was used to assess variability, and Mann-Whitney U test to compare medians.

Results: Of the 38 patients who experienced a flare and did not restart NA treatment, 19 experienced a bad flare, 13 experienced a good flare, and six did not fit into either category and were excluded from further analysis. Following the initial flare, patients with a bad flare displayed more fluctuations in ALT levels compared to patients with a good flare. The mean standard deviation (SD) of ALT was 22.7 U/L in patients with bad flares compared to 9.7 U/L in patients with good flares (p = 0.002). Among patients with good flares, three achieved HBsAg loss, three had an HBsAg decline >1 log10, and seven had sustained off-therapy virological control. The median peak ALT was similar in patients with good and bad flares (89 (interquartile range (IQR) 52–179) vs. 103 (IQR 74–154) U/L; p = 0.66).

Conclusion: After discontinuing NA therapy in HBeAg-negative chronic hepatitis B patients, ALT variability following the initial flare might serve as a prognostic factor and distinguish good flares from bad flares.

WED-308

Improvement in 3 noninvasive tests through 144 weeks of bulevirtide monotherapy in patients with chronic hepatitis delta with and without virologic response

Email: maurizia.brunetto@unipi.it

Background and aims: Bulevirtide (BLV) is an entry inhibitor approved in Europe and Australia as a therapy for patients with chronic hepatitis delta (CHD); noninvasive tests (NITs) have

demonstrated improvements in hepatic function and burden of liver disease with BLV treatment. Here we describe changes in NITs through up to 3 years of treatment.

Method: A longitudinal analysis was conducted using the Phase 3 MYR301 (NCT03852719) study data to determine the effect of BLV on results of alanine aminotransferase (ALT) level measurements and 3 NITs: fibrosis index based on 4 factors (FIB-4), aspartate aminotransferase to platelet ratio index (APRI), and liver stiffness measurement (LSM). In total, 150 patients with CHD were randomised to either no treatment for 48 weeks (W) followed by BLV 10 mg/d for 96W, or to BLV 2 or 10 mg/d for 144W. Change from baseline (BL) in NITs was assessed through 96W and 144W of treatment. This analysis was repeated for the pooled immediate treatment groups stratified by hepatitis delta virus (HDV) RNA response at W144: virologic responders (VR; undetectable HDV RNA or ≥2 $\log_{10}$ IU/mL decline in HDV RNA from BL), partial responders (PR; ≥1 $\log_{10}$ IU/mL but <2 $\log_{10}$ IU/mL decline in HDV RNA from BL), and nonresponders (NR; <1 $\log_{10}$ IU/mL decline in HDV RNA from BL). Patients with HDV RNA values missing at W144 were excluded. Results are reported as median (quartile [Q]1, Q3) unless otherwise stated.

Results: Overall, 149 patients with CHD were treated with BLV monotherapy (BLV 2 mg [n = 49]; BLV 10 mg [n = 100]); 99 were randomised to immediate BLV treatment for 144W, and 50 in the BLV 10 mg group received treatment for 96W. NITs showed improvements in all cohorts after 48W of therapy, which were maintained through 144W of therapy. Changes from BL at W144 were: BLV 2 mg group, FIB-4, −0.52 (−1.19, −0.03); LSM, −4.00 (−6.00,−1.00) kPa; immediate BLV 10 mg treatment group, FIB-4, −0.43 (−0.94, −0.14); LSM, −3.80 (−6.70, −1.20) kPa; and BLV delayed treatment group at W144 after 96W of treatment, FIB-4, −0.27 (−0.62, 0.02); LSM, −3.15 (−7.00, −0.40) kPa. Improvements at W144 in NITs were also seen across all viral response groups in the pooled immediate treatment cohort, including VR (n = 74), PR (n = 7), and NR (n = 8) at W144. Among VR, changes from BL were FIB-4, −0.43 (−1.05, −0.11); and LSM, −3.85 (−6.50, −1.20) kPa. Among PR, changes from BL were FIB-4, −0.39 (−0.48, −0.09); and LSM, −1.30 (−3.80, 0.20) kPa. Among NR, changes from BL were FIB-4, −1.02 (−1.60, −0.78); and LSM, −4.00 (−15.70, −1.10) kPa. Changes from BL in ALT levels and APRI scores were consistent with the trends observed in FIB-4 across all treatment cohorts.

Conclusion: Treatment with BLV 2 or 10 mg monotherapy for up to 3 years resulted in longitudinal improvements in NITs in patients with CHD and were numerically greater with longer treatment duration. These improvements were seen even among the few patients without viral response.

Response-guided interferon add-on to bulevirtide treatment: updated real-world insights from the austrian hepatitis D cohort study

Michael Schwarz[1], Caroline Schwarz[1,2], Marlene Panzer[3], Nikolaus Pfisterer[4], Nina Loschko[5], Lukas Hartl[1], Livia Dorn[6], Hermann Laferl[7], Michael Trauner, Albert Friedrich Stättermayer[1], Mattias Mandorfer, Ivo Graziadei[8], Andreas Maieron[6], Alexander Moschen[5], Elmar Aigner[9], Christian Madl[4,10], Stephan Aberle[11], Heinz Zoller[3], Michael Gschwantler[2,10], Thomas Reiberger, Mathias Jachs. *[1]Medical University of Vienna, Department of Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria; [2]Klinik Ottakring, Department of Internal Medicine IV, Vienna, Austria; [3]Medical University of Innsbruck, Department of Internal Medicine I, Innsbruck, Austria; [4]Klinik Landstraße, Department of Internal Medicine IV, Vienna, Austria; [5]Johannes Kepler University Linz, Department of Internal Medicine 2, Linz, Austria; [6]University Hospital of St. Pölten, Department of Internal Medicine 2, Gastroenterology and Hepatology and Rheumatology, Sankt Pölten, Austria; [7]Klinik Favoriten, Department of Internal Medicine IV, Vienna, Austria; [8]Hospital Hall in Tirol, Department of Internal Medicine, Hall in Tirol, Austria; [9]Paracelsus Medical University Salzburg, First Department of Medicine, Salzburg, Austria; [10]Sigmund Freud University, Vienna, Austria; [11]Medical University of Vienna, Center for Virology, Vienna, Austria*
Email: thomas.reiberger@meduniwien.ac.at

Background and aims: Chronic Hepatitis D (CHD) causes rapid progression towards advanced chronic liver disease (ACLD) and hepatocellular carcinoma (HCC). Bulevirtide (BLV) is the only approved treatment for CHD, yet the management of suboptimal response and the option of finite treatment remain unclear.

Method: Patients were characterized at BLV initiation (baseline, BL) and virologic (HDV-RNA ≥2log-drop or PCR negativity) and biochemical (ALT normalization) response rates were recorded in six-months (M6-M24) intervals. Biomarkers, liver stiffness measurements (LSM), and clinical outcomes were assessed. Pegylated interferon alpha-2a (IFN) was added in some patients with inadequate response.

Results: Fifty-seven CHD patients (median age: 46.0 years, 62.4% male, median LSM: 13.2 kPa, ACLD: 73.7%) receiving BLV treatment (median treatment duration: 24 [IQR 17–36] months) were included. Virologic (M6: 33.3%, M12: 60.4%, M24: 66.7%), biochemical (M6: 57.4%, M12: 71.7%, M24: 69.2%), and combined response (M6: 22.2%, M12: 41.5%, M24:46.2%) rates increased over time. At M6, significant declines in median HDV RNA (1.90E+05 [IQR 1.10E+04–5.20E+05] co/mL vs. 1.56E+03 [IQR 3.33E+02–7,48E+03], p < 0.001), ALT (73 [IQR 45–123] U/L vs. 40 [29–60], p < 0.001), and LSM (13.2 [IQR 9.1–18.6] kPa vs. 10.7 [IQR 7.4–15.0], p < 0.01) and markers of systemic inflammation like C-reactive protein (0.29 [IQR 0.12–0.50] mg/dL vs. 0.25 [IQR 0.10–0.29], p < 0.01) and procalcitonin (0.11 [IQR 0.08–0.14] ng/mL vs. 0.05 [IQR 0.03–0.09], p < 0.01) were observed. Eighteen (31.6%) patients received IFN addon after a median 10 [IQR 7–16] months on BLV monotherapy, which resulted in a further median HDV RNA log10 decline of 1.49 (IQR 0.56–2.11) after 6 months (p = 0.004) and a significant a reduction in HBs antigen (median log10 3.85 [IQR 3.34–4.04] IU/mL vs. 3.57 [IQR 3.23–3.98], p = 0.008). Median IFN treatment duration was 12 months. Seventeen (29.8%) patients stopped BLV treatment, seven (41.2% of 17) after addon IFN, resulting in following outcomes: (1) n = 11 patients remained HDV RNA negative (n = 2 after liver transplantation resulting in CHD cure), (2) n = 3 patients relapsed, (3) n = 3 patients received an unapproved treatment as compassionate use. While on BLV treatment, one (1.8%) patient was diagnosed with HCC and two (3.5%) patients died. Mostly asymptomatic bile acids elevations were recorded (median BL 6.6 [IQR 4.33–14.4] µmol/L vs. M6 levels 21.9 [IQR 11.18–49.40], p < 0.001). No serious adverse events related to BLV or IFN occurred.

Conclusion: High BLV response rates were reproduced in our Austrian real-life CHD patient cohort comprising predominately of ACLD patients. Decreases in liver stiffness, hepatic and systemic inflammation, and the low liver-related event rate suggest an improved clinical course of CHD under BLV treatment. Add-on IFN to suboptimal BLV responders may rescue virologic response.

WED-310

A mathematical viral load model characterises the exposure-response relationship between bulevirtide and hepatitis delta virus and identifies the minimum duration of on-treatment viral load monitoring required for accurate prediction of long-term virologic response

Parag Kumar[1], Anna Mc Laughlin[2], Nieves Velez de Mendizabal[1], Luzelena Caro[1], David Damoiseaux[2], Amos Lichtman[1], Dmitry Manuilov[1], Renee-Claude Mercier[1], Liyun Ni[1], Yang Liu[1], Hongmei Mo[1], Ana Ruiz-Garcia[1]. *[1]Gilead Sciences, Inc., Foster City, United States; [2]Pharmetheus AB, Uppsala, Sweden*
Email: parag.kumar31@gilead.com

Background and aims: Bulevirtide (BLV) is a first-in-class entry inhibitor of hepatitis delta virus (HDV) and is approved in the European Union (EU) and other non-EU countries at 2 mg once daily

(QD) for treatment of chronic hepatitis delta. Ongoing investigations are also evaluating the efficacy and safety of BLV 10 mg QD and combined treatment with pegylated interferon alpha (PegIFN). We aimed to develop a mathematical model of the relationship between BLV exposure and the HDV viral load in blood samples from patients who received BLV with or without PegIFN during clinical trials. We used the model to determine the minimum duration of on-treatment viral load monitoring needed to accurately predict patient virologic response with longer BLV treatment.

Method: Data from 414 patients from 4 clinical studies (MYR202, MYR203, MYR204 [interim], and MYR301 [interim]) were included. Patients received subcutaneous injections of BLV 2, 5, and 10 mg QD, or 5 mg twice daily; 35% of the patients received PegIFN cotreatment. HDV viral load from blood samples was assessed at baseline, week (W)2, W4, and every 4–12 weeks thereafter up to W96. A mathematical model of hepatitis C infection was adapted to characterise the HDV viral load data. A saturable inhibitory effect of BLV exposure on the infectivity rate and a stimulatory categorical effect for PegIFN on the elimination rate constant of infected cells were implemented. Exploratory covariate testing was performed to identify correlations between patient- or treatment-related characteristics and model parameter variability. The final model was refitted to datasets with viral load data from W96 and earlier iteratively removed to evaluate the accuracy of predicted patient virologic responses at W96 with reduced viral load data.

Results: The developed model characterised the observed HDV viral load well; the estimated effective concentration causing 50% of the maximal response (EC50) of BLV was similar to the sub-nanomolar range of the in vitro EC50. BLV 10 mg QD dosing, but not 2 mg QD, exceeded the EC 95% (EC95) for most of the dosing interval. The estimated elimination rate constant of infected cells for PegIFN cotreatment was 21% greater than for BLV alone. No covariate effects on the drug parameters were identified. By iterative modelling, viral load sampling until W48 was necessary to achieve >90% accuracy in identifying virologic responder status (complete, partial, or no response) at W96; sampling beyond W48 minimally improved accuracy.

Conclusion: We identified a significant exposure-response relationship and a significant influence of PegIFN treatment on the elimination of HDV-infected cells, supporting further investigation of BLV 10 mg QD therapy with and without PegIFN to potentially enhance virologic response. Notably, viral load monitoring for at least 48 weeks of treatment was needed for reliable predictions of patient virologic response.

WED-311

Paediatric pharmacokinetic-pharmacodynamic extrapolation to identify suitable bulevirtide doses for children and adolescents with chronic hepatitis delta

Parag Kumar[1], Anna Mc Laughlin[2], Nieves Velez de Mendizabal[1], Luzelena Caro[1], Kathryn Kersey[1], Carolina Iglesias-Lopez[3], Joanna Koziara[1], Ana Ruiz-Garcia[1]. *[1]Gilead Sciences, Inc., Foster City, United States; [2]Pharmetheus AB, Uppsala, Sweden; [3]Gilead Sciences, Inc., UC Dublin Central, Ireland*
Email: parag.kumar31@gilead.com

Background and aims: Bulevirtide (BLV) 2 mg once daily (QD) is approved in the European Union (EU) and other non-EU countries for treatment of chronic hepatitis delta (CHD) in adults; ongoing investigations are evaluating the potential of BLV 10 mg QD. No treatment options are currently approved for children with CHD. Given the unfeasibility of conducting a clinical trial in paediatric patients, we applied paediatric pharmacokinetic (PK)-pharmacodynamic extrapolation and exposure matching to identify BLV doses that would achieve similar exposure levels in children and adolescents as those seen in adults treated with BLV 2 or 10 mg QD.

Method: In the paediatric population PK model of BLV, the dosing regimens investigated were age-based dosing (3–6 years of age [y]: 1 mg QD; 6–12 y: 1.5 mg QD; 12–18 y: 2 mg QD), body weight–based dosing (10–25 kg: 1 mg QD; 25–35 kg: 1.5 mg QD; ≥35 kg: 2 mg QD), and flat subcutaneous (SC) dosing (1 mg QD, 1.5 mg QD, and 2 mg QD). Simulated PK profiles and steady-state exposures were compared with exposures in adults who received SC BLV 2 or 10 mg QD in Phase 2 and 3 studies (MYR202, MYR203, MYR204, and MYR301). A BLV effective concentration causing 50% of the maximal response (EC50) in adults with CHD treated with BLV was previously estimated via a longitudinal hepatitis delta viral load model and compared to the simulated paediatric exposures.

Results: The simulated age- and body weight–based dosing approaches produced similar BLV exposures across all paediatric age ranges. With flat dosing, younger children generally had higher exposures than older children and adolescents. For the 12–18 y range, flat 1 mg dosing yielded interquartile ranges (IQRs) of BLV exposure that extended below the 5th percentile of that in adults who received BLV 2 mg QD. For the 3–6 y and 6–12 y ranges, flat 1.5 mg and 2 mg doses generally yielded IQRs of BLV exposures exceeding the 95th percentile of exposure in adults who received BLV 2 mg QD, but the IQRs of exposures were generally contained within the 5th–95th percentiles for adults who received BLV 10 mg QD. For all paediatric age- or weight-based BLV doses, BLV exposure IQRs were generally within the 5th–95th percentiles for adults who received BLV 2 mg QD. With all dosing strategies, median simulated paediatric exposures in each age group exceeded the adult BLV EC50 over ≥80% of the dosing interval. Only the age-based, weight-based, and 2 mg flat dosing strategies produced simulated BLV exposures that exceeded the adult BLV EC 95% (EC95) for ≥25% of the dosing interval in all age groups.

Conclusion: Simulated age-based and body weight–based BLV dosing in children and adolescents predicted similar exposures compared to those in adults with CHD who received the BLV 2 mg QD dose, which is established as safe and efficacious. BLV exposures comparable to those observed with up to BLV 10 mg QD in adults with CHD may be achievable in children and adolescents with a 2 mg QD flat dose.

Pharmacokinetics, pharmacodynamics, and safety of bulevirtide 10 mg once daily for 6 days in participants with moderate hepatic impairment and in matched control participants with normal hepatic function

Parag Kumar[1], Wildaliz Nieves[1], Carolina Machado[1], Steve Tseng[1], Yuejiao Jiang[1], YeHong Wang[1], Ann Qin[1], Teckla Akinyi[1], Renee-Claude Mercier[1]. *[1]Gilead Sciences, Inc., Foster City, United States*
Email: parag.kumar31@gilead.com

Background and aims: Bulevirtide (BLV) is a 47–amino acid lipopeptide, hepatitis delta virus (HDV) entry inhibitor that binds to the sodium taurocholate cotransporting polypeptide (NTCP) receptor. BLV is approved in the European Union (EU) and other non-EU countries for the treatment of chronic HDV with compensated liver disease at a subcutaneous dose of 2 mg once daily (QD). Evaluations exploring the potential benefit of an increased dose of 10 mg QD are in progress. By inhibiting NTCP, BLV treatment results in asymptomatic and transient elevations in bile acids (BAs). This study evaluated the influence of moderate hepatic impairment (HI) on the pharmacokinetics (PK), pharmacodynamics (PD), and safety of BLV.

Method: This was an open-label, multicentre, parallel-group, multiple-dose, Phase 1 study in participants without HBV/HDV infection with moderate HI (Mod HI; Child-Turcotte-Pugh Class B, n = 10) and matched controls (MCs) with normal hepatic function (n = 10, matched for age [±10 years], sex, and body mass index [±20%]). Participants received BLV 10 mg subcutaneously QD for 6 days (D), with intensive serial sampling for BLV PK and PD (total BAs). Geometric least-squares mean ratios (GLSMRs) and 90% confidence intervals (CI) of maximum plasma concentration (Cmax; ng/mL) and area under the time-vs-concentration curve (AUC; ng/mL·h) over 24

hours (AUC0–24) were evaluated for PK, and GLSMRs (90% CI) for Cmax and baseline-adjusted AUC (NetAUC; μM·h) values were evaluated for total BAs. Safety was assessed by clinical laboratory tests and evaluation of adverse events (AEs).
Results: BLV PK on D1 and D6 were lower in participants with Mod HI than in MCs: GLSMR (90% CI): D1, Cmax: 0.54 (0.26, 1.12), AUC0–24: 0.67 (0.40, 1.12); D6, Cmax: 0.58 (0.41, 0.83), AUC0–24: 0.73 (0.54, 0.99). Median elimination half-life was similar between groups (~3–4 hours). On D1 and D6, mean apparent clearance and apparent volume of distribution were higher in the Mod HI group than in MCs. Similar trends in transient BA elevations were observed between the Mod HI and MC groups on D1 and D6. Plasma BA elevations returned to predose levels within 24 hours of dosing. There were no Grade ≥3 treatment-emergent (TE) AEs, serious AEs, or AEs leading to BLV discontinuation. The frequency of TEAEs was similar between the two groups, and TEAEs were generally mild with no increased severity in participants with Mod HI vs MCs.
Conclusion: PK exposures following BLV 10 mg QD in the Mod HI group were reduced (~30%–40%) compared to those in MCs; however, exposures were still >5-fold higher than those observed with the currently approved 2 mg dose. There were no incremental elevations in total BAs observed with BLV 10 mg in participants with Mod HI versus MCs with normal hepatic function. BLV was generally safe in participants with Mod HI.

WED-313
Pharmacokinetics, pharmacodynamics, and safety of bulevirtide 10 mg once daily for 6 days in participants with severe renal impairment and in matched control participants with normal renal function

YeHong Wang[1], Renee-Claude Mercier[1], Wildaliz Nieves[1], Carolina Machado[1], Steve Tseng[1], Yuejiao Jiang[1], Ann Qin[1], Teckla Akinyi[1], Parag Kumar[1]. [1]*Gilead Sciences, Inc., Foster City, United States*
Email: yehong.wang22@gilead.com

Background and aims: Bulevirtide (BLV) is a 47–amino acid lipopeptide that binds to the sodium taurocholate cotransporting polypeptide (NTCP) receptor and blocks entry of hepatitis delta virus (HDV) into hepatocytes. BLV 2 mg once daily (QD) is approved in the European Union (EU) and other non-EU countries for treatment of HDV infection in adults. Evaluations exploring the potential benefit of an increased dose of 10 mg QD are in progress. By inhibiting NTCP, BLV causes asymptomatic and transient elevations in bile acids (BAs), which could possibly increase in renal impairment (RI). We assessed the pharmacokinetics (PK), pharmacodynamics (PD), and safety of multiple doses of BLV 10 mg in participants with severe RI vs matched controls (MCs) with normal renal function.
Method: This was an open-label, multicentre, multiple-dose, Phase 1 study in participants without HBV/HDV infection with severe RI (estimated glomerular filtration rate [eGFR] ≥15 to ≤29 mL/min/1.73 m^2, n = 10) and MCs (matched for age [±10 years], sex, and body mass index [±20%], n = 10) with normal renal function administered BLV 10 mg subcutaneously (SC) QD for 6 days (D). Intensive plasma BLV PK and PD (total BAs) samples were assessed on D1 and D6. Maximum BLV plasma concentration (Cmax; ng/mL) and area under the time-vs-concentration curve (AUC; ng/mL·h) over 24 hours (AUC0–24) were evaluated for BLV PK; Cmax and baseline-adjusted AUC (NetAUC; μM·h) were evaluated for total BAs. PK geometric least-squares mean ratios (GLSMRs) with 90% confidence intervals (CI) were calculated. Safety was assessed by clinical laboratory tests and evaluation of adverse events (AEs).
Results: On D1 and D6, BLV PK was similar between participants with severe RI and MCs: GLSMR (90% CI): D1, Cmax: 0.78 (0.43, 1.24), AUC0–24: 1.00 (0.56, 1.79); D6, Cmax: 1.08 (0.78, 1.51), AUC0–24: 1.04 (0.81, 1.33). Overall, both severe RI and MC groups had an estimated median BLV elimination half-life of ~ 2.8 hours. Total BAs showed similar trends of transient elevations after dosing with returns to near predose concentrations within 24 hours of dosing. Total BA parameters for participants with severe RI vs MCs were as follows: D1, Cmax: 0.87 (0.53, 1.41), NetAUC: 0.86 (0.54, 1.36); D6, Cmax: 0.73 (0.50, 1.05), NetAUC: 0.70 (0.49, 0.99). There were no BLV-related Grade ≥3 treatment-emergent (TE) AEs, serious AEs, or AEs leading to BLV discontinuation. The frequency of TEAEs was similar in both groups, with most AEs being Grade 1 or 2.
Conclusion: Following 6 D of BLV 10 mg SC QD dosing, there were no differences in BLV PK exposures and total BA changes from baseline between participants with severe RI and MCs. BLV was generally safe in participants with severe RI. These results suggest no dose adjustments are needed for BLV treatment with 10 mg QD dosing in the RI population.

WED-314
Hepatocellular carcinoma risk in patients with chronic hepatitis B: Tenofovir Disoproxil Fumarate vs Tenofovir Alafenamide from a korean nationwide study

Ji won Yang[1], Jihye Lim[2], Jina Park[1], Ye-Jee Kim[1], Hwa Jung Kim[1], Jonggi Choi[1]. [1]*Asan Medical Center, Seoul, Korea, Rep. of South;* [2]*Yeouido St. Mary's Hospital, Seoul, Korea, Rep. of South*
Email: jkchoi0803@gmail.com

Background and aims: In phase 3 trials, tenofovir alafenamide (TAF) showed antiviral efficacy comparable to that of tenofovir disoproxil fumarate (TDF) for chronic hepatitis B (CHB), with an improved safety profile. This study aimed to compare the clinical efficacy of TAF and TDF in terms of the risk of hepatocellular carcinoma (HCC).
Method: We conducted a nationwide historical population cohort study on treatment-naïve adult patients with CHB receiving TAF (n = 29,309) or TDF (n = 58,046) as first-line therapy from 2017 to 2022 using data from the Korean National Health Insurance Service database. Cumulative HCC incidence and associated risk factors were estimated using competing risk factors. Propensity score (PS)-matched analysis was used to minimize the confounding effects.
Results: A total of 20,994 patients were included in the TAF group, and 33,191 in the TDF group. The annual incidence of HCC was significantly lower in the TAF group (7.5/1,000 patient-years [PYs]) than in the TDF group (10.3/1,000 PYs; SHR, 0.74; $p < 0.001$). After PS matching, TAF continued to exhibit a protective effect against HCC (7.5/1,000 PYs vs. 9.9/1,000 PYs; $p < 0.001$). Multivariable analysis Fine–Gray proportional subdistribution hazards model identified TAF as significantly associated with a reduced HCC incidence (SHR: 0.76; $p < 0.001$). Subgroup analysis confirmed the protective effect of TAF against HCC even in patients with cirrhosis (SHR: 0.78; $p = 0.003$).
Conclusion: This study showed that TAF had a protective effect against HCC in patients with CHB, providing valuable guidance for clinicians in selecting the appropriate initial treatment for these patients.

WED-315
Atherosclerotic cardiovascular risk in patients with chronic hepatitis B: Tenofovir Disoproxil fumarate vs Tenofovir Alafenamide from a korean nationwide study

Ji won Yang[1], Jihye Lim[1], Jina Park[1], Ye-Jee Kim[1], Hwa Jung Kim[1], Jonggi Choi[1]. [1]*Asan Medical Center, Seoul, Korea, Rep. of South*
Email: jkchoi0803@gmail.com

Background and aims: Concerns have been raised about the safety of tenofovir alafenamide (TAF) regarding potential changes in lipid profiles in chronic hepatitis B (CHB) patients, which could contribute to development of atherosclerotic cardiovascular disease (ASCVD). This study aimed to evaluate long-term risk of ASCVD in CHB patients treated with either TAF or tenofovir disoproxil fumarate (TDF).
Method: We retrospectively analyzed patients diagnosed with CHB and received either TAF or TDF as an initial antiviral treatment between 2017 and 2022. All claim data were obtained from the Korean National Health Insurance Service. Cumulative incidence of ASCVD was estimated by Kaplan-Meier method and compared

between two groups using the log-rank test. Propensity score (PS)-matched analysis was also performed, and risk factors associated with ASCVD were analyzed by Cox regression analysis.
Results: Among 44,714 patients with CHB, 16,120 (36.1%) and 28,594 (63.9%) were treated with TAF and TDF, respectively. During median follow-up period of 3.01 years, ASCVD developed in 817 patients, with an annual incidence of 6.18/1,000 patient-years (PYs). The cumulative incidence rates of ASCVD were 1.06% at 1 year, 1.60% at 2 years, 2.06% at 3 years, and 3.08% at 5 years in the TDF group, compared to 0.48%, 0.91%, 1.36%, and 2.75% in the TAF group. After PS-matching, TAF showed a significantly lower risk of ASCVD compared to TDF (4.67/1,000 PYs vs. 6.67/1,000 PYs; hazard ratio: 0.70, $P < 0.001$). In a multivariable analysis, TAF had a 27% lower risk of ASCVD, while increasing age, concurrent hypertension, current history of smoking, and elevated AST were identified as risk factors for ASCVD.
Conclusion: TAF showed a significantly lower risk of ASCVD compared to TDF in patients with CHB, providing valuable guidance for clinicians in selecting the appropriate initial treatment for these patients.

Email: sandmann.lisa@mh-hannover.de

Background and aims: Portal hypertension (PH) drives hepatic decompensation in patients with advanced chronic liver disease. The extent to which antiviral treatment with bulevirtide (BLV) improves PH and thereby reduces morbidity and mortality in patients with chronic hepatitis D (CHD) is unknown.
Method: CHD patients with PH treated with BLV were prospectively enrolled in this observational, multicenter study. Hepatic venous pressure gradient (HVPG) measurements were performed before (BL) and after a treatment minimum of 12 months (M12). HVPG-response (≥10% decline) rates were compared between patients achieving virological response (VR; HDV-RNA decline by ≥2 $\log_{10}$ IU or HDV-RNA undetectable), biochemical response (BR; ALT normalization), or combined response (CR, both VR and BR) at M12 and patients who did not achieve the respective endpoints. Biomarkers of bacterial translocation (CD163, lipopolysaccharide-binding protein), (dys) angiogenesis/endothelial dysfunction (Angiopoietin-1 and –2 [Ang2]) and fibrogenesis (transforming growth factor beta, platelet-derived growth factor), and systemic inflammation (measured by a 48-cytokine multiplex panel) were compared between BL and M12.
Results: Twenty patients with BLV treatment and paired HVPG measurements were included. At BL, 17 (85%) patients had CSPH (≥10 mmHg HVPG). After a median treatment duration of 13 months (IQR 12–17), HVPG significantly decreased in treatment responders, but not in non-responders (CR achieved by n = 12: 15.5 mmHg [IQR 10.5–21.8 mmHg] at BL to 12 mmHg [IQR 7.3–15.8 mmHg] at M12, Wilcoxon signed-rank test: $p < 0.001$; VR achieved by n = 14: 14.5 mmHg [IQR 10–21.3 mmHg] to 12 mmHg [IQR 7.8–16.5 mmHg], $p = 0.003$; BR achieved by n = 16: 12.5 mmHg [IQR 10–20.5 mmHg] to 10.5 [IQR 8–15 mmHg], $p = 0.002$; non-responders: all not significant). Among the patients with CSPH at BL, HVPG-response was achieved by all patients who showed CR (n = 10/10), and most of virological (83%, n = 10/12) and biochemical responders (85%, n = 11/13). Meanwhile, none of the CSPH patients without any treatment response (CR/VR/BR) achieved HVPG-response at M12. In two of the three patients with subclinical PH at BL, HVPG declined at M12, with PH fully resolving in one patient. Markers of bacterial translocation (CD163; $p = 0.001$), (dys)angiogenesis/endothelial dysfunction (Ang2; $p = 0.001$) and systemic inflammation (IFN-gamma, IL-1RA, sCD25/IL-2R alpha, CCL3/MIP-1alpha, HGF, all $p < 0.05$) decreased in responders but not in non-responders from BL to M12.
Conclusion: Along with biomarkers reflecting liver disease severity and systemic inflammation, HVPG decreased in CHD patients responding to BLV treatment as defined by endpoints used in clinical trials, indicating that their achievement confers a clinically meaningful benefit.

WED-317

Exploring predictive factors for treatment response to Bulevirtide in Delta-positive patients

Verdiana Zulian[1], Chiara Taibi[2], Elisa Biliotti[2], Alessia Rianda[2], Silvia Pauciullo[1], Martina De Sanctis[1], Giampiero D'Offizi[2], AnnaRosa Garbuglia[1]. *[1]Laboratory of Virology, National Institute for Infectious Diseases "Lazzaro Spallanzani" - IRCCS, Rome, Italy; [2]Hepatology and Infectious Diseases Unit, National Institute for Infectious Diseases "Lazzaro Spallanzani" - IRCCS, Rome, Italy*
Email: verdiana.zulian@inmi.it

Background and aims: Bulevirtide (BLV) therapy can give rise to resistance phenomena; in fact, non-responses were observed (HDV RNA decline≤1Log IU/mL at week 24 of treatment). To date, it is not clear if therapy failure is linked to HDV genotype/subtypes, viral resistance, or host factors. Moreover, the treatment should be prolonged for life, and some adverse events could arise. We analyze clinical and virological parameters such as HBsAg, HBcrAg, HBcAb, HDV RNA viral load, and HDV polymorphisms that could be associated with the success of BLV therapy in patients chronically infected HBV/HDV.
Method: Patients with chronic HBV/HDV infection treated with BLV were enrolled in this study (n = 30). Sequential serum/plasma samples were collected at T0 (baseline), at 4 weeks, 12 weeks, 24 weeks, and 48 weeks to measure virological and clinical parameters. HBV core-related antigen (HBcrAg) and anti-HBc IgG (HBcAb) levels in the serum were quantified using Lumipulse G600II system (Fujirebio). HBV RNA levels were analyzed using the HBV RNA Quantitative Fluorescence Diagnostic Kit (Sansure Biotech Inc., LOD 100copies/ml), and HDV full genome was analysed by Sanger sequencing.
Results: HDV RNA levels decreased from 4.6 (IQR1-IQR3, 3.8–5.7) Log cp/ml at baseline to 2.9 (IQR1-IQR3, 0.0–4.0) Log cp/ml at week 48 ($p < 0.001$). A virological (v) response, defined as either achieving undetectable HDV RNA or a reduction of more than 2 Log from baseline, was observed in 33.3% patients at W24 and in 58.3% patients at W48. Three patients showed an increase in viral load indicative of a viral breakthrough. HBcrAg levels did not statistically differ between v-responder (vr), v-non-responder (vnr), and patients with viral breakthrough. The median HBcAb values were lower in vr compared to vnr: at T0, vr had a median value of 39.25 COI, while non-responders had a median value of 283.7 COI. At W24, responders had a median of 36.7 COI, while non-responders had 266.35 COI ($p = 0.0001$). Finally, the HBcAb levels did not differ statistically during

treatment for both groups, with p = 0.77 for responders and p = 0.44 for non-responders. ALT and AST levels declined in 90% patients at W48. HDV strains: 79% patients harbored HDV GT1e, 2 patients GT1b, 1 patients GT1c, one GT1a, and 3 patients have undetermined HDV1 subtype. Among vnr patients, 7 out of 8 harbored GT1e, the other patient had an undetermined GT1 subtype. In the RBD1 domain, the position N22 showed high variability in vr (50%) whereas in nvr (10%). In addition, certain substitution were observed exclusively in v-responders N22 V (GT1e) and N22 T (GT1a). The amino acid change V16 T (GT1e) was present only in nvr.
Conclusion: Baseline HBcAb values showed the greatest predictability of vr. No conclusive observations could be made regarding the sensitivity of GT1 subtypes to BLV, as most strains were GT1e, and no specific HDV amino acid mutations could be associated to BLV therapy failure.

WED-318
Ethnicity and socioeconomic disparities in diagnostic and hepatic event incidences in patients with chronic viral hepatitis
Vicki Wing-Ki Hui[1], Terry Cheuk-Fung Yip[2,3], Jimmy Che-To Lai[3,4], Junlong Dai[4], Vincent Wai-Sun Wong[4], Grace Lai-Hung Wong[5].

Email: 1155063467@link.cuhk.edu.hk

Background and aims: Ethnicity and socioeconomic status significantly influence the diagnosis and outcomes of chronic viral hepatitis. This study evaluated the secular trends in diagnostic rates of chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infection and the incidences of hepatic events, focusing on disparities by ethnicity and socioeconomic region over two decades.
Method: Patients were identified from a territory-wide database. Socioeconomic status was classified based on indigenous degree, individual productivity, populous grassroots, and young age, with regions grouped into four clusters (low, middle, high, upper-middle) using time series clustering. Diagnostic rates were stratified by race (Chinese, non-Chinese) and socioeconomic region and calculated based on the number of individuals tested annually. HCV rates were determined using census population data. Incidences of hepatic events, including hepatocellular carcinoma, decompensating events, and liver transplantation, were calculated among HBV and HCV-infected patients.
Results: A total of 234,865 individuals were diagnosed with HBV. Diagnostic rates for Chinese individuals increased from 0.43% [0.42%–0.44%] in 2000 to 3.58% [3.51%–3.65%] in 2020. Non-Chinese diagnostic rates rose from 0.20% [0.18%–0.22%] in 2000 to 2.31% [2.13%–2.49%] in 2020. Regions with low socioeconomic status showed the most significant rise in diagnostic rates, reaching 3.58% [3.48%–3.69%] in 2020, while high socioeconomic regions had consistently lower rates, peaking at 2.56% [2.26%–2.85%] in 2020. HCV diagnostic rates remained low throughout the study period, with a slight increase among both ethnic groups. Hepatic event incidences also showed significant disparities, with non-Chinese individuals experiencing an increase from 0.15% [0.08%–0.22%] in 2000 to 3.07% [2.31%–3.83%] in 2020, and Chinese individuals rising from 0.35% [0.32%–0.37%] in 2000 to 4.73% [4.49%–4.97%] in 2020. Regions with low socioeconomic status had the highest increases, with rates rising from 0.41% [0.35%–0.46%] in 2000 to 6.53% [5.90%–7.15%] in 2020.
Conclusion: Socioeconomic disparities have a substantial impact on HBV diagnostic rates and hepatic event incidences in Hong Kong. Regions with lower socioeconomic status faced the greatest burden. Reducing socioeconomic disparities is essential to decrease health inequalities and support hepatitis elimination efforts.

Email: wranke.anika@mh-hannover.de

Background and aims: Chronic delta hepatitis represents a major health burden. Until recently, pegylated interferon-alfa-2a (PEG-IFNa) therapy was the only treatment option for patients infected with hepatitis D virus (HDV). The aim of this study was to evaluate long-term clinical and virological outcomes after 96 weeks of treatment with PEG-IFNa with or without tenofovir disoproxil fumarate (TDF).
Method: We performed a retrospective follow-up study of the Hep-Net-International-Delta-Hepatitis-Intervention-Study 2 (HIDIT-2 trial). Patients had received 96 weeks of treatment with either PEG-IFNα-2a plus TDF or PEG-IFNα-2a alone. Patients were included if they had completed the 96-week treatment period and had at least one follow-up visit (PEG-IFNα-2a plus TDF; n = 51, PEG-IFNα-2a alone; n = 56). Liver-related complications were defined as liver-related death, liver transplantation, hepatocellular carcinoma (HCC) and hepatic decompensation defined as ascites, variceal bleeding and/or hepatic encephalopathy.
Results: Patients who received PEG-IFNα-2a plus TDF were younger (37 vs 42 years), no significant differences were observed in other baseline characteristics between the two treatment groups. The mean follow-up period was 8.4 years (with a range of 1.8 to 13.1 years). A total of 26 patients (24%) developed one or more liver-related endpoints after a mean time of 6.0 (1.4–12.6) years. Twenty-two patients were re-treated with IFN and 41 with Nucs. Histological cirrhosis was detected in 42 patients (39%) at baseline and another 29 patients progressed to cirrhosis after a mean time of 1.8 (0.9–6.8) years. At the end of treatment 48 patients had undetectable HDV RNA, of whom 59% patients experienced a relapse during the mean follow-up of 8.5 years. Fifteen patients lost HBsAg; none of them developed an event (p = 0.01). No significant differences were observed between the two treatment arms with regard to HDV RNA relapse, HBsAg loss, re-treatment administration, or progression to cirrhosis. However, patients who received PEG-IFNα-2a alone demonstrated a significantly greater incidence of clinical complications (p = 0.01). The development of clinical complications was further found to be associated with non-response to therapy (HDV RNA and HBsAg), high values of HBV DNA at EOT, age and baseline cirrhosis, as well as baseline values of platelets, AST, GGT, bilirubin and albumin using a Cox regression model. In multivariate analysis baseline cirrhosis, age, undetectable HDV RNA at EOT and high values of HBV DNA at EOT were significantly associated with endpoints.

Conclusion: The 10-year follow-up of a large randomized clinical trial demonstrates that HDV RNA response to PEG-IFNα-2a treatment and loss of HBsAg are associated with an improved clinical long-term outcome. Furthermore, concomitant therapy with TDF seems to be independently associated with a favorable clinical course.

WED-320

Serum hepatitis B surface antigen decline combined with the quantification of hepatitis B virus antigen and hepatitis B surface antibody at the end of treatment of pegylated Interferon predict hepatitis B surface antigen loss at 96 weeks after withdrawal

Qianjun Wu[1], Jie You[1], Wenyu Wu[1], Misi Gu[1], Di Wu[1], Weiming Yan[1], Peng Wang[1], Qin Ning[1], Meifang Han[1]. [1]*The Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Huazhong University of Science and Technology, Wuhan, China*
Email: mfhan@foxmail.com

Background and aims: Functional cure is the ideal goal recommended by chronic hepatitis B (CHB) management guideline. Pegylated interferon alpha (Peg-IFN alpha) therapy could help CHB patients achieve HBsAg loss. This study aims to explore the predictive factors involved in predicting HBsAg loss at follow up 96 weeks after 96 weeks of nucleos(t)ide analogues (NUCs) and Peg-IFN alpha combination and sequential therapy.
Method: This is a multicenter prospective study named of OCEAN study (NCT03358108), in which 170 NUCs experienced patients received a combination treatment of NUCs (ETV or TDF) and Peg-IFN alpha for 48 weeks, followed by Peg-IFN alpha monotherapy for another 48 weeks, and then withdraw the antiviral therapy. All patients were followed up every 24 weeks after the discontinuation of anti-virus therapy, and HBV related indicators were tested. Finally, a total of 114 patients completed the 96 weeks follow up after discontinuation of medication. The indicators predicting HBsAg loss at follow up 96 weeks (FU 96 weeks) were identified by univariate and multivariate analysis, then the nomogram model was constructed and internally validated. The primary endpoint analyzed in the study was HBsAg loss at the end of follow up (EOF), defined as serum HBsAg loss and HBV DNA undetected up to 96 weeks after withdrawal, with or without seroconversion to HBsAb.
Results: After 96 weeks of discontinuing antiviral therapy, there were 28.07% (32/114) patients with HBsAg negative. The univariate and multivariate analysis showed that the serum quantification of HBcrAg ≤4.25 log10U/mL, HBsAb >20 IU/L at EOT and HBsAg decline more than 630 IU/mL from baseline to week 24 during treatment could predict HBsAg loss at 96 weeks after discontinuation. The nomogram model was developed based on the risk factors, and the internal validation was conducted using Bootstrap method, with a concordance index (C-index) of 0.829. Meanwhile, the calibration curve and decision curve of the nomogram model also performed well. The joint indicators could predict HBsAg loss at FU 96 weeks with the areas under the ROC curves (AUROC) = 0.834 ($p < 0.0001$).
Conclusion: Serum HBsAg decline more than 630 IU/mL from baseline to week 24 combined with the quantification of HBcrAg and HBsAb at the EOT of Peg-IFN predict HBsAg loss at FU 96 weeks after withdrawal for CHB patients. We provide novel and effective predictive factors to predict functional cure at follow up 96 weeks after Peg-IFN withdrawal.

WED-321

Impact of hepatic steatosis on hepatitis B virus infection and antiviral treatments

Guanghui Ren[1], Shi Yin[1], Ying Zhu[1]. [1]*Department of Infectious Disease, Liver Disease Center of Integrated Traditional Chinese and Western Medicine, The First Affiliated Hospital of Dalian Medical University, Dalian, China*
Email: zhuyingsh52@126.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and chronic hepatitis B (CHB) often co-occur. The interactions between these conditions and their effects on HBV infection and antiviral treatment outcomes are not well understood. This study investigates the impact of hepatic steatosis on HBV prognosis and antiviral treatment efficacy.
Method: A total of 608 chronic HBV-infected patients were categorized into two groups: CHB+MASLD (241 patients) and CHB-only (367 patients). All participants received antiviral therapy, including nucleos(t)ide analogs (NAs), pegylated interferon α-2b (PegIFNα-2b), or a combination. MASLD severity was classified based on the Controlled Attenuation Parameter (CAP) score (mild, moderate, severe). Baseline virological characteristics and antiviral responses at weeks 24 and 48 were analyzed. Kaplan-Meier (KM) survival analysis and Cox regression were used to assess the impact of MASLD on treatment outcomes.
Results: The CHB+MASLD group had lower baseline serum pgRNA levels (2.48 vs. 2.99, $p < 0.05$) and a lower proportion of HBeAg-positive patients (22.0% vs. 33.2%, $p < 0.05$) compared to the CHB-only group. In non-fibrotic CHB+MASLD patients (n = 164), increasing MASLD severity correlated with lower pgRNA ($p < 0.001$) and HBsAg levels ($p = 0.003$). In fibrotic CHB+MASLD patients (n = 77), HBV markers (HBV DNA, HBsAg, pgRNA) decreased from mild to moderate MASLD but increased from moderate to severe MASLD. Liver stiffness (LSM), APRI, and FIB-4 indices increased with worsening MASLD, though not significantly. At weeks 24 and 48, the CHB+MASLD group had higher HBsAg response rates than the CHB-only group (24w: 11.5% vs. 3.8%, $p = 0.026$; 48w: 24.4% vs. 8.4%, $p = 0.001$), and higher pgRNA response rates at week 48 (48w: 48.8% vs. 28.3%, $p = 0.049$). In non-fibrotic patients, CHB+MASLD patients had higher HBsAg response rates (24w: 22.4% vs. 8.1%, $p = 0.028$; 48w: 30.4% vs. 8.1%, $p = 0.003$). No significant difference was found in the fibrotic subgroup. KM survival analysis revealed that in non-fibrotic patients, median time to HBsAg response was significantly shorter in the CHB +MASLD group (HR = 10.05, 44.81 weeks vs. 47.07 weeks, $p = 0.002$). Cox regression identified predictors of HBsAg response: younger age (HR = 0.947, $p = 0.012$), combination therapy with NAs and PegIFNα-2b (HR = 3.90, $p = 0.005$), lower baseline HBsAg (HR = 0.606, $p = 0.005$), and MASLD presence (HR = 3.321, $p = 0.002$).
Conclusion: Hepatic steatosis is associated with reduced viral markers in non-fibrotic CHB patients. In patients with liver fibrosis, moderate MASLD may represent a threshold where viral replication and fibrosis progression are balanced. In non-fibrotic CHB patients, MASLD enhances antiviral response. Predictors of a favorable response include younger age, combination therapy, lower baseline HBsAg levels, and MASLD presence.

Background and aims: Bepirovirsen is an investigational unconjugated antisense oligonucleotide, currently in Phase 3 clinical trials for the treatment of chronic hepatitis B virus (HBV) infection. Data from a Phase 2b study (B-Clear; NCT04449029) indicated that a subset of participants achieved a response at the end of bepirovirsen treatment, which was sustained for 24 weeks off-bepirovirsen treatment. This occurred in participants 'on' and 'not-on' background nucleos(t)ide analogue (NA) therapy (On-NA and Not-on-NA). Participants who achieved a complete (CR) or partial (PR) response at the end of B-Clear were eligible for this long-term durability study (B-Sure; NCT04954859; ongoing). Here we present data on the durability of response and functional cure (FC) in B-Clear Not-on-NA complete responders (CRs) and partial responders (PRs) who entered B-Sure (duration of follow-up: 2.5 years).
Method: CR was defined as hepatitis B surface antigen (HBsAg) <0.05 IU/mL and HBV DNA < lower limit of quantification (LLOQ), and PR as HBsAg <100 IU/mL and HBV DNA < LLOQ at the end of B-Clear. Following entry into B-Sure, participants are assessed at baseline and at Months 3, 9, 15, 21, 27 and 33. Participants maintaining a CR at Month 3 (i.e., at least 9 months off bepirovirsen), were considered to have achieved FC. Adverse events were recorded, with physical examinations and blood tests performed at each visit for safety and efficacy, including time from achieving response in B-Clear to loss of response in B-Sure.
Results: Overall, 17 B-Clear Not-on-NA participants (11 CRs, 5 PRs and 1 non-responder) were enrolled into B-Sure. Participants had a mean age of 44.1 years. All participants were hepatitis B e-antigen (HBeAg)-negative and 9/17 (53%) had HBsAg ≤1000 IU/mL at B-Clear baseline. For CRs, at 3 months of B-Sure follow-up, 8/11 (73%) participants maintained a CR, thus achieving FC. All 8 participants maintained FC for at least 18 months. Of these 8, 6 maintained FC for 24 months. The 3 participants who did not achieve FC had HBsAg reversion by 3 months of B-Sure; 1 of these participants subsequently experienced HBsAg loss (Month 15) and this was maintained through to the latest available data. For PR participants, only 1/5 maintained a PR at 3 months and through 27 months of B-Sure follow-up. Two PR participants started NA treatment after B-Sure enrollment. There were no new safety signals.
Conclusion: These data provide evidence of longer durability of FC observed with bepirovirsen.
Funding: GSK (206882; NCT04954859).

Email: chenxydoc@163.com

Background and aims: This study aimed to investigate the efficacy and safety of achieving functional cure (HBsAg loss) using Pegylated Interferon alpha-2b (PEG IFNα-2b) treatment in inactive HBsAg carriers (IHC).
Method: The STARHB Project (The STUDY ON TREATMENT FOR INACTIVE CARRIERS OF HEPATITIS B) is a multicenter real-world study in China focused on the functional cure of IHC, aiming to onboard approximately 25,000 patients (ChiCTR2200061541). Based on patient preferences, participants were assigned to a control group (without antiviral treatment) or treatment groups (NAs group and PEG IFNα-2b ± NAs group). The basic treatment duration was 48 weeks, extendable to 96 weeks as needed.
Results: As of Nov. 2024, 15,070 individuals were screened, and 10,894 eligible IHC patients were included in the mITT population baseline analysis. This cohort was 64.9% male with a mean age of 43 years; 6.3% were under 30 years old, and 41.5% had fatty liver. The mean HBsAg level was 223 IU/ml, with 81.8% below 500 IU/ml. The mean HBV DNA level was 220 IU/ml, with 58.5% having undetectable HBV DNA at baseline. The mean ALT was 22 U/L. Liver biopsies were performed on 60 patients at baseline, with 33.3% showing significant liver necroinflammation and/or fibrosis (≥G2 and/or ≥S2). At present, 729 patients have completed the 48-week follow-up. In the control group (n = 11), 4 achieved virological response (VR), with 1 achieved HBsAg loss. In the NAs group, the VR rate at 48 weeks was 100% (17/17), with 1 achieved HBsAg loss. Among those treated with PEG IFNα-2b ± NAs, the VR rate at 48 weeks was 91.01% (638/701), with an HBsAg loss rate of 30% (210/701). ROC analysis indicated that baseline HBsAg levels, 12-week and 24-week HBsAg levels, and 12-week AST levels could predict HBsAg loss at 48 weeks.
Conclusion: PEG IFNα-2b therapy can effectively achieve functional cure in IHC patients, with a 48-week HBsAg loss rate of 30%. Lower baseline, 12-week, and 24-week HBsAg levels, along with higher 12-week AST levels, are predictors of functional cure at 48 weeks. Thus, the IHC population is a favorable group for pursuing clinical cure for hepatitis B.

Combination treatment of TLR7 agonist and anti-PD-L1 reconstitute protective immunity in virally suppressed chronic hepatitis B patients

Yuying Chen[1], Ting Wu[1], Di Wu[1], Weiming Yan[1], Qin Ning[1]. [1]*State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Department and Institute of Infectious Disease, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China, Wuhan, China*
Email: 357987401@qq.com

Background and aims: The combination treatment of Toll-like receptor (TLR) 7 agonist TQ-A3334 and PD-L1 inhibitor TQ-B2450 has been demonstrated to induce a remarkable decline of HBsAg in viral-suppressed chronic hepatitis B (CHB) patients with good safety and tolerability in a pilot RCT phase II study (OCEAN cure05 Study). In this study, we aimed to characterize the immunological features responsible for the efficacy of combination therapy.
Method: Totally 24 nucleos(t)ide analogues (NUCs)-treated CHB patients were randomized to receive Entecavir (ETV) monotherapy (n = 6), ETV+TQA3334 dual therapy (n = 9) or NA+TQA3334+TQB2450 triple therapy (n = 9) for 24 weeks and then followed up for 24 weeks. Serum and Peripheral Blood Mononuclear Cells (PBMCs) were collected at indicated timepoints. The serum levels of Interferon Stimulating Genes (ISGs) and cytokines were analyzed by Quantitative Polymerase Chain Reaction (qPCR) and Meso Scale Discovery (MSD) electrochemiluminescence assay, respectively. HBV specific CD8+T cell responses were determined by flow cytometry. Then PBMCs from NUCs-treated CHB patients were treated in HBV peptides conditioned culture system in vitro for further validation.
Results: Compared to NA monotherapy and dual therapy, triple therapy was associated with greater HBsAg reduction at the end of treatment (EOT). After 12 weeks of treatment, expression level of MX1 and ISG15 significantly elevated among patients received triple therapy. The patients receiving triple therapy displayed significantly higher level of IFN-γ, IP-10 and sPD-1 as well as lower sPD-L1 at week 12. While after 24 weeks of treatment, the IL-21 level in patients with triple therapy significantly increased and was the highest among the three treatment groups, the sPD-L1 level reduced to the lowest. Significantly elevated level of IFN-α was found in patients with dual or triple therapy, and was comparable at EOT between the two groups. In terms of HBV specific CD8+T cells, patients receiving triple therapy demonstrated stronger and broader HBV specific response. Both the production of IFN-γ and degranulation by CD8+T cells stimulated with core peptides pool in patients with triple therapy were significantly higher than those of patients in dual therapy and monotherapy group at EOT. And the elevation of core specific CD8+T IFN-γ remained significantly at 24w after EOT. In vitro, co-stimulation of TQ-A3334 and TQ-B2450 resulted in a significant increase in the frequency of core and polymerase pentamer specific CD8+T cell. In a co-culture system containing PBMCs and HepAD38 cell line, TQA-3334 in combination with TQB-2450 triggered obviously higher viral lysis rate of HepAD38 and strengthened viral control.
Conclusion: The combination of TLR7 agonist and anti-PD-L1 could reconstitute antiviral immunity in virally suppressed CHB patients by inducing the production of ISGs, antiviral cytokines, and reinvigorating HBV-specific CD8+T cell response, thus potentially favouring improved clinical outcome.

Viral kinetics and sequence analysis of a phase I monotherapy study in subjects with chronic hepatitis B reveals a high barrier of resistance to the capsid assembly modulator ALG-000184

Andreas Jekle[1], Kathy Jackson[2], Jacinta O'Keefe[2], Ros Edwards[2], Lilly Yuen[2], Doris Chibo[2], Thanh Van[1], Jen Rito[1], Maida Maderazo[1], Julian Symons[1], Lawrence Blatt[1], Rolando Viani[1], Hardean Achneck[1], Tse-I Lin[3], Min Wu[1]. [1]*Aligos Therapeutics, Inc., South San Francisco, United States;* [2]*Victorian Infectious Diseases Reference Laboratory, Royal Melbourne Hospital, at the Peter Doherty Institute for Infection and Immunity, Victoria, Australia;* [3]*Aligos Belgium BV, Leuven, Belgium*
Email: ajekle@aligos.com

Background and aims: The hepatitis B virus (HBV) Capsid Assembly Modulator (CAM) ALG-000184 demonstrated substantial reductions in HBV DNA, RNA and viral antigens during Part 4 Cohort B of the Phase I clinical trial ALG-000184-201, where 21 chronic hepatitis B (CHB) participants were treated with 300 mg ALG-000184 monotherapy for up to 96 weeks. No viral breakthrough as assessed by HBV DNA was observed. In this study, baseline samples of all 21 participants and the last available on-treatment sample with an HBV DNA viral load of ≥1000 IU/mL were sequenced to identify the presence of known CAM resistance mutations.
Method: Next-generation sequencing was performed on the baseline samples of all 10 HBeAg-positive and 11 HBeAg-negative participants; in addition, at least one on-treatment sample of the HBeAg-positive participants and one HBeAg-negative was analyzed. The minimum plasma HBV DNA concentration for sequencing was 1000 IU/mL. Sequences were compared to their respective genotype reference. Amino acid substitutions in the HBV core protein with a frequency of ≥1% are reported.
Results: All samples except one on-treatment sample were successfully sequenced, with an average read-coverage of >50,000. The three known main ALG-000184 resistance mutations, which mediate a ≥7-fold loss in antiviral activity in vitro, namely T33N, T33P and V124G were not detected (frequency <1%) in any of the samples. F23Y, which causes a 3-fold loss of activity in vitro, was detected in the baseline sample of one subject at a frequency of 5.1%. I105L was detected in the baseline samples of two subjects, with frequencies of 1.98 and 11.2%, respectively. In one of the two subjects, I105T at a frequency of 6.52% was also found. I105L/T reduce the in vitro activity of ALG-000184 ≤2.1-fold. The viral load of the 3 subjects with F23Y, I105L or I105T reached the lower limit of quantification rapidly (HBV DNA 10 IU/mL) by Day 14 and no on-treatment plasma sample with a sufficiently high HBV DNA concentration was available for sequencing. Other resistance mutations, which significantly reduce the in vitro antiviral activity of other CAMs but not ALG-000184 were detected in baseline samples but not in any on-treatment samples. These include Y38F (frequency 97%), T109M (>99%) and Y118F (8.6%).
Conclusion: No viral breakthrough or non-response, as measured by HBV DNA levels was observed in the 21 CHB participants undergoing ALG-000184 monotherapy for up to 96 weeks. Consistently, none of the major ALG-000184 resistance mutations identified in vitro (T33N, T33P and V124G) were detected in any of the baseline or on-treatment samples, indicating a high barrier to resistance. The lack of viral breakthrough and emerging resistance, combined with the significant reduction in HBV DNA, positions ALG-000184 as a promising candidate for further clinical development as a potential backbone of therapy for chronic viral suppression.

Background and aims: The phase 2 SOLSTICE study is investigating the antiviral activity and safety of the monoclonal antibody tobevibart alone and in combination with the small interfering RNA (siRNA) elebsiran in chronic HDV infection (NCT05461170).
Method: Participants with chronic HDV infection, with or without compensated cirrhosis on NRTI therapy, were randomized 1:1 to receive either tobevibart 300 mg plus elebsiran 200 mg subcutaneously (SC) every 4 weeks (tobevibart + elebsiran Q4W *de novo*) or tobevibart 300 mg SC every 2 weeks (tobevibart Q2W) for 96 weeks. Here we present a subgroup analysis of the week 24 preliminary results based on cirrhotic status, HDV viremia and hepatitis B surface antigen (HBsAg) at enrollment from N = 32 participants receiving tobevibart + elebsiran Q4W *de novo* (56.3% cirrhotic CPT-A) and N = 33 participants receiving tobevibart Q2W (45.5% cirrhotic CPT-A).
Results: After 24 weeks of tobevibart+elebsiran Q4W *de novo* therapy, all participants demonstrated viral suppression (HDV RNA < limit of detection (<LOD, 14 IU/mL) or a ≥ 2 $\log_{10}$ decrease from baseline) with 75% achieving <LOD and 41% achieving target not detected (TND). The percentage of participants achieving TND within 24 weeks was similar regardless of baseline cirrhotic status, HDV viremia, or HBsAg. In contrast, 82% of participants receiving tobevibart Q2W demonstrated viral suppression with 58% achieving <LOD and 30% achieving TND; and fewer participants with baseline HDV viremia >10^5 IU/mL achieved TND. TND response rates were similar between non-cirrhotic and cirrhotic participants in both cohorts at week 24. ALT normalization was achieved by week 24 in 47% of participants receiving tobevibart + elebsiran Q4W *de novo* and 76% of participants receiving tobevibart Q2W regardless of the presence baseline compensated cirrhosis or baseline HDV viremia in both cohorts. Approximately 88% of participants receiving tobevibart + elebsiran Q4W *de novo* achieved HBsAg values <10 IU/mL by week 24 regardless of baseline HBsAg levels. In contrast, 22% of participants receiving tobevibart Q2W achieved HBsAg values <10 IU/mL at week 24 and the likelihood was decreased in participants with baseline HBsAg > 3,000 IU/mL. Treatment-emergent adverse events (TEAEs) were primarily Grade 1–2 and transient in nature, with the most common being influenza-like syndrome, myalgia, headache, and chills. There were low rates of treatment discontinuation.
Conclusion: In preliminary 24 weeks data, participants receiving tobevibart+elebsiran Q4W *de novo* therapy achieved high rates of viral suppression, regardless of baseline viral parameters or the presence of compensated cirrhosis, whereas participants receiving tobevibart Q2W with high baseline HDV viremia showed a trend towards decreased viral response. These results support continued development of tobevibart in combination with elebsiran for chronic HDV infection.

THU-244
Tissue virological response is the main predictor of hepatitis D relapses

Pavel Bogomolov[1], Maria Arapova[2], Natalia Barsukova[1], Alexander Demyanov[1], Nadezhda Shub[2], Alexey Bueverov[1], Ekaterina Isaeva[1], Sergei Koblov[1], Michail Kalashnikov[1], Natalia Gasilova[3], Anna Belyakova[3], Cagan Lidzhieva[3], Elena Kondrasheva[3]. *[1]State Budgetary Institution of Health Care of Moscow Region "Moscow Regional Research Clinical Institute Named After M.F. Vladimirsky", Moscow, Russian Federation; [2]Center of targeted therapy Ltd., Moscow, Russian Federation; [3]«Independent Laboratory INVITRO» LLC, Moscow, Russian Federation*
Email: bpo73@list.ru

Background and aims: Chronic hepatitis delta (CHD) infection is the most aggressive form of viral hepatitis, leading to early development of cirrhosis, cirrhosis-related complications, and primary liver cancer. The only effective treatment for CHD patients is bulevirtide (BLV) with or without pegylated interferon alfa (PEG-IFN). Assessing the response to antiviral therapy in CHD patients relies on detecting and quantifying hepatitis delta virus (HDV) RNA in blood serum using PCR testing. However, achieving and maintaining undetectable HDV RNA during antiviral treatment predicts sustained virological response (SVR) in only 63% of patients; relapse occurs in one-third of patients after the end of treatment (EOT). The optimal time for discontinuing treatment remains debated, as undetectable HDV RNA at week 12 or 24 of antiviral therapy is not a strong predictor of SVR, defined as the absence of HDV RNA for 48 weeks in blood serum after EOT. This study aims to demonstrate that the presence of HDV RNA in liver tissue is a marker of active replication and a predictor of relapse post-EOT. Despite long periods of aviremia during antiviral therapy, lasting 36 to 96 weeks, most patients relapse after the EOT.
Method: The study included 24 CHD patients treated with combined antiviral therapy of PEG IFN and BLV 2 mg/day for 48 weeks, followed by BLV 2 mg/day monotherapy until 96–144 weeks. All patients achieved and maintained undetectable HDV RNA (complete virologic response) until EOT, with undetectable HDV RNA by PCR for at least 48 to 96 weeks of therapy. At EOT, liver biopsies were conducted for all patients. In addition to histological response assessment, HDV RNA detection by PCR in liver tissue was performed.
Results: Among the 24 patients maintaining undetectable HDV RNA (complete virological response) in serum, HDV RNA was detected in the liver tissue in 16 patients. All 16 patients relapsed within 24 weeks post-EOT.
Conclusion: In CHD patients who achieved and maintained undetectable HDV RNA during antiviral therapy with PEG IFN and BLV, the absence of tissue virologic response (detection of HDV RNA in liver biopsy by PCR) at EOT is the main predictor of HDV relapse post-EOT. Therefore, antiviral treatment should be prolonged based on the risk of relapse, which can be predicted by positive HDV RNA testing in liver tissue (tissue virologic response - tVR) obtained at EOT.

Background and aims: RO7565020 (RG6449) is a neutralizing human IgG1 monoclonal antibody (mAb) targeting the antigenic loop present in all forms of hepatitis B surface antigen (HBsAg). A neonatal Fc receptor (FcRn) affinity-enhancing Fc mutation was introduced to improve the pharmacokinetic (PK) properties. In vitro and in vivo studies of RO7565020 showed potent and cross-reactive neutralization against the main hepatitis B virus (HBV) genotypes (A-D). Here, we report the safety, tolerability, PK, and pharmacodynamics (PD) results of the first-in-human study of RO7565020 (NCT05763576).
Method: Part 1 is a randomized study in healthy volunteers (HVs), including 5 single ascending dose (SAD) cohorts and 1 ethnic bridging cohort, each with 8 participants (in a 6:2 ratio of active treatment to placebo). Part 2 is an open-label, active treatment-only study in virologically suppressed participants with chronic hepatitis B (CHB) treated with nucleos(t)ide analogues, including 3 and 2 SAD cohorts (each with 6 participants) with baseline low or high HBsAg (cutoff: 3000 IU/mL). Participants were followed for 24 to 36 weeks post-administration.
Results: Across 6 cohorts in Part 1, 32/48 (67%) participants reported 91 adverse events (AEs), all were Division of AIDS (DAIDS) Grade 1 or 2. Six (7%) treatment-related AEs and 1 unrelated serious adverse event (SAE) were reported. Across 2 of the 5 cohorts in Part 2 (the first 2 dose levels in participants with baseline low HBsAg), 3/12 (25%) participants reported 7 AEs, all were DAIDS Grade 1. One treatment-related AE was reported. No SAEs or evidence of immune complex disease. No dose-related trends in AEs or safety lab parameters were observed. Low anti-drug antibody titers were observed in 6 (13%) HVs and 1 (8%) participant with CHB, without impact on PK parameters. In Part 1, a single dose of RO7565020 was absorbed with a median Tmax ranging from 11 to 28 days and had a mean half-life of approximately 90 days. Exposure (Cmax and AUCinf) increased in a dose-proportional manner. PK profiles were similar between Asian and Caucasian participants. In both cohorts of Part 2, the median Tmax was 11 days and the half-life was dose-dependent. A clear temporal relationship between the increase in total serum active RO7565020 concentrations and the decrease in serum HBsAg levels was observed. The mean (SD) HBsAg reduction from baseline reached its nadir at Day 8, with similar values in both cohorts: 1.38 (0.54) log10 IU/mL for cohort 1 and 1.43 (0.29) log10 IU/mL for cohort 2. By Day 57, the reduction appeared more sustained in cohort 2 (1.06 (0.39) log10 IU/mL) than in cohort 1 (0.68 (0.60) log10 IU/mL). Additional data from these cohorts will be presented.
Conclusion: RO7565020 administered as a single dose was generally safe and well-tolerated. It demonstrated proof-of-mechanism with rapid reductions in serum HBsAg in participants with CHB who had baseline HBsAg ≤3000 IU/mL.

THU-246

Safety, tolerability and immunogenicity of GS-2829 and GS-6779, a novel arenaviral vectored therapeutic hepatitis B vaccine: results from a phase 1a study in healthy participants

Edward J. Gane[1], Dana Tedesco[2], Frida Abramov[2], Scott Balsitis[2], Mario Cortese[2], David Pan[2], Teri Chew[2], Sarah Arterburn[2], Audrey Lau[2], Anu Osinusi[2]. [1]*University of Auckland, Auckland, New Zealand;* [2]*Gilead Sciences, Inc., Foster City, United States*
Email: dana.tedesco@gilead.com

Background and aims: Achieving a functional cure for hepatitis B virus (HBV) infection may require novel combinations of agents that target viral replication and generate a sustained immune response. One approach to elicit such a response is therapeutic vaccination. Nonreplicating arenaviral vectors GS-2829 and GS-6779 were engineered to express highly conserved HBV proteins. Here, we present the results from a Phase 1a study evaluating the safety, tolerability and immunogenicity of GS-2829 and GS-6779.
Method: This randomised (4:1), blinded, placebo-controlled Phase 1a study (NCT05770895) was conducted at 1 centre in New Zealand in healthy participants. Cohorts (C)1 and C2 received a total of 2 intramuscular (IM) administrations of either a low dose of GS-2829 (C1), or GS-6779 (C2) once every 8 weeks (W). Alternating IM doses of GS-2829 or GS-6779 every 4 weeks (e.g. GS-2829 at W0, followed by GS-6779 at W4) were evaluated in multiple cohorts: C3, four total low doses; C4, four total high doses; C8, six total high doses. Safety and tolerability, including treatment emergent adverse events (TEAEs), serious adverse events (SAEs) and laboratory abnormalities, were monitored throughout the study. Immunogenicity was evaluated via interferon-gamma ELISpot analysis of HBV-specific T cells and anti–hepatitis B surface antigen (HBsAg) antibody titres.
Results: A total of 51 participants were enrolled and treated: C1–4, n = 10 per cohort; C8, n = 11. The median age was 33 years, 49% were male, 35% were Asian, 41% were White, 4% were Native Hawaiian or Pacific Islander and 20% were other races. Both single and alternating vector administrations were safe and well tolerated. TEAEs occurred in 98% (50 of 51) of participants and were Grade 1 or 2 and nonserious, except for one Grade 3 unrelated SAE (Lisfranc fracture due to a road collision). Commonly reported TEAEs were injection-site reaction (55%, 28 of 51) and flu-like symptoms (headache [43%, 22 of 51], fatigue [41%, 21 of 51] and malaise [25%, 13 of 51]), that were transient in nature. No AEs led to discontinuation of the study drugs or death. Vaccine-elicited immune responses were dose dependent; in several participants (C8), addition of doses 5 and 6 further increased the magnitude of T cell responses. Participants generated HBV-specific T cells to all vaccine-encoded HBV antigens and high-magnitude, durable anti-HBsAg titres.
Conclusion: Alternating doses of GS-2829 and GS-6779 were safe and well tolerated in healthy participants. Common TEAEs were consistent with the vaccines as a drug class. Immunogenicity was dose-level dependent, and vaccine-elicited T cell responses were progressively increased with additional vaccine doses. These data support further investigation of GS-2829 and GS-6779 in participants with chronic HBV infection in this ongoing Phase 1 study.

THU-247

HBsAg declines, and T cell increases, observed in CHB patients: Interim results from P1b trial of VRON-0200, a novel checkpoint modifier, following prime only, and prime and boost dosing

Edward J. Gane[1], Sue Currie[2], Andrew Luber[2], Tien Huey Lim[3], Marie Bonhomme[4], Grace Lai-Hung Wong[5]. [1]*New Zealand Liver Transplant Unit, Auckland City Hospital, University of Auckland, Auckland, New Zealand;* [2]*Virion Therapeutics, LLC, Philadelphia, United States;* [3]*Middlemore Hospital, Auckland, New Zealand;* [4]*Laboratory Services, Vaccine Sciences Department, PPD, Part of Thermo Fisher Scientific, Richmond, United States;* [5]*Medical Data Analytics Centre, Department of Medicine and Therapeutics, and Institute of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, Hong Kong*
Email: edgane@adhb.govt.nz

Background and aims: VRON-0200 is a therapeutic vaccine for CHB functional cure that expresses a genetically encoded checkpoint modifier, fused with HBV core and pol (but not S) antigens, designed to enhance, broaden, and prolong $CD8^+$ T cell responses. This is the first report of HBsAg and immunogenicity of i.m. prime and boost doses of VRON-0200.
Method: CHB patients (pts), virologically suppressed on nucleos(t)ide analogues and with HBsAg ≤500IU/mL, are randomized to receive i.m. VRON-0200 1×10^{10}vp(Cohort 1) or 5×10^{10}vp(Cohort 2). Cohort 1a/2a receives a prime, followed by a boost, on D91; Cohort 1b/2b receives prime only. Safety, virologic, and immunologic assessments are performed. T cell frequencies are assessed pre-tx (2 timepts) and at multiple post-tx timepts, via IFN-γ ELISpot(LLOD<30 SFU/1e6) from PBMCs using 3 peptide pools (core & pol representing the vaccine peptides, and S antigen peptides). All pts who received VRON-0200, with PBMC results, for the analyses are included.

Immunologic responders are defined as 2 consecutive core plus pol ELISpot values at D28 above the avg of the 2 pre-tx values. A one-sided paired t-test assessed if there was a difference between pre-tx and D28 values. A D91 response was defined as a core plus pol ELISpot value on D91 that is above the avg of the 2 pre-tx values. HBsAg levels were assessed in patients with results at their most recent study visit ≥ D91; declines ≥ 0.4 $\log_{10}$IU/mL are reported.

Results: 25 pts were included in this analysis (13-Cohort 1;12-Cohort 2): 80% male, 85% Asian, mean age, 46yrs, median BL HBsAg, 179 IU/mL (range:10–623). As of November 26, 2024, 5,830 pt safety days were evaluable, with 30 AEs reported in 15 patients (24-Grade 1;6-Grade 2). The frequency and severity of AEs were not related to dose or additional boost dosing. ELISpot results through D28, 91 and 154 were evaluable in 22,16 and 5 patients, respectively. At BL, most pts (n = 20;91%) had either one or both pre-tx ELISpot values to core or pol below LLOD. At D28, responses to core and pol increased 2.2-fold overall (p = 0.02) and 5.5-fold higher among the 7 responders.10/16 pts (63%) were determined to have a D91 response, with 5 of 6 (83%) D28 responders having a D91 response. Of the 22 pts with HBsAg evaluable at their last study visit, 5 pts (23%) had −2.3, −0.8, −0.6, −0.4 and −0.4 $\log_{10}$IU/mL declines. ELISpot and HBsAg responses following boost dosing are ongoing and will be reported.

Conclusion: In a CHB pt population with limited preexisting HBV immunity, VRON-0200 was safe, well tolerated, and significantly increased T cell responses and reduced HBsAg levels in >20% of patients, reflecting restored broad HBV-specific immune responses (vaccine does not contain S). VRON-0200 is a potential simple, easy-to administer, IFN-sparing immunotherapy, alone or in combination, for HBV functional cure. Immunologic, clinical, and safety analyses are ongoing.

THU-248

Preliminary safety, tolerability, pharmacokinetics and pharmacodynamics of single and multiple doses of AB-101, a small-molecule PD-L1 inhibitor, in healthy and chronic hepatitis B subjects

Edward J. Gane[1], Marta Dobryanska[2], Alina Jucov[3,4], Man-Fung Yuen[5], Grace Lai-Hung Wong[6], Emily P. Thi[7], Timothy Eley[7], Sharie C. Ganchua[7], Christine L. Email: tvarughese@arbutusbio.com

Background and aims: Programmed death 1 (PD-1)/ programmed death-ligand 1 (PD-L1) checkpoint inhibition using immune checkpoint inhibitor antibodies (ICI Abs) has been associated with HBsAg loss and seroconversion in chronic hepatitis B (CHB) subjects with low baseline HBsAg. A concern with the use of ICI Abs in CHB subjects is the development of immune related adverse events (irAEs). AB-101 is an oral small-molecule PD-L1 inhibitor being developed for the treatment of CHB infection in combination with other agents. As AB-101 is expected to have a shorter half-life than ICI Abs, dose modification or discontinuation may mitigate unanticipated safety issues. Better tissue penetrance leading to high concentrations in the liver by AB-101 may also permit lower doses to be used in CHB subjects compared to ICI Ab doses used in oncology patients. A Phase 1a/1b study is ongoing to assess the characteristics of AB-101 in healthy subjects (HS) and nucleos(t)ide analogue (NA)-suppressed CHB subjects. Preliminary results of completed single ascending dose (SAD) and multiple ascending dose (MAD) cohorts in HS are reported.

Method: AB-101-001 (NCT05960240) is a randomized, double-blind, placebo-controlled 3-part study evaluating the safety, tolerability, pharmacokinetics (PK) and pharmacodynamics (PD) of AB-101 in HS and HBV DNA-negative CHB subjects on NA therapy. In Part 1, HS were randomized 6:2 to receive single doses of AB-101 or placebo (PBO) and in Part 2, HS were randomized 8:2 to receive AB-101 or PBO once daily (QD) for 7 days. Part 3 in CHB subjects dosed with AB-101 or PBO for 28 days is ongoing. Safety was monitored throughout the study via adverse event (AE) reporting, vital signs, physical examination, ECGs, and laboratory assessments. Blood samples for single and repeat dose PK and PD were collected. PD was assessed via measurement of PD-L1 levels from peripheral cells (receptor occupancy [RO]).

Results: To date, HS SAD cohorts up to 40 mg and MAD cohorts up to 25 mg QD for 7 days are complete and the 40 mg QD for 7 days cohort is in follow up. All subjects in Parts 1 and 2 were male with an overall mean age of 29.6 years (SD 7.2). AB-101 was well tolerated with no serious adverse events (SAEs), irAEs, Grade 3 or 4 treatment emergent adverse events (TEAEs) or discontinuations due to TEAEs reported. All AB-101 related TEAEs (N = 6) were Grade 1. No clinically significant laboratory, vital sign, or ECG abnormalities were reported. There were dose-related increases in AB-101 C_{max}, AUC, and RO. RO >30% was observed after single doses of AB-101, with no obvious increase with repeat dosing at the same dose level. Mean maximal RO was 48%, 83%, and 94% for 10 mg, 25 mg, and 40 mg QD for 7 days, respectively.

Conclusion: Single doses of AB-101 up to 40 mg and repeat doses up to 40 mg QD for 7 days were well tolerated in healthy subjects. Preliminary PD data shows AB-101 RO at doses ≥10 mg, with dose-related increases in RO observed. Dosing in Part 3 in CHB subjects is ongoing and available data, including RO and HBV virologic biomarkers, will be presented.

Email: ethi@arbutusbio.com

Background and aims: Functional cure (FC) of chronic hepatitis B (CHB) requires suppression of viral replication, reduction of HBV antigens and induction of anti-HBV immune responses. Imdusiran (IDR) is a *N*-Acetylgalactosamine–conjugated, pan-genotypic small interfering RNA therapeutic that blocks all HBV RNA transcripts, including HBV X protein, resulting in suppression of viral replication

and all viral antigens. IM-PROVE I is an ongoing Phase 2a study assessing 24 weeks (W) of IDR lead-in followed by 12W or 24W of pegylated interferon alfa-2a (IFN) with or without additional IDR doses in 43 nucleos(t)ide analogue (NA) treated CHB subjects. Exploratory HBV biomarker profiles of subjects who achieved FC are compared to subjects who did not achieve FC but who had HBV DNA <LLOQ or experienced HBsAg seroreversion after NA discontinuation during follow-up.

Method: Longitudinal plasma and serum samples were collected from subjects who attained FC (n = 6) and compared to subjects who did not achieve FC but who had HBV DNA <LLOQ (n = 3) or experienced HBsAg seroreversion during follow-up (n = 1). HBsAg (LLOQ = 0.05 IU/mL), anti-HBs antibodies (LLOQ = 1 IU/L), HBcrAg (LLOQ = 1.0 kU/mL) and HBV DNA (LLOQ = 10 IU/mL) were quantified using chemiluminescent immunoassays or molecular assay. HBV RNA, HBsAg isoforms and immune complex were assessed using the Abbott HBV RNA v2.0 assay (LLOQ = 0.49 Log_{10} U/mL or 3.09 U/mL) and exploratory assays.

Results: All subjects in IM-PROVE I with quantifiable HBV RNA at baseline (n = 36) showed declines during IDR lead-in, with mean (± standard deviation) maximal log_{10} changes from baseline of −1.06 (0.20), −0.99 (0.19), −0.80 (0.21) and −1.04 (0.18) in Cohorts A1, A2, B1 and B2, respectively. In 5/6 FC subjects and 2/3 subjects who had HBV DNA <LLOQ but did not attain FC, HBV RNA declined to undetectable during IDR lead-in; in contrast, HBV RNA undetectability during IDR lead-in was not achieved in one subject who lost HBsAg and later seroreverted. Transient increases in HBV RNA were observed during IFN treatment in 5/6 FC subjects which occurred prior to or concomitant with HBsAg loss. In contrast, subjects who had HBV DNA <LLOQ but did not achieve HBsAg loss or later seroreverted also experienced increases in HBV RNA, but these were associated with transient increases in HBV DNA off treatment. In the HBsAg seroreversion subject, an increase in HBsAg was observed to follow a decline in anti-HBs antibodies, suggesting unmasking of HBsAg from immune complexes. Further assessment of HBcrAg, immune complex and HBsAg isoforms levels in these subjects will be presented.

Conclusion: Subjects who achieved functional cure after combination treatment with IDR + IFN showed rapid HBV RNA decline during IDR lead-in, with 5/6 subjects achieving HBV RNA undetectability during this period. Transient elevations in HBV RNA were observed to occur during the IFN treatment period which was associated with further HBsAg decline and loss in some FC subjects.

THU-254

First-in-human pharmacokinetics and pharmacodynamics of oral small-molecule PD-L1 inhibitor AB-101 and correlation to preclinical models

Emily P. Thi[1], Sharie C. Ganchua[1], Christine L. Espiritu[1], Ingrid Graves[1], Christina Iott[1], Timothy Eley[1], Tilly Varughese[1], Varun Sharma[1], Fran Xu[1], Amanda Pohl[1], Andrew G. Cole[1], Gavin D. Heffernan[1], Seyma Ozturk[1], Troy O. Harasym[1], Angela M. Lam[1], Edward J. Gane[2], Michael J. Sofia[1], Karen D. Sims[1]. *[1]Arbutus Biopharma, Warminster, United States; [2]University of Auckland and New Zealand Clinical Research, Auckland, New Zealand*
Email: ethi@arbutusbio.com

Background and aims: Functional cure of chronic hepatitis B (CHB) requires suppression of viral replication, reduction of HBV antigens (particularly HBsAg), and induction of anti-HBV immune responses. The PD-1/PD-L1 immune checkpoint axis plays a key role in HBV immune tolerance, which is a critical driver of CHB persistence. AB-101 is an oral small-molecule PD-L1 inhibitor with favorable liver distribution in preclinical species and the potential to enable tunable on-target engagement while reducing toxicities associated with systemic exposure. Preliminary pharmacodynamic (PD) data from an ongoing Phase 1a/1b study of AB-101 dosing in healthy subjects is presented. PD association with pharmacokinetic (PK) data is described and compared to PK-PD relationships observed in preclinical efficacy models.

Method: AB-101-001 is a double-blind, randomized, placebo-controlled single- and multiple-dose Phase 1a/1b study evaluating the safety, tolerability, PK, and PD of AB-101 in healthy subjects and subjects with CHB infection. Receptor occupancy (RO) and target engagement in peripheral blood cells and plasma were assessed at multiple timepoints after single and multiple ascending doses in healthy subjects, and clinical PK and PD of AB-101 is presented and compared to AB-101 PK-PD association in humanized PD-1/PD-L1 adenovirus-associated HBV mice and a humanized PD-1/PD-L1 MC38 tumor mouse model.

Results: To date, single dose cohorts up to 40 mg and multiple dose cohorts up to 25 mg QD for 7 days have been completed, and a 40 mg QD for 7 days cohort is in follow-up in healthy subjects. Dose-responsive increases in RO were observed, with mean maximal RO of 48%, 83%, and 94% following AB-101 dosing at 10 mg, 25 mg, and 40 mg QD for 7 days, respectively, with data through 7 days of follow-up. Increases in RO paralleled the increases in AB-101 plasma concentrations. AB-101 plasma concentrations rapidly declined after reaching a T_{max} at ~1 h post-dosing, indicating rapid distribution into tissues. Similar plasma PK profiles of AB-101 were observed in preclinical mouse efficacy models, which were associated with concomitantly high AB-101 concentrations (≥5 × serum-shifted EC_{90}) in liver and tumor with demonstrated RO and target engagement.

Conclusion: AB-101 was safe and well-tolerated in both single- and multiple-dose administrations in healthy subjects. Dose-responsive increases in RO were observed in peripheral blood cells, which correlated with dose-dependent increases in AB-101 plasma concentrations. The clinical plasma PK profile of AB-101 to date indicates rapid distribution into tissues, mirroring the plasma profiles seen in preclinical efficacy models, which exhibited high liver biodistribution and target engagement.

THU-255

The safety and efficacy of PD-1 antibody combined with pegylated interferon-α therapy to promote the clinical cure in nucleoside (acid) analogues-suppressed chronic hepatitis B patients

Hongmin Wang[1], Xiaoying Li[2], Fu-Sheng Wang, Junliang Fu.
[1]Department of Infectious Diseases, the Fifth Medical Center of Chinese PLA, The First Affiliated Hospital of USTC, University of Science and Technology of China, Beijing, China; [2]Shandong Public Health Clinical Center, Jinan, China
Email: fjunliang@163.com

Background and aims: The clinical cure of chronic hepatitis B (CHB) is an ideal goal of therapy, which is associated with improved long-term outcome. Studies have shown that PD1 antibody therapy can reduce HBsAg in patients with CHB. This study was used to evaluate the efficacy and safety of a novel strategy, PD-1 antibody combined with Peg-IFNα, in NAs-treated CHB patients.

Method: This study was designed as two cohorts. Cohort 1 was a prospective, multicenter, open-labled, randomized controlled study. Total 45 viral suppressed CHB patients with NAs treatment (HBeAg and HBV DNA nagetive, HBsAg ranged from 200 to 1000 IU/mL) were enrolled and randomly assigned to Peg-IFNα group, PD-1 antibody group and Combined group. Cohort 2 was a prospective, multicenter, single group assignment study. Fifty patients with HBsAg <200 IU/ml were treated with PD-1 antibody for 12 weeks and then efficacy was evaluated. If the HBsAg reduction of patients was less than 0.5log, Peg-IFNα-2b therapy was added, otherwise, the original treatment regimen was continued. The primary endpoint was rate of HBsAg loss at 24 weeks and 48 weeks, while safety was evaluated by the adverse events (AEs) profile.

Results: By the time this abstract was submitted, 12 eligible CHB patients were enrolled in cohort 2 and randomized to Peg-IFNα group (n = 3), PD-1 antibody group (n = 5) or Combined group (n = 4), and 11 patients were enrolled in cohort 2. The decline in levels of HBsAg

from baseline in combined group of cohort1 was 0.04 log10 IU/ml (range – 0.69–0.10) after 6–9 weeks treatment (n = 3), in PD-1 group was –0.05 log10 IU/ml (range –1.02–0.01) after 3–18 weeks treatment (n = 5) and in Peg-IFNα group was –1.96 log10 IU/ml (range –2.37 – –0.01) after 9–24 weeks treatment (n = 3). The media decline in cohort 2 was –0.21 log10 IU/ml (range –2.51 – –0.02) after 6–18 weeks treatment (n = 11). One patient obtained HBsAg loss only receiving 2 doses of PD-1 antibody in cohort 2. All 22 patients were included in the safety analysis. In total, 51 AEs were reported in 100% (3/3), 20% (1/5) and 75% (3/4) patients in Peg-IFNα group, PD-1 antibody group and Combined group of cohort1, respectively. In cohort 2, 17 AEs were reported in 30% (3/10) patients during firsts 12weeks PD-1 antibody therapy. Peg-IFNα was added to 3 patients at the 12-week evaluation, and 10 AEs were reported in all these 3 patients. There was no study drug-related serious adverse event (SAE).

Conclusion: PD-1 antibody or combined with Peg-IFNα was shown to be safe and well-tolerated in CHB patients according to our preliminary data. And more comprehensive data in our study later will provide evidence to verify the safety and efficacy of this strategy in promoting clinical cure.

THU-256

The safety and antiviral effect of oral daily 300 mg ALG-000184 in combination with Entecavir for up to 96 Weeks in untreated HBeAg-positive subjects with chronic hepatitis B virus infection

Jinlin Hou, Hong Ren[1], Xieer Liang, Xian Yu[1], Jia Xu[2], Edward J. Gane[3], Man-Fung Yuen[4], Kosh Agarwal, Min Wu[5], Kha Le[5], Thanh Van[5], Jen Rito[5], Lawrence Blatt[5], Sushmita Chanda[5], Tse-I Lin[5], Yanhua Ding[2]. Email: jlhousmu@163.com

Background and aims: ALG-000184 is a prodrug of ALG-001075, a highly potent capsid assembly modulator-empty (CAM-E) that has been shown in vitro to induce the formation of empty capsids, inhibit hepatitis B virus (HBV) replication, and prevent the establishment/replenishment of cccDNA.

Method: ALG-000184-201 is a multi-part, multi-center, randomized clinical trial evaluating the safety, pharmacokinetics, and antiviral activity of ALG-000184 in healthy volunteers and subjects with untreated chronic HBV infection (NCT04536337). Here, we report safety and antiviral activity data from untreated HBeAg+ subjects who received 300 mg ALG-000184 plus entecavir (ETV) for ≤96 weeks.

Results: 15 subjects were enrolled from Chinese sites and randomly assigned to the active (ALG 000184 + ETV, n = 12) or placebo arm (placebo of ALG-000184 + ETV, n = 3) for 12 weeks of treatment, followed by open label daily 300 mg ALG-000184 plus ETV for ≤96 weeks in all subjects. All subjects were Asian (mean age 31.4 years, HBV genotype B or C). 7 of 15 subjects had persistent normal ALT levels during screening. The mean levels of HBV markers at baseline were HBV DNA 8.1 $\log_{10}$ IU/mL, HBV RNA 6.7 $\log_{10}$ copies/mL, HBsAg 4.4 $\log_{10}$ IU/mL, HBeAg 3.0 $\log_{10}$ PEI U/mL, and HBcrAg 8.3 $\log_{10}$ U/mL, respectively. The mean reduction of HBV DNA at Week 12 was higher in the active arm than in the control arm (5.1 $\log_{10}$ IU/mL vs. 3.8 $\log_{10}$ IU/mL with ETV alone). Adding 300 mg ALG 000184 to ETV after Week 12 led to similar HBV DNA reductions at Week 24 as in the active arm. Nine subjects in the active arm received at least 48 weeks of treatment. Among them, maximum mean reduction in HBV DNA was 7.0 $\log_{10}$ IU/mL. The numbers of subjects who achieved HBV DNA <10 IU/mL at Weeks 48, 72 and 96 were 3/9, 4/8, and 4/5, respectively. All subjects achieved HBV RNA suppression (<200 copies/mL) by Week 28. Maximum mean reduction of HBsAg was 0.9 $\log_{10}$ IU/mL, HBeAg 2.0 $\log_{10}$ PEI U/mL, and HBcrAg 2.3 $\log_{10}$ IU/mL. The safety profile was favorable with no serious adverse events reported. One subject experienced a Grade 3 TEAE of ALT elevation probably associated with underlying liver progression (cirrhosis) and/or concomitant medication with known potential for hepatoxicity, which led to withdrawal. ALT levels had improved before stopping ALG-000184, showing a similar pattern of fluctuations during follow-up. All other Grade ≥3 TEAEs of ALT elevation (n = 2), eGFR decrease (n = 1), uric acid increase (n = 1), and neutropenia (n = 1) resolved during continued dosing.

Conclusion: ALG-000184, in combination with ETV for up to 96 weeks, was well tolerated and led to profound suppression of HBV DNA in untreated HBeAg+ subjects with high baseline HBV DNA levels. These results indicate the potential of ALG-000184 in different combination therapies for chronic HBV infection. Full data for 96 weeks of treatment and 8 weeks of follow-up will be shared at the EASL conference.

THU-257

Genetic prediction of causality of immune cell-mediated plasma metabolites and acute hepatitis B: a Mendelian randomization study

Size Li[1], Shihao Zheng, Xiaoke Li[1], Hongbo Du[1], Wenying Qi[1], Qiyao Liu[1], Xiaobin Zao[1], Yong'an Ye[1]. [1]*Dongzhimen Hospital of Beijing University of Chinese Medicine, Beijing, China*
Email: yeyongan@vip.163.com

Background and aims: Plasma metabolites play an important role in the progression of acute hepatitis B (AHB). Several studies have shown that metabolic reprogramming of immune cells is a key factor in chronic liver inflammation and hepatocellular damage, leading to the persistence of hepatitis B infection. This Mendelian randomization (MR) study aimed to investigate the causal relationship between immune cell-mediated plasma metabolites and AHB.

Method: Genome-wide association study (GWAS) data on plasma metabolites, AHB and immune cells were obtained from public databases. Five methods were used for analysis: inverse variance weighted (IVW), weighted median estimation, Mendelian randomization (MR)-Egger regression, single model and weighted model. Among them, the IVW method was used as the main analysis method to determine the causal relationship between metabolites and AHB, sensitivity analysis was used to evaluate the reliability of the MR results, the stability of the MR results was assessed using the leave-one-out method, and mediation analysis was used to explore the mediating role of immune cells.

Results: Our analysis identified a causal relationship between 56 plasma metabolites and AHB. 4-methylguaiacol sulfate levels (OR_{IVW} = 1.517; 95% CI (2.0770–10.0109); P < 0.001) 1-methylnicotinamide levels (OR_{IVW} = 1.91; 95% CI (1.06–3.44); P = 0.032), Cortisone to cortisol ratio ($OR_{IVW=}$2.34; 95% CI (1.06–5.19); P = 0.032)), etc. 10 metabolites play a key role in the progression of acute hepatitis B. Further mediation analysis showed that CD38 on naive-mature B cell (mediation effect accounted for 7.37% of the total effect, 95% CI: –2.36%, 17.1%) partially mediated the effect of 4-methylguaiacol sulfate levels on AHB, CD4 on CD39+ secreting Treg (–6.1%, 95% CI: 0.738%, –12.9%) partially mediates the association between 1-methylnicotinamide levels and AHB, and HLA DR on CD14- CD16- (4.3%, 95% CI: –1.38%, 9.98%) partially mediates the association between Cortisone to cortisol ratio and AHB.

Conclusion: This MR study provides evidence supporting a causal relationship between immune cell-mediated plasma metabolites and AHB. Immune cell-mediated identification of plasma metabolites with potential causal effects on AHB has been proposed as a potential therapeutic target for acute hepatitis B.

THU-258

Patient characteristics and treatment patterns amongst hepatitis D patients: results from a real-world survey in Europe

Maria Buti[1], Fraser Barrable[2], Tia Pennant[2], Fritha Hennessy[2], Caroline Burk[3], Chong Kim[3], Marvin Rock[3], Pietro Lampertico[4,5].
[1]Liver Unit, Hospital Universitario Valle Hebron, Barcelona, Spain; [2]Adelphi Real World, Bollington, United Kingdom; [3]HEOR – Global Value & Access, Gilead Sciences, Foster City, California, United States; [4]Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [5]CRC "A.M. and A Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy
Email: mariabutiferret@gmail.com

Background and aims: While data are readily available on antiviral drugs treating hepatitis B virus (HBV), real-world evidence on bulevirtide (BLV) – the first antiviral drug for the treatment of hepatitis D virus (HDV) – is lacking. We aimed to describe demographics, clinical characteristics, and treatment adherence of HDV patients receiving treatments including BLV.
Method: Data were drawn from the Adelphi Real World Hepatitis Disease Specific Programme™, a cross-sectional survey, with retrospective data collection, of physicians and patients with HDV in France, Italy, Spain and the United Kingdom (UK) from February 2024 to November 2024. Analysis focused on physician reported demographics, clinical characteristics and adherence for up to four consecutively consulting patients with chronic hepatitis D, with two prescribed BLV. Analyses were descriptive.
Results: Overall, 127 physicians reported data on 369 patients. Mean patient age was 45.9 (SD 13.0) years, 70% were White, 66% male. Mean (SD) time since diagnosis of HBV and HDV was 6.8 (9.1) and 4.7 (6.7) years, respectively. At survey, 65% of patients were reported to have mild HDV, 29% moderate and 6% severe. A third (33%) of patients in this study sample were not prescribed HDV treatment (No HDV Tx), 57% were treated with BLV monotherapy (mBLV), 6% had Peginterferon/interferon monotherapy (mIFN) and 2% had both therapies. Concomitant conditions were present in half of patients (mBLV: 53%; mIFN: 48%; No HDV Tx: 57%), including anxiety (mBLV: 13%; mIFN: 29%; No HDV Tx: 21%), chronic pulmonary disease (mBLV: 9%; mIFN: 10%; No HDV Tx: 10%) and diabetes without chronic complications (mBLV: 8%; mIFN: 5%; No HDV Tx: 7%). A similar range of patients had liver cirrhosis across the groups (mBLV: 15%; mIFN: 14%; No HDV Tx: 20%). The most common reasons for prescribing current treatment were long-term efficacy (mBLV: 64%; mIFN: 52%) reduction in viral shedding (mBLV: 58%; mIFN: 62%) and reduction in HDV transmission (mBLV: 53%; mIFN: 43%) Longer acting medication and less frequent administration were reported as treatment improvement areas for 24% and 23% of mBlV patients, respectively and for 19% and 5% of mIFN patients, respectively. Physicians stated most patients (mBLV: 80%; mIFN: 81%) were completely or mostly adherent to treatment, with only 15% of mBLV, and 14% of mIFN having poor adherence.
Conclusion: Analysis of physicians' data showed that half of the patients with chronic HDV had a high comorbidity burden, most HDV treated patients received BLV monotherapy, and the majority were adherent to treatment. Prescribers treat HDV with BLV or IFN due to their long-term efficacy in reducing viral shedding and transmission. Physicians reported a remaining unmet need for longer-acting medication with a less frequent dosing schedule and further research is needed into factors affecting high patient adherence to BLV.

Email: mdclimsg@nus.edu.sg

Background and aims: Bepirovirsen (BPV) is an unconjugated antisense oligonucleotide currently in Phase 3 for the treatment of chronic hepatitis B virus (HBV) infection. Data from a Phase 2b study (B-Clear) indicated that a subset of participants (pts) achieved a response at the end of BPV treatment, which was sustained for 24 weeks. This occurred in pts on and not on nucleos(t)ide analogues (NA) (On-NA and Not-on-NA). Pts who had a complete (CR) or partial (PR) response at the end of the B-Clear (parent) study were eligible for the B-Sure long-term durability study (NCT04954859; ongoing). Here we present up to 2.5-year follow-up data on the durability of response for B-Clear On-NA complete responders (CRs) and partial responders (PRs) who entered B-Sure.
Method: CR was defined as hepatitis B surface antigen (HBsAg) <0.05 IU/mL and HBV DNA < lower limit of quantification (LLOQ, <20 IU/mL), and PR as HBsAg <100 IU/mL and HBV DNA <LLOQ at the end of B-Clear. If eligible, pts discontinued NA 3 months (mo) into B-Sure (≥9 mo from their last BPV dose) and were followed further to determine functional cure (FC) and durability of response off all HBV therapy. Adverse events (AEs) were recorded, with physical examinations and blood tests performed at each visit for safety and efficacy, including time from NA cessation to loss of response.
Results: In total, 44 pts (11 CRs, 29 PRs and 4 non-responders) were enrolled into B-Sure; 33/44 (75%) were male, with a mean age of 53.8 years, and 24/44 (55%) were Asian. At entry into B-Clear, the majority of pts were hepatitis B e-antigen (HBeAg) negative (34/44 [77%]), 19/44 (43%) had HBV duration of ≥20 years and 32/44 (73%) had HBsAg ≤1000 IU/mL. Of the 11 CRs, 9 (82%) discontinued NAs 3 mo after rollover into B-Sure; 7/9 (78%) maintained a CR to 6 mo post–NA cessation, thus achieving FC, and all 7 maintained FC to 24 mo post–NA cessation. Of the 2 pts who did not achieve FC at 6 mo post–NA cessation, 1 had restarted NA therapy by 24 mo post–NA cessation. Of the 29 PRs, 23 (79%) discontinued NAs 3 mo after rollover into B-Sure. 3/23 (13%) achieved delayed FC 6 months post–NA cessation and were maintaining FC at 24 months post–NA cessation. 5/23 (22%) maintained PR status at 6 mo post–NA cessation, 3/23 (13%) at 9 mo post–NA cessation and 2/23 (9%) at 24 mo post–NA cessation; all 3 losses of PR beyond 6 mo post NA cessation were due to HBV DNA reversion. Among 23 PRs who discontinued NAs, 13 had restarted NA therapy by 24 mo post–NA cessation. Of all CRs/PRs who discontinued NAs, 5 had alanine aminotransferase (ALT) ≥2x upper limit of normal (ULN). After NA cessation, no pt who continued without needing to restart NA had an ALT increase of >5 × ULN. Post–NA cessation 3 pts reported AEs of ALT increased (2 with mild severity, 1 with moderate severity). There were no new safety signals.
Conclusion: These data provide evidence of longer durability of FC observed with BPV.
Funding: GSK (206882; NCT04954859).

THU-260

IM-PROVE I: characterization of chronic hepatitis B (CHB) subjects with functional cure or HBV DNA suppression after completion of imdusiran plus short courses of pegylated interferon alfa-2a (IFN) and discontinuation of nucleos(t)ide analogue (NA) therapy

Man-Fung Yuen[1], Ronald G. Nahass[2], Grace Lai-Hung Wong[3], Tatiana Burda[4], Tuan T. Nguyen[5], Young-Suk Lim[6], Wan-Long Chuang[7], Eugene R. Schiff[8], Kalyan Bhamidimarri[9], Kevin Gray[10], Emily P. Thi[10], Christine L. Espiritu[10], Elina Medvedeva[10], Timothy Eley[10], Mark Anderson, Tiffany Fortney[11], Gavin Cloherty, Karen D. Sims[10]. *[1]The University of Hong Kong, Queen Mary Hospital, Hong Kong, China; [2]ID Care, Hillsborough, NJ, United States; [3]Medical Data Analytics Centre (MDAC), Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China; [4]Arensia Exploratory Medicine, Chisinau, Moldova; [5]Research and Education, Inc, San Diego, CA, United States; [6]Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [7]Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; [8]University of Miami Miller School of Medicine, Miami, FL, United States; [9]Cleveland Clinic Florida, Weston, FL, United States; [10]Arbutus Biopharma, Warminster, PA, United States; [11]Abbott Laboratories, Infectious Disease Research, North Chicago, IL, United States*
Email: ksims@arbutusbio.com

Background and aims: Baseline (BL) characteristics of study subjects and biomarker levels at key timepoints that predict functional cure (FC, defined as sustained HBV DNA <LLOQ and HBsAg loss 24 weeks after treatment cessation) in subjects who complete finite courses of experimental treatment for CHB remain unclear. Low levels of HBsAg at BL (specifically <1000 IU/mL) appear to be associated with increased HBsAg loss and FC rates, but other factors have not yet been identified.

Method: The IM-PROVE I study was a Phase 2a proof-of-concept study in 43 NA-suppressed, HBeAg-negative CHB subjects who received 4 doses of imdusiran (60 mg every 8 weeks) prior to randomization to 24 weeks or 12 weeks of IFN with or without additional imdusiran doses. Eligible subjects discontinued (d/c) NA therapy 24 weeks after end-of-treatment. Six subjects in this study achieved functional cure after NA d/c; 3 additional subjects had HBV DNA <LLOQ with low HBsAg levels during NA d/c follow-up. Further characterization of these subjects including all available demographic and baseline characteristics, HBV treatment history, and additional HBV biomarkers such as HBV and IL28b genotypes (GT), hepatitis B core-related antigen (HBcrAg) via Fujirebio Lumipulse G (LLOQ = 1.0 kU/mL), and HBV RNA via Abbott v2.0 RUO assay (LLOQ = 0.49 log10 U/mL or 3.0 U/mL), are presented at key timepoints during the study.

Results: Among the 6 subjects who achieved FC, mean (±SD) age was 51 (±2.8) years, 3/6 were male, 5/6 were Asian, and ongoing NA therapy at BL included 1/6 on entecavir and 5/6 on tenofovir based-therapy, with a mean (±SD) duration of current NA treatment of 7.8 (±2.6) years. HBcrAg was <LLOQ in 4/6 at BL (range <1.0–8.4 kU/mL) and at NA d/c (range <1.0–4.8 kU/mL); HBV RNA was <LLOQ in 1/6 at BL (range <3.0–478.6 U/mL) and in 5/6 at NA d/c (range <3.0–8.31 U/mL). HBsAg at BL was <1000 IU/mL in 5/6 subjects, and at time of NA d/c was ≤LLOQ in the same 5 subjects; all 5 had anti-HBs levels >25 mIU/mL. Two of the 6 subjects had IFN dose reductions to 90 mcg/week with dose interruptions of 6–8 weeks due to ALT increase and/or neutropenia, while the other 4 had no dose adjustments. The BL characteristics of the 3 subjects with HBV DNA <LLOQ/low HBsAg after NA d/c were similar with the exception of HBsAg and anti-HBs at time of NA d/c (0/3 were HBsAg <LLOQ and 1/3 had anti-HBs > 25 mIU/mL). HBV GT was B or C in those with available data, and host IL28b genotype (rs12979860) was C/C in 5/6 and 2/3 in FC and HBV DNA <LLOQ subjects respectively, but the majority of study participants were C/C (26/36 with available data).

Conclusion: Within this small group of subjects who achieved FC or HBV DNA<LLOQ after NA discontinuation in the IM-PROVE I study, HBsAg at baseline and at the time of NA d/c appear to be the only factors associated with FC, with no apparent differences in other baseline characteristics or HBV biomarkers collected, including HBcrAg and HBV RNA. Additional analysis of this dataset is ongoing, and these BL characteristics and HBV biomarkers should continue to be evaluated in larger trials.

THU-261

Monotherapy with the novel capsid assembly modulator ALG-000184 for up to 96 weeks results in profound and sustained HBV DNA suppression in untreated subjects with chronic HBV infection

Man-Fung Yuen[1], Kosh Agarwal[2], Alina Jucov[3], Alexei Haceatrean[3], Min Wu[4], Kha Le[5], Thanh Van[4], Jen Rito[4], Lawrence Blatt[4], Sushmita Chanda[4], Tse-I Lin[4], Hardean Achneck[4], Edward J. Gane[6]. *[1]Department of Medicine, School of Clinical Medicine, The University of Hong Kong, Hongkong, China; [2]King's College Hospital, Institute of Liver Studies, London, United Kingdom; [3]ARENSIA Exploratory Medicine, Republican Clinical Hospital and Nicolae Testemitanu State University of Medicine and Pharmacy, Chisinau, Moldova; [4]Aligos Therapeutics, Inc., South San Francisco, United States; [5]Aligos Therapeutics, Inc., South San francisco, United States; [6]Faculty of Medicine, University of Auckland, Auckland, New Zealand*
Email: mfyuen@hku.hk

Background and aims: ALG-000184 is a prodrug of ALG-001075, a highly potent capsid assembly modulator-empty (CAM-E) that has been shown in vitro to induce the formation of empty capsids, inhibit hepatitis B virus (HBV) replication, and prevent the establishment/replenishment of cccDNA.

Method: ALG-000184–201 is a multi-part, multi-center, randomized clinical trial evaluating the safety, pharmacokinetics, and antiviral activity of ALG-000184 in healthy volunteers and in subjects with untreated chronic HBV infection (NCT04536337). Here, we report safety and antiviral activity data in untreated HBeAg+ and HBeAg- subjects who received open-label monotherapy with 300 mg ALG-000184 for ≤ 96 weeks.

Results: 21 subjects (n = 10 HBeAg+, n = 11 HBeAg-) received 300 mg of ALG-000184 monotherapy for ≥ 48 weeks and ≤ 96 weeks. HBeAg+ subjects were younger, with more Asian patients, and lower BMI than HBeAg- subjects. Higher baseline levels of HBV markers were seen in HBeAg+ subjects vs HBeAg- subjects, with a mean HBV DNA level 8.0 vs 4.3 $\log_{10}$ IU/mL, HBV RNA 5.3 vs 2.0 $\log_{10}$ copies/mL, HBsAg 4.3 vs 3.5 $\log_{10}$ IU/mL, and HBcrAg 8.3 vs 3.2 $\log_{10}$ U/mL, respectively. The mean baseline level of HBeAg in HBeAg+ subjects was 2.6 $\log_{10}$ PEI U/mL. By Week 96, maximum mean reductions in HBV DNA were 7.3 (HBeAg+) and 3.4 $\log_{10}$ IU/mL (HBeAg-), with individual maximum reductions of 8.0 and 4.4 $\log_{10}$ IU/mL, respectively. At Weeks 48, 72 and 84, 60% (6/10), 8/9 (89%), and 7/7 (100%) subjects achieved sustained HBV DNA < 10 IU/mL (lower limit of quantification, LLOQ). All HBeAg- subjects (11/11) achieved sustained HBV DNA < LLOQ by Week 24, and 10/11 achieved HBV DNA < 4.29 IU/mL (lower limit of detection) by Week 48. The maximum mean reductions from baseline in HBsAg was 1.2 $\log_{10}$ IU/mL; HBeAg 1.7 $\log_{10}$ PEI U/mL; and HBcrAg 2.6 $\log_{10}$ U/mL in HBeAg+ subjects. A maximum mean reduction of 0.4 $\log_{10}$ U/mL from baseline in HBcrAg was observed in HBeAg- subjects. No clinical viral breakthrough, as assessed by HBV DNA levels, occurred in any subject. Treatment was well tolerated with no serious adverse events (AEs) reported and without any discontinuations due to treatment-emergent AEs (TEAEs). Grade 3 TEAEs were reported in four subjects: asymptomatic ALT elevations (HBeAg+: n = 3; HBeAg-: n = 1) and cholesterol/triglycerides increase

(n = 1), all resolving with continued dosing. All Grade 3 ALT elevations occurred along with a significant decline in HBV DNA, without associated changes in other liver function parameters.
Conclusion: ALG-000184, in combination with ETV for up to 96 weeks, was well tolerated and led to profound suppression of HBV DNA in untreated HBeAg+ subjects with high baseline HBV DNA levels. These results indicate the potential of ALG-000184 in different combination therapies for chronic HBV infection. Full data for 96 weeks of treatment and 8 weeks of follow-up will be shared at the EASL conference.

THU-262
Quality of life in HDV-infected patients prior to bulevirtide treatment: chronic hepatitis versus compensated cirrhosis
Mirela Chitul[1,2], Speranta Iacob[1,2], Mihaela Ghioca[1], Carmen Ester[1,2], Razvan Cerban[1,2], Corina Pietrareanu[1], Liana Gheorghe[1,2]. *[1]Centre for Digestive Diseases and Liver Transplantation, Fundeni Clinical Institute, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania*
Email: mirela_onica@yahoo.com

Background and aims: Delta hepatitis is endemic in Romania and, until recently, lacked effective treatment options, making it the leading indication for liver transplantation in the country. This study evaluates the quality of life (QOL) in HDV-infected patients prior to initiating bulevirtide therapy, comparing those with chronic hepatitis and compensated cirrhosis.
Method: Patients meeting the criteria for bulevirtide treatment were enrolled in the study. Before therapy initiation, participants completed a standardized quality of life questionnaire – HQLQv2™. Demographic data, along with HBV and HDV viral loads, were collected. Statistical analyses were conducted using SPSS IBM 29.0.
Results: A total of 45 patients were included (mean age 52.1 ± 12.6 years); 80% had compensated cirrhosis, and 20% had chronic hepatitis. Undetectable HBV viremia was observed in 53.7% of patients (58.8% in cirrhotics vs. 20.8% in CHD, p = 0.219), with a mean HDV RNA level of 1,186,550 ± 3,316,474 IU/mL. Although no significant differences were found in overall health status, 39.1% of cirrhotics reported limitations in daily activities, compared to none in CHD (p = 0.153). Emotional symptoms, including melancholia (54.8% vs. 0%, p = 0.046), discouragement (41.8% vs. 11.2%, p = 0.082), stress (60.6% vs. 11.1%, p = 0.02), and frustration (51.3% vs. 0%, p = 0.082), were more prevalent among cirrhotics. Conversely, CHD patients reported feeling energetic (77.8% vs. 49.8%, p = 0.013) and viewing life positively (88.9% vs. 52.1%, p = 0.103) more frequently. Correlations were identified between cirrhosis and melancholia (p = 0.005), illness susceptibility (p = 0.05), frustration (p = 0.069), and social difficulties (p = 0.094). Detectable HBV viremia was linked to increased illness susceptibility (p = 0.096), and higher HDV RNA levels correlated with functional impairments, such as difficulty carrying a shopping bag (p = 0.031), walking 1 km (p = 0.106), and expecting disease progression (p = 0.048).
Conclusion: Patients with compensated cirrhosis exhibit a poorer quality of life compared to those with chronic hepatitis, with significant correlations between clinical markers and QOL parameters. A reassessment of QOL after six months of bulevirtide treatment is strongly recommended to evaluate the therapy's impact.

THU-263
Besifovir reduces hepatocellular carcinoma risk compared to Tenofovir Disoproxil Fumarate: large-scale cohort study
Yoon E. Shin[1], Jae-Young Kim[1], Jeong-Ju Yoo[2], Sang Gyune Kim[2], Young Seok Kim[2]. *[1]Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South; [2]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South*
Email: passion_97@naver.com

Background and aims: Besifovir dipivoxil maleate (BSV) is a newly developed acyclic nucleotide phosphonate derivative. A recent study using a predictive model highlighted a significantly reduced hepatocellular carcinoma (HCC) risk with BSV. This study aims to further evaluate whether BSV reduces HCC incidence compared to TDF, utilizing clinical big data from the Korean healthcare system.
Method: A total of 32,383 individuals were analyzed, comprising 2,358 patients in the BSV group and 30,025 in the TDF group. To minimize confounding effects, propensity score matching was conducted in a 1:3 ratio.
Results: The incidence rate ratio for HCC was 1.59 (95% CI: 1.20–2.12, p = 0.001). The hazard ratio (HR) for HCC in the TDF group compared to the BSV group was 1.703 (95% CI: 1.282–2.262, p < 0.001). In Cox regression analysis, the HR for cirrhosis in the TDF group was significantly lower than in the BSV group, with an HR of 0.670 (95% CI: 0.597–0.753, p < 0.001).
Conclusion: This analysis suggests that BSV is more effective than TDF in reducing the incidence of HCC.

THU-264
Safety and pharmacokinetics of bepirovirsen, delivered subcutaneously by vial, or prefilled syringe fitted with a safety syringe device in healthy adult participants, and syringe device ease of use: a randomised phase 1 trial
Poonam Shah[1], Amir Youssef[2], Pei Hu[3], Helene Plein[4], Sarah Mole[1], Abhishek Roy[5], T Ravi[5], Magdalena Blazejczyk[6], Rachel Green[7], Wendy Cross[1], Brian Spears[8], Samuel Pak[9], Rejbinder Kaur[1], Ahmed Nader[2], Dickens Theodore[10], Marjan Hezareh[4]. *[1]GSK, Stevenage, United Kingdom; [2]GSK, Collegeville, Pennsylvania, United States; [3]GSK, Shanghai, China; [4]GSK, London, United Kingdom; [5]GSK, Bangalore, India; [6]GSK, Warsaw, Poland; [7]GSK, Ware, United Kingdom; [8]PPD, Austin, Texas, United States; [9]PPD, Las Vegas, Nevada, United States; [10]GSK, Durham, North Carolina, United States*
Email: poonam.c.shah@gsk.com

Background and aims: Bepirovirsen is an unconjugated antisense oligonucleotide in Phase 3 development for the treatment of chronic hepatitis B virus infection. Currently, bepirovirsen is supplied in clinical trials as a clear glass vial for subcutaneous injection. A ready-to-use prefilled syringe (PFS) assembled with a safety syringe device (SSD) has been developed to make administration more convenient (vs vial) and facilitate patient self-administration. The formulation of bepirovirsen is identical between the vial and the PFS SSD. This study aimed to evaluate the safety, tolerability and relative bioavailability of bepirovirsen when delivered by subcutaneous injection from a vial or PFS SSD, and the ease of use of the PFS SSD for self-administration. Here, we report safety, topline pharmacokinetic (PK) and PFS SSD ease-of-use data.
Method: In this Phase 1, open-label, randomised, parallel group study, 160 healthy adult participants were randomised 3:3:2:2 to receive a single 300 mg dose of bepirovirsen from a vial by a healthcare professional (HCP; Group 1), or PFS SSD administered by an HCP (Group 2), or self-administered PFS SSD with training from an HCP (Group 3), or self-administered PFS SSD without training (Group 4). Participants in Groups 3 and 4 were also provided with instructions for use. All participants were monitored for adverse events (AEs) and had PK samples collected. Participants in Groups 3 and 4 completed an ease-of-use questionnaire, which contained multiple-choice questions relating to the ease of self-administration of the PFS SSD.
Results: Of the total population, 159/160 participants were included in the safety population, and 153/160 participants were included in the PK population. In total, 94% (150/159) of participants reported AEs, with similar proportions of participants reporting AEs across all treatment groups (88–100%). There were no serious or fatal AEs. AEs of special interest made up the majority of AEs reported, largely due to injection site reactions (148/159 [93%]). Most AEs were Grade 1/2 in severity. The majority of participants reported that the PFS SSD for

self-administration was very easy or easy to use both with and without HCP training (81–100% and 67–94%, respectively). Bepirovirsen PK was similar across all treatment groups.
Conclusion: Participants were able to self-administer bepirovirsen using the PFS SSD, and it had a similar safety profile whether administered by an HCP or a participant, with no new safety concerns identified for bepirovirsen. The use of PFS SSD is a viable alternative for bepirovirsen administration in patients. The PK of bepirovirsen was similar across all treatment groups.
Funding: GSK (study 219239).

Interim results of a phase I/II study to determine the safety, immunogenicity and efficacy of therapeutic hepatitis B virus synthetic long peptide vaccination

Roel Pieterman[1], Anna-Sophia Wiekmeijer[2], May Young Lin[2], Robbie Luijten[1], Patrick Boor[1], Judith Verhagen-Oldenampsen[1], Elke Verhey[1], Hanneke van Soest[3], Cornelis Melief[2], Patrick Van der Veek[4], Pieter Honkoop[5], R. Bart Takkenberg[6], Rachida Bouamar[1], Milan J. Sonneveld[1], Harry L.A. Janssen[1], Dave Sprengers[1], Sonja Buschow[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]ISA Pharmaceuticals B.V., Oegstgeest, Netherlands; [3]Haaglanden MC, Den Haag, Netherlands; [4]Haaglanden MC, Rotterdam, Netherlands; [5]Albert Schweitzer Ziekenhuis, Dordrecht, Netherlands; [6]Amsterdam UMC, Amsterdam, Netherlands*
Email: r.pieterman@erasmusmc.nl

Background and aims: Immunotherapy is emerging as a pivotal component of HBV cure strategies as it may both increase on-treatment response and off-treatment durability of response obtained with novel antivirals. Synthetic long peptide (SLP) vaccines represent an innovative approach to stimulating robust T-cell responses. These vaccines contain carefully designed peptides representing viral epitopes capable of inducing both CD4+ and CD8+ T-cell responses. By targeting conserved and immunodominant regions of the hepatitis B virus (HBV), SLP vaccines have the potential to be included in a multidrug combinatorial treatment regime to overcome immune tolerance and re-establish effective viral control. We aimed to study safety and immunogenicity of SLP vaccination in virally suppressed patients with chronic hepatitis B (CHB).
Method: This ongoing single-center, double-blind, placebo-controlled, dose-escalation Phase I/II clinical trial investigates the safety, tolerability, and immunogenicity of 12 SLPs, along with the TLR1/2 ligand-based adjuvant Amplivant® in 24 patients. Eligible participants are HBeAg-negative CHB patients without significant fibrosis who have been on nucleos(t)ide analog (NUC) therapy > 1 year and have undetectable HBV DNA at time of screening. The trial includes three dose-escalation cohorts, each testing a different vaccine dose (10 µg, 20 µg, or 40 µg) Each cohort will consist of eight participants, with six receiving the vaccine and two receiving a placebo.
Results: In the first 9 patients (qHBsAg 1237 IU/ml ± SD 1302) dosed with 10 ug, 20 ug or placebo (n = 2–3 out of 9) possible TAEA events observed were: injection site adverse events (n = 6), fatigue (n = 2) and pyrexia (n = 1). Baseline and Post-vaccination T cell responses to the vaccine were measured by overnight IFN-y ELISpot in blood samples from the first 6 patients included (receiving either 10ug of vaccine or placebo (max n = 2 out of 6)). Increased IFN-y responses relative to baseline were observed in 2 out of these 6 patients. Result will be updated as they become available.
Conclusion: Preliminary results from this ongoing trial suggests that this SLP vaccine has a favorable safety profile, with the main TEAE injection site reactions. Potential induction of an IFN-y immune response was observed in a subset of patients. These results support further escalated dosing and efficacy evaluation of this promising new treatment modality. Further analysis of the induced immune response will provide data on the best combinatorial regime to fully realize the potential of this immunotherapeutic approach in re-establishing antiviral immunity and achieving functional cure.

HBV genotype association with response to xalnesiran in nucleos(t)ide analogue treated participants with chronic hepatitis B infection in the Piranga phase 2 platform study

Emma Bell[1], Annabelle Lemenuel-Diot[1], Maria Teresa Catanese[1], Cong Cheng[2], Farouk Chughlay[1], Jean-Christophe Hoflack[1], Matteo Metruccio[1], Karolin Rommel[1], Ruchi Upmanyu[3], Qiaoqiao Xie[2], Claire McGeown[1], Rémi Kazma[1]. *[1]F. Hoffmann-La Roche Ltd, Basel, Switzerland; [2]Roche R&D Center (China) Ltd, Shanghai, China; [3]Roche Products Ltd, Welwyn Garden City, United Kingdom*
Email: remi.kazma@roche.com

Background and aims: The global distribution of hepatitis B virus (HBV) genotype (GT) varies significantly among patients with chronic hepatitis B (CHB). HBV GTs are associated with disease severity and response to approved antiviral therapy. Therefore, the early identification of HBV GTs that could impact the efficacy of novel direct-acting antivirals is essential. The Piranga phase 2 platform study (NCT04225715) assessed the efficacy and safety of multiple combinations of new molecules in nucleos(t)ide analogue treated participants (pts) with CHB. We report the association between HBV GT and HBsAg response to treatment with xalnesiran, a GalNAc-conjugated small interfering ribonucleic acid targeting HBsAg transcripts.
Method: Data from 126 pts were pooled across 4 arms of Piranga, which started with a 12-week period of treatment with xalnesiran 200 mg Q4W monotherapy. Pts were recruited in 11 countries across Asia-Pacific, Europe, and North America. HBV GT was determined using HBV RNA sequencing, HBsAg serotyping, and/or medical history. HBV RNA sequencing was performed using Illumina short-read sequencing and HBV GT was determined by homology with reference sequences. HBsAg serotyping was performed using the IMMUNIS® HBV genotype enzyme immunoassay which detects GT-specific epitopes in the preS2 region. GT-specific distributions of baseline and change from baseline in HBsAg levels after 12 weeks of treatment with xalnesiran were evaluated in all pts and stratified by low (<1000 IU/mL) vs. high HBsAg at screening.
Results: HBV RNA sequencing and HBsAg serotyping failed in 102 (81.6%) and 19 (15.2%) of 125 tested samples, primarily due to poor RNA amplification and HBsAg <3 IU/mL, respectively. The concordance rate between assays was 20/22 (91%). Among 126 pts, 6 GTs were observed, the most frequent being C (61, 48.4%), B (27, 21.4%), and D (18, 14.3%). The distribution of HBV GTs across regions matched with known global distributions. The mean of HBsAg at baseline was lower for GT B (2.57 $\log_{10}$ IU/mL) than for GTs C and D ($p < .01$). Among pts with low HBsAg at screening (18, 22, and 7 pts in GTs B, C, and D, respectively), the reduction of HBsAg after 12 weeks of treatment with xalnesiran was lower for GT D than for GTs B and C: 0.60 vs. 1.35 and 1.15 $\log_{10}$ IU/mL, respectively ($p < .001$). This association was significant in the overall group as well, with reductions of HBsAg of 0.84 vs. 1.26 and 1.17 $\log_{10}$ IU/mL for GTs D vs. B and C, respectively ($p < .01$).
Conclusion: Treatment with xalnesiran led to a marked reduction in HBsAg levels across all GTs. In this exploratory analysis with limited sample size, GT D was associated with a smaller reduction in HBsAg after 12 weeks of xalnesiran treatment than for GTs B and C, mainly among pts with low HBsAg. HBV GT should be considered a potentially important factor in studies testing novel direct-acting antivirals aiming to achieve functional cure.

Background and aims: Sustained virological response (SVR) improves prognosis in chronic hepatitis C virus (HCV) infected patients with compensated liver disease, but whether similar benefit can be obtained in patients with decompensated cirrhosis is controversial. Therefore, we studied whether SVR was associated with a reduced risk of liver-related events (LREs) in patients with decompensated HCV cirrhosis.
Method: We conducted an international multicenter retrospective cohort study including patients with decompensated HCV cirrhosis (Child-Turcotte-Pugh (CTP) ≥7 and/or history of decompensation) treated with direct-acting antivirals (DAA). Survival analyses were used to assess the association between SVR and LREs (defined as a composite of further decompensation, hepatocellular carcinoma (HCC), liver transplantation (LT) or death) in the overall population and stratified by baseline MELD score. Additionally, the association between SVR related change in MELD score with LREs was assessed.
Results: In total, 914 patients were included with a median age of 54.7 (IQR 48.8–60.8) years, 68% was male, 45% had (a history of) alcohol abuse, 87% was CTP-B, and the median MELD score was 12.1 (IQR 10.0–14.5). SVR was achieved in 834 (91.2%) patients during the study period. Median follow-up time was 28 (IQR 13–39) months. In the overall population, the 3-year cumulative incidence of LREs was lower in patients who attained SVR compared to those who did not (47.5% vs. 58.6%, $p < 0.001$). Findings were consistent in multivariable analysis (adjusted hazard ratio (*a*HR): 0.692, 95%CI 0.52–0.92, $p = 0.011$). Stratification by baseline MELD revealed that SVR was associated with a reduced 3-year incidence of LREs amongst patients with a baseline MELD <15 (44.4% vs. 57.6%, *a*HR: 0.601, 95%CI 0.43–0.85, $p = 0.004$), but not amongst patients with a baseline MELD ≥15 (62.8% vs. 58.9%, *a*HR: 0.936, 95%CI 0.56–1.56, $p = 0.801$). Amongst patients with SVR, 23.4% achieved a decrease in MELD score of ≥2 points. A ≥2 point decrease in MELD score was not associated with a reduced 3-year incidence of LREs compared to patients with a stable or increased MELD score (52.1% vs. 50.7%, $p = 0.473$). Findings were consistent in multivariable analysis (*a*HR: 0.730, 95% CI 0.49–1.09, $p = 0.122$), and in the subset of patients with a MELD score ≥15 at baseline.
Conclusion: Amongst patients with decompensated HCV cirrhosis, SVR was associated with a reduced risk of LREs in patients with a MELD score <15, whereas no clinical benefit was observed in those with higher MELD scores despite an SVR associated decrease in MELD. These findings provide important guidance for the timing of DAAs versus potential liver transplantation in decompensated HCV cirrhosis.

Email: yenchun923@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) surveillance is recommended for chronic hepatitis C (CHC) patients with advanced liver disease (ACLD) after achieving sustained virological response (SVR). However, the risk of HCC persists in non-ACLD CHC patients, who are often outside the current surveillance scope. This study aimed to identify high-risk HCC patients within a non-ACLD population using a simple stratification algorithm feasible for primary care settings and validated in external cohorts.
Method: CHC patients who achieved HCV eradication with direct-acting antiviral agents (DAA) and had pre-therapy FIB-4 scores <3.25 were enrolled from Chang Gung Memorial Hospital, Linkou Medical Center. ACLD was defined as FIB-4 ≥3.25. All patients underwent liver ultrasonography and AFP assessments every 6–12 months. HCC was diagnosed using dynamic liver imaging and/or histological confirmation. Cox regression analysis was performed to identify independent risk factors for HCC occurrence in non-ACLD patients. A predictive score (SFA score) was developed based on adjusted hazard ratios from multivariate Cox regression analysis of patients younger than 65 years and was validated in external non-ACLD cohorts from Chang Gung Memorial Hospital, Chia-Yi branch, and Chia-Yi Christian Hospital.
Results: The derivation cohort included 1902 non-ACLD patients (mean age: 59 years; 44% male; median FIB-4: 1.77, IQR: 1.26–2.36).

Validation cohorts included 3839 DAA-treated patients (mean age: 62 years; 46% male; median FIB-4: 1.71, IQR: 1.21–2.31). Over a median follow-up of 3.4 years, 29 HCC cases occurred in the derivation cohort, with annual and 5-year cumulative incidences of 0.49% and 2.8%, respectively. Multivariate Cox regression identified age ≥65 years [adjusted hazard ratio (aHR): 2.986; p = 0.005], male sex (aHR: 3.399; p = 0.005), and pre-therapy AFP ≥6 ng/mL (aHR: 10.370; p < 0.001) as independent predictors of HCC. Patients aged ≥65 years had an annual HCC incidence of 0.8%, exceeding the updated threshold for HCC surveillance (0.7%/year). Among patients aged <65 years, those with an SFA score ≥3 (1×[male:1, female:0] + 2 × [FIB-4 ≥2.5:1, <2.5:0] + 1 × [AFP ≥6:1, <6:0]) had an annual/5-year HCC incidence of 2.9%/12.8%, compared to 0.1%/2.9% for those with SFA <3 (log-rank test, P < 0.001). The model demonstrated strong predictive performance (Harrell's C-index: 0.896 in the derivation cohort and 0.837 in the DAA-treated validation cohort) and was validated in external cohorts (HCC annual/5-year incidence for SFA ≥3 vs. <3: 1.5%/4.7% vs. 0.09%/0.2%; log-rank test, P < 0.001).
Conclusion: The SFA score effectively identifies high-risk HCC patients among non-ACLD CHC patients with SVR in primary care settings. Non-ACLD CHC patients aged ≥65 years or those aged <65 with an SFA score ≥3 should continue HCC surveillance after viral eradication.

THURSDAY 08 MAY

THU-207-YI
Clinical follow up in patients treated for hepatitis C

Pragati Gupta[1], Thurkga Moothathamby[1], Upkar Gill[2,3], Apostolos Koffas[2,3], Arron Jones[2]. [1]*Queen Mary University of London, London, United Kingdom;* [2]*Barts Health NHS Trust, London, United Kingdom;* [3]*Centre for Immunobiology, Blizard Institute, Barts and The London, School of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom*
Email: arron.jones@nhs.net

Background and aims: Over 80,000 people have been treated for hepatitis C in the UK since 2015, as a result of the advent of direct-acting antivirals (DAAs) and the national hepatitis C virus (HCV) elimination programme. A proportion of these patient remain at risk of developing hepatocellular carcinoma (HCC) despite achieving sustained virologic response (SVR). EASL recently issued a position paper on clinical follow-up after HCV cure. Our study aims to determine the follow-up status of patients who achieved SVR in Barts Health NHS Trust, London, UK, in line with the guidance outlined in the EASL position paper.
Method: A retrospective service evaluation of patients treated for hepatitis C at Barts Health NHS Trust since 2016 was conducted. Patients with a baseline liver stiffness measurement (LSM) ≥8 kPa and/or APRI ≥1.0 and/or documented history of cirrhosis were included. Diagnosis of steatotic liver disease (SLD), cardiometabolic risk factors and harmful alcohol intake were also recorded. Post SVR LSM and current follow-up status was assessed. Rate of HCC development and hepatitis C recurrence were documented. Patients with a baseline LSM of <8.0 kPa, APRI <1.0 or no documented history of cirrhosis were excluded.
Results: 1346 patients treated for HCV from 2016 to 2024 were reviewed, with 262 meeting the inclusion criteria. 211 patients (80.5%) had a baseline LSM of ≥10 kPa or were identified as having cirrhosis, and 51 patients (19.4%) had a baseline LSM between 8 and 10 kPa. 125 (47.7%) had a post-SVR LSM available, with 66/125 (52.8%) having a post-SVR LSM of ≥8 kPa. 46 (17.5%) patients had a harmful alcohol history documented and 92 (35.1%) had a diagnosis of SLD. Only 79 (30.1%) patients remain under hepatology follow-up and HCC surveillance, with 55 (20.9%) patients discharged and 27 (10.3%) deceased. The remaining 107 (40.8%) patients have been lost to follow-up. 4 (1.5%) patients developed a hepatocellular carcinoma (HCC).
Conclusion: We found that a significant number of HCV patients had been discharged or lost to follow-up from the Hepatology service at Barts Health NSH Trust. Many of those would require long-term follow-up or a single non-invasive assessment of their liver fibrosis status, as per the EASL position statement. Services might be required to review discharge pathways after SVR.

THU-208
Post-treatment outcomes for patients with hepatitis C cirrhosis treated through west London operational delivery network

Eleanor Davies[1], Maya Thrasher[2], Ashley Brown[2]. [1]*Imperial College Medical School, London, United Kingdom;* [2]*Imperial College Healthcare NHS Trust, London, United Kingdom*
Email: ashley.brown6@nhs.net

Background and aims: Untreated chronic hepatitis C (HCV) can lead to cirrhosis, liver failure, and hepatocellular carcinoma (HCC). Over the last decade, the treatment paradigm has shifted to direct-acting antivirals (DAAs), which are known to be effective, but their impact on long-term mortality and HCC risk in cirrhotic patients remains unclear. It is crucial to understand the role of cofactors influencing these endpoints to improve outcomes for local populations. This study aimed to assess mortality rates and factors affecting HCC development in cirrhotic patients with a sustained viral response (SVR) after DAA treatment as well as the regression of liver fibrosis using Fibroscan data.
Method: In this retrospective regional study, electronic patient records and National Health Service (NHS) HCV registries were used to collect data, including paired pre- and post-treatment Fibroscan scores, for patients with cirrhosis and SVR 12 weeks post DAA treatment received through the West London HCV Operational Delivery Network between 2015 and 2023. Data was analysed using multiple and simple logistic regression, Kaplan-Meier analysis, and comparative statistical tests.
Results: A total of 702 patients were included in the analysis. The mortality rate was 36.6 deaths/1000 person-years with factors such as harmful alcohol use identified as significant predictors of outcome. Mortality associated with HCC occurred at a rate of 23.2 diagnoses/1000 person-years and was significantly associated with genotype 3. Fibroscan scores for 377 patients were analysed. SVR at 12 weeks resulted in a median score reduction of 6.9 kPa ($p < 0.0001$). A significant reduction in HCC occurrence was detected between scores of ≤7 kPa and ≥11.5 kPa ($chi^2 = 4.17$; $p = 0.0101$).
Conclusion: This was one of the largest studies of outcomes in patients with HCV and cirrhosis in the DAA era. Alcohol misuse and HCC are significant drivers of post-treatment mortality, highlighting the importance of holistic follow-up care. Fibroscan score reduction may be associated with increased disease-free survival, but there is not yet enough evidence to guide screening decisions. Further prospective studies could evaluate the roles of serum biomarkers, duration of infection and metabolic dysfunction-associated steatotic liver disease on post-treatment outcomes.

THU-209
Impact of hepatitis C eradication with direct-acting antivirals on metabolic and liver-related outcomes in diabetic patients

Clelia Asero[1], Claudia Grisanti[2], Giuseppina Russo[3], Annalisa Giandalia[4], Maria Stella Franzè[4], Concetta Pitrone[5], Roberto Filomia[5], Gaia Caccamo[5], Carlo Saitta[6], Angela Alibrandi[7], Irene Cacciola[1]. Diabetology Unit, University Hospital of Messina, Italy, Messina, Italy; [4]Department of Clinical and Experimental Medicine, University of Messina, Italy, Messina, Italy; [5]Internal Medicine and Hepatology Unit, University Hospital of Messina, Italy, Messina, Italy; [6]Department of Clinical and Experimental Medicine, University of Messina, Italy, Internal Medicine and Hepatology Unit, University Hospital of Messina, Italy, Messina, Italy; [7]Department of Economics, Unit of Statistical and Mathematical Sciences, University of Messina, Messina, Italy
Email: clelia.asero@gmail.com

Background and aims: Data on the long-term impact of hepatitis C virus (HCV) eradication on metabolic and liver-related outcomes in patients with type 2 diabetes (T2D) and chronic liver disease (CLD) after direct-acting antiviral (DAAs) therapy remain scarce. This study aimed to evaluate these outcomes (primary endpoint) over an extended follow-up period and their impact on overall survival (OS).
Method: All patients with T2D and HCV-related CLD treated with DAAs from April 1st, 2014, to December 31st, 2016, followed up until September 31st, 2024 at the Medicine and Hepatology Unit of the University Hospital of Messina were enrolled in the study. Demographic, biochemical and clinical features were collected for each patient at baseline and during follow-up. Regression models were applied to identify predictors independently associated with metabolic and liver-related outcomes.
Results: One-hundred eighty-two patients [53.3% males; median age 71 years (41–97); 55.5% with cirrhosis] followed for a median of 56.5 months were included in the study. Forty-six of 182 patients (25.3%) maintained clinical stability over time, 31 (17%) died and 38 (20.9%) had liver disease progression [Liver decompensation (LD) and hepatocellular carcinoma (HCC)]. One-hundred-fifty patients (82.4%) developed T2D-related complications (89 macrovascular/61 microvascular). Significant improvements in liver stiffness ($p < 0.001$), glycated hemoglobin (HbA1c) ($p = 0.004$), serum gamma-globulins ($p < 0.001$), and aminotransferase ($p < 0.001$) levels were noted at the end of follow-up. LD was associated with higher liver stiffness ($p = 0.003$), bilirubin values ($p = 0.002$) and lower LDL-cholesterol (LDL-c) levels ($p = 0.017$), while HCC with higher liver stiffness ($p = 0.003$). Kaplan-Meier analysis revealed a significant difference in HCC onset between cirrhotic and non-cirrhotic ($p < 0.001$). Major cardiovascular events were related to higher BMI ($p = 0.024$) and low LDL-c ($p = 0.043$), while peripheral artery disease to higher HbA1c ($p = 0.036$), total cholesterol (TC) ($p = 0.006$) and triglycerides (TG) ($p = 0.045$) levels. Diabetic neuropathy was associated with higher fasting glucose levels ($p = 0.03$), T2D retinopathy with lipid-lowering therapy ($p = 0.036$) and higher TC ($p = 0.04$), while diabetic nephropathy to elder age ($p < 0.001$), higher serum creatinine and HbA1c values ($p < 0.001$; $p = 0.023$). Lipid-lowering therapy showed a protective role against T2D nephropathy ($p = 0.039$). Cox regression analysis showed that higher liver stiffness ($p < 0.001$), creatinine levels ($p = 0.007$) and lower TG levels ($p = 0.03$) were independent predictors of death.
Conclusion: DAA treatment of HCV infection significantly improves liver disease and the natural course of T2D. Early intervention is crucial, as the severity of hepatic disease before starting DAA therapy could impact liver-related outcomes and OS.

THU-210
Evaluation of transient elastography and platelets count for predicting hepatocellular carcinoma in patients with chronic hepatitis C and sustained virological response to direct-acting antivirals

Paula Guedes[1], Juliana Piedade[2], Hugo Perazzo[3], Livia Villela-Nogueira[1], Helena Peixoto[1], Gustavo Pereira[2], Lailiane Novaes[2], Miriam Chinzon[2], Joyce Roma[2], Flavia Fernandes[4], Cristiane Villela-Nogueira[1]. *[1]Clementino fraga filho university hospital, Rio de Janeiro, Brazil; [2]Bonsucesso federal hospital, Rio de Janeiro, Brazil; [3]Oswaldo cruz foundation, Rio de Janeiro, Brazil; [4]Pedro ernesto university hospital, Rio de Janeiro, Brazil*
Email: docpaulag@gmail.com

Background and aims: The risk of developing hepatocelular carcinoma (HCC) in chronic hepatitis C patients with advanced fibrosis and cirrhosis remains after sustained virological response (SVR) with direct-acting antivirals (DAA). Targeting patients at the highest risk of HCC would reduce healthcare costs. Our aim was to evaluate transient elastography (TE) and platelet count as prognostic markers for HCC after SVR.
Method: A bicentric retrospective longitudinal study included patients with SVR with a liver stiffness measurement (LSM) ≥10 kPa at baseline. Baseline and 1 year after the end of treatment (EOT) LSM and laboratory results were analyzed. A survival analysis was performed to identify the HCC associated factors.
Results: 425 patients (62 ± 10 years; 65.2% female; 56.5% white non-hispanic; 36.7% diabetics; 20% clinically significant portal hypertension) were included and followed for 48 months (SD ± 23). The median baseline and 1 year LSM were 15.0 kPa (11.8–23.2) and 12 kPa (7.9–19.9) respectively. In one year, there was a 27% (2.7–43%) reduction in the median LSM. At follow-up, 6% (n = 26) developed HCC. Among these 65.4% developed HCC after 24 months after EOT and 84.6% were F4 at baseline. A greater HCC-free survival was observed for baseline [LSM <20 kPa (log-rank 17.3; $p < 0.001$), LSM <25 kPa (log-rank 16.8; $p < 0.001$) and platelets ≥ 150.000 (log-rank 14.6; $p < 0.001$)] and also for 1 year post EOT, [LSM < 20 kPa (log-rank 14.9; $p < 0.001$), LSM < 25 kPa (log-rank 13.2; $p < 0.001$) and platelets ≥150.000 (log-rank 4.8; $p = 0.028$)]. The variation in LSM did not impact on survival ($p = 0.64$). At Cox Regression analyzes, baseline platelets (HR 0.98 CI95% 0.96–0.99, $p = 0.004$), 1 year EOT platelets (HR 1.01 CI95% 1.00–1.02, $p = 0.032$) and 1 year EOT LSM (HR 1.04 CI95% 1.01–1.07, $p = 0.003$) as well as age (HR 1.06 CI95% 1.01–1.11, $p = 0.012$) were associated with HCC occurrence. At 1 year post EOT, those who fulfilled Baveno criteria (LSM ≥20 kPa and platelets <150.000) were at higher risk of HCC (log-rank 15.0; $p < 0.001$) and those who presented a LSM <10 kPa and platelets ≥150 had a better prognosis (log-rank 13.1; $p = 0.001$). Considering 1 year post EOT LSM <10 kPa and platelets ≥150 as the best prognostic scenario, among the 6% of patients with HCC (n = 26) only 11% (n = 3) fulfilled the entire favorable criteria compared to 50% (n = 13) who didńt present any favorable component of the criteria and 38% (n = 10) who presented only one component.
Conclusion: In patients with a baseline LSM > 10 kPa, neither baseline LSM or LSM variation predicted post-SVR HCC development. The evaluation of 1 year follow-up LSM associated with a platelet count, specially a LSM <10 kPa and platelet ≥150 confered a lower risk for HCC and should be considered in post-SVR HCC risk stratification.

THU-211
PRO-Link HCV: automated detection and Re-engagement of hepatitis C patients lost to follow-up. A pilot study in southern Spain

Alberto Vázquez Blanquiño[1], Ana Fuentes[1], Francisco Franco Álvarez De La Luna[2], Lucía Pérez-Rodríguez[1], Marta Illescas-López[1], Lucía Chaves-Blanco[1], Ana Belén Pérez[3], Federico García[1,4,5]. *[1]Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Hospital Universitario Juan Ramón Jiménez, Huelva, Spain; [3]Hospital Universitario Reina Sofía, Córdoba, Spain; [4]Centro de Investigación Biomédica en Red en Enfermedades Infecciosas (CIBERINFEC), ISCIII, Madrid, Spain; [5]Instituto de Investigación Biosanitaria Ibs.Granada, Granada, Spain*
Email: albertovb97@hotmail.com

Background and aims: Hepatitis C is recognized as a major global public health challenge by the World Health Organization (WHO). In Spain, addressing "lost-to-follow-up" patients remains a pivotal strategy to achieve elimination goals. Despite multiple attempts, traditional methods have often demonstrated limited success in re-engaging these patients. This study evaluates the outcomes of an

innovative "opportunistic" retrieval strategy integrated within the healthcare system.
Method: This prospective pilot study was conducted at two hospitals in Andalusia, Spain: the Hospital Universitario Clínico San Cecilio (Granada) and the Hospital Universitario Juan Ramón Jiménez (Huelva). It assessed a novel "opportunistic" approach to re-engage patients lost to follow-up. A daily automated process was implemented within the Laboratory Information System (LIS), generating lists of individuals with a history of positive anti-HCV antibodies and a currently available serum sample, submitted for any clinical purpose. These lists were reviewed daily to analyze electronic health records (EHR) for evidence of sustained virologic response (SVR) or previous antiviral treatment. For patients without documented SVR, HCV RNA testing was conducted using the available serum sample to confirm active viremia. This approach facilitated immediate identification and evaluation without requiring additional sample collection or direct patient contact. Clinical outcomes and follow-up actions were subsequently analyzed.
Results: Between May 2023 and November 2024, a total of 2,789 patients with positive anti-HCV antibodies were identified. Among these, 89% (2,484/2,789) had documented SVR and no apparent reinfection risk. For the remaining 305 patients, HCV RNA testing was performed on 294, identifying 95 (31.1%) as viremic, representing 3.4% of the total screened population. The majority of viremic patients were male (69.15%), with a median age of 59 years (IQR: 54–68). Among the viremic patients, 67.4% had been lost to follow-up without achieving SVR, and 31.6% had no prior confirmatory viral load test. Patient referrals originated from Primary Care (65.3%), Hospital Care (18.9%), and Emergency Services (15.8%). All viremic cases were reported to the referring physicians for evaluation and potential treatment. Of the 95 viremic patients, 67.4% (64/95) attended follow-up appointments; 60.9% (39/64) initiated antiviral treatment, while 12 declined therapy and 19 missed their appointments.
Conclusion: This study highlights the feasibility and efficacy of an "opportunistic" retrieval strategy utilizing LIS automation to identify and re-engage patients with incomplete hepatitis C diagnostic workups. By focusing on patients undergoing care for unrelated conditions, this approach streamlines re-entry into the care continuum and makes a meaningful contribution to elimination efforts.

Overweight, but not alcohol is associated with increased risk for advanced liver disease in patients with chronic hepatitis C infection- results from the german hepatitis C-registry (DHC-R)

Katharina Luise Hupa-Breier[1], Peter Buggisch[2], Hartwig Klinker[3], Stefan Mauss[4], Renate Heyne[5], Karl-Georg Simon[6], Thomas Berg[7], Andreas Geier[8], Heiner Wedemeyer[1,9], Monika Rau[8]. *[1]Department for Gastroenterology, Hepatology, Infectious Disease and Endocrinology, Hannover Medical School, Hannover, Germany; [2]ifi-Institute for Interdisciplinary Medicine, Hamburg, Germany; [3]Division of Infectious Diseases, Department of Internal Medicine II, University of Würzburg Medical Center, Würzburg, Germany; [4]Center for HIV and Hepatogastroenterology, Düsseldorf, Germany; [5]Leberzentrum Checkpoint, Berlin, Germany; [6]MVZ Dres. Eisenbach, Simon, Schwarz GbR, Leverkusen, Germany; [7]Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany; [8]Medizinische Klinik II, Universitätsklinikum Würzburg, Würzburg, Germany; [9]Leberstiftungs-GmbH Deutschland, Hannover, Germany*
Email: hupa.katharina@mh-hannover.de

Background and aims: Obesity and alcohol are important risk factors for the development of liver cirrhosis. However, their impact in patients after chronic HCV infection (cHCV) remains unknown. Data are lacking weather the co-existence of both risk factors has a supra-additive effect on disease progression. We aimed to analyze the impact of obesity and alcohol consumption in cHCV patients.
Method: Patients from the German Hepatitis C-Registry were classified into four groups according to the presence of overweight (BMI≥25 vs. BMI<25) and the presence of alcohol consumption (none, vs. any alcohol). Primary endpoint was progression to liver cirrhosis. Secondary endpoint was mortality in combination with disease progression.
Results: In total, n = 5967 patients were included after antiviral treatment. Patients with BMI≥25/no alcohol (O/nA) had an increased risk for progress of liver cirrhosis compared to BMI<25/ alcohol (L/A). In a multivariate analysis, obesity and diabetes were independent risk factors for disease progression (OR for BMI > 35 2.833 (1.682–4.771), OR for diabetes 1.489 (1.004–2.208). O/nA patients also had an increased risk for overall mortality and disease progression compared to L/A. Multivariate analysis of the secondary endpoint identified again diabetes and obesity as the only independent cardiometabolic risk factors for disease progression and mortality. Interestingly, neither alcohol consumption alone nor in combination with obesity influences disease progression.
Conclusion: In conclusion, obesity increased the risk for disease progression after cHCV infection, while neither alcohol consumption alone nor in addition to obesity impacts disease progression. Therefore, weight management in patients after cHCV is important to prevent disease progression.

HCC risk stratification scores: insights from large multi-center national cohort study

Imam Waked[1,2], Wafaa El-Akel[3,4], Mohamed AbdAllah[5], Magdi El-Serafy[4,6], Mohamed Hassany[4,7], Aisha Elsharkawy[3,4], Riham Soliman[8,9], Gamal Shiha[10,11], Gamal Esmat[4,6], Wahed Doss[3,4]. *[1]National Liver Institute, Menoufia University, Shebeen El Kom, Shebeen El Kom, Egypt; [2]National Committee for Control of Viral Hepatitis, MOH, Egypt, Egypt, Egypt; [3]Endemic Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt; [4]National Committee for Control of Viral Hepatitis, MOH, Egypt, Cairo, Egypt; [5]Medical Research Division, National Research Center, Giza, Egypt, Giza, Egypt; [6]Endemic Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt; [7]National Hepatology and Tropical Medicine Research Institute, Cairo, Egypt; [8]Egyptian Liver Research Institute and Hospital (ELRIAH), Sherbin, El Mansoura, Egypt, Shirbin, Egypt; [9]Tropical Medicine Department, Faculty of Medicine, Port Said University, Egypt, Port Said, Egypt; [10]Hepatology and Gastroenterology Unit, Internal Medicine Department, Faculty of Medicine, Mansoura University, Egypt, Mansoura, Egypt; [11]Egyptian Liver research Institute and Hospital, Mansoura, Egypt*
Email: g_shiha@hotmail.com

Background and aims: More than four million Egyptians have successfully cleared the HCV virus during the national HCV elimination program, and about 20% of them require HCC surveillance. Consequently, there is unmet need for HCC risk stratification. Several HCC risk prediction scores have been developed to tailor HCC surveillance strategies more precisely. Our aim was to evaluate the discriminative ability and clinical utility of these scores in a large multi-center national study.
Method: We conducted a multi-center retrospective study across 58 HCC screening centers across 28 governorates affiliated with the National Committee for the Control of Viral Hepatitis (NCCVH) in Egypt from the period of January 2020 till June 2024. We evaluated the predictive performance and clinical utility of several HCC risk scores.
Results: Of the 33,797 SVR-HCV patients with advanced liver fibrosis and cirrhosis, 13,632 has all the parameters of the scores. We included 8,577 are valid for the evaluation. The cohort was 56% female, with a median age of 60 years (range 53–67) and a median follow-up duration of 24 months The ALBI score showed no statistical significance (log-rank test; P = 0.21) The cumulative incidence of HCC in low, intermediate and high were 0.10, 0.09, and 0.01

respectively. The aMAP had a log-rank p-value of 0.15 which is not statistically significant. The cumulative incidence of HCC in low, intermediate and high were 0.03, 0.06, and 0.14 respectively. The FIB-4 with a log-rank p-value of 0.10, which was not statistically significant. The cumulative incidence of HCC in low, intermediate and high were 0.05, 0.10 and 0.10 respectively. Notably, GES successfully stratified the patients into low (74%), intermediate (11%), and high (15%) risk groups, with highly significant log-rank p-value < 0.01 with cumulative incidence of HCC in low, intermediate and high 0.03, 0.12 and 0.31 respectively. AFP levels <10 ug/dl (97%), 10–200 ug/dl (3%).

Conclusion: GES and changes in the AFP levels demonstrated robust performance and highly significant discriminative ability, outperforming the suboptimal results of aMAP, ALBI, and FIB-4. Applying the EASL policy statement of liver cancer screening, GES classified over 70% of patients as low-risk suggesting that these patients could either be excluded from surveillance or screened at extended intervals. This outcome could minimize patients' physical and psychological harm and markedly reduce healthcare system costs.

THU-214

An innovative peer-led, smartphone-based intervention to enhance engagement for patients with untreated hepatitis C

Jennifer Plunkett[1], Kathleen Bryce[1], Paul Trembling[1], Valentino Omar[2], Chris White[2], John Gibbons[3], Douglas Macdonald[1], Amy Teague[1], Amelia Davies[4], Claire St John[5]. *[1]Royal Free Hospital, London, United Kingdom; [2]North Central London Hepatitis C Trust, London, United Kingdom; [3]Find&Treat, University College London Hospitals, London, United Kingdom; [4]London North West University Healthboard, London, United Kingdom; [5]North Central London ODN, London, United Kingdom*
Email: j.plunkett1@nhs.net

Background and aims: Individuals living with hepatitis C may experience barriers accessing treatment including constrained resources, lack of means of communication and negative healthcare experiences. This study aims to evaluate use of smartphones and peer support to improve engagement with treatment.

Method: In this peer led, structured support intervention in North Central London, patients with HCV deemed the most challenging to engage were offered a smartphone and 2-year contract, peer support and bespoke social support. Eligibility criteria included those delayed longest from diagnosis to treatment, patients leaving prison without a phone, and those deemed highest risk of disengagement by our outreach team. The smartphone contract was terminated if the participant was uncontactable. Replacement phones were offered to those demonstrating engagement. Engagement and treatment outcome data were collected, patient satisfaction was assessed via survey.

Results: 47 participants were enrolled over 18 months. Year of diagnosis ranged from 1999–2023; 53% were delayed > 1 year from diagnosis and 43% were delayed for ≥5 years. Nearly 1/3 had previously failed treatment. Following the intervention, 46 (98%) patients started treatment, 39 (83%) within one month of receiving the smartphone. Of those with sufficient time to do so, 32 out of 45 (71%) participants completed treatment. 13 out of 18 (72%) participants with adequate time who were delayed ≥5 years completed treatment. 10 out of 15 (67%) participants who had previously failed treatment completed treatment. Overall, 24 (65%) participants who were enrolled with enough time to achieve cure of HCV were successfully treated. At study completion, 29 (62%) patients had an active handset; 15 handsets were lost, stolen or broken and 10 patients had received a second handset. 81% of those who had a phone at the end completed a course of treatment and 56% who did not have a phone at the end completed treatment. Participants who completed the survey rated the project's helpfulness an average of 9/10 in supporting their treatment; all agreed that it improved their wellbeing and made their life easier.

Conclusion: This intervention has had a significant positive impact in patients considered the most difficult to engage. Although unable to match a group with similar barriers who did not have a phone, there is clear benefit with most patients maintaining engagement with treatment. Those delayed ≥5 years from time of diagnosis represent a particularly disengaged subgroup and a high proportion completed treatment. Each smartphone and contract costs £326.35. Given that cost of untreated HCV includes the burden of managing advanced liver disease, earlier deaths and societal impacts[1], we propose that this is a cost saving initiative warranting further health economic analysis. Our study indicates that a simple, inexpensive technology-based intervention improves treatment outcomes, however long-term patient engagement may require additional strategies.

THU-215

Characterising prevalence and unmet needs in the setting of funded hepatitis C therapy - automated hepatitis screening in australian emergency departments can assist

Julia Di Girolamo[1,2,3], Alexander Prudence[1,2,3], Melissa Bagatella[2], Sicha Manandhar[2], Joseph Pipicella[1,2,3], Krishan Pratap[4], Irena Petrovski[5], Sokaina Ahmadi[6,7], Alice Lee[7], Ian Turner[5], Jeremy Lawrence[8], Richard Cracknell[5], Laura Hutchinson[7], Matthew Smith[4], Alex Mackey[2], Michael Maley[2,9], Hong Foo[2,9], Nathan Jones[2], Gregory Dore[10], David Prince[1,2,11], Miriam Levy[1,3]. *[1]Ingham Institute for Applied Medical Research, Sydney, Australia; [2]Liverpool Hospital, Sydney, Australia; [3]The University of New South Wales, Sydney, Australia; [4]Bankstown Hospital, Sydney, Australia; [5]Campbelltown Hospital, Sydney, Australia; [6]Concord Repatriation General Hospital, Sydney, Australia; [7]Canterbury Hospital, Sydney, Australia; [8]Fairfield Hospital, Sydney, Australia; [9]NSW Health Pathology, Sydney, Australia; [10]The Kirby Institute, UNSW, Liverpool, Australia; [11]The University of New South Wales, Sydney, Australia*
Email: miriam.levy@health.nsw.gov.au

Background and aims: With availability and full funding of curative therapies for hepatitis C (HCV) in Australia, patients may remain undiagnosed or untreated. We evaluate the use of universal, automated hepatitis screening in the emergency department (ED) to determine HCV Antibody (HCV Ab) prevalence, viraemia, treatment rates and the characteristics of the untreated population.

Method: A novel pilot clinical service utilising automated universal hepatitis screening in the ED, SEARCH 3X (Screening Emergency Admissions at Risk of Chronic Hepatitis 3 Extension) was implemented in five metropolitan hospitals in Sydney, Australia during 2023–2024. A computer algorithm automatically added HCV Ab tests when an adult underwent blood draw for routine biochemistry. Serology was performed in the biochemistry autoanalyser. Data was collected on patient demographics, risk factors, prevalence of HCV Ab and HCV RNA.

Results: Of 25,045 patients tested, 529 were positive of whom 92% were contactable, 73% had a HCV RNA test and 3% were medically unfit for follow up. HCV Ab was positive in 2.1% with a younger median age (54.3 years, 54.1–64.7) and higher proportion of males (64%) compared to the tested cohort (62.8 years, 40.8–79.3 and 46% male, p < 0.00001). HCV Ab prevalence was 1.4% in overseas born (195/14,028), 2.3% in non-Indigenous Australians (238/10,330) and 11.8% (81/687) in Indigenous Australians (p < 0.00001). The diagnosis was new in 16% (64/406), and rates similar across overseas born 18% (29/160), non-Indigenous 13% (24/183) and Indigenous cohorts 17% (11/63). Overseas born patients reported significantly lower intravenous drug use rates 46% (62/135) compared to Australian born (74%, 29/199, p < 0.00001) and Indigenous patients (95%, 56/59, p < 0.00001). Viraemia was detected in 17% (67/387). Viraemia was present in 0.27% (67/25,045) and similar across Indigenous, non-Indigenous, or overseas born cohorts. Of 67 viraemic, the diagnosis was new in 36% (24) and known in 64% (43). Of the known, 29% (13) reported past treatment and 12 were people who inject drugs (PWID) suggesting reinfection. Of the 277 "ever-eligible" for treatment, 81%

(223) had been treated previously and 54 were untreated, including 24 newly detected and 30 with known diagnosis. Current PWID were significantly more likely to be viraemic compared to non-viraemic patients (46%, 23/50 vs 28%, 54/193, p = 0.0175). Viraemic patients, were more likely to have diagnosed psychiatric conditions than non-viraemic patients, (61%, 41/67 vs 47% 142/300, p = 0.00434). Of the 67 viraemic patients, 54 initiated antiviral treatment, 6 were under assessment for treatment and 7 had medical contraindications.
Conclusion: ED screening revealed high HCV Ab prevalence, high treatment rates and relatively low viraemia rates (0.27%) suggesting a successful HCV treatment program. Nevertheless, the higher viraemic rates in some cohorts suggest PWID and those with mental illness are being left behind.

THU-216

A step toward eliminating recalls and follow-up testing: first australian implementation of hepatitis C RNA reflexive testing utilising a single blood sample collected in the emergency department setting

Julia Di Girolamo[1,2,3], David Prince[1,2,3], Alexander Prudence[1,2], Robert Porritt[2,4], Kiran Thapa[2,4], Melissa Bagatella[2], Sicha Manandhar[2], Hong Foo[2,4], Michael Maley[2], Miriam Levy[1,2,3].
[1]Ingham Institute for Applied Medical Research, Sydney, Australia; [2]Liverpool Hospital, Sydney, Australia; [3]The University of New South Wales, Sydney, Australia; [4]NSW Health Pathology, Sydney, Australia
Email: miriam.levy@health.nsw.gov.au

Background and aims: Case detection remains a challenge for hepatitis C virus (HCV) elimination. Recognised plateauing of testing and diagnosis rates suggest the need for implementation of universal screening programs, however HCV diagnostic testing methods may be a barrier. Australian guidelines recommend a sequent approach to hepatitis C diagnostic testing with an initial hepatitis C antibody (HCV Ab) serology assay, followed by molecular confirmation of active infection using polymerase chain reaction (PCR) of hepatitis C RNA. The latter often requires patient recall for a new specimen collection. This multi-step process is complicated by instances of loss to follow up and introduces inefficiencies as many recalled patients may not have active infection. Laboratories may, at first blood collection, reserve a second blood tube in advance of an antibody test to reduce patient recall, however this is not a practical solution in the context of large-scale automated universal hepatitis screening programs. We have reported findings of a novel pilot Screening Emergency Admissions at Risk of Chronic Hepatitis 3 Extension (SEARCH 3X). In this paper we describe the outcomes of a novel hepatitis C RNA reflexive testing process.
Method: SEARCH operation at two tertiary hospital sites in Sydney Australia, a computer algorithm automatically added HCV Ab tests when an adult underwent routine biochemistry testing in the Emergency Department (ED). Initial positive HCV Ab serology results were identified and if sufficient volume available (minimum 650μL), specimens were retrieved from the Cobas e801 biochemistry analyser and aliquoted for PCR testing of HCV quantitative nucleic acid on Cobas 4800 instrument. Patients were recalled for a dedicated collection to confirm the validity of the HCV RNA results obtained by reflexive testing.
Results: SEARCH tested 9,521 patients of which 255 (2.7%) were HCV Ab positive specimens eligible for reflexive HCV RNA testing. The proportion successfully tested by the reflexive methodology was 100/255 (39%) of which, 13 (13%) were positive, 86 (86%) were negative and 1 invalid. Testing could not be performed on 155 (61%) due to insufficient sample volume. Of the 99 with valid results, 70 (71%) to date, have been recalled for a subsequent HCV RNA test on a dedicated tube. Of the 13 RNA positive specimens, 12 were confirmed (one patient died). Of the 86 RNA negative, 58 (67%) were confirmed and 21 (24%) are being followed-up. Four were lost to follow up and three declined further testing. No false positive or false negative results were identified using the reflexive HCV RNA single tube methodology.
Conclusion: Reflexive HCV RNA single tube methodology was efficient in establishing a complete HCV diagnosis in 99 patients, without the need for a second blood collection. The challenge of insufficient sample volume could be mitigated by using alternative validated PCR methods for HCV RNA testing.

THU-221-YI

Sex-related differences in patients with chronic hepatitis c virus infection treated with direct-acting antiviral drugs

Krystyna Dobrowolska[1], Dorota Zarębska-Michaluk[2], Małgorzata Pawłowska[3], Magdalena Tudrujek-Zdunek[4], Beata Lorenc, Hanna Berak[5], Ewa Janczewska, Włodzimierz Mazur[6], Justyna Janocha-Litwin[7], Jakub Klapaczynski[8], Marek Sitko[9], Dorota Dybowska[3], Anna Parfieniuk-Kowerda[10], Piekarska Anna[11], Jerzy Jaroszewicz[12], Robert Flisiak[10]. *[1]Collegium Medicum, Jan Kochanowski University, Kielce, Poland; [2]Department of Infectious Diseases and Allergology, Jan Kochanowski University, Kielce, Poland; [3]Department of Infectious Diseases and Hepatology, Faculty of Medicine, Collegium Medicum Bydgoszcz, Nicolaus Copernicus University, Bydgoszcz, Poland; [4]Department of Infectious Diseases, Medical University of Lublin, Lublin, Poland; [5]Outpatient Clinic, Hospital for Infectious Diseases in Warsaw, Warszawa, Poland; [6]Clinical Department of Infectious Diseases in Chorzów, Medical University of Silesia, Chorzów, Poland; [7]Department of Infectious Diseases and Hepatology, Wrocław Medical University, Wrocław, Poland; [8]Department of Internal Medicine and Hepatology, The National Institute of Medicine of the Ministry of Interior and Administration, Warszawa, Poland; [9]Department of Infectious and Tropical Diseases, Jagiellonian University, Krakow, Poland; [10]Department of Infectious Diseases and Hepatology, Medical University of Białystok, Białystok, Poland; [11]Department of Infectious Diseases and Hepatology, Medical University of Łódź, Łódź, Poland; [12]Department of Infectious Diseases and Hepatology, Medical University of Silesia in Katowice, Katowice, Poland*
Email: krystyna.dobrowolska98@gmail.com

Background and aims: Sex is one of the known factors influencing the risk of hepatitis C virus (HCV) infection and the natural course of disease, characterized by a higher rate of spontaneous HCV elimination, less severe fibrosis and slower progression to cirrhosis compared to men. The aim of this study was to evaluate sex-related differences in the characteristics of HCV-infected patients and to assess the impact of female sex on treatment with direct-acting antivirals (DAAs) depending on age and menopausal status.
Method: The analysis used data of the consecutive 18,986 patients, 9,457 women and 9,529 men, treated with DAA for chronic HCV infection collected in the nationwide multicenter retrospective EpiTer-2 project. Women were divided into groups according to their menopausal status, defined by the recommendations of the World Health Organization, creating three age brackets: 15–44 years (pre-menopause), 45–55 years (menopause) and >55 years (post-menopause), which were compared with age-matched men.
Results: Regardless of age, women were characterized by a significantly lower BMI and a lower percentage of genotype (GT) 3 and a significantly lower incidence of cirrhosis compared to men. Comorbidities were reported significantly less frequently in youngest women compared to men of that age (p = 0.003), while in older age groups the percentages were comparable. Depression was more common reported among women, with differences reaching statistical significance in the 45–55 (p = 0.0003) and over-55 (p = 0.0007) age groups, while other psychiatric disorders were more frequent among men. HBV and HIV coinfections, as well as alcohol and drug addiction, were significantly less common in women than in men of all ages. Women in each age group were treated significantly more often with genotype-specific regimens as compared to men. Overall, the sustained virologic response rate was significantly higher in women compared to men and amounted to 98.4% and 96.6%,

respectively ($p < 0.001$). In all age groups, statistically significant differences in the effectiveness of therapy in favor of women were documented, although the oldest group achieved the relatively lowest SVR rate. Mild adverse events were reported significantly more often by women, regardless of age with highest percentage in the postmenopausal group, while serious events and deaths were reported more often in men.

Conclusion: Women chronically infected with HCV have lower BMI, less frequent GT3 infection, less frequent co-infection with HBV and HIV, and less advanced liver disease compared to men. DAA treatment is more effective in women compared to men, regardless of age, although in postmenopausal women the effectiveness is relatively the lowest and the rate of adverse effects is the highest. Antiviral therapy should be administered as soon as possible to avoid consequences related to the loss of protective sex hormones.

THU-222

Development of a hepatitis C infection integrated care model for prisoners in chinese population

Lung Yi Loey Mak[1,2], Rex Wan-Hin Hui[3], James Fung[3], Wai Pan To[3], Vivien Wai-Man Tsui[3], Kwan Lung Ko[3], Grace Lai-Hung Wong[4], Frances Yik Wa Law[3], Kai Tai Wong[5], Wai-Kay Seto[1], Man-Fung Yuen[1].
[1]The University of Hong Kong, State Key Laboratory of Liver Research, Hong Kong, China; [2]Queen Mary University of London, London, United Kingdom; [3]The University of Hong Kong, Hong Kong, China; [4]The Chinese University of Hong Kong, Hong Kong, China; [5]Correctional Services Department, Hong Kong, China
Email: loeymak@gmail.com

Background and aims: In the current era of highly effective direct acting antiviral (DAA) therapy, one of the remaining obstacles to elimination of hepatitis C virus (HCV) is identification of undiagnosed individuals. Prisoners or person-in-custody (PIC) are high-risk for HCV due to criminalization of drug use and engagement in criminal activity to fund illicit drug habits. Only 35% countries with national plans for hepatitis elimination outlined interventions for HCV among prisoners. We aimed to determine the prevalence of HCV among PICs in Hong Kong and evaluate the feasibility of a prison-based integrated care model.

Method: Since 2023, we initiated an outreach program to conduct site visits to prisons in Hong Kong, which are operated by the Correctional Services Department by the Hong Kong Government. Eligible participants watched an educational video on natural history, course and implication of HCV. We then performed point-of-care (POC) test for antibody to HCV (anti-HCV) by Oraquick®. PICs with positive POC test received reflex venipuncture for HCV RNA and on-site vibration-controlled transient elastography assessment by a portable version of Fibroscan®. PICs with confirmed active HCV viremia were treated with DAA in the prison under direct observation within 4 weeks. Sustained virological response 12 weeks after DAA completion (SVR12) was evaluated by onsite POC test for HCV RNA by Xpert HCV VL Fingerstick on the Cepheid GeneXpert ® system.

Results: In this interim analysis, 11 site visits were conducted and 346 PICs were screened: median age was 42 years old, 100% male, 36.1% primary level of education, 76.5% chronic smokers, 32.7% had tattoo, 2.4% admitted history of injection drug use and half of them practiced needle sharing. The most common route of illicit drug use was inhalational. The awareness of HCV was 0% and willingness to receive treatment was 100%. A total of 17 PICs had +ve anti-HCV (anti-HCV seroprevalence rate: 4.9%). Compared to PICs without HCV exposure, those with anti-HCV+ were older (56 vs 40 years old, $p < 0.001$), more likely to had primary level of education (76.5% vs 34%, $p = 0.002$), more likely to be chronic smoker (100% vs 75.3%, $p = 0.016$), had tattoo (70.6% vs 30.7%, $p = 0.002$), had intravenous drug injection (25% vs 1.2%, $p < 0.001$), longer time in the prison (9.3 vs 5.5 years, $p = 0.003$) and longer time from release (6.8 vs 3.2 years, $p = 0.001$). Among 16 PICs with RNA +ve (viremic rate 4.6%), only 1 had HBV co-infection and 0 had HIV co-infection. The most common genotype was 6 (47.1%), followed by 1b (17.6%) and 3 (11.8%). 5/16 (32.5%) had advanced fibrosis at diagnosis (defined as liver stiffness >9.5 kPa), with 8 (47%) noted to have raised ALT. DAA was started in all 16 subjects with good tolerance. Among 7 PICs who had post-treatment evaluation, SVR12 was achieved in 100%.

Conclusion: Micro-elimination is an effective strategy to identify PICs with HCV in Chinese populations where the overall prevalence of HCV in background population is low.

THU-223-YI

Implementation of a systematic hepatitis C screening program: insights from a regional approach and its impact on diagnosis and treatment outcomes

Madalena Pestana[1], Vítor Magno Pereira[1], Elisa Xavier[2], Nancy Faria[3], Ana Reis[3], Nuno Ladeira[1], Paulo Câmara[1], Alba Carrodeguas[4], José Luis Gonzalez[4], Nuno Canhoto[1], José Bruno Freitas[1], Henrique Morna[1]. *[1]Hospital Dr Nélio Mendonça, Funchal, Portugal; [2]Serviços de Saúde da Região Autónoma da Madeira, Funchal, Portugal; [3]Hospital dos Marmeleiros, Funchal, Portugal; [4]Gilead Sciences, Madrid, Spain*
Email: madalenaibp795@gmail.com

Background and aims: Hepatitis C (HCV) is a curable chronic viral infection. Nonetheless, there is still a high proportion of undiagnosed cases. In 2016, WHO announced the goal of HCV elimination until 2030. In line with the World Health Organization, we have implemented in our region a global HCV screening programme in 2020.

Method: A systematic, opportunistic HCV screening was adopted in patients aged 18–70 who required blood work regardless of the clinical indication. Screening was integrated across hospital wards, emergency departments and primary care from January 2020 to December 2024 via electronic health record algorithms and oral opt-out consent. Viremic patients were identified either with reflex testing wherein positive HCV antibody tests triggered HCV core antigen confirmation on the same specimen or HCV viral load on a second sample.

Results: We screened 63,299 patients from January 2020 to December 2024, upscaling HCV and found 0.42% antibody prevalence ($n = 263$) and 0.13% ($n = 80$) viremia. When analyzing the provenance, almost two-thirds ($n = 160$) of HCV-positive cases were identified in the context of hospital emergency, followed by primary care settings (29%). Viremic patients were stratified according to non-invasive liver fibrosis scores with Fibrosis-4 Index for Liver Fibrosis (FIB-4), and the AST to Platelet Ratio Index (APRI). Approximately half of these patients were at low risk ($n = 38$), followed by intermediate and high risk. The majority ($n = 69$; 85%) had transaminase abnormalities at diagnosis. However, almost one-third ($n = 22$) had no risk factor identified and 11 patients did not have hepatic function test abnormalities. Treatment was successfully completed in 34 patients, with only one first-line therapeutic failure, and 85% achieved normalization of liver tests after sustained virologic response. On the other hand, 16 treated patients (47%) showed an elevation in their lipid profile.

Conclusion: Emergency departments appear to be the most effective setting for large-scale population screening. Nearly half of the viremic patients had a low fibrosis risk by non-invasive methods, and many patients exhibited no red flags, such as risk factors or abnormal test results. This underscores the importance of implementing screening programs that enable early disease detection.

Email: magdalena.hahn@medizin.uni-leipzig.de

Background and aims: Hepatitis C virus infection is a risk for hepatocellular carcinoma (HCC). After successful therapy with direct antiviral agents (DAA) risk stratification is needed to decide on individualized HCC surveillance. This analysis explores follow-up and HCC incidence of all German hepatitis C registry (DHC-R) patients.
Method: In this retrospective analysis all DHC-R patients were included, that had no HCC at baseline (BL) before therapy. Patients were prospectively followed for up to 7 years. HCC risk was calculated at BL with the HCC risk calculator (Ioannou et al., 2018) and aMAP score (Fan et al., 2020).
Results: The cohort included 8,508 patients with a median age of 53 (IQR 43–61) years and 60% of whom were men. Liver cirrhosis was present in 33% of patients. The mean aMAP score at baseline predicted medium risk (52.8 SD +/– 9 points, translating as HCC risk of 1.2–3% in 3 years). According to the HCC risk calculator overall median 5-year HCC risk was 2.1 (IQR 1.5–3.5) % at BL. During the 7 years of follow-up, 152 HCCs were diagnosed. The cumulative incidence of HCC was 1.15% after 3 years, 1.47% after 5 years and 1.77% after 7 years. After 24,222 patient years of follow-up, the annual incidence was 0.63% for all patients, with 0.55% for cirrhotic and 0.08% in non-cirrhotic patients. The actual HCC incidence was lower than predicted. More than half of HCCs were diagnosed in the first two years (52% of HCCs), but the incidence remained stable throughout follow-up visits. The number of patients that were followed declined with each year (from n = 7,190 year 1 to n = 937 year 7) irrespective of abundance of liver cirrhosis, diabetes mellitus or obesity (data not shown). Patients with HCC as compared to patients without HCC had more often liver cirrhosis (88%, 29%, Chi^2 test $p < 0.001$), diabetes mellitus (22%, 9%, $p < 0.001$), a BMI > 30 kg/m^2 (21%, 15%, $p = 0.0036$) and showed fewer sustained-virological response 12 weeks after end of treatment (88%, 95%, $p < 0.001$). Male sex and age were no significant risk.
Conclusion: Cumulative HCC incidence after 3 and 5 years in DHC-R patients was lower than predicted with the HCC risk calculator and aMAP score. DHC-R is an observational registry that primarily focuses on hepatitis C and is hence probably not completely covering HCC onset and screening for it.

THU-225-YI
Systematic screening for HBV, HCV and HIV in hospitalised psychiatric patients: a feasible approach on the road towards elimination of viral hepatitis

Marie Coessens[1,2], Hannes Ruymbeke[1], Jeoffrey Schouten[1], Ilse Velghe[3], Jeroen Kleinen[4], Lieven De Weirdt[5], Ann Berens[6], Manuel Morrens[6], Marianne Destoop[7], Jeroen Decoster[8], Wim Verlinden[1,2]. Email: wim.verlinden@vitaz.be

Background and aims: Cost-effective screening strategies for hepatitis B and C virus (HBV/HCV) are important on the road towards elimination of viral hepatitis. People with serious mental illnesses are at increased risk of these infections and human immunodeficiency virus (HIV) has similar transmission routes. We aim to assess the prevalence of these blood-borne viruses (BBV) by means of a generalised screening approach in hospitalised psychiatric patients and identify associations between BBV infections and psychiatric diagnosis.
Method: This multi-center prevalence study was conducted between 2017 and 2024 in 6 Belgian psychiatric hospitals (PH). For all newly admitted adult patients who were willing to participate, psychiatric diagnosis according to DSM-IV criteria was documented, and BBV serum testing was performed. Patients with positive serology were referred to a hepatologist or infectious disease specialist. In addition, serological data were obtained retrospectively of two forensic psychiatric centres (FPC), as a generalised BBV screening was already in place here.
Results: A total of 2213 patients were included in the study [PH: 1634 (73.8%); FPC 579 (26.2%)]. HBsAg, HCVAb, HIVAb test results were obtained in 93.1%, 97.1% and 89.7% of included patients. Psychiatric diagnoses were obtained in 4 out of 6 psychiatric hospitals for 1061 patients. In total, 20.6% suffered from a psychotic disorder, 12.8% from intranasal or intravenous (IN/IV) drug dependency, and 12.9% from a personality disorder. In total, HBsAg seroprevalence was 0.68%. HBsAg seroprevalence was higher in the FPC group ($p < 0.0001$) and in the total study population ($p = 0.0003$), compared to the general Belgian population (0.27%). HCV seroprevalence was 3.44% (74/2149). HCV seroprevalence was higher in the total study population ($p < 0.0001$), and in the PH (36/1588, 2.27%, $p < 0.0001$) and FPC group (38/561, 6.77%, $p < 0.0001$), compared to the general Belgian population (0.22%). HCV seroprevalence was higher in the FPC group compared to the PH group ($p < 0.0001$). 22/62 patients tested HCV PCR+. HCV antibodies were more prevalent in patients with IV/IN drug dependency ($p < 0.0001$). Even in the patient population where IV/IN drug dependency was not the reason of admission, HCV seroprevalence was still higher than in the GBP (1.66%, $p < 0.0001$). No associations between HBV and HIV and any psychiatric diagnoses were identified. HIV antibodies were found in 9/1986 (0.45%) of patients. Prevalence of HIV was higher in the PH group ($p = 0.003$) and in the total study population ($p = 0.002$), compared to the general Belgian population (0.17%).
Conclusion: As the seroprevalence of HBV, HCV and HIV is significantly higher in the study population than in the general Belgian population, we recommend general screening in all psychiatric hospitals as an effective and feasible strategy on the road towards elimination of viral hepatitis.

Email: michal.brzdek@gmail.com

Background and aims: There is a bidirectional relation between arterial hypertension (AH) and chronic hepatitis C, with the former exacerbating the risk of severe liver disease while the latter leading to cardiovascular complications. Therefore, it is essential to treat hypertensive patients infected with HCV, though the data on the effectiveness and safety of direct-acting antivirals (DAAs) is scarce. This study aimed to assess the effectiveness and safety of HCV treatment with DAAs in patients with (AH).
Method: This study employed a retrospective, real-world analysis of adult patients infected with HCV who were treated with direct-acting antivirals (DAAs) in Poland between 2015 and 2023. Data were extracted from national HCV treatment registries and collected across 22 national hepatology centers. The records included information on patient demographics, comorbidities, HCV genotype, liver disease status, treatment regimens, and outcomes.
Results: The analysis encompassed 18,968 patients treated with DAAs for chronic hepatitis, including 5,976 (31.5%) diagnosed with AH. These individuals were older, more frequently women, had a higher prevalence of obesity and other comorbidities, liver function decompensation, cirrhosis, and hepatocellular carcinoma, and were more commonly infected with genotype 1b. The percentage of patients achieving sustained viral response was high and did not differ between those with and without AH in the intent-to-treat and per-protocol analysis (94.8% vs. 94.2% and 97.6 vs. 97.6%, respectively). AH was not the independent predictor of treatment failure (OR, 95%: 0.87, 0.69–1.10). The predictors of treatment failure in AH patients included genotype 3 infection, decompensated liver function, cirrhosis, thrombocytopenia, and treatment with asunaprevir +daclatasvir. Adverse events (AEs), including fatigue and anemia, were more common in hypertensive patients, with one-fifth reporting AEs. Hypertensive patients were also more prone to therapy discontinuation and had higher mortality, though no deaths were attributed to antiviral therapy.
Conclusion: Although hypertensive patients were more prone to therapy discontinuation, the vast majority of them completed it, with only one-fifth reporting adverse events, mostly fatigue. The study shows that DAAs therapy is safe and effective in hypertensive patients and underscores the need for targeted screening strategies, particularly in hypertensive individuals, to optimize treatment success and reduce the long- term burden of HCV in this population.

THU-227
Relinking lost to follow up patients with hepatitis C: a modeling approach to assess liver-related outcomes

Manuel Mendizabal[1], Marcelo Silva[1], Federico Piñero[1], Martin ÓFlaherty[2]. *[1]Hospital Universitario Austral, Pilar, Argentina; [2]University of Liverpool, Liverpool, United Kingdom*
Email: mmendiza@cas.austral.edu.ar

Background and aims: Relinking patients with hepatitis C virus (HCV) who were lost to follow-up (LTFU) represents an accessible and effective strategy to enhance HCV elimination efforts. This study aimed to model the impact of relinkage to care among LTFU patients on key outcomes over a 10-year period follow-up, including the need for liver transplantation (LT), hepatocellular carcinoma (HCC) development, and mortality, under varying treatment uptake scenarios.
Method: We developed a Markov closed cohort state-transition model to simulate the natural progression of chronic HCV in 100,000 patients who were LTFU. The model compared the impact of relinkage strategies compared to no intervention. Transition probabilities and health utilities were derived from the literature and expert consensus. The analysis assessed the 10-year relative risk reduction (RRR) for the following outcomes under three scenarios: (1) LT need, (2) HCC development, and (3) mortality.
Results: Compared to a no relinkage to care program as the baseline scenario, a 10% relinkage rate (Scenario 1) achieved a 10-year RRR of 15% for LT need, 17% for HCC development, and 30% for mortality. Increasing the relinkage rate to 25% (Scenario 2) resulted in greater RRR: 27% for LT need, 31% for HCC development, and 53% for mortality. Achieving an ideal 100% relinkage rate (Scenario 3) would reduce the relative risk of LT need, HCC development, and mortality by 41%, 35%, and 78%, respectively.
Conclusion: Our model demonstrates that relinkage programs can significantly reduce liver-related complications and mortality, highlighting their potential as a transformative public health interventions.

THU-228
Effectiveness of automatic alerts from microbiology laboratories to liver units for linking to hepatitis C treatment

Nuria Cañete[1], Esther Garrido[1], José Muñoz[2], Susana Coll[1], Jose A. Carrión[1], Lidia Canillas[1], Diego Rojo[3], Marc Puigvehí[1], Diego Lázaro[1], Rosa Fernández[3], Eduardo Padilla[2], Montserrat Garcia-Retortillo[1]. *[1]Liver Unit, Gastroenterology Department, Hospital del Mar, Hospital del Mar Reasearch Institute, Barcelona, Spain; [2]Laboratori de Referència de Catalunya, Barcelona, Spain; [3]Liver Unit, Gastroenterology Department, Hospital del Mar, Barcelona, Spain*
Email: mgarciaretortillo@psmar.cat

Background and aims: Automatic alerts sent from Microbiology laboratories to requesting physicians upon detecting a positive HCV RNA have become widespread in recent years. These alerts aim to reduce the number of patients with hepatitis C not linked to treatment. Their effectiveness has been minimally studied, and the limited data available has shown modest impact (56%) (D. Morales-Arraez et al. Am J Gastroenterol 2020). Our aim was to analyze the effectiveness of automatic alerts for positive HCV RNA issued from the Microbiology laboratory when sent directly to the Liver Unit for linking to hepatitis C treatment.
Method: Observational, prospective, and single-center study that included all automatic alerts sent from the Microbiology Laboratory to the Liver Unit of our center. The case manager at the Liver Unit contacted the patient and informed them of the appointments. In a single visit, medical history, physical examination, liver elastography, laboratory tests, and initiation of antiviral treatment were conducted. Sociodemographic data, clinical factors and risk behaviours for hepatitis C transmission were collected.
Results: From 04/18/2023 to 09/30/2024, 87 alerts were issued. The majority were men (82.8%) with a median age of 46 years (range: 24–96) and foreign-born (57.5%). Forty-four cases (50.6%) were previously unknown infections, and among the known cases, 20/43 (46.5%) had never been referred for treatment. Thirty-seven (42.5%) did not have stable housing. Forty-one patients (47%) reported a history of drug use, and 25 (28.7%) reported high-risk sex. Ten cases (11.5%) were excluded from treatment due to advanced age or comorbidities, and 8 were already being treated in other centers. Ultimately, 58/69 (84%) were linked to treatment. Eleven cases (15.9%) were considered uncontactable. Homelessness was the only factor independently associated with failure to link to treatment ($p = 0.018$, OR: 14.5).

Conclusion: Automatic alerts for positive HCV RNA sent from the Microbiology lab to Liver Units help identify patients with hepatitis C and allow 84% of treatable cases to be linked to treatment. The effectiveness of the alerts is much lower in the homeless population, where specific strategies are needed.

THU-229-YI

Increasing risk of hepatic decompensation in patients with HCV related liver cirrhosis during long-term follow up after sustained virological response (SVR) - data from the german hepatitis C-registry (DHC-R)

Christian Niehaus[1,2,3], Mathias Jachs, Peter Buggisch[4], Hartwig Klinker[5], Stefan Mauss[6], Renate Heyne[7], Karl-Georg Simon[8], Frank Tacke[9], Stefan Zeuzem[10], Thomas Berg[11], Heiner Wedemeyer[1,12], Benjamin Maasoumy[1,13]. *[1]Department for Gastroenterology, Hepatology, Infectious Disease and Endocrinology, Hannover Medical School (MHH), Hannover, Germany; [2]Centre for Individualised Infection Medicine (CiiM), a joint venture between the Helmholtz Centre for Infection Research (HZI) and Hannover Medical School (MHH), Hannover, Germany; [3]Twincore, Centre for Experimental and Clinical Infection Research, a joint venture between the Helmholtz Centre for Infection Research (HZI) and the Hannover Medical School, Hannover, Germany; [4]ifi-Institute for Interdisciplinary Medicine, Hamburg, Germany; [5]Division of Infectious Diseases, Department of Internal Medicine II, University of Würzburg Medical Center, Würzburg, Germany; [6]Center for HIV and Hepatogastroenterology, Düsseldorf, Germany; [7]Leberzentrum Checkpoint, Berlin, Germany; [8]MVZ Gastroenterologie Leverkusen GbR, Leverkusen, Germany; [9]Department of Hepatology and Gastroenterology, Campus Virchow-Klinikum and Campus Charité Mitte, Charité - Universitätsmedizin Berlin, Berlin, Germany; [10]Goethe University Hospital, Frankfurt, Germany; [11]Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany; [12]Leberstiftungs-GmbH Deutschland, Hannover, Germany; [13]German Center for Infection Research (DZIF), Partner-site Hannover-Braunschweig, Hannover, Germany*
Email: niehaus.christian@mh-hannover.de

Background and aims: Hepatic decompensation leads to a substantial amount of morbidity and mortality in patients with liver cirrhosis and chronic viral hepatitis despite a sustained virological response (SVR). In this study, we aim to identify risk factors to predict hepatic decompensation after SVR in a large, multicenter real-world cohort.
Method: We retrospectively analyzed a total of 6,714 patients achieving SVR included in the well-established German Hepatitis C Registry (DHC-R) comprising 2,021 patients with liver cirrhosis. The diagnosis of cirrhosis was based on clinical, radiological, or histological findings, and hepatic decompensation was defined by the manifestation of ascites, hepatic encephalopathy, and/or variceal hemorrhage. Patients with a history of acute decompensation and/or hepatocellular carcinoma (HCC) were excluded from this study. Univariable Cox regression was performed to analyze risk factors for hepatic decompensation.
Results: After successful viral eradication, a total of 132 patients with compensated liver cirrhosis experienced hepatic decompensation during the seven-year follow-up period, with a median follow-up time of three years. The cumulative incidence of hepatic decompensation increased from 2.0% at follow-up year one to 6.7% at follow-up year seven. Age at SVR (HR: 1.02, 95%CI: 1.01–1.05, $p = 0.013$) and platelet count (HR: 0.99, 95%CI: 0.98–0.99, $p < 0.001$) as well as serum albumin (HR: 0.94, 95%CI: 0.91–0.96, $p < 0.001$) and MELD score (HR: 1.57, 95%CI: 1.45–1.7, $p < 0.001$) were identified as risk factors for acute decompensation in patients with compensated liver cirrhosis. Furthermore, post-treatment liver stiffness measurement (LSM) ≥25 kPa ($p = 0.01$) rather than change during treatment (LSM decrease ≥20%, vs. <20%, $p = 0.828$; LSM decrease ≥20% to final value <20 kPa, vs. others, $p = 0.555$) was associated with hepatic decompensation.
Conclusion: The findings suggest that demographic and laboratory data, in conjunction with LSM, may assist in the identification of patients with compensated HCV related liver cirrhosis and SVR who are at risk of hepatic decompensation and therefore may benefit from intensive surveillance.

THU-230

Predictors of hepatocellular carcinoma risk after hepatitis C viral clearance - data from the german hepatitis C-registry (DHC-R)

Christian Niehaus[1,2,3], Mathias Jachs, Peter Buggisch[4], Hartwig Klinker[5], Stefan Mauss[6], Renate Heyne[7], Karl-Georg Simon[8], Frank Tacke[9], Markus Cornberg[1,2,3,10], Christoph Sarrazin[11,12], Thomas Berg[13], Benjamin Maasoumy[1,10]. *[1]Department for Gastroenterology, Hepatology, Infectious Disease and Endocrinology, Hannover Medical School (MHH), Hannover, Germany; [2]Centre for Individualised Infection Medicine (CiiM), a joint venture between the Helmholtz Centre for Infection Research (HZI) and Hannover Medical School (MHH), Hannover, Germany; [3]Twincore, Centre for Experimental and Clinical Infection Research, a joint venture between the Helmholtz Centre for Infection Research (HZI) and the Hannover Medical School, Hannover, Germany; [4]ifi-Institute for Interdisciplinary Medicine, Hamburg, Germany; [5]Division of Infectious Diseases, Department of Internal Medicine II, University of Würzburg Medical Center, Würzburg, Germany; [6]Center for HIV and Hepatogastroenterology, Düsseldorf, Germany; [7]Leberzentrum Checkpoint, Berlin, Germany; [8]MVZ Gastroenterologie Leverkusen GbR, Leverkusen, Germany; [9]Department of Hepatology and Gastroenterology, Campus Virchow-Klinikum and Campus Charité Mitte, Charité - Universitätsmedizin Berlin, Berlin, Germany; [10]German Center for Infection Research (DZIF), Partner-site Hannover-Braunschweig, Hannover, Germany; [11]St. Josefs-Hospital, Wiesbaden, Germany; [12]Goethe University Hospital, Frankfurt am Main, Germany; [13]Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany*
Email: niehaus.christian@mh-hannover.de

Background and aims: Hepatocellular carcinoma (HCC) is the leading cause of death in patients with chronic viral hepatitis C after achieving a sustained virological response (SVR). Prediction models for HCC development after SVR still require further validation but are crucial for clinical practice. In this study, we aim to determine risk factors to predict HCC development after SVR as well as validate previously suggested HCC risk scores in a large multicenter, real-world cohort.
Method: We retrospectively analyzed a total of 6,714 patients achieving SVR included in the well-established German Hepatitis C Registry (DHC-R) comprising 4,693 patients with and 2,021 without liver cirrhosis, respectively. Patients with a history of HCC and/or acute decompensation of liver cirrhosis were excluded. Univariable Cox regression was performed to analyze risk factors for HCC development. Previously proposed risk scores, i.e., the aMAP score comprising age, gender, bilirubin, albumin and platelet count, were validated.
Results: Overall, 67 patients developed de novo HCC during the first seven years after SVR. The cumulative incidence rates at seven years after SVR were 3.6% in all patients, 7.4% in patients with liver cirrhosis, and 1% in patients without cirrhosis. Moreover, the aMAP risk score was associated with an increased risk for HCC development in the entire cohort and in patients with liver cirrhosis (HR: 1.15, 95%CI: 1.09–1.21, $p < 0.001$). Furthermore, evaluating differential risk factors for the onset of HCC after SVR, we observed that liver stiffness measurement (LSM) at SVR (HR: 1.05, 95%CI: 1.02–1.09, $p = 0.003$), age (HR: 1.06, 95%CI: 1.04–1.09, $p < 0.001$), body mass index (BMI) (HR: 1.07, 95%CI: 1.01–1.14, $p = 0.03$), diabetes (HR: 2.71, 95%CI: 1.55–4.76, $p = 0.001$), and platelet count (HR: 0.99, 95%CI: 0.985–0.993, $p < 0.001$) were factors associated with the incidence of HCC in the overall cohort, whereas within the subcohort of patients with liver cirrhosis, only LSM ($p = 0.045$), age ($p = 0.007$) and diabetes ($p = 0.033$) were significantly associated with de novo HCC. Interestingly,

α-fetoprotein (AFP) did not emerge as a risk factor for the development of HCC in patients with (p = 0.196) and without liver cirrhosis (p = 0.854).
Conclusion: These results emphasize LSM, age, BMI, diabetes and platelet count as predictors for the onset of HCC in patients with hepatitis C virus infection after SVR and highlight the aMAP score as an effective tool for predicting HCC development.

THU-231
Microelimination project for HCV in patients with elevated ALT using pooling PCR technique in a health area. Preliminary results
Natalia Marcos Carrasco[1], Elena Velasco Martinez[1], Belen Lorenzo[2], Carolina Almohalla[1], Irene Peñas Herrero[1], Félix García Pajares[1], Pedro Enrile Sanchez[1], Jorge Lillo Diez[1], Isabel Ruiz Nunez[1], Jorge Ruiz Rodríguez[1], Jose Maria Eiros Bouza[2], Gloria Sánchez Antolín[1]. *[1]Gastroenterology, Hepatology and Liver Transplantation Unit, Hospital Universitario Rio Hortega, Valladolid, Spain; [2]Microbiology, Hospital Universitario Rio Hortega, Valladolid, Spain*
Email: gsanchezan@saludcastillayleon.es

Background and aims: Screening for Hepatitis C Virus (HCV) in patients with elevated ALT levels is a recommended clinical practice. However, various factors often prevent its routine implementation in clinical settings in primary care centers. Aim To implement a microelimination program for hepatitis C by screening for HCV RNA using a pooling PCR technique in all patients in the Valladolid West Health Area with elevated ALT levels and FIB-4 scores above 2.67. Also, to analyze the prevalence of active HCV infection in this population, and identify and treat positive cases, evaluating the efficiency of this screening strategy.
Method: The study included all blood tests ordered by primary and hospital care from January 1, 2024, to October 2024, excluding hospitalized patients. Samples with elevated ALT and FIB-4 >2.67 were forwarded to the Microbiology Department for HCV RNA detection using the pooling PCR technique. Initially, 10 pools were created, each containing 10 samples. Positive results were communicated to the ordering physician and the Hepatology Department, which scheduled patients for a high-resolution clinic visit, including FibroScan evaluation, prior to initiating treatment.
Results: Between January 1, 2024, and October 7, 2024, 1,300 samples with elevated ALT were analyzed, of which 25 (1.92%) tested positive for HCV RNA. The average age of patients was 67.60 ± 13.48 years, with no significant differences between positive and negative groups (p = 0.526). A significantly higher proportion of males were observed among HCV-positive patients compared to negatives (76.0% vs. 49.6%, p = 0.016). No significant differences were found in mean AST or ALT levels between positive and negative groups. FIB-4 scores were significantly lower in the positive group than in the negative group (4.17 ± 1.68 vs. 5.79 ± 12.30, p < 0.01), and this difference persisted across all age groups. Positive patients originated in similar proportions from primary and hospital care (1.9% in both settings).
Conclusion: Automating HCV RNA testing via pooling PCR for patients with elevated ALT demonstrated a 1.9% prevalence in this population. Pooling PCR is an efficient approach to support microelimination programs in patients with elevated ALT.

THU-232
Treatment of genotype 3 chronic hepatitis C infection: age reduces the efficacy of treatment with sofosbuvir and daclatasvir but the reduction is less marked with sofosbuvir and velpatasvir
Saeed Sadiq Hamid[1], Huma Qureshi[2], Asad Chaudhry[3], Saad Niaz[4], Beatrice Emmanouil[5], Hamzah Z. Farooq[6], Naheed Choudhry[6], Tesfa Alamneh[7], HepFreePak Consortium[6], Graham R. Foster[6]. *[1]Aga Khan University, Karachi, Pakistan; [2]Doctors Plaza, Karachi, Pakistan; [3]Chaudhry Hospital, Gujranwala, Pakistan; [4]Dow University, Karachi, Pakistan; [5]NHS England, London, United Kingdom; [6]QMUL, London, United Kingdom; [7]Bristol University, Bristol, United Kingdom*
Email: g.r.foster@qmul.ac.uk

Background and aims: Generic antiviral medicines give resource poor countries an opportunity to eliminate HCV infection. However, the more potent NS5A inhibitors (e.g. velpatasvir) are more expensive than daclatasvir, which is less effective in people infected with genotype 3, particularly in those with cirrhosis. Given that genotype 3 infection dominates in the Indian sub-continent, including Pakistan, a simple, inexpensive means of understanding which patient populations can be effectively treated with daclatasvir, rather than velpatasvir would be beneficial and allow consideration of treatment stratification. We explored the efficacy of sofosbuvir/daclatasvir and sofosbuvir/velpatasvir in people with genotype 3 HCV infection and examined the effect of age.
Method: HepFreePak is an observational study of the impact of sofosbuvir/daclatasvir treatment in Pakistan that examines response to current standard of care (sofosbuvir/daclatasvir for 12 weeks in people with an APRI score of <1.5 or 24 weeks in those with an APRI score of >1.5 or other features of cirrhosis). We examined SVR12 in people treated in this program. The NHSE registry records treatment outcomes and strategies for people in England treated for HCV and we examined registry SVR data for people with genotype 3 receiving sofosbuvir/velpatasvir therapy to compare with data from Pakistan.
Results: 2,214 people treated with sofosbuvir/daclatasvir in Pakistan had documented SVR12 outcomes. Overall SVR12 was 87.1% (87.8% in those without cirrhosis (1,575/1,793) and 85.3% (359/421) in those with cirrhosis). 14,475 people from the English treatment registry received sofosbuvir/velpatasvir and overall SVR12 was 90.5% (11,116/12,135) in those without cirrhosis (91.60%) and 1,920/2,254 (85.18%) in those with cirrhosis) not significantly different from sofosbuvir/daclatasvir, although we did find a significant difference in response rates in those with self-declared origin in Pakistan (851/901, 94.45%, p < 0.001). Assessment of cirrhosis in resource poor settings is difficult (APRI is unreliable and fibroscan/biopsy are unaffordable) so we examined age (a surrogate marker for advanced fibrosis and multi-morbidity). In sofosbuvir/daclatasvir treated people there was a reduction in efficacy with age – SVR in those aged <40 was 89.49%, falling to 82.78% in those >60 years old. In sofosbuvir/velpatasvir treated patients this reduction was not seen in those > 60 years (SVR12 in <40 was 91.33%, SVR12 in >60 was 89.35%,) but SVR12 rates dropped to (86.92%) in people aged 70 or more.
Conclusion: Efficacy with sofosbuvir/daclatasvir reduces by a modest amount with increasing age in Pakistan. This reduction is less marked but also seen in people with genotype 3 treated with sofosbuvir/velpatasvir in England. This likely reflects the higher rate of cirrhosis and co-morbidity in the elderly. These data show minimal benefits from switching to expensive sofosbuvir/velpatasvir in a young population and limited benefits in a subset of elderly people.

THU-237-YI
Effectiveness and outcomes of routine opt-out screening for hepatitis C in a UK emergency department
Samuel Hey[1], Deepika Thapa[1], Hannah Williams[1], Jane Knowles[1], Catriona Lane[1], Jamie Mellen[1], Sarah Essex[1], David Chadwick[1]. *[1]The James Cook University Hospital, Middlesbrough, United Kingdom*
Email: iddoc66@gmail.com

Background and aims: A national programme for Emergency Department (ED) opt-out blood-borne virus screening (BBV) started in England in 2022. Initially targeted at areas of high HIV incidence, universal screening for hepatitis B (HBV) and hepatitis C (HCV) was later implemented. Some areas of the UK have higher prevalence of HCV than HIV. James Cook University Hospital (JCUH) has implemented an ED opt-out screening programme for BBVs and syphilis. We sought to explore the demographic characteristics and outcomes of patients identified with HCV through our screening programme.

Method: All patients attending the ED at JCUH had routine testing for HIV, HCV IgG (with reflex HCV RNA if positive), hepatitis B surface antigen and syphilis serology unless they opted out. Positive HCV/HBV results were highlighted to the hepatitis team for MDT discussion, initiation of treatment and testing for sustained virological response (SVR) at the end of treatment. Data was collected using electronic patient records for demographic characteristics including deprivation index, number of ED attendances in the past year and outcomes of hepatitis C management.
Results: Over the study period 3,875 patients attending ED had samples tested for viral hepatitis. Of these 96 (2.5%) were positive for HCV and 4 (0.11%) were positive for HBV (2 known and 2 new diagnoses). The population of patients testing HCV positive in JCUH ED were predominantly male (73.8%) and white analysis (92.9%). They visited the ED more than the general ED population (mean ED visits 7.3 (SD 7.7) vs 3.4 (SD 4.6)). Logistic regression analysis showed significant associations between male sex (aOR 2.7 [95% CI, 1.41–5.16]), white ethnicity (aOR 2.9 [1.1–8.3]) and residence in highly deprived area (aOR 4.0 [1.9–7.3]) in those with HCV compared to general ED patients. 91 patients had sufficient documentation to assess their outcomes. 14 (15.4%) were newly diagnosed cases of HCV and have started treatment. 6 (6.6%) have completed treatment and have achieved SVR. 39 (42.9%) were previously treated under the hepatitis service and screening confirmed SVR. 2 (2.2%) patients had previously started treatment but were lost to follow up and had relapses confirmed and treatment restarted. 4 (4.2%) patients who had previously completed treatment with SVR were found to be re-infected and were re-treated. 2 (2.2%) patients had a false positive HCV IgG; for 30 patients (33%) testing HCV IgG+ it was not possible to trace them or perform confirmatory HCV RNA.
Conclusion: Opt-out BBV screening in EDs is an effective form of case-finding and engaging new cases of HCV, as well as those out of care, in hepatitis services. Additionally, it can confirm SVR or re-infection in patients previously treated by hepatitis services but out of care. This is particularly useful in a cohort of patients who may primarily seek healthcare via the ED with high levels of drug use and deprivation.

Email: wilhelm.laura@mh-hannover.de

Background and aims: Our findings demonstrate that there is a clinical impact of previous HBV in patients with SVR. Occult HBV infection should be considered a contributing factor for adverse disease outcomes underscoring the need for accurate and frequent clinical follow-up assessments.
Method: We analyzed clinical endpoints (≥3-point increase in MELD score, esophageal variceal bleeding, ascites, encephalopathy, liver transplantation, death, with/without HCC; HCC alone) in patients cured from HCV. Data were obtained from the German Hepatitis C Registry. Patients after organ transplantation, a history of HCC, or HIV co-infection were excluded. Statistical analyses included Kaplan-Meier curves to analyze the influence of HBV serological markers and logistic regression to identify predictors of clinical endpoints.
Results: A cohort of 6,355 patients fulfilled inclusion criteria, the median time of follow-up was 2.5 years (range 0.04–8.01). Serological evidence of previous HBV exposure was present in 1,889 patients (HBsAg negative/anti-HBc positive) while 157 patients had active hepatitis B (HBsAg positive). Univariate analysis identified age 50–70 years (odds ratio [OR], 2.04), sex (OR, 1.38), cirrhosis (OR, 4.88), anti-HBc-positivity (OR, 1.49) and diabetes mellitus (OR, 2.71) as risk factors for LRE. Multivariate analysis confirmed male sex, older age, cirrhosis and diabetes as independent risk factors.
Conclusion: The clinical impact of previous HBV in HCV patients after SVR requires further investigation. We suggest that occult HBV infection should be considered a contributing factor for potential adverse disease outcomes also in Caucasian patients.

THU-239

Long-term prognosis and changes in liver function after direct-acting antiviral treatment in decompensated cirrhotic patients with hepatitis C virus

Background and aims: The sustained virologic response (SVR) rate of decompensated cirrhotic patients with hepatitis C virus (HCV) is approximately 90% by direct-acting antiviral (DAA) treatment, and improvements in liver function and prognosis are expected in the short term. However, long-term changes in liver function and prognosis after DAA treatment in decompensated cirrhotic patients with HCV are unclear.
Method: A total of 206 decompensated cirrhotic patients with HCV treated with DAA between February 2019 and December 2021 at 31 Japanese hospitals were enrolled. Decompensated cirrhosis was defined as Child-Pugh class B or C at enrolment, or class A with a history of decompensating events. All patients were treated with 12 weeks of sofosbuvir and velpatasvir. SVR was defined as undetectable serum HCV-RNA at 12 or 24 weeks after the end of treatment (EOT). We assessed the changes in Child-Pugh class, and incidence rate of and factors associated with liver transplantation (LT)-free survival after DAA treatment.
Results: The median age was 68 years, 51% of the patients were male, and 40% had a history of hepatocellular carcinoma prior to DAA treatment. The percentages of patients with Child-Pugh class A, B, and C at baseline were 10%, 76%, and 14%, respectively. Seven patients had virologic failure, two had missing HCV-RNA levels, five died before SVR confirmation, four were lost to follow-up, and the SVR rate was 91.3%. The proportions of patients with Child-Pugh class A at baseline, EOT, 24 weeks after the EOT, 1 year after the EOT, 2 years after the EOT, 3 years after the EOT, 4 years after the EOT, and 5 years after the EOT were 10%, 32%, 45%, 44%, 48%, 40%, 35%, and 14%, respectively. During the 43.7 months after starting DAA, 43 patients died (30 died due to liver-related causes) and four underwent LT. The 5-year LT-free survival rate was 69.0%. In multivariate Cox proportional hazard analyses, virologic response and Child-Pugh class at 12 weeks after the EOT were significantly associated with LT-free survival. The 3-year LT-free survival rates in patients with SVR and virologic failure were 86.3% and 50%, respectively, and those in patients with Child-Pugh class A, B and C at 12 weeks after the EOT were 91.9%, 86.4% and 46.0%, respectively.
Conclusion: In decompensated cirrhotic patients with HCV treated with DAA, liver function improved up to 24 weeks after the EOT, but may deteriorate at 5 years after the EOT. The 5-year LT-free survival rate was 69.0%, and virologic response and Child-Pugh class at 12 weeks after the EOT were associated with LT-free survival.

Viral hepatitis C – Therapy and resistance

TOP-251

Efficacy and safety of Bemnifosbuvir and Ruzasvir after 8 weeks of treatment in patients with chronic hepatitis C virus (HCV) infection

Alina Jucov[1], Saeed Sadiq Hamid[2], Laura Iliescu[3], Elena Ermacicova[4], Shannan Lynch[5], Marina Majarian[5], Sergey Izmailyan[5], Qi Huang[5], Xiao-Jian Zhou[5], Keith Pietropaolo[5], Bruce Belanger[5], Maria Arantxa Horga[5], Janet Hammond[5]. *[1]Arensia Exploratory Medicine GmbH, Nicolae Testemitanu State University of Medicine and Pharmacy, Chisinau, Moldova; [2]Aga Khan University, Karachi, Pakistan; [3]Institutul Clinic Fundeni, Bucharest, Romania; [4]Arensia Exploratory Medicine GmbH, Chisinau, Moldova; [5]Atea Pharmaceuticals, Inc., Boston, United States*
Email: alina.jucov@arensia-em.com

Background and aims: Bemnifosbuvir (BEM) and ruzasvir (RZR) are potent pan-genotypic inhibitors of the HCV NS5B polymerase and NS5A protein, respectively. The combination of BEM+RZR demonstrated strong synergistic antiviral activity in vitro. A Phase 2 open-label study was conducted to evaluate the efficacy and safety of BEM +RZR administered for 8 weeks in HCV-infected patients (NCT05904470).
Method: In this single arm study, direct-acting antiviral (DAA) naïve patients with chronic HCV infection received 550 mg BEM + 180 mg RZR once daily (QD) for 8 weeks. Patients without cirrhosis or with compensated cirrhosis were eligible. Objectives included assessment of safety (adverse events [AEs], laboratory abnormalities, ECGs) and efficacy (primary endpoint of SVR12). The primary efficacy population was the pharmacokinetic and pill compliant per-protocol (PK/PC-PP) population, which included those who were study drug adherent; corroborated by pill counts and plasma drug levels adjudicated by an independent clinical pharmacologist. A secondary efficacy evaluable per-protocol (EE-PP) population included patients regardless of drug adherence. Plasma HCV RNA was measured using the Roche cobas® HCV quantitative nucleic acid test for use on the cobas® 6800/8800 systems, with a lower limit of quantitation (LLOQ) of 15 IU/mL.
Results: 275 patients were enrolled in the study with the following HCV genotypes: GT1 (n = 189), GT2 (n = 7), GT3 (n = 77) and GT4 (n = 2). 13% (37/275) had compensated cirrhosis. 88% (240/274 with sequence data) had NS5A resistance-associated substitutions (RASs) at baseline. SVR12 was 98% (208/213) in the primary PK/PC-PP population and 95% (242/256) in the EE-PP population, which included 17% (43/256) who were treatment non-adherent. In the PK/PC-PP, SVR12 was 99% (178/179) in non-cirrhotic patients, with high efficacy across genotypes. SVR12 was 88% (30/34) in cirrhotic patients, with all achieving HCV RNA <LLOQ by end of treatment Week 8. Five patients (4 cirrhotic and 1 non-cirrhotic) experienced virologic failure (post-treatment relapse) in the PK/PC-PP. There were no clear patterns with respect to baseline or treatment-emergent RAS. There were no drug-related serious adverse events (SAEs) or premature treatment discontinuations due to AEs. AEs were mostly mild/moderate, and no clinically significant trends in laboratory or ECG abnormalities were observed.
Conclusion: In this population with NS5A RAS high prevalence at baseline, high efficacy was observed, regardless of treatment adherence. These data support that non-cirrhotic patients can effectively be treated for 8 weeks with BEM+RZR, while cirrhotic patients will require 12 weeks of dosing to maximize efficacy. The regimen was well tolerated with no drug-related SAEs or treatment discontinuations due to AEs. Data support prompt Phase 3 development of this regimen.

Email: ccooper@toh.on.ca

Background and aims: Although glecaprevir/ pibrentasavir (G/P) is highly effective and has a well-documented safety profile, co-administration of G/P with concomitant medications that are substrates of P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), and organic anion transporting polypeptide (OATP) 1B1/3 may result in an increased plasma concentration of these drugs. While the effect of G/P on the exposures of these concomitant medications is expected to be small, herein we analyze the safety and tolerability of a subset of concomitant medications including antipsychotics (aripiprazole, quetiapine, risperidone, paliperidone, lurasidone, clozapine), cardiovascular agents (statins, beta-blockers, calcium-channel blockers, hypertensives) and opioids (fentanyl, oxycodone and hydrocodone).
Method: An integrated pooled analysis was carried out across 21 randomized controlled clinical trials in patients with chronic HCV genotype 1–6 infection with or without compensated cirrhosis receiving G/P for 8, 12 or 16 weeks.
Results: Among 6547 patients in this analysis, 136 patients were on antipsychotic medications, 219 received statins, 226 hypertensives, 94 beta-blockers and 44 calcium-channel blockers that had potential interactions with G/P; however, none of the patients experienced a treatment-related serious adverse event (SAE). Of the 133 patients on opioids with potential interactions, 1 patient experienced a treatment-related SAE. Treatment discontinuations due to any AEs were rare with only 1 discontinuation in the antipsychotics class, 3 in the cardiovascular class and 3 in the opioid class. High adherence (>94%, as defined by percentage of tablets taken versus expected) was observed across these specific concomitant medication classes. Sustained virologic response at 12 weeks post-treatment (SVR12) by modified intent-to-treat (ITT; excluding patients who failed to achieve SVR12 due to reasons other than virologic failure) was 99.2% when used concomitantly with antipsychotics, 99.5% with statins, 100% with beta-blockers, calcium channel blockers and antihypertensive agents and 96.9% with opioids.
Conclusion: This integrated pooled analysis demonstrated that G/P when concomitantly administered with medications such as those belonging to the antipsychotic (aripiprazole, quetiapine, risperidone, paliperidone, lurasidone, clozapine), cardiovascular (statins, beta-blockers, calcium-channel blockers, hypertensives) and opioid class, was safe, well tolerated, and demonstrated high efficacy and adherence.

The annual incidence of HCV RNA positivity detected by rapid on-site RT PCR doesn't decrease and remains relatively high over the last 3 years among drug users

Denis Ouzan[1], Camerlo Nicolas[2], Tallec Erwan[3], Dupuis Justine[3], Namouni Teresa[4], Blasi Bruno[5], Lebrun Maela[3], Stéphane Chevaliez[6,6]. [1]Institut Arnault Tzanck RHECCA, Nice, France; [2]Lou Passagin, Nice, France; [3]Bus 31/32, Marseille, France; [4]CSAPA Emergence, Nice, France; [5]CAARUD Lou Passagin, Nice, France; [6]Hôpital Henri Mondor, Creteil, France
Email: denis.ouzan@wanadoo.fr

Background and aims: The eradication of HCV infection requires the elimination of HCV infection among drug users (DU). However, the number of drug users screened and treated for hepatitis C remains low. Many DU are lost to follow-up after serological diagnosis. Measuring viral load by rapid PCR from capillary blood (Xpert® HCV Viral Load Finger stick) provides a result in 1 hour, and increases the percentage of PCR+ DU who could benefit from treatment. Measuring changes in the annual incidence of rapid PCR introduced since March 2021 was used to define the reduction in HCV infection in this population. The aim of this study was to measure the annual incidence of C viral load measured directly on site by rapid PCR, over the last 3 years in DU followed up in 3 addiction centers (CAARUD/CSAPA: 2 in Nice and 1 in Marseille).
Method: From March 1, 2021, the date of implementation of on-site rapid PCR, all HCV-positive DU (previously known or detected using a TROD targeting HCV, HBV and HIV) followed up in 3 CAARUD/CSAPA were offered rapid PCR (Xpert HCV Viral Load Finger stick), directly on-site. If the HCV PCR was positive, treatment was offered.
Results: From March 2021 to 2024, 413 DU were included: 183 in year 1, 120 in year 2 and 110 in year 3: 80% men with an average age of 43 years, 85 without social rights, 103 homeless, 198 declared having injected: heroin, crack, other, 175 having inhaled: cocaine, crack, other, and 235 excessive alcohol consumption, 185 were receiving substitution treatment. HCV serology was documented in 180 of the 183 DU followed up in year 1, in 118 of the 120 DU in year 2, and in 107 of the 110 DU in year 3. It was positive in 85 (47%), 60 (51%) and 49 (46%) of them respectively. 82/85 anti-HCV subjects in year 1, 59/60 in year 2 and 46/49 in year 3 agreed to undergo rapid PCR. The annual incidence of PCR positivity was 16%, 21% and 16% respectively in each of these 3 years. Anti-HCV treatment was initiated in 18 of 29 PCR+ DUs in year 1, in 12 of 25 PCR+ DUs in year 2 and in 12 of 18 PCR+ DUs in year 3. Six out of 11, 11 out of 13 and 4 out of 6 PCR+ DU in each of these 3 years could not be treated because they had no access to social rights.
Conclusion: The annual incidence of C viral load over a 3-year period from 2021 in DU followed up in 3 French addiction centers does not decrease and remains relatively high. While rapid on-site PCR almost always results in a virological diagnosis, in order to achieve viral eradication, it would be necessary to be able to treat all positive PCR drug users and in particular those who do not have access to social rights.

WED-270

A decade of hepatitis C virus management: insights from a large population-based cohort on treatment patterns, adherence, and outcomes

Fadi Abu Baker[1], Rawi Hazzan[2], Tarek Saadi[3], Randa Taher[1], Saif Abu Mouch[1], Oren Gal[1], Ariel Israel[4]. [1]Hillel Yaffe medical center, Hadera, Israel; [2]Haemek medical center, Afula, Israel; [3]Rambam Health Care Campus, Haifa, Israel; [4]Research Institute-Leumit Health Services, Tel Aviv, Israel
Email: Fa_fd@hotmail.com

Background and aims: The global effort to eradicate hepatitis C virus (HCV) has achieved remarkable progress; however, significant hurdles remain in achieving comprehensive elimination. This study leverages a large-scale, population-based cohort of HCV patients from Leumit Health Services (LHS) to derive insights into treatment patterns, adherence, and outcomes, aiming to improve patient care and inform public health strategies.
Method: A retrospective cohort study was conducted using the LHS database, encompassing data from 2015–2023. The cohort included HCV-infected patients identified by ICD-9-CM codes and serological confirmation. Extracted data included demographic, social, clinical, and laboratory variables, as well as fibrosis staging, treatment records, and therapeutic outcomes. Adherence was meticulously monitored through medication dispensation records and electronic visit logs, with outcomes analyzed across HCV subpopulations.
Results: A total of 1,380 patients were treated with direct-acting antivirals (DAAs). The cohort's mean age was 55.1 ± 7.7 years, with a male predominance (60.2%). HIV coinfection was present in 1.4% of patients, 1.3% had a concomitant diagnosis of hepatocellular carcinoma (HCC), and 44.7% were classified as having advanced fibrosis (F3–F4). Additionally, 22.9% of the cohort were obese, and 17.3% had diabetes. The rates of excessive alcohol use and intravenous drug use (IVDU) were 10.8% and 5.4%, respectively. Of the total cohort, 136 patients (9.9%) discontinued follow-up without post-treatment

HCV RNA testing. This subgroup exhibited significantly higher rates of moderate-to-low adherence (57.4% vs. 8.9%), minority ethnicity (5.9% vs. 3.7%), excessive alcohol consumption (22.8% vs. 9.5%), Alzheimer's disease (15.4% vs. 1.2%), and IVDU (17.6% vs. 4.0%) compared to those who completed follow-up. Among the 1,244 patients who completed follow-up, 94.5% achieved SVR. SVR rates were higher with newer pangenotypic regimens such as Epclusa (96.4%) and Maviret (96.2%) compared to older medications but markedly lower in DAA-experienced patients (85.0%) and those with moderate-to-low adherence (56.8%). Multivariate analysis identified major depressive disorder, dementia/Alzheimer's disease, IVDU, and excessive alcoholism as independent factors associated with moderate-to-low adherence.

Conclusion: This comprehensive decade-long analysis underscores critical insights into the management and outcomes of HCV in a large, population-based cohort, revealing that while high SVR rates are achievable, adherence remains a pivotal determinant of success. Our findings highlight specific subpopulations at risk for poor adherence and incomplete follow-up, emphasizing the need for targeted interventions to address these barriers in the pursuit of HCV eradication.

WED-271

8 weeks of Glecaprevir/Pibrentasvir is highly effective in patients with genotype 3 hepatitis C related cirrhosis, irrespective of the presence of clinically significant portal hypertension

Fiona Marra[1], Alison Boyle[1], Erica Peters[1], Helen Cairns[1], Rachael Swann[1], Janice Mcavennie[1], Elaine Reilly[1], Stephen Barclay[1].
[1]*NHS Greater Glasgow & Clyde, Glasgow, United Kingdom*
Email: fiona.marra3@nhs.scot

Background and aims: The final iteration of EASL HCV guidelines recommend that patients with genotype 3 (GT3) hepatitis C (HCV) infection and compensated cirrhosis may be treated with 8 weeks of Glecaprevir/Pibrentasvir (GP). This comes caveated that more data are needed to consolidate this recommendation. It highlights the lack of outcome data amongst those patients with cirrhosis and clinically significant portal hypertension (CSPH). We sought to examine the real world treatment outcomes of 8 weeks GP in patients with GT3 infection and cirrhosis, with or without CSPH.

Method: Patients with a diagnosis of GT3 HCV with cirrhosis, receiving 8 weeks of GP, were identified from a HCV database. Data on baseline demographics, opioid substitution therapy (OST), liver stiffness measurement (LSM), platelet count, Child's Pugh Score (CPS) and treatment outcomes were obtained. CSPH was ruled in according to Baveno criteria of LSM > = 25 kPa. SVR rates were calculated on an intention to treat (ITT) and a per protocol (PP) basis. PP analysis excluded those not achieving SVR due to missing blood tests or confirmed re-infection.

Results: 97 treatment episodes were identified, relating to 91 patients with cirrhosis and GT3 infection: median age 51 (7.7) years, 8 (8.2%) HIV co-infection, 29 (29.9%) on OST. 90 pre-treatment Fibroscans were performed, with a median LSM of 19.3 kPa (11.2 kPa), the remainder were diagnosed with cirrhosis based on imaging/clinical/laboratory characteristics. Median platelet count was 159 (93), and 42 (43.3%) of patients had platelets below 150. 3 (3.1%) patients had CPSB7/8, 32 (33%) CPSA6, and 62 (63/9%) CPSA5. 88/97 (90.7%) achieved ITT SVR. Excluding 5 patients with confirmed re-infection prior to SVR bloods and 3 with missing SVR data, the PP SVR was 87/88 (98.9%). 26 (26.9%) of patients had CSPH, amongst whom 25/26 (96.1%) achieved ITT SVR. Excluding one patient with missing SVR bloods, the PP SVR was 26/26 (100%). All 3 patients with CPSB7/8 cirrhosis, and 31/32 (96.9%) of CPSA6 achieved SVR. Excluding missing data the PP SVR was 31/31 (100%).

Conclusion: Our real-world data support the use of an 8-week regimen of GP amongst patients with GT3 infection and cirrhosis. In a cohort of patients where 1 in 4 patients had CSPH and 1 in 3 had CPS6 or higher, SVR rates remained excellent irrespective of these baseline factors.

Background and aims: The eight-week glecaprevir/pibrentasvir (GLE/PIB) regimen is recommended for treatment-naïve patients with chronic hepatitis C (CHC). With the Taiwanese government's goal of hepatitis C elimination by 2025, this study aimed to gather real-world evidence on 8-week GLE/PIB for treatment-naïve patients with chronic kidney disease (CKD) through the Taiwan Association for the Study of the Liver HCV Registry (TACR).
Method: Data of CHC patients treated with an 8-week regimen of GLE/PIB were extracted from the TACR, managed by the Taiwan Association for the Study of the Liver (TASL). Treatment efficacy, measured as sustained virologic response at 12 weeks post-treatment (SVR12), was evaluated in the modified intention-to-treat (mITT) population, excluding those lost to follow-up or without SVR12 data. The safety profile was analyzed in the intention-to-treat (ITT) population.
Results: Of 1,072 CHC patients with CKD received at least one dose of GLE/PIB (ITT population), 1,054 had SVR12 data available (mITT population). The overall mITT SVR12 rate was 99.6% (1,050/1,054), with rates of 99.7% in pre-ESRD patients (571/573) and 99.6% in early CKD patients (479/481). Among specific subgroups, SVR12 rates were 100% for genotype 3 infection (21/21) and dyslipidemia (48/48), 99.5% for diabetes (368/370), 99.4% for cardiovascular disease (328/330), 96.9% for those with a history of cerebral vascular accident (31/32), and 95.5% for people who injected drugs and those with HIV coinfection (21/22). Adverse events (AEs) occurred in 16.8% (181/1,072) of patients, with nine patients (0.8%) experiencing serious AEs and eleven events (1%) leading to permanent drug discontinuation, although only two events were deemed treatment-related. Additionally, the estimated glomerular filtration rate (eGFR) significantly increased from 39.2 ± 16.5 ml/min/1.73 m² to 41.9 ± 21.8 ml/min/1.73 m² ($P < 0.01$) overall, with notable improvements in early CKD patients (from 53.5 ± 4.3 ml/min/1.73 m² to 57.1 ± 13.5 ml/min/1.73 m², $P < 0.01$) and pre-ESRD patients (from 27.1 ± 12.8 ml/min/1.73 m² to 29.2 ± 19.1 ml/min/1.73 m², $P < 0.01$) at SVR12.
Conclusion: Eight-week GLE/PIB therapy was effective and well-tolerated in treatment-naïve patients with early CKD or pre-ESRD. Additionally, there was a significant improvement in renal function at SVR12 for both early CKD and pre-ESRD patients.

WED-273

Exploring a hepatitis C elimination model among ex-drug users in community drug rehabilitation centers insights from Guangdong, China

Hong Li[1], Jiajun Guan[1], Zhiming Liang[2], Xiaoqiao Chen[1], Liting Fan[1], Yong Huang[1], Yanling Ouyang[1], Long Tong[2], Tingshan He[1], Huixin Liang[1]. *[1]Shunde Hospital of Southern Medical University, Foshan City, Guangdong Province, China; [2]Foshan Shunde District Center for Disease Control and Prevention, Foshan City, Guangdong Province, China*
Email: holly202410@126.com

Background and aims: There is a lack of data on the prevalence of hepatitis C virus (HCV) infection among ex-drug users (EDUs) in community drug rehabilitation centers (CDRCs) in mainland China. This study aimed to evaluate the HCV burden in this population and develop a feasible screening-to-referral model. A micro-elimination approach tailored for EDUs was implemented and assessed in Shunde, Guangdong Province.
Method: This prospective observational study was initiated by Shunde Hospital of Southern Medical University, in collaboration with the Office of Drug Control (ODC), the Center for Disease Control (CDC), CDRCs. This novel four-party linkage model include EDUs recruitment, conducting surveys, performing HCV antibody (HCV-Ab) reflex testing, recalling HCV RNA-positive individuals for referral, initiating direct-acting antiviral (DAA) therapy, and treatment follow-up.
Results: Over one year, 11 free consultations across 10 CDRCs enrolled 246 EDUs, with a fingerstick HCV-Ab testing rate of 99.2% (244/246). The median age was 48 years (IQR: 43–52), with 91.8% male. Among participants, 79.1% had an education level of middle school or below, 25.4% lacked stable income, and 48.8% had a history of intravenous drug use. Additionally, 48.8% of participants had controlled attenuation parameter (CAP) values >238 dB/m, indicative of steatotic liver disease, while 39.3% and 14.3% were suspected of liver fibrosis and cirrhosis, respectively, based on liver stiffness measurements. The HCV-Ab positivity rate was 49.2% (120/244). Of these, 95.2% (119/125) underwent HCV RNA testing, with 84.3% (86/102) testing RNA-positive. The referral rate for RNA-positive individuals was 44.2% (38/86), and 89.5% (34/38) of referred individuals initiated DAA therapy. Among those treated, HCV genotype 6a was the most common (16/28), followed by genotypes 3b (6/28), 1b (4/28), and 3a (2/28), consistent with regional patterns. Currently, among those undergoing treatment, rapid virologic response (RVR) was achieved in 96.7% (29/30) of patients tested at week 4 of treatment.
Multivariable analysis revealed that low referral rates were significantly associated with poor disease awareness (86.8% vs. 43.8%, $p < 0.001$) and financial constraints (81.6% vs. 60.4%, $p = 0.034$). Overall, this approach increased the EDUs' HCV diagnosis rates from 46.4% (58/125) to 95.2% (119/125) and treatment rates from 22.4% (28/125) to 50.4% (63/125).
Conclusion: This study is the first to report an HCV elimination model for EDUs in CDRCs in mainland China. The HCV prevalence among EDUs is significantly higher than in the general population. The four-party linkage model effectively improved HCV screening, referral, and treatment rates. However, economic and awareness barriers remain significant challenges. Further optimization of the screening and referral process is essential to meet the WHO's HCV elimination targets.

WED-274

Real-world outcomes in patients with Voxilaprevir (VOX)/ Velpatasvir (VEL)/Sofosbuvir (SOF) treatment failure: a follow-up study

Email: julia.dietz@em.uni-frankfurt.de

Background and aims: The global elimination of hepatitis C virus (HCV) is feasible with highly effective direct-acting antivirals achieving SVR (sustained virological response) rates above 95%. However, eliminating HCV requires addressing difficult-to-treat patients, particularly those with failure to regimens like VOX/VEL/SOF. Data on the retreatment outcomes of VOX/VEL/SOF failures is limited. The characterization of these patients supports the development of salvage therapies to achieve SVR. This study aimed to follow-up patients with VOX/VEL/SOF failure and evaluated retreatment efficacies.
Method: We analyzed samples from 1420 patients included in the European Resistance Database (between the years 2014–2024) who experienced DAA treatment failure. NS3, NS5A, and NS5B regions were amplified and subjected to population sequencing, with resistance-associated substitutions (RASs) exhibiting >2-fold reduced DAA susceptibility being examined. Clinical and virological parameters were collected retrospectively.
Results: A total of 31 patients with virological failure to VOX/VEL/SOF retreatment were identified. Of those, 77% (24/31) patients were male, with a median age of 58.8 years. Cirrhosis was present in 58% (18/31) and 19% (6/31) had a history of hepatocellular carcinoma (HCC). 48% were infected with HCV genotype (GT) 3 (15/31), 27% (9/31) with GT1a and 21% (7/31) with GT1b. Most of the patients had been pre-treated with VEL/SOF (55%, 17/31), 13% (4/31) each had received G/P (glecaprevir/pibrentasvir) or GZR/EBR(grazoprevir/elbasvir) ± SOF and 10% (3/31) each had been pretreated with LDV (ledipasvir)/SOF or DCV(daclatasvir)/SOF. HCV RASs were uncommon in NS3 and NS5B after VOX/VEL/SOF failure. In contrast, NS5A RASs were detected in 80% of patients, with L31M and Y93H being most frequently observed, largely reflecting the pre-treatment resistance profile. During follow-up, 10% (3/31) of patients died from HCC, and 31% (10/31) did not receive salvage therapy due to HCC progression, being lost to follow-up, or return to home country. Salvage therapy was initiated in 58% of patients (18/31) and the most common administered regimen was G/P+SOF ± RBV (83%, 15/18), followed by VEL/SOF ± RBV (11%, 2/18) and one patient received G/P (6%, 1/18). SVR data were available for 94% (17/18) of patients. The modified intention-to-treat SVR-rate was 77% (13/17). Notably, two patients died from comorbidities during treatment, and one patient was lost to follow-up. Only one case of virological failure was observed after suboptimal retreatment with VEL/SOF+RBV, however, the patient finally achieved SVR after G/P+SOF+RBV.
Conclusion: The combination of G/P+SOF represents an effective third-line treatment option for difficult-to-treat patients, including those with cirrhosis, HCC, or HCV GT3 infection. These findings highlight the importance of tailored salvage therapy to achieve optimal outcomes in this challenging population.

Email: matthew.foxton@nhs.net

Background and aims: Despite the high efficacy of direct acting antiviral (DAA) therapies in the treatment of chronic hepatitis C (HCV) infection, retreatment (ReTx) is required, due to treatment failures, poor compliance with the treatment regimen and reinfection. Previously identified risk factors requiring ReTx include patients with rare genotypes, people who are actively injecting drugs (PWID) and men who have sex with men. We examined these factors and the outcomes of retreatment in London, with a population of 9.7 M.
Method: All patients undergoing DAA therapy in 18 centres in London from 09/13–03/24 were registered centrally. This data was interrogated for those patients undergoing 2 treatment episodes > 6 months apart. Demographics and outcomes were compared with all patients undergoing a single treatment episode over the same period. Reinfection was defined as new HCV RNA positivity following a confirmed sustained virological response (SVR12), or a differing genotype in any individual lost to follow-up following their first treatment episode without a confirmed SVR12. All treatment outcomes are expressed as intention to treat.
Results: There were 16471 patients treated with DAA therapy, with ReTx occurring in 342 patients having 2 treatment episodes (2.1%) and 12 patients had 3 treatment episodes. The retreated patients were younger, (53 years old vs 64 years), more likely to be male (81.6% vs 69.8%), have HIV (11.3% vs 9.8%) and PWID (30.2% vs 12.3%) or have alcohol as a contributing factor to their liver disease (18.1% vs 10.7%). Reinfection accounted for 145 patients (115 having had an SVR12 and 30 patients with a different genotype). 29 had HIV (20%), 49 were

current PWID (33.7%). In the remaining 209 patients, the outcomes of their first treatment episode were relapse, breakthrough and 'non-response' in 77. No outcome was documented in 19, with 81 lost-to-follow-up, incomplete treatment in 4 and other reasons in 28. In this cohort, 11 had HIV (5.3%; p < 0.001) and 58 were current PWID (27.8%, p = NS). The median time between treatments was 697 days (IQR 425–1173). The median time between retreatments in the reinfected was 946 days versus 600 days in the non-reinfected cohort. The overall SVR12 rate in the retreated group was 60.1%. The SVR12 rates in reinfected were 64.8% and 56.9% in non-reinfected (p = NS). Seventy nine patients were retreated with the same drug regimen. The SVR12 rate in this group was 26/79 (32.9%). Thirty three of these were reinfection (14 PWID and 11 with HIV). SVR rates were higher in those treated with voxilaprevir-containing regimens (n = 107, 73.8%) and differing non-voxilaprevir-containing regimens 1(n = 167, 55.7%).

Conclusion: The need for retreatment of HCV occurs more commonly in treatment failures rather than reinfection. The reinfection risk was higher in patients with HIV rather than current PWID. Retreatment with the same drug regimen was associated with worse outcomes. Factors associated with 1st treatment episode failures should be modified prior to retreatment if possible.

Background and aims: A previously published real-world data analysis demonstrated high effectiveness of sofosbuvir/velpatasvir (SOF/VEL) in > 6,000 HCV patients from 12 clinical cohorts across Australia, Canada, Europe & USA. Irrespective of age, male patients were more likely to have advanced fibrosis and infection with HCV GT 3, and median time to treatment initiation was numerically shorter in male patients across the age spectrum. The aim of this large real-world analysis was to evaluate characteristics and outcomes in an expanded pool of HCV patients treated with SOF/VEL across regions globally.

Method: A previously published real-world data analysis demonstrated high effectiveness of sofosbuvir/velpatasvir (SOF/VEL) in > 6,000 HCV patients from 12 clinical cohorts across Australia, Canada, Europe & USA. Irrespective of age, male patients were more likely to have advanced fibrosis and infection with HCV GT 3, and median time to treatment initiation was numerically shorter in male patients across the age spectrum. The aim of this large real-world analysis was to evaluate characteristics and outcomes in an expanded pool of HCV patients treated with SOF/VEL across regions globally.

Results: Overall, 7,027 patients were included, with a median age of 55 years [IQR 46–64], with patients over 50 y.o. representing two thirds (66%) of the overall population. Patients were mainly male (65%), with 72% females vs 62% males being > = 50 yo (p < 0.001). HIV/HCV coinfection was more prevalent in males (5.8% vs 2.1%, p < 0.001), as well as GT3 (35% vs 20%, p < 0.001), these differences were seen mostly in males > = 50 yo. TTI with the HCV therapy was shorter in females, with 40% treated in the first month, as compared to 25% of males, for both above and under 50 yo (p < 0.001). SVR was achieved in 98.9% of the treated population, with SVR rates ranging from 97.1% to 100% in all sites. SVR remained higher than 98% for males and females of all ages, and for patients with mental disorders or intravenous drug use. SVR remained higher than 97% in the concomitant presence of GT3 and a cirrhotic status.

Conclusion: Results on treatment effectiveness in diverse geographical regions did not differ from real world studies of patients in Western countries, reinforcing the effectiveness of pangenotypic/panfibrotic/pangeographic DAA therapy such as SOF/VEL and supporting the global applicability of HCV treatment guidelines.

WED-277

Efficacy and safety of glecaprevir/pibrentasvir in acute HCV participants with a history of prior infection(s)

Thomas Reiberger, Shweta Raina[1], Patrick Lank[1], Christoph Boesecke[2], Montserrat García-Retortillo[3], Linda Fredrick[1], Anne Welhaven[1], John Marcinak[1], Dimitri Semizarov[1], Brian Conway[4], Patrick Ingiliz[5], Joseph Doyle[6], Massimo Puoti[7]. *[1]AbbVie Inc., North Chicago, United States; [2]Department of Medicine I, University of Bonn, Bonn, Germany; [3]Liver Unit, Hospital del Mar, Barcelona, Spain; [4]Vancouver Infectious Diseases Centre, Vancouver, Canada; [5]APHP Henri-Mondor University Hospital, INSERM U955, Créteil, France; [6]Department of Infectious Diseases, The Alfred and Monash University, Melbourne, Australia; [7]8School of Medicine University of Milano-Bicocca and Infectious Diseases Unit, ASST Grande Ospedale Metropolitano Niguarda, Milano, Italy*
Email: thomas.reiberger@meduniwien.ac.at

Background and aims: Reinfection is a major obstacle to hepatitis C virus (HCV) elimination, occurring mostly in people who inject drugs (PWIDs) and men who have sex with men (MSM), with reinfection rates of 4–30/100 person years and 7.3–15.2/100 person years (y), respectively. Oral, direct-acting antivirals (DAAs) such as the 8-week regimen of glecaprevir/pibrentasvir (G/P) are highly effective in curing acute or recently acquired and chronic HCV infection. Previously, high efficacy, safety and tolerability was confirmed in n = 286 acute HCV participants (AASLD 2024 abstract #5031). This analysis aims to confirm the efficacy and safety of G/P in persons with acute infection (AHC) with a history of prior HCV infection.

Method: A post-hoc analysis of safety, tolerability and efficacy of G/P was carried out in a subset of participants from a single-arm, prospective phase 3 study (NCT04903626) of adults with AHC and a history of prior HCV infection categorized by the number of prior HCV infections.

Results: Among 286 participants with AHC, 52 (18.2%) had ≥1 prior HCV infection: 32 had 1, 10 had 2, 6 had 3, 2 had 4, and 2 had 6 prior infections. A majority of the participants with prior infections had HCV/HIV-1 co-infection (92.3%), were MSMs (78.8%) or PWUDs (ongoing or history of illicit drug use, 69.2%) with a median age of 48.0 y (range 31–69). Risk behaviors for current AHC included unprotected sexual activity with multiple partners (59.6%), shared drug-injection equipment (28.8%), shared non-injection drug use equipment (19.2%). Treatment for prior HCV infections included IFN/PEG-IFN/RBV, G/P SOF/VEL or SOF-based regimens or other DAA-based regimens. Sustained virologic response at 12-weeks post-treatment (SVR12) rates in participants with one or more prior infections were 98.1% (ITT) and 100% (mITT: excludes participants who failed to achieve SVR12 due to reasons other than virologic failure). Safety demonstrated by treatment related (TR) adverse events (AEs) or serious AEs (SAEs) was similar between participants with ≥1 and no prior infections. In participants who had prior infections, TR-AEs

were reported in 9 participants (17.3%), with no TR-SAEs, no TR-AEs leading to G/P discontinuation, no deaths and only 1 AE-related treatment interruption. During treatment, none of the participants in the prior infection group experienced an elevation in alanine aminotransferase (ALT) ≥ Grade 2 or in total bilirubin ≥ Grade 3 that had worsened from their baseline grade, and non experienced ALT >3 × upper limit of normal (ULN) with total bilirubin >2 × ULN.
Conclusion: G/P is highly effective, safe, and tolerable when used for treating acute or recently acquired HCV regardless of a history of prior HCV infections. These data provide insight into the role of prior infections in the management of acute infections in populations critical for HCV elimination.

Pharmacokinetics of bemnifosbuvir in participants with hepatic impairment
Xiao-Jian Zhou[1], Thomas Marbury[2], Juan Rondon[3], William Smith[4], Maureen Montrond[1], Shannan Lynch[1], Keith Pietropaolo[1], Bruce Belanger[1], Maria Arantxa Horga[1], Janet Hammond[1]. *[1]Atea Pharmaceuticals, Inc., Boston, United States; [2]Orlando Clinical Research Center, Orlando, United States; [3]Clinical Pharmacology of Miami, LLC., Miami, United States; [4]Alliance for Multispecialty Research, LLC, Knoxville, United States*
Email: zhou.xj@ateapharma.com

Background and aims: Bemnifosbuvir (BEM, AT-527) is an oral double prodrug of a guanosine nucleotide analog with potent activity against coronaviruses and flaviviruses including hepatitis C virus (HCV). BEM in combination with ruzasvir (HCV NS5A inhibitor), is under clinical development for the treatment of chronic HCV infection. We report here results from a phase 1 study evaluating the effect of hepatic impairment (HI) on the pharmacokinetics (PK) of BEM (NCT05724693).
Method: HCV-negative participants with mild [Child-Pugh (CP) score 5–6, category A, N = 8], moderate [CP score 7–9, category B, N = 8], or severe [CP score 10–15, category C, N = 7] hepatic impairment, as well as healthy participants (N = 16) matched by gender, age (± 10 yrs) and body mass index (± 20%) were enrolled and received a single oral dose of 550 mg BEM under fasted conditions. Intensive PK sampling was performed over 120 h and plasma concentrations of BEM and metabolites were quantitated using validated bioanalytical methodologies. Plasma protein on BEM PK was determined at 0.5 h post dosing.
Results: Compared with the control group, maximum plasma concentration (Cmax) and area under the curve (AUC) of the parent BEM increased by approximately 30, 45 and 80% (Cmax), and 35, 50 and 160% (AUC) in participants with mild, moderate or severe HI, respectively. HI had reduced effects on the plasma exposure of AT-551, the L-alanyl intermediate metabolite (Cmax and AUC increased by up to approximately 35 and 60%, respectively), while had no effect on the plasma PK of AT-273, the inactive metabolite considered the surrogate of the active intracellular triphosphate of the drug. BEM was not highly bound to human plasma protein (about 80%) and the fraction unbound, ranging from ~20 to 27%, was not meaningfully affected by HI. There were few mild to moderate adverse events reported (in 3 of 39 subjects), with no safety patterns observed between HI and control groups.
Conclusion: BEM 550 mg was safe and well-tolerated in participants with impaired or normal hepatic function. Plasma exposures to the parent BEM, but not the metabolite AT-273, surrogate for the active triphosphate, increased as hepatic function worsened. These results provide PK support for dosing BEM 550 mg in HCV-infected participants with compensated or decompensated cirrhosis.

WED-279
No DDI between Bemnifosbuvir/Ruzasvir and Bictegravir/Emtricitabine/Tenofovir Alafenamide
Xiao-Jian Zhou[1], Gaetano Morelli[2], Maureen Montrond[1], Shannan Lynch[1], Keith Pietropaolo[1], Bruce Belanger[1], Maria Arantxa Horga[1], Janet Hammond[1]. *[1]Atea Pharmaceuticals, Inc., Boston, United States; [2]Altasciences, Montreal, Canada*
Email: zhou.xj@ateapharma.com

Background and aims: Bemnifosbuvir (BEM) and ruzasvir (RZR) are potent, pan-genotypic inhibitors of the HCV NS5B polymerase and NS5A protein, respectively. The combination of BEM 550 mg/RZR 180 mg once daily (QD) for 8 weeks was safe and achieved high SVR rates in the lead-in cohort (60 patients) of an ongoing Phase 2 study. We report clinical pharmacokinetic (PK) drug-drug interaction (DDI) results between BEM/RZR and co-formulated antiretroviral bictegravir (B) 50 mg/emtricitabine (FTC) 200 mg/tenofovir alafenamide (TAF) 25 mg (Biktarvy) in healthy subjects.
Method: Two groups of healthy male and female subjects (14/group) were enrolled. Group 1 received BEM/RZR QD alone from day 1 to day 7, with B/FTC/TAF QD added from day 8 to day 17, and then B/FTC/TAF QD alone from day 18 to day 24; Group 2 received B/FTC/TAF QD alone from day 1 to day 10, with BEM/RZR QD added from day 11 to day 17, and then BEM/RZR QD alone from day 18 to day 24. Dosing occurred on an empty stomach and PK samples were obtained over 24 h. Safety assessments included adverse events (AEs), vital signs, electrocardiograms (ECGs) and standard safety laboratory tests. Plasma samples were quantitated for all study drugs/metabolites using validated LC/MS-MS methodologies.
Results: Study regimens alone and in combination were well tolerated in healthy subjects with no discontinuations, serious AEs, clinically significant changes in vital signs or ECGs. Steady-state plasma PK of BEM, its metabolites, including the guanosine nucleoside AT-273 representing the active intracellular triphosphate, and RZR were not affected by co-administered B/FTC/TAF. Similarly, steady-state plasma PK of B and FTC were not affected by BEM/RZR. Plasma exposure of TAF and tenofovir was about 50% higher in the presence of BEM/RZR, which was not considered clinically significant.
Conclusion: BEM/RZR and B/FTC/TAF, alone and co-administered, were well tolerated in healthy subjects with no clinically relevant PK DDI. These results support the enrollment of HCV/HIV-co-infected subjects receiving B/FTC/TAF in BEM/RZR clinical trials.

WED-280
Pharmacokinetics of bemnifosbuvir in participants with renal impairment
Xiao-Jian Zhou[1], Gaetano Morelli[2], Jean-Philippe Lafrance[3], Maureen Montrond[1], Shannan Lynch[1], Keith Pietropaolo[1], Bruce Belanger[1], Maria Arantxa Horga[1], Janet Hammond[1]. *[1]Atea Pharmaceuticals, Inc., Boston, United States; [2]Altasciences, Montreal, Canada; [3]Centre de recherche de l'Hôpital Maisonneuve-Rosemont, Montreal, Canada*
Email: zhou.xj@ateapharma.com

Background and aims: Bemnifosbuvir (BEM) is an oral guanosine nucleotide prodrug with potent activity against coronaviruses and flaviviruses including hepatitis C virus (HCV). BEM in combination with ruzasvir (HCV NS5A inhibitor), is under clinical development for the treatment of HCV. We report here results from a phase 1 study evaluating the effect of renal impairment (RI) on the pharmacokinetics (PK) of BEM (NCT05618314).
Method: HCV-negative participants with mild [eGFR 60–<90 mL/min/1.73 m^2, N = 6], moderate [eGFR 30–<60, N = 6], severe [eGFR 15–<30, N = 6] renal impairment (RI), or end-stage renal disease (ESRD) requiring hemodialysis (N = 6), as well as healthy participants (N = 12) matched by gender, age (±10 yrs) and body mass index (±20%) were enrolled. Non-dialytic participants received a single oral dose of 550 mg BEM fasted. ESRD participants received a single dose of BEM 550 mg ~ 2 h prior to the start of a 4-h dialysis session, and a second

dose 15 days later, ~ 2 h after the completion of dialysis. Plasma and urine PK sampling were performed up to 120 h and concentrations of BEM and metabolites were quantitated using validated bioanalytical methodologies.

Results: Compared with control, plasma exposure to BEM was not affected by any degree of RI. BEM was not highly bound to human plasma protein (about 80%) and the fraction unbound, ranging from ~15 to 20%, was not meaningfully affected by RI. Plasma exposure to AT-551, the L-alanyl intermediate metabolite, was not affected by mild or moderate RI whereas its area under the curve (AUC) increased by ~110 and ~225% in the severe category and ESRD with post-dialysis dosing, respectively. The AUC of plasma AT-273, the inactive metabolite considered the surrogate of the active intracellular triphosphate of the drug, was similar between mild RI and control, but increased by ~100% and ~400% respectively in moderate and severe RI. In participants with ESRD, a 4-h dialysis removed (based on AUC) ~55% of AT-551 and 40% of AT-273 without affecting BEM. Cumulative urine excretion for BEM and metabolites was about 30% of dose and was similar between RI and normal. AT-273 exhibited high and renal function dependent renal clearance ranging from ~300 mL/min in mild RI and normal control to ~100 mL/min in severe RI. Reported adverse events (in 12 of 30 subjects) were generally mild, with no safety patterns observed between RI and control groups.

Conclusion: BEM 550 mg was safe and well-tolerated in participants with impaired or normal renal function. Plasma exposure to BEM was not affected by RI but increased with worsening renal function especially for the inactive nucleoside metabolite AT-273. The high renal clearance of AT-273 which exceeded GFR indicated the involvement of active transport in its renal elimination. Intermittent hemodialysis was effective in removing the BEM metabolites from circulation. These results provide PK support for dosing BEM 550 mg in HCV-infected participants with renal impairment.
