This journal and the individual contributions contained in it are protected under copyright, and the following terms and conditions apply to their use in addition to the terms of any Creative Commons or other user license that has been applied by the publisher and the European Association for the Study of the Liver to an individual article:

Photocopying: Single photocopies of single articles may be made for personal use as allowed by national copyright laws. Permission is not required for photocopying of articles published under the CC BY license nor for photocopying for non-commercial purposes in accordance with any other user license applied by the publisher and the European Association for the Study of the Liver. Permission of the publisher and the European Association for the Study of the Liver and payment of a fee is required for all other photocopying, including multiple or systematic copying, copying for advertising or promotional purposes, resale, and all forms of document delivery. Special rates are available for educational institutions that wish to make photocopies for non-profit educational classroom use.

Derivative Works: Users may reproduce tables of contents or prepare lists of articles including abstracts for internal circulation within their institutions or companies. Other than for articles published under the CC BY license, permission of the publisher and the European Association for the Study of the Liver is required for resale or distribution outside the subscribing institution or company. For any subscribed articles or articles published under a CC BY-NC-ND license, permission of the publisher and the European Association for the Study of the Liver is required for all other derivative works, including compilations and translations.

Storage or Usage: Except as outlined above or as set out in the relevant user license, no part of this publication may be reproduced, stored in a retrieval system or transmitted in any form or by any means, electronic, mechanical, photocopying, recording or otherwise, without prior written permission of the publisher and the European Association for the Study of the Liver.

Permissions: For information on how to seek permission visit www.elsevier.com/permissions.

Author rights: Author(s) may have additional rights in their articles as set out in their agreement with the publisher and the European Association for the Study of the Liver (more information at http://www.elsevier.com/authorsrights).

Notice: Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds or experiments described herein. Because of rapid advances in the medical sciences, in particular, independent verification of diagnoses and drug dosages should be made. To the fullest extent of the law, no responsibility is assumed by the publisher or the European Association for the Study of the Liver for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions or ideas contained in the material herein.

Although all advertising material is expected to conform to ethical (medical) standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claims made of it by its manufacturer.

Publication information: Journal of Hepatology (ISSN 0168-8278). For 2025, volumes 82 and 83 are scheduled for publication. Subscription prices are available upon request from the Publisher or from the Elsevier Customer Service Department nearest you or from this journal's website (http://www.elsevier.com/locate/jhep). Further information is available on this journal and other Elsevier products through Elsevier's website: (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Orders, claims, and journal inquiries: Please visit our Support Hub page https://service.elsevier.com for assistance.

Advertising information: Advertising orders and enquiries can be sent to: **USA, Canada and South America:** Elsevier Inc., 360 Park Avenue, Suite 800, New York, NY 10169-0901, USA; phone: (+1) (212) 989 5800. **Europe and ROW:** Robert Bayliss, Pharma Solutions, Elsevier Ltd., 125 London Wall, London EC2Y 5AS, UK; phone: (+44) 207 424 4454; e-mail: r.bayliss@elsevier.com.

Author enquiries: Visit the Elsevier Support Center (https://service.elsevier.com/app/home/supporthub/publishing) to find the answers you need. Here you will find everything from Frequently Asked Questions to ways to get in touch.
You can also check the status of your submitted article via https://service.elsevier.com/app/answers/detail/a_id/29155/ or find out when your accepted article will be published via https://service.elsevier.com/app/answers/detail/a_id/5981/.

Funding body agreements and policies: Elsevier has established agreements and developed policies to allow authors whose articles appear in journals published by Elsevier, to comply with potential manuscript archiving requirements as specified as conditions of their grant awards. To learn more about existing agreements and policies please visit http://www.elsevier.com/fundingbodies.

Special regulations for authors: Upon acceptance of an article by the journal, the author(s) will be asked to transfer copyright of the article to EASL. Transfer will ensure the widest possible dissemination of information.

Registration of Clinical Trials
The *Journal of Hepatology* endorses the policy of the WHO and the International Committee of Medical Journal Editors (ICMJE) on the registration of clinical trials. Therefore, any trial that starts recruiting on or after July 1, 2005 should be registered in a publicly owned, publicly accessible registry and should satisfy a minimal standard dataset. Trials that started recruiting before that date will be considered for publication if registered before September 13, 2005.
More detailed information regarding clinical trials and registration can be found in New Engl J Med 2004; 351:1250–1251 and New Engl J Med 2005; 352:2437–2438.

EASL DeepDive

Exploring Key Topics in Hepatology

Panel of 4 experts

Target audience: all healthcare professionals interested in liver diseases

EASL DeepDive is a free educational webinar series offering an in-depth exploration of specific topics in hepatology and liver research, ensuring that medical professionals stay updated on the latest developments and best practices in the field.

Goal

Deepen the knowledge of healthcare professionals on critical aspects of liver diseases.

Format

Live 60-min, interactive Q&A, free registration

Assessment

Quiz test pre and post webinar

Accreditation

1 EACCME® credit for live attendance

Access

On-demand content available on EASL Campus

Watch previous webinars

EASL CAMPUS

HEALTHY LIVERS HEALTHY LIVES

A global coalition for action across the clinical, public health and policy level

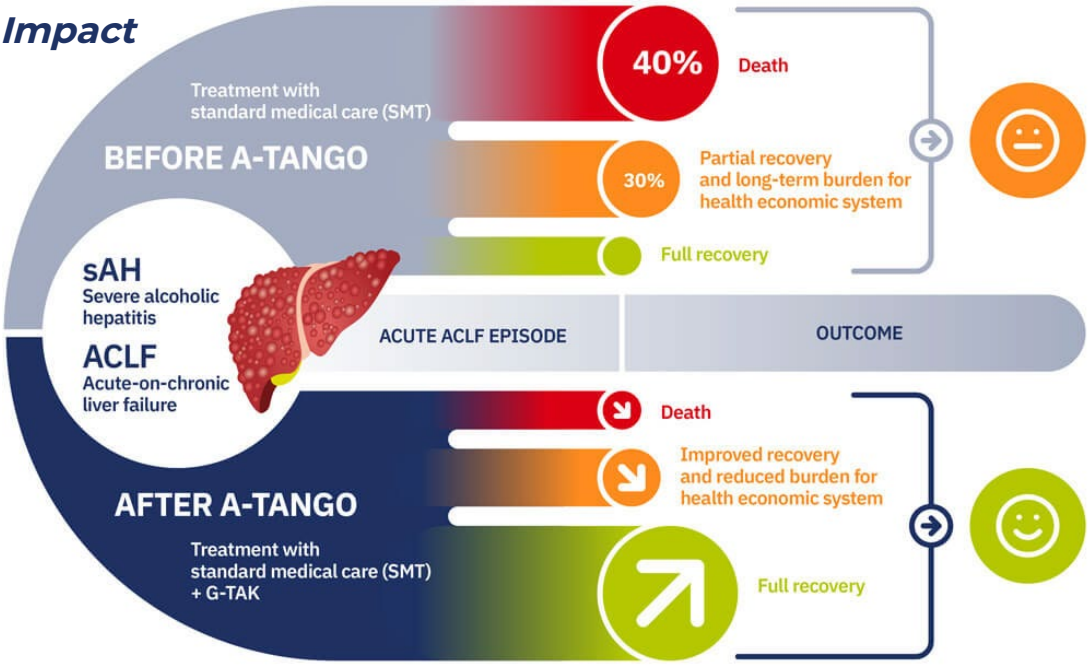
Our Vision

A world free of liver diseases

Our Mission

To mobilise action for liver diseases

Our Goal



Reducing the prevalence of liver diseases worldwide

READ MORE

A-TANGO

Featuring G-TAK, a novel combinatorial therapy for acute-on-chronic liver failure (ACLF)

Expected Impact

- More than **10 million people** suffer from **decompensated cirrhosis** worldwide.
- Effective treatment of ACLF is an urgent and unmet need.
- A-TANGO performs **Phase II clinical studies of G-TAK,** a novel and innovative therapeutic strategy that aims to **reduce inflammation** and **improve hepatocyte proliferation.**
- A-TANGO also strives to identify **reliable biomarkers** for better patient stratification and increased survival.

13 partners, one goal: Helping cirrhosis patients in Europe and beyond

kick-off
1st March 2021

project duration
5.0 years

grant amount
6.0 million €

a-tango.eu

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 945096.

DECISION

decision-for-liver.eu

DEcompensated CIrrhoSIs: identification of new cOmbiNatorial therapies based on systems approaches

Key facts

- **Project start**: 1st April 2020
- **Duration**: 5.5 years
- **Members**: 21 institutions from 10 European countries
- **EC funding**: € 6 million

AIM 1
Understanding at systems level

- Using **high-throughput technologies** to understand decompensated cirrhosis at systems level
- Re-analyzing standardized biobank samples from **2,200 patients** with decompensated cirrhosis by characterizing
  - **epigenetics »** manuscript in preparation
  - **transcriptomics »** presented at EASL 2025 and manuscript submitted
  - **metabolomics »** presented at EASL 2024 and manuscript submitted
  - **microRNA »** manuscript in preparation
  - **extracellular vesicles »** presented at EASL 2024

AIM 2
New combinatorial therapy

COMBAT-Trial: proof-of-concept, phase II randomized controlled clinical study

- **Goal**: Evaluate safety and tolerability of a novel combinatorial therapy (human albumin and enoxaparin) in patients with decompensated cirrhosis discharged from the hospital; comparison to standard medical treatment
- First patient enrolled in July 2024

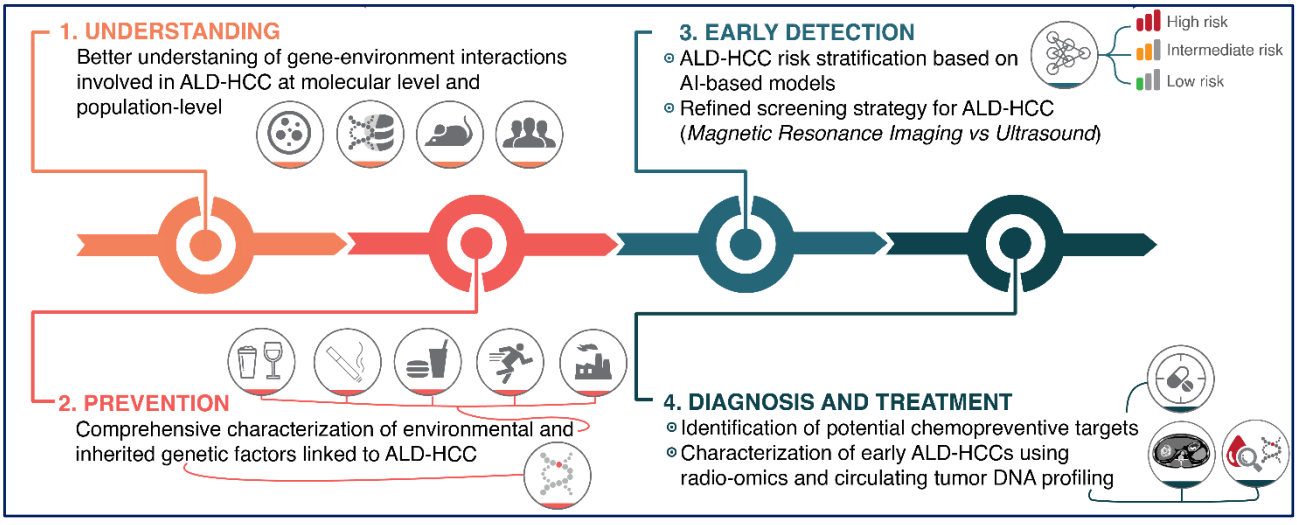
PROSPECT study: prospective, multicenter observational cohort study on post-discharge outcomes in patients with cirrhosis and AD

- **Goal**: Test the prognostic accuracy of novel biomarkers identified within DECISION
- First patient enrolled in March 2025

AIM 3
Pre-clinical models

- Existing rat models for acute decompensation of cirrhosis leading to ACLF lack full replication of human disease heterogeneity
  » We therefore aim to refine existing animal models
- Publications:
  - Development & characterization of **novel rodent ACLF models**
    » manuscript in preparation
  - Acceleration of an advanced **NASH model** by acute and toxic effects of Phenobarbital
    » published: *Kraus N, Uschner FE et al. Cells (2024)*

AIM 4
Prognostic and response tests



- Novel and robust **stratification method** identifies three clusters of patients with acute decompensation of cirrhosis (AD)
  » published: *Palomino-Echeverria S et al. J Transl Med (2024)* and *Ortega-Lagerreta A, Palomino-Echeverria S et al. PLOS Comp Bio (2024)*
- Potential tool for healthcare providers to enhance patient monitoring or preventative measures using existing electronic health record data and method could guide future clinical trial design
- Further results will be published soon

This project received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 847949.

GENIAL is a pioneering initiative targeting **alcohol-related liver cancer** (**ALD-HCC**). Our primary goal is to identify **genetic** and **environmental** factors contributing to ALD-HCC risk and unravel how their **interactions** drive alcohol-related liver carcinogenesis. By pinpointing individuals at risk, GENIAL will pave the way for innovative **prevention strategies** and potential **chemopreventive targets** to tackle this devastating disease. Moreover, GENIAL is dedicated to **educating** and empowering the entire EU community with vital knowledge for effective disease prevention and **early detection**.

The GENIAL Project is funded by the European Union within the Horizon Europe programme under grant agreement No 101096312.

AIM LIVER

A biomarker-based platform for early diagnosis of chronic liver disease to enable personalized therapy

Academia and industry are collaborating on one of the largest project's ever in the field of liver diseases

AIM

To design and validate an AI-powered screening platform using biomarkers for the early diagnosis of liver diseases in the general population, and to establish connections to care through personalized interventions

LIVER SCREEN

Funded by the European Union

Screening for liver fibrosis population-based study across European Countries

A project that will change the paradigm of diagnosis of chronic liver diseases

AIM:

To assess the prevalence of liver fibrosis in the general population using Transient Elastography, with the objective of establishing criteria for screening for liver fibrosis in the population.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 847989

MICROBiome-based biomarkers to PREDICT decompensation of liver cirrhosis and treatment response

MICROB-PREDICT

Project duration
6 1/4 years

Start
01 January 2019

Follow us:

@MicrobPredict
MICROB-PREDICT
@microb-predict.bsky.social

Grant amount
15 million €

10 Countries
22 Partners

www.microb-predict.eu

MICROB-PREDICT investigates

the human microbiome to identify predictors and mechanisms associated with the development of decompensation of cirrhosis and progression to acute-on-chronic liver failure (ACLF).

- → New microbiome-based tests for better stratification of cirrhosis patients
- → Personalized prediction and prevention of decompensation and ACLF
- → Clinical trial to predict response to treatment
- → Modern, effective nanobiosensors as clinical tools with improved specificity
- → More personalized treatment
- → Increased survival times
- → Decreased costs for the health systems

Abstract GS-001 is under embargo until Wednesday 7 May 2025, 08:00 CET, after which this abstract will be made publicly available on the congress website and will be released for publication in the supplement issue of the *Journal of Hepatology*.
Industry must not issue press releases – even under embargo – covering the data contained in abstracts selected to be highlighted during official EASL Press Office activities or in official EASL Press Office materials until the individual embargo for each data set lifts. Media must not issue coverage of the data contained in abstracts selected to be highlighted during official EASL Press Office activities

or in official EASL Press Office materials until the individual embargo for each data set lifts.
Journalists, industry, investigators and/or study sponsors must abide by the embargo times set by EASL. Violation of the embargo will be taken seriously. Individuals and/or sponsors who violate EASL's embargo policy may face sanctions relating to current and future abstract submissions, presentations and visibility at EASL Congresses. The EASL Governing Board is at liberty to ban attendance and/or retract data.
Copyright for abstracts (both oral and poster) on the website and as made available during The EASL Congress 2025 resides with the respective authors. No reproduction, re-use or transcription for any commercial purpose or use of the content is permitted without the written permission of the authors. Permission for re-use must be obtained directly from the authors.

A palliative care approach for cirrhosis patient: feasibility and preliminary results from a prospective Danish multi-center study

Birgitte Jacobsen[1], Mette Lauridsen[1], Ane Soegaard Teisner[2], Marie Louise Hamberg[2], Nina Kimer[3], Malene Barfod O'Connell[3], Palle Bager[4], Janni Mendahl[2], Kristoffer Marsaa[5], Mai-Britt Guldin[6], Lea Ladegaard Grønkjær[1]. *[1]University Hospital of Southern Denmark, Esbjerg, Denmark; [2]Herlev Hospital, Herlev, Denmark; [3]Hvidovre Hospital, Hvidovre, Denmark; [4]Aarhus University Hospital, Aarhus, Denmark; [5]Steno Diabetes Center Copenhagen, Herlev, Denmark; [6]Aarhus University, Aarhus, Denmark*
Email: birgitte.gade.jacobsen@rsyd.dk

Background and aims: Cirrhosis is linked to a high symptom burden, hospitalization and mortality, and reduced quality of life for patients and relatives. Despite these challenges, palliative care remains underutilized due to stigma, misperceptions, and a healthcare focus on curative treatment. While evidence suggests palliative care benefit other patient groups, more research is needed to develop and evaluate interventions. This study aimed to assess the feasibility, acceptability, and preliminary outcomes of a palliative care intervention for patients with cirrhosis and their relatives.

Method: This study was a prospective multicenter study including four Danish hospitals. The intervention was developed by a multidisciplinary team comprising hepatologists, specialized nurses, researchers from the participating centers, palliative care specialists, and a psychologist. The intervention included (1) education and training of all healthcare professionals involved and monthly online supervision sessions with palliative care specialists, and (2) a palliative care intervention based on advance care planning and the actions taken as part of the conversations. The goal was to identify, assess, and treat mental, physical, social, or spiritual symptoms and problems. The effects were measured in interviews and with the PRO PAL symptom burden questionnaire, the hospital anxiety and depression scale (HADS), the Euro Quality of Life (EQ-5D-5L), and the Zarit Burden (ZCB). Feasibility across eight general areas (acceptability, demand, implementation, practicality, adaption, integration, expansion, limited-efficacy testing) was evaluated using a mixed-methods approach.
Results: Sixty-eight patients (75% male, mean age 65 years, 88% with alcohol-related etiology, MELD 13) were invited to participate. Of these, 42 agreed, 25 asked a relative to join, and 12 completed a 6-month follow-up. Patients and relatives found the intervention positive and informative and that it provided clarity regarding disease progression and emotional support at qualitative assessments and provided. The patient-reported outcomes (PRO PAL, HADS, EQ-5D-5L) remained unchanged, but the caregiver burden decreased (ZCB score 25 vs.16). Healthcare professionals reported that the collaboration and supervision were beneficial and deemed the intervention feasible. The education and training program was well received. The patient who declined to participate lacked resources or felt no need for the intervention.
Conclusion: This study demonstrates that a structured palliative care intervention for patients with cirrhosis and their relatives is feasible and acceptable, and preliminary results demonstrate a significant improvement in caregiver burden. Results will inform adjustments and a larger evaluation study with 240 patients, including the effects on healthcare utilization.

OS-002-YI

Identifying training needs to improve detection and management of metabolic dysfunction-associated steatotic liver disease in primary care settings: a qualitative interview study with healthcare professionals

Hollie Smith[1], Rebecca Livingston[2], Helen Jarvis[3,4], Yusuf Soni[5], Stuart McPherson[6,7,8], Leah Avery[1,8], Kate Hallsworth[6,7,8]. *[1]Centre for Rehabilitation, School of Health and Life Sciences, Teesside University, Middlesborough, United Kingdom; [2]School of Social Sciences, Humanities and Law, Teesside University, Middlesborough, United Kingdom; [3]Population and Health Sciences Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [4]The Bellingham Practice, Bellingham, Northumberland, United Kingdom; [5]Hartlepool and Stockton Health GP Federation, Stockton-on-Tees, United Kingdom; [6]NIHR Newcastle Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom; [7]Liver Unit, Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom; [8]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom*
Email: h.a.smith@tees.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent liver disease globally. People with MASLD have an increased risk of overall mortality when compared to the general population, however MASLD often goes undetected until it reaches an advanced stage. Raising awareness and motivation of healthcare professionals (HCPs) to detect MASLD, and arming them with the appropriate knowledge and skills to manage it is crucial. Due to high prevalence and common risk factors, primary care is ideally placed to identify and manage the majority of patients

with MASLD. However, previous research suggests that many primary HCPs do not have a full understanding of what MASLD is, how it can be detected, or how it should be managed. The aim of this study was to identify the training needs of primary HCPs for improving detection and management of MASLD.
Method: A qualitative interview study was conducted with primary HCPs in the Tees Valley region (UK). Interviews were audio-recorded, transcribed verbatim and data were thematically analysed using the Theoretical Domains Framework (TDF).
Results: 25 primary HCPs were recruited from 16 practices across Teesside (IMD deciles 1–7) between March and June 2024. The mean age of participants was 41 (± 8 years) and 15/25 participants were female. Participants were GPs (n = 16), practice nurses (n = 6), and clinical pharmacists (n = 3). Mean length of time in post was 4 years (range: 1 month-20 years). Preliminary themes generated from the data represent barriers and/or enablers to detecting and managing MASLD in primary care. Themes concerning detection (n = 10) included: 'understanding MASLD aetiology and symptomatology', including distinguishing MASLD from other diseases; 'assigning roles and responsibilities to MASLD detection and escalation'; and 'detection leads to a 'Pandora's Box' of unanswered questions' - i.e., lack of management approaches reduced motivation to detect MASLD. Themes concerning management (n = 9) included: 'competence in providing MASLD-specific lifestyle advice'; 'establishing clear referral pathways to secondary care'; and 'believing that MASLD is reversible' - i.e., motivation for MASLD management is evident when primary HCPs are aware that MASLD can be managed or reversed.
Conclusion: Several barriers and enablers to the detection and management of MASLD in primary care were identified. Findings suggest that training targeting the knowledge, skills and beliefs of primary HCPs could facilitate increased detection and management of MASLD. However, it was highlighted that specific pathways (i.e. clarification of HCP roles in MASLD detection and management; streamlining care pathways between primary and secondary care) and resources (i.e. MASLD-specific management options) should also be addressed to facilitate integration of detection and management of MASLD in primary care.

OS-003
A quality improvement project: multidisciplinary nutrition approach to improve the nutritional and functional status of pre-liver transplant patients

Valerie Goh[1], Hooi Yen Tan[1], Wei Yee Wong[1], Mark Muthiah[1], Brenda Kok[1], Diana Teh[1], Eunice Tan[1]. *[1]National University Hospital - Singapore, Singapore, Singapore*
Email: valerie_xh_goh@nuhs.edu.sg

Background and aims: Pre-liver transplant patients are at high risk of malnutrition and its associated complications, which can lead to increased hospitalisation and elevated infection rates. The progressive nature of liver diseases exacerbates malnutrition, potentially impacting eligibility for transplant. The aim of this quality improvement project is to improve nutrition and functional status of chronic liver disease patients planned for liver transplant using a multidisciplinary approach.
Method: Participants who were potential candidates for liver transplant were recruited over two distinct periods in inpatient and outpatient settings (Cohort 1: 2020–2021 and Cohort 2: 2022–2023). Standard care was provided to participants in Cohort 1. Key factors contributing to the decline in nutritional and functional status of pre-liver transplant patients were identified using data from Cohort 1 and illustrated with an Ishikawa diagram, which mapped potential causes and areas for improvement. A multidisciplinary approach was piloted in Cohort 2, involving a structured nutrition protocol that included the use of a nutrition screening tool at outpatient clinic, closer follow-up and timely referrals to a dietitian, nutrition education and collaboration with physiotherapists to improve functional status. Parameters measured include mid-arm muscle circumference, handgrip strength, and liver frailty index (LFI) at initial assessment, 3 months, and 6 months to monitor changes over time.
Results: 24 patients in Cohort 1 and 17 patients in Cohort 2. Comparing Cohort 2 to Cohort 1, we found an increase in mid-arm muscle circumference and handgrip strength at 6 months in Cohort 2 by 40% and 22%, respectively. Participants in Cohort 2 showed a significant increase in handgrip strength (3.2 kg ± 1.2, p = 0.0141) and mid-arm muscle circumference (9.9 mm ± 3.4, p = 0.0105) when measured at 6 months against initial assessment. We found a reduction in prevalence in frailty from 18.5% to 4.3% using the LFI after multidisciplinary intervention in Cohort 2. The proportion of participants in robust status increased by 5.2% in Cohort 2, demonstrating a significant improvement in overall functional status following intervention.
Conclusion: These findings demonstrate that a multidisciplinary approach combined with a structured nutrition protocol led to significant improvements in both nutritional and functional status among pre-liver transplant patients. However, larger-scale studies are needed to explore additional clinical outcomes in both pre- and post-transplant patients.

OS-004
Development and implementation of an innovative allied health professional (AHP)-led group education programme for patients with metabolic dysfunction-associated steatotic liver disease (MASLD)

Thomas Crame[1], Rachel Howarth[1], Elizabeth Johnstone[1], Stuart McPherson[1,2,3], Kate Hallsworth[1,2,3]. *[1]Liver Unit, The Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom; [2]NIHR Newcastle Biomedical Research Centre, The Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom; [3]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle Upon Tyne, United Kingdom*
Email: thomas.crame1@nhs.net

Background and aims: MASLD affects up to 30% of adults worldwide and is a common cause of cirrhosis, HCC and liver failure. With few pharmacological agents available, lifestyle changes are the cornerstone of treatment. Clinical guidelines recommend structured education programmes however these are uncommon in practice. We developed and implemented an AHP-led structured group education programme for patients with MASLD. We aimed to assess patient engagement and experiences of attending the groups and evaluate whether attendance led to weight loss.
Method: Patients with MASLD attending hepatology clinics at a tertiary liver unit were offered 3x 1-hour sessions either face-to-face (F2F) or online. Sessions were designed/delivered by Dietitians and Physiotherapists specialising in MASLD. Content included what MASLD is, how lifestyle change can improve outcomes and signposting to appropriate resources. Patient Related Experience Measures (PREMs) and clinical outcomes were collected.
Results: 152 patients were invited to attend the groups between Oct 23 – Oct 24. 21/152 self-referred, and a further 80/152 agreed to attend after a follow-up call. 51/152 declined, mainly due to session timing. 68/152 attended (46 F2F; 22 online) within the study period (mean age 60y; 54% male; BMI 38 kg/m2). To date, mean weight change at 3-months was −3.8 kg (−3.6%); 42% achieved >3% weight loss, 33% >5% and 11%>10%. Patients attending F2F achieved mean weight loss −2.7 kg (−2.8%) (−11.3 to +3.8 kg); patients attending online achieved −6.8 kg (−5.2%) (−23.0 to +0.5 kg). PREMs reported overall satisfaction with the programme (mean score: 9.6/10); the sessions provided "more information than a Doctor's consultation can". Patients were likely to recommend the "informative and motivational" course to friends/family (mean score: 9.9/10) and it helped patients "to think more about what I eat and to do more exercise little by little.".

Conclusion: The group education programme was feasible to deliver and well received by patients. On average attendees lost weight which will likely improve liver health and reduce cardiometabolic risk. Most patients invited to the programme booked to attend; a minority of patients self-referred, however the addition of a follow-up call significantly increased uptake highlighting the crucial role of administrative support in facilitating patients joining the groups. Offering additional sessions, particularly outside of working hours, may improve accessibility.

Liver tumours: Experimental and Pathophysiology

OS-005-YI

Crosstalk between senescent cancer cells and the TME reveals myeloid cell centric therapeutic targets in HCC

Efi Tsouri[1], Jing Xu[2], Masami Ando Kuri[1], Leila Akkari[1], Serena Vegna[1].
[1]*The Netherlands Cancer Institute, Oncode Institute, Amsterdam, Netherlands;* [2]*Sun Yat-sen University Cancer Center, Guangzhou, China*
Email: e.tsouri@nki.nl

Background and aims: The liver tumor microenvironment (TME) plays a key role in hepatocellular carcinoma (HCC), representing an attractive therapeutic target. Senescence-inducing therapy (SIT) can be enforced in tumor cells to restrict their proliferative capacity, while promoting non-cell autonomous effects on the TME. Senescent cancer cells (SCCs) reprogram the TME through their senescence-associated secretory phenotype (SASP) and expression of immuno-modulatory surface receptors. XL413-mediated CDC7 inhibition is a novel senescence-inducing therapy (SIT) in *Tp53*-deficient HCC, promoting tumor-associated macrophage (TAM) expansion in the TME. In this project, we aim to characterize the interaction between SCCs and the liver TME to combine SIT with immunomodulation strategies in HCC.
Method: Through multi-omic analyses encompassing scRNAseq, flow cytometry and multiplex immunofluorescence we have characterized the changes in SIT-treated *Tp53*-deficient HCC tumors. To gain insight on the spatial niches in SIT-treated tumors and characterize the interactions between SCCs and TAMs, we have performed visium spatial transcriptomics. Our findings have been further validated in *in vivo* mouse studies where we have explored the combination of SIT and targeted immunomodulation in *Tp53*-deficient HCC.
Results: The anti-tumorigenic functions of CDC7i *in vivo* encompassed a dynamic induction of senescence in cancer cells associated with a spatiotemporal reorganization of the surrounding microenvironment. These effects involve the structural and functional remodelling of the tumor vasculature accompanied by an expansion of chronically exhausted T cells and TAMs. In SIT-treated tumors, we detected TAM subsets with antigen-presenting, angiogenic and immunosuppressive features. Interestingly, combining CDC7i and pan-macrophage depletion prolonged HCC mouse survival while changing the tumor vasculature. Importantly, spatial transcriptomic analysis highlighted the heterogeneity of senescent cancer cells *in vivo* which correlated with a distinct spatial organization of TAM clusters. Indeed, different senescent cancer cell subsets localized in distinct tumor niches and displayed unique inflammatory profiles and interactions with TAM populations.
Conclusion: These data highlight, for the first time, the importance of distinct TAM clusters in shaping the senescence-educated liver TME, while offering new myeloid centric targets to enhance SIT efficacy.

OS-006

Oleic acid-PPARgamma-FATP1 loop fuels cholangiocarcinoma colonization in lymph node metastases through lipid metabolic reprogramming

Xiuxian Li[1], Zhixiao Song[1], Yanyang Kuang[1], Honghua Zhang[1], Chao Liu[1]. [1]*Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, China*
Email: lixx258@mail2.sysu.edu.cn

Background and aims: Lymph node metastasis is one of the most significant risk factors for patients with cholangiocarcinoma (CCA), but the mechanisms underlying the colonization of metastatic cancer cells within the lymph nodes, which are rich in fatty acids, remain unclear. We aim to elucidate the mechanisms by which CCA cells survive and colonize lymph nodes, and to identify and validate potential therapeutic targets.
Method: Metabolomics and single-cell RNA sequencing (scRNA-seq) were employed to identify differential metabolites and pathways between the primary lesions and paired lymph node metastases of CCA, characterizing the specific metabolic reprogramming that occurs within the lymph node microenvironment of CCA. Orthotopic CCA and lymph node CCA inoculation mouse models were constructed to investigate the progression of CCA in both primary and metastatic lesions. Proteomics was utilized to identify key targets that fuel CCA colonization in lymph node microenvironment. ChIP-qPCR, dual-luciferase reporter assays, and fatty acid oxidation (FAO) assays were applied to explore the mechanisms by which the identified target promotes CCA colonization in lymph node microenvironment, whose therapeutic vulnerability was validated in patient-derived organoids and mouse models.
Results: Our metabolomic and scRNA-seq analyses revealed an enrichment of oleic acid (OA) in lymph node metastases of CCA and the activated peroxisome proliferator-activated receptor gamma (PPARgamma)-regulated lipid metabolism reprogramming in CCA cells within lymph node microenvironment. Differential proteomic analysis of in vivo models illustrated the sequential up-regulation of long-chain fatty acid transport protein 1(FATP1) in CCA cells in lymph node microenvironment in a time-dependent manner. Immunohistochemical analysis identified the higher expression of FATP1 in lymph node metastases from CCA patients, which correlates with worse prognosis and further progression. Cellular experiments, patient-derived organoids, and lymph node CCA inoculation mouse models demonstrated that OA facilitates lipid accumulation and FAO in CCA cells, thereby promoting cell proliferation in a FATP1-dependent manner. Dual-luciferase reporter assays and ChIP-qPCR confirmed the transcriptional regulation of PPARgamma, which is activated in CCA cells within the lymph node microenvironment, on the expression of FATP1. Furthermore, both in vitro and in vivo models showed that knockdown of FATP1 or treatment with its specific inhibitor, FATP1-IN-1, significantly inhibits lipid metabolism in CCA, reducing its proliferative and colonizing capabilities within the lymph node microenvironment.
Conclusion: Our findings reveal the role of the oleic acid-PPARgamma-FATP1 positive feedback loop in fueling CCA colonization in lymph nodes, where FATP1 is a promising therapeutic target for alleviating CCA lymph node metastatic burden and reducing further progression.

Email: patricia.aspichueta@ehu.eus

Background and aims: Cholangiocarcinoma (CCA) comprises a heterogeneous group of biliary tumors with a poor prognosis, exhibiting an increasing incidence and mortality over the past decades. It is often diagnosed at an advanced stage, typically with metastasis, limiting access to curative-intent surgery. Metabolic reprogramming is a hallmark of cancer, and lipid metabolism plays an important role in cholangiocarcinogenesis. The cell cycle regulators E2F1 and E2F2 have been identified as modulators of energy metabolism in hepatocellular carcinoma, but their role in CCA remains unknown. This study aimed to: 1) investigate whether E2F1 and E2F2, and/or their targets, are involved in the development of CCA, and 2) determine whether they contribute to the reprogramming of lipid metabolism associated with CCA progression.
Method: Gene expression data from two CCA patient cohorts were analyzed, along with human CCA cell lines and primary cultures of normal human cholangiocytes (NHC). The *sleeping beauty* technique was employed to generate murine models of CCA (hepatic overexpression of *Akt1*/NOTCH1 intracellular cytoplasmic domain (*Nicd1*), *Akt1/Yap*, or of *Akt1/Taz*) in WT, *E2f1*$^{-/-}$, and *E2f2*$^{-/-}$ mice. The impact of pharmacological inhibition of E2F activity or its targets on cell and tumor viability, proliferation, mitochondrial respiration, and fatty acid oxidation was evaluated.
Results: *E2F1* and *E2F2* levels were elevated in human CCA samples and in cellular and murine models of CCA. Both *E2f1*$^{-/-}$ and *E2f2*$^{-/-}$ mice developed liver lesions similarly to WT mice when overexpressing *Akt1/Nicd1*. However, *E2f1*$^{-/-}$ mice were protected against the development of CCAs induced by the Hippo signaling (*Akt1/Yap* and *Akt1/Taz*), whereas no protection was observed in *E2f2*$^{-/-}$ mice. YAP and TAZ, coactivators of the Hippo pathway, interact with E2F1 to drive the transcription of several target genes, including MCM proteins, which are helicases involved in DNA replication. *Mcm2-7* expression was decreased in the liver of *E2f1*$^{-/-}$ mice resistant to CCA induction by *Akt1/Yap* or *Akt1/Taz*, compared to WT or *E2f2*$^{-/-}$mice. Furthermore, *MCM2-7* expression was elevated in human CCA tumors and correlated positively with *E2F1* levels. Pharmacological inhibition of E2F or MCM activity significantly reduced mitochondrial respiration, fatty acid oxidation, cell viability, proliferation, and spheroid and organoid growth in CCA cells.
Conclusion: E2F1 is essential for the progression of CCA subtypes characterized by Hippo pathway activation, cooperating with YAP/TAZ for the transcription of MCM2-7 helicases. Pharmacological inhibition of E2F/MCM activity decreases mitochondrial lipid metabolism and slows CCA progression, representing a potential therapeutic strategy.

OS-008
Microenvironment-responsive bispecific T-cell receptor-engineered T cells against hepatocellular carcinoma

Xinyu Lu[1], Yiyue Wang[1], Xin Fu[1], Jinzhang Chen[1], Guosheng Yuan[1], Weikang Xu[2], Guoheng Mo[1], Anan Chen[1], Chou Yang[1], Sha Wu[3], Lei Huang[4], Jinlin Hou, Wei Zhu[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Key Laboratory of Infectious Diseases Research in South China, Ministry of Education, Guangzhou, China; [2]Department of Gastroenterology, The Second Affiliated Hospital of Guangzhou Medical University, Guangzhou, China; [3]Department of Immunology, School of Basic Medical Sciences, Southern Medical University, Guangzhou, China; [4]Translational and Clinical Research Institute, Faculty of Medical Sciences, Framlington Place, Newcastle University, Newcastle-Upon-Tyne, United Kingdom*
Email: zhuwei317@smu.edu.cn

Background and aims: Clinical efficacies of Adoptive Cell Transfer (ACT) therapy including T-cell receptor (TCR)-engineered T cells (TCR-T) and Chimeric Antigen Receptor-engineered T cells (CAR-T) are hindered by the immunosuppressive tumor microenvironment (TME) in Hepatocellular Carcinoma (HCC). Cancer associated fibroblasts (CAFs) are a pivotal contributor of the immune suppressive TME in HCC. CAFs secret collagen and other immune suppressive factors to establish physical and immune barriers within the tumor to limit the function of immune cells in the tumor. We hypothesize that treatment targeting both malignant cells and CAF will overcome the therapy resistance from the TME in ACT therapy. Here, we report an engineered bispecific TCR-T targeting both HCC and CAF cells in the tumor in order to improve therapeutic efficacy.
Method: We developed bispecific T cells, called TRuC/TCR-T, that combines aspects of T cell receptor fusion constructs (TRuC) comprising an anti-FAP single-chain variable fragment (ScFv)-based binding domain fused to CD3ε subunit against CAFs and α-fetoprotein (AFP)-specific TCR against HCC. The therapeutic efficacy of TRuC/TCR-T is tested in two models (1) HLA-A201 restricted AFP specific TCR to treat HepG2 xenograft in NOD-SCID mice, (2) To further explore immune landscape after treating with TRuC/TCR-T cells, here we report a new type model of murine TCR-T cell therapy for HCC. Utilizing a H2-Kb restricted AFP specific TCR to treat DEN/Cl4C induced spontaneous HCC in C57BL/6 mice. T cells were injected when the TME is considered to be establish.
Results: The TRuC/TCR-T cells elicit strong cytotoxicity to both HCC cells and CAFs in vitro. In vivo, the TRuC/TCR-T significantly reduced tumor size in the xenograft model. Moreover, TRuC/TCR-T cells injection significantly reduced liver tumor burden in mice treated with DEN/Cl4C with negligible toxicity. TRuC/TCR-T cells depleted the tumor stroma within the tumor residue, suggesting a critical role of TRuC/TCR design in overcoming physical and immune barriers via increase T cells infiltration to tumors. Furthermore, TRuC/TCR-T cells exhibited low tonic activation signals in vivo, and better activation response when encounter to its specific antigen.
Conclusion: Our data suggest that TRuC/TCR-T can respond within the immunosuppressive TME and is a novel and effective therapeutic candidate in treating HCC.

Email: tacconi.carlotta@hsr.it

Background and aims: Effector CD8+ T cells eliminate antigen-expressing hepatocytes by extending cytoplasmic protrusions through endothelial fenestrations, bypassing the need to migrate into the tissue. However, the impact of anatomical, hemodynamic, and environmental factors acquired by tumors during growth on the immune surveillance capacity of CD8+ T cells remains poorly understood.
Method: To investigate this, we developed a mouse model of hepatocellular carcinoma (HCC) that mimics key features of the human disease. This model enables longitudinal visualization and non-invasive assessment of CD8+ T cell behavior and antitumor potential, leveraging advanced imaging techniques, flow cytometry, single-cell RNA sequencing, and spatial transcriptomics.
Results: Our findings revealed a marked reduction in the antitumor potential of effector CD8+ T cells as tumor lesions reached a size beyond 100 mm³. In "non-responder" lesions, CD8+ T cells exhibited impaired antigen recognition and activation, whereas in "responder" lesions (≤10 mm³), T cells efficiently recognized and attacked tumor cells. Mechanistic analysis revealed that non-responder lesions were characterized by the replacement of liver sinusoidal endothelial cells (LSECs) with capillarized endothelial cells (cECs) lacking fenestrations. Single-cell RNA sequencing of endothelial cells from non-responder lesions revealed the upregulation of immunomodulatory genes (e.g., *Cxcr4, Esm1,* and *Cd200*) and the downregulation of LSEC-specific genes (*Gata4, Lyve1,* and *Maf*) as well as leukocyte adhesion molecules (*Vcam1* and *Icam1*). Notably, the non-responder endothelial cell signature closely resembled that of endothelial cells in human HCC. In both mouse and human cancers, activated CD8+ T cells localized near LSECs but were absent from areas dominated by cECs. Finally, pharmacological restoration of endothelial fenestrations in non-responder lesions significantly enhanced antigen recognition by CD8+ T cells and reinstated their antitumoral activity.
Conclusion: These findings uncover a size-dependent endothelial switch in liver cancers that impairs CD8+ T cell-mediated immune surveillance. Restoring endothelial fenestrations in non-responder tumors offers a promising strategy to enhance tumor immune surveillance, not only by endogenous T cells but also by engineered therapies such as CAR T cells or TCR-redirected T cells.

MASLD: Clinical and therapeutical aspects

OS-010-YI

Informing management of patients at increased risk of hepatic decompensation by two-step non-invasive assessment - a multicentre cohort study of 12,950 patients with metabolic dysfunction-associated steatotic liver disease (MASLD)

Email: wongv@cuhk.edu.hk

Background and aims: While affecting 30% of the general population, MASLD only leads to hepatic decompensation in a minority of patients. We aimed to determine cut-offs of non-invasive tests for selecting this high-risk population for timely management and interventions.
Method: The vibration-controlled transient elastography (VCTE)-Prognosis Study was a longitudinal study at 16 centres from the US, Europe and Asia (prospective data at 14 centres). Adult patients with MASLD who underwent liver stiffness measurement (LSM) by VCTE and fibrosis-4 index (FIB-4) were included. We excluded patients who developed hepatic decompensation or hepatocellular carcinoma

before or within the first 3 months of follow-up. Cumulative incidence was estimated by the Aalen-Johansen method and converted to annual incidence.
Results: Of 12,950 patients (mean age 51.7 [SD 13.9] years; 5,316 [41.1%] female; 4,429 [34.2%] diabetes; median LSM 5.9 [IQR 4.6–8.3] kPa; median BMI 27.2 [IQR 24.7–30.4] kg/m^2),174 (1.3%) patients developed hepatic decompensation at a median follow-up of 47.7 (IQR 23.3–72.3) months. FIB-4 was below the low cut-off (1.3 for <65 years and 2.0 for ≥65 years) for 8,582 (66.3%) patients, with an annual incidence of hepatic decompensation at 0.04% (95% CI 0.02%-0.07%). If LSM by VCTE was performed in 4,368 patients with FIB-4 above the low cut-off, 2,398 (54.9%), 498 (11.4%), 352 (8.1%), 350 (8.0%), 265 (6.1%), 182 (4.2%), and 323 (7.4%) had LSM of <8, 8–10, 10–12, 12–15, 15–20, 20–25, and ≥25 kPa, respectively. Their annual incidence (95% CI) of hepatic decompensation was: <8 kPa: 0.05% (0.02%–0.12%); 8–10 kPa: 0.14% (0.03%–0.47%); 10–12 kPa: 0.40% (0.15%–0.88%); 12–15 kPa: 0.88% (0.45%–1.53%); 15–20 kPa: 2.46% (1.56%–3.58%); 20–25 kPa: 1.77% (0.93%–2.94%); and ≥25 kPa: 4.27% (3.28%–5.35%). Aligned with Baveno VII's rule of 5, the annual incidence of hepatic decompensation exceeded 0.2% with LSM ≥10 kPa and 1% with LSM ≥15 kPa. While FIB-4 below the low cut-off consistently classified patients with a low risk of hepatic decompensation in different patient subgroups based on age, sex, body mass index (BMI), and the presence of diabetes (annual incidence ranged from 0.025% to 0.14%), heterogeneity existed on the cut-off of LSM as the second assessment. The cut-off of LSM ≥15 kPa pointed to an annual hepatic decompensation incidence of ≥1% in patients aged <65 years, females, those with BMI ≥30 kg/m^2, and those with diabetes, while a lower cut-off of 12 kPa was required in those aged ≥65 years, males, with BMI <30 kg/m^2, or without diabetes targeting an annual incidence of ≥1%.
Conclusion: FIB-4 below the low cut-off safely excludes the majority of patients at risk of hepatic decompensation. In patients with elevated FIB-4, LSM ≥15 kPa predicts an increased risk of hepatic decompensation, while a lower cut-off of LSM ≥12 kPa predicts an increased risk in those aged ≥65 years, males, with BMI <30 kg/m^2, or without diabetes.

OS-011-YI
Comparison of diagnostic accuracy and utility of 10 non-invasive tests for clinically significant liver disease among a general population with metabolic dysfunction

Laurens A. van Kleef[1], Jesse Pustjens[1], Jörn M. Schattenberg[2], A.G. (Onno) Holleboom[3], Manuel Castro Cabezas[4], Maarten Tushuizen[5], Robert J. de Knegt[1], Arfan Ikram[6], Harry L.A. Janssen[1], Sven Francque[7], Willem Pieter Brouwer[1].

Email: l.vankleef@erasmusmc.nl

Background and aims: Screening for liver health in the general population requires accurate non-invasive tests (NITs). A head-to-head comparison of NITs for early detection of clinically relevant liver disease among large general population cohorts with metabolic dysfunction – the target population for screening - has not yet been performed.
Method: Among a pooled population from the Rotterdam Study and NHANES with metabolic dysfunction aged 18–80 years, 10 NITs were investigated: AST to platelet ratio (APRI), Cirrhosis Outcome Risk Estimator (CORE), fibrosis-4 index (FIB-4), Fibrotic NASH index (FNI), FORNS, Hepamet Fibrosis Score (HFS), LiverRisk score (LRS), Metabolic dysfunction associated fibrosis score-5 (MAF-5), NAFLD fibrosis score (NFS) and steatosis associated fibrosis estimated (SAFE). The diagnostic accuracy (area under curve, AUC) was assessed for the detection of increased liver stiffness measurement (LSM ≥8 kPa, LSM ≥12 kPa), MASH (FibroScan AST score ≥0.35), advanced fibrosis (Agile 3+ ≥0.679) or cirrhosis (Agile 4 ≥0.565). Subgroup analysis included stratification by age group, level of obesity and diabetes mellitus status. Sensitivity analysis included an assessment of (1) test characteristics at the threshold corresponding with 80% sensitivity and (2) diagnostic yield when 20% of the at-risk population with the highest NIT score was selected for further work-up.
Results: We analysed 11,404 participants. MAF-5 had the highest AUC for increased LSM (LSM ≥ 8/12 kPa, AUC 0.80/0.87) and advanced fibrosis (AUC 0.90). FNI and MAF-5 were most suited for MASH (AUC 0.93 and 0.92). SAFE and NFS performed best for cirrhosis (AUC 0.92 and 0.91). At the NIT cut-off to obtain at least 80% sensitivity for LSM ≥ 8 kPa, the corresponding MAF-5 cut-off resulted in fewer referrals compared to FIB-4 (42% vs 77%) and had higher specificity (62% vs 24%); the MAF-5 was also superior for detecting LSM ≥ 12 kPa and advanced fibrosis. Age-dependent scores yielded lower sensitivity amongst younger individuals e.g., by referring 20% of the population with the highest NIT-scores, the FIB-4, SAFE, NFS, FORNS and HFS yielded < 10% sensitivity for LSM ≥ 8 kPa amongst individuals aged 18–35y while the FNI and MAF-5 obtained 40% and 71%, respectively.
Conclusion: Of the 10 investigated NITs, the MAF-5 was most suited for ruling in and ruling out all conditions except cirrhosis, for which SAFE yielded the highest accuracy. The performance of FIB-4 was overall low, implying that referral pathways for significant liver disease in low prevalence populations can be improved when more accurate NITs such as MAF-5 are employed.

OS-012
Efimosfermin alfa once monthly treatment improves collagen biomarker profiles and rapidly induces histological fibrosis regression in subjects with MASH stage F2-F3 fibrosis in a 24-week phase 2 trial

Rohit Loomba[1], Kris Kowdley[2], Gerard Bain[3], Matthew Bryant[3], Jeff Zhao[3], Margaret Koziel[4], Mazen Noureddin[5]. *[1]University of California, San Diego, CA, United States; [2]Liver Institute Northwest, Elson S Floyd College of Medicine, Seattle, WA, United States; [3]Boston Pharmaceuticals, Cambridge, MA, United States; [4]Boston Pharmaceuticals, Cambridge, United States; [5]Houston Methodist Hospital, Houston Research Institute, Houston, TX, United States*
Email: roloomba@health.ucsd.edu

Background and aims: Efimosfermin alfa (formerly BOS-580) is a once monthly subcutaneous administered long-acting FGF21 analogue that has demonstrated significant MASH resolution without worsening of fibrosis and fibrosis improvement ≥1 stage without worsening of MASH compared to placebo at week 24 in subjects with biopsy-confirmed stage F2/F3 fibrosis due to metabolic dysfunction-associated steatohepatitis (MASH) in a Phase 2 trial. The effects of efimosfermin on collagen biomarkers and the changes in extracellular matrix (ECM) remodeling were also evaluated during the trial (NCT04880031).
Method: Subjects (N = 84) were randomized 1:1 to receive once monthly efimosfermin 300 mg or placebo and underwent pre- and post-treatment liver biopsy. Serum samples were collected at baseline and weeks 4, 12 and 24. Pro-C3, Pro-C6, and CTX-III collagen fragments were measured according to standard methods and analyzed for absolute and relative changes over time. To determine if there were any differences in response based on fibrosis stage, changes in these biomarkers at week 24 were compared between the total study population and those with stage F2 and F3 fibrosis at baseline. Changes in collagen biomarkers stratified by their baseline

levels were also assessed. Pro-C3/CTX-III ratio was calculated to assess the overall balance between fibrogenesis and fibrolysis.
Results: Levels of profibrogenic biomarkers Pro-C3 and Pro-C6 were significantly reduced at week 4 after treatment with once monthly efimosfermin and remained low through the end of the study. Pro-C3 declined by 44.6% at week 24, and Pro-C6 achieved a maximum reduction of 11.2% at week 4. CTX-III, a profibrolysis biomarker of ECM degradation, also demonstrated steady decline over time, with a maximum decrease of 9.2% at week 24. Efimosfermin treatment was equally effective at reducing collagen biomarkers in subjects with MASH stage F2 or F3 fibrosis. Subjects with baseline levels at or above the median value in the treatment groups generally showed a greater decline compared to those with baseline values below the median. The Pro-C3/CTX-III ratio was significantly lower at all timepoints compared to placebo, with a maximum decrease of 33.9% at week 24, suggesting an overall shift towards clearance of fibrosis in response to efimosfermin treatment.
Conclusion: Efimosfermin treatment rapidly induces fibrosis regression in subjects with MASH stage F2/F3 fibrosis as evidenced by significant improvements in ECM remodeling during a 24-week Phase 2 trial. Efimosfermin showed improvements in collagen biomarkers regardless of baseline MASH stage F2 or F3 fibrosis. Consistent with histology data, decreases in the Pro-C3/CTX-III ratio show a shift in the overall balance between fibrogenesis and fibrolysis towards fibrosis clearance in the efimosfermin treated subjects with MASH stage F2/F3 fibrosis.

Background and aims: The target patient population studied in pre-cirrhotic clinical trials for metabolic dysfunction-associated steatotic liver disease (MASLD) is "at-risk MASH," defined histologically as MAS score of ≥4 and fibrosis stage ≥ F2. Improving the ability to accurately pre-select cases for biopsy using non-invasive tests (NITs) could significantly reduce screen-failure rates that commonly exceed 80% of patients screened. In the multi-center LITMUS Study, we evaluated NIT-based pre-screening strategies to reduce the histological screen failure rates (SFR) in future trials.
Method: We analyzed data on 19 NITs acquired across 13 countries in Europe and the US (2018–2023). For each NIT, we identified a threshold to minimize biopsy-based screen failures when recruiting at-risk MASH patients. We split the LITMUS Study Cohort into development and evaluation sets by recruitment country. The development set was used to find thresholds for each marker corresponding to a SFR ≤33% while maximizing sensitivity. The evaluation set then assessed marker performance using these thresholds. To evaluate potential inequities, we compared true positive and false negative cases by age, gender, Body Mass Index (BMI), and diabetes status. Imbalances between these groups were quantified using standardized differences (SD), with values ≥0.2 indicating a meaningful impact on distribution.
Results: The evaluation of the diagnostic screening performance of the markers in the evaluation set, using the thresholds selected in the development set, showed that several markers could reduce histological SFR to 33% in trials. The best screening performance for at-risk MASH was observed for SomaSignal with a number needed to test (NNT) to find one true positive of four tested. This was followed by NIS2+ (NNT = 5), NIS4 (NNT = 7), FAST (NNT = 8), TSP2 (NNT = 8), and CK18-M65 (NNT = 8). All the other markers resulted in a NNT greater than 8. Using the selected thresholds to evaluate a potential imbalance in the distribution of age, gender, BMI, and diabetes between true positives and false negatives showed variable results for different markers. Notable differences (SD ≥ 0.2) for several markers were observed in the proportion of patients with type 2 diabetes.
Conclusion: NIT-based pre-screening strategies could lead to substantial efficiencies in recruitment of trials targeting at-risk MASH: reducing the number of cases biopsied to identify each eligible patient. Given the high SFR in current trials, such preselection could facilitate trial recruitment and accelerate drug development. These results also have implications to guide risk-stratification in routine clinical practice. Our analysis of demographic differences between true positives and false negatives highlighted the need to consider such factors in non-invasive screening tools.

Penttilä[6], Johanna Arola[7], Anne Juuti[6], Hannele Yki-Järvinen[1,2], Panu K. Luukkonen[1,2,3]. *[1]Minerva Foundation Institute for Medical Research, Helsinki, Finland; [2]Department of Internal Medicine, University of Helsinki, Helsinki, Finland; [3]Abdominal Center, Helsinki University Hospital, Helsinki, Finland; [4]Department of Veterinary Biosciences, and Finnish Centre for Laboratory Animal Pathology (FCLAP), Helsinki Institute of Life Science (HiLIFE), University of Helsinki, Helsinki, Finland; [5]Metabolomics Unit, Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; [6]Department of Gastrointestinal Surgery, Abdominal Center, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [7]Department of Pathology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland*
Email: panu.luukkonen@helsinki.fi

Background and aims: Bariatric surgery is one of the most effective interventions to ameliorate metabolic dysfunction-associated steatotic liver disease (MASLD). However, MASLD persists in 7–12% after the surgery. To elucidate the underlying metabolism, we investigated which plasma metabolites associate with 1) severity, 2) improvement and 3) persistence of MASLD after bariatric surgery. We asked whether the identified metabolites replicate in a mouse model of MASLD. Finally, we investigated whether the identified metabolites predict incident MASLD-related clinical outcomes in the UK Biobank (UKB).
Method: We assigned 84 bariatric surgery patients (mean age 52.8 years, 70.2% women) into three groups based on baseline liver histology. The control group (n = 28) had normal livers, the MASL group (n = 26) had steatosis and the MASH group (n = 30) had steatohepatitis and/or fibrosis ≥ F2. After an average of 7.7 years, we invited the patients for a follow-up visit, where liver stiffness (LS) was measured using transient elastography. At both baseline and follow-up, 249 plasma metabolites were quantified using nuclear magnetic resonance. We fed C57BL/6J mice (n = 18) either the Gubra Amylin NASH (GAN) diet or chow for 16 weeks, after which we extracted their livers for histology and metabolomics. In the UKB (N = 101,153), we conducted multivariable Cox regressions to evaluate whether baseline plasma metabolites predict liver disease, cardiovascular disease and type 2 diabetes during a median of 13.8-year follow-up.
Results: The control, MASL and MASH groups had similar age, sex and BMI. At follow-up, body weights were decreased by 20.1% ($p < 0.0001$) similarly in all groups. Thirteen plasma metabolites distinguished the groups at baseline, of which four improved after bariatric surgery ($p < 0.05$). LS was high (>8 kPa) after bariatric surgery in 10.7% of patients. Only one of the four metabolites differentiated patients with high LS from those without ($p < 0.05$). This metabolite – an amino acid – associated inversely with hepatic and adipose tissue insulin resistance ($p < 0.05$). The concentration of the amino acid decreased by 47.3% in the GAN-fed mouse livers compared to controls and correlated inversely with severity of MASLD ($p < 0.001$). In the UKB, the amino acid protected against incident MASLD, alcohol-related liver disease, cirrhosis, and hepatocellular carcinoma (HR 0.50–0.76, $p < 0.0001$) as well as cardiovascular events (HR 0.92, $p < 0.0001$) and type 2 diabetes (HR 0.72, $p < 0.0001$).
Conclusion: We identified a distinct amino acid which: 1) associates with reduced histological severity of MASLD, 2) increases after bariatric surgery, 3) is lower in patients with high LS after bariatric surgery compared to those without, 4) decreases in a mouse model of MASLD, and 5) predicts reduced risk of MASLD-related clinical outcomes. These data suggest that this amino acid may protect against MASLD.

Email: rsalpini@yahoo.it

Background and aims: Hepatitis D virus (HDV) infection is often underdiagnosed, despite the severity of the related liver disease. Here, we investigate the rates of HDV screening and the prevalence of HDV RNA among antiHDV+ individuals in routine care across Europe and parts of the Middle East, as well as the characteristics of individuals with active HDV infection.
Method: We collected data from 15,200 HBsAg+ people attending 16 tertiary centres during 2021–2023: Northwestern Europe (NWE: UK, Switzerland, Luxembourg, Germany, Sweden; N = 3596, 23.6%), Southern Europe (SE: Spain, Italy, Slovenia, Croatia; N = 3203, 21.1%), and Eastern Europe (EE: Romania, Serbia, Slovakia; N = 4136, 27.2%) and the Middle-East (ME: Israel, Turkey; N = 4265, 28.1%).
Results: Participants were predominantly males (59.5%), HBeAg-negative (90.7%) with a median (IQR) age of 49 (39–60) years and only 28.6% received nucleos(t)ide analog treatment. The rate of HDV screening varied widely across regions: 23.9%, EE; 59.3%, NWE; 71.5%, ME; 79.1%, SE. Overall, HDV seroprevalence was 5.9% (523/8801) with the highest rate of anti-HDV positivity in EE (9.9%), followed by ME (7.0%), NWE (5.8%) and SE (3.3%). By country, anti-HDV positivity peaked in Romania (10.4%), Turkey (8.7%), Germany (7.9%) and Italy (6.8%). Compared to individuals with HBV infection, people with anti-HDV had significantly higher HBsAg (median [IQR]: 3225 [591–9784] vs 2568 [242–11163] IU/ml, p < 0.001), lower HBV-DNA (3.1 [2.2–3.9] vs 2.4 [1.6–3.7] log IU/ml, p < 0.001) and a more advanced liver disease (Ishak score >4: 25.7% vs 4.6%, HCC: 5.9% vs 1%, p < 0.001 for both). HIV coinfection was also more common (10.8% vs 4.1%, p < 0.001). Overall, among 523 individuals with anti-HDV, 82.6% were tested for HDV-RNA and 46.9% showed active HDV infection with a median (IQR) HDV-RNA of 5.7 (4.2–7.1) log IU/ml and ALT of 92 (58–171) U/L. Strikingly, large regional variations were noted in both HDV-RNA detection (ME: 39.6%, NWE: 40%, SE: 56.1% and EE: 71.6%, p = 0.0002) and HDV-RNA levels (median [IQR] log IU/ml: 6.4 [4.9–7.2] in ME, 5.4 [3.9–6.7] in EE, 5.4 [4.0–7.4] in NWE and 4.0 [3.2–4.7] in SE, p = 0.001).
Remarkably, among 344 participants tested for HDV-RNA despite anti-HDV negativity, a total of 7 (2%) from EE (N = 5), SE (N = 1) and Africa (N = 1) had detectable HDV-RNA with median levels of 5.4 (5–6) log IU/ml.
Conclusion: Despite the substantial burden of HDV infection and related liver disease, there remain significant gaps in HDV screening across Europe, particularly in specific regions. Notably, we observed a small but appreciable proportion with HDV RNA despite lack of anti-HDV, underscoring the need for greater standardisation of HDV diagnostics. Overall, the data supports the urgent need to improve and harmonize HDV screening measures and promote the access to antiviral treatment at pan-European level.

OS-016
Cirrhosis death rates are increasing rapidly among young Americans – analysis of national death certificate data

Andrew Moon[1], Sasha Deutsch-Link[1], Oren Fix[1], Neil Shah[1], Hersh Shroff[1], A. Sidney Barritt Iv[1]. *[1]University of North Carolina, Chapel Hill, United States*
Email: andrew.moon@unchealth.unc.edu

Background and aims: In the United States (US), there has been a concerning increase in the prevalence of obesity, diabetes, unhealthy alcohol use, and incident chronic hepatitis C virus infections among younger individuals. We aimed to assess trends in cirrhosis mortality among Americans younger than 35 years old.
Method: The National Vital Statistics System provides a publicly available database of vital statistics based on death certificates from the entire US. Using this data source, we identified deaths with an underlying cause from cirrhosis (K70.3, K71.7, K72.9, K74.3, K74.4, K74.5, K74.6) or complications of cirrhosis (I85.0, I86.4, K76.6, K76.7, R18) among individuals younger than 35 from 1999–2022. We extracted the number of deaths and calculated annual mortality rates overall and stratified by gender. As a comparison group, we assessed deaths among individuals ≥65 years. We additionally examined trends of cirrhosis deaths with a contributing cause from alcohol-associated liver disease (ALD), metabolic dysfunction-associated steatotic liver disease (MASLD) and viral hepatitis. Using the NCI Joinpoint program, we assessed statistically significant changes in average percentage change (APC) and the overall average annual percentage change (AAPC) in death rates.
Results: The median crude mortality rate from 1999–2022 was significantly higher in individuals ≥65 years (median 31.7 per 100,000 population) compared to those <35 (median 0.3 per 100,000). The average annual percentage change in death rates was significantly higher in individuals <35 years (AAPC 5.2, 95% CI 4.5, 5.9) vs ≥65 years (AAPC 0.7, 95% CI 0.6, 0.8). Joinpoint analysis demonstrate that, among individuals <35 years, death rates were stable from 1999–2008 (APC −1.7, 95% CI −6.0, 0.3), increased from 2008–2018 (APC 7.0, 95% CI 3.5, 9.4), and further accelerated from 2018–2022 (APC 17.3, 95% CI 12.5, 26.6). Recent increases were less pronounced among those ≥65 years (from 2019–2022 APC 4.4, 95% CI 2.9, 6.3). Among those younger than 35 years, the AAPC was lower among females (APC 4.8, 95% CI 4.1, 5.6) compared to males (APC 5.3, 95% CI 4.6, 6.1), but this difference was not statistically significant. The Joinpoint analysis demonstrated a steady, statistically significant increase in death rate APC in younger females from 2011–2022 (APC 10.7, 95% CI 9.0, 13.2) while males had a significant increase from 2006–2018 (APC 5.7, 95% CI 3.6,8.3) and further acceleration from 2018–2022 (APC 20.6, 95% CI 15.1, 30.2). Deaths from ALD-associated cirrhosis among individuals age <35 years increased from 1999–2022

(AAPC 10.9, 95% CI 8.9, 13.6). The joinpoint analysis could not be performed for MASLD or viral hepatitis due to small numbers.
Conclusion: Cirrhosis death rates have increased more rapidly among younger individuals and these increases accelerated from 2018–2022, particularly among younger males. Increased alcohol use in recent years has likely contributed to recent rises in cirrhosis death rates among Americans under age 35.

OS-017

Long-term air-pollution exposure is associated with metabolic-dysfunction steatotic liver disease and liver fibrosis in the general population

Jesse Pustjens[1], Bigina N.R. Ginos[2], Laurens A. van Kleef[1], Harry L.A. Janssen[3], Trudy Voortman[2], Willem Pieter Brouwer[1].
[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Centre, Rotterdam, Netherlands; [2]Department of Epidemiology, Erasmus MC, University Medical Center, Rotterdam, Netherlands; [3]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Centre, Centre for Liver Research, Department of Gastroenterology and Hepatology, Toronto, Canada, Rotterdam, Netherlands
Email: j.pustjens@erasmusmc.nl

Background and aims: Chronic liver disease has emerged as a critical global health challenge, primarily driven by the obesity epidemic. Air pollution, the leading contributor to the global burden of disease, has been linked to metabolic dysfunction-associated steatotic liver disease (MASLD). This study examines the associations between different air pollutants, MASLD, and liver fibrosis in the general population.
Method: This study is embedded within The Rotterdam Study, an ongoing prospective cohort study in a suburban area of the city of Rotterdam, The Netherlands. We included participants with available ultrasound and reliable liver stiffness measurement (LSM) data. Exclusion criteria were viral hepatitis, excessive alcohol consumption (≥50 grams daily for females and ≥60 grams daily for males) and prevalent heart failure. MASLD was defined as steatosis with at least one metabolic dysfunction according to clinical practice guidelines, and liver fibrosis was defined as an LSM ≥8 kPa. Annual air pollutant concentrations of PM2.5, NO_2, ozone, and black carbon were determined at participants' residential addresses using land-use regression models. Average pollutant levels for the previous 1, 5, and 10 years were calculated for each participant. Cross-sectional associations between each pollutant and liver outcomes were assessed using logistic regression models, adjusted for age, age², sex, smoking, alcohol consumption, waist circumference, insulin resistance, and education level.
Results: We analyzed data from 4,185 participants (median age: 66 years [IQR 61–73], 44% male). The prevalence of MASLD was 34% (n = 1,409), while liver fibrosis was present in 5.7% (n = 239) of participants. Risk of MASLD was associated with black carbon (aOR 1.92; 95%CI 1.26–2.92), NO_2 (aOR 1.03; 95%CI 1.01–1.05), and PM2.5 (aOR 1.12; 95%CI 1.02–1.23) for up to 5 years of exposure. Significant associations with liver fibrosis were observed for PM2.5 (aOR 1.19; 95%CI 1.00–1.41) at 5 years and black carbon (aOR 2.31; 95%CI 1.10–5.27) at 10 years of exposure. No significant associations were found for ozone with MASLD or liver fibrosis at any exposure duration, neither for annual means or during warm seasons.
Conclusion: In this population-based study, we demonstrated that long-term exposure to air pollutants may increase the risk of liver disease. Specifically, NO_2, PM2.5, and black carbon at 5 years, were associated with MASLD, but only PM2.5 and black carbon were linked to the long-term risk of liver fibrosis. These results suggest that air pollution control policies may play a role in mitigating chronic liver disease risks at the population level.

OS-018

Impact of weekend warrior physical activity on all-cause mortality in metabolic dysfunction-associated steatotic liver disease

James M. Paik[1], Shira Zelber-Sagi[1,2], Elizabeth Pekas[3], Dana Ivancovsky Wajcman[1], Leyla de Avila[4], Yusuf Yilmaz[1,5], Saleh Alqahtani[1,6,7], Mohamed El-Kassas[1,8], Lynn H. Gerber[1,9], Zobair Younossi[9,10,11]. *[1]The Global NASH Council, Washington DC, United States; [2]School of Public Health, University of Haifa, Haifa, Israel; [3]The American Diabetes Association, Arlington, United States; [4]The Global NASH/MASH Council, Washington, DC, United States; [5]Department of Gastroenterology School of Medicine, Recep Tayyip Erdoğan University, Rize, Türkiye; [6]Liver, Digestive, and Lifestyle Research Section, and Organ Transplant Center of Excellence, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; [7]Division of Gastroenterology & Hepatology, Weill Cornell Medicine, New York, United States; [8]Endemic Medicine and Hepatology Department, Faculty of Medicine, Helwan University, Cairo, Egypt; [9]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, United States; [10]Global NASH Council, Washington DC, United States; [11]Center for Outcomes Research in Liver Disease, Washington DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: Recent EASL-EASD-EASO guidelines on metabolic dysfunction-associated steatotic liver disease (MASLD) recommend more than 150 minutes of moderate to vigorous physical activity (MVPA) per week. However, it is unclear if concentrating MVPA into 1–2 days per week ("weekend warrior" pattern) offers comparable benefits as spreading activity throughout the week. We aimed to evaluate whether the weekend warrior activity pattern is associated with lower odds of MASLD and reduced mortality in MASLD patients.
Method: We conducted cross-sectional and prospective analyses of data from NHANES (2003–2006) linked to mortality records from the National Death Index (through 2019). Using accelerometer data, participants were classified into 3 groups: weekend warrior (>150 minutes of MVPA with ≥50% of total MVPA accomplished over 1–2 days), active (>150 minutes of MVPA, not meeting weekend warrior criteria), and inactive (≤150 minutes of MVPA weekly). U.S. Fatty Liver Index (FLI) ≥30 with at least one cardiometabolic risk without other liver disease and excessive alcohol use was defined as probable MASLD. Logistic regression and Cox models were adjusted for age, sex, race, income, and total amount of physical activity.
Results: Among 2,490 participants (mean age: 48.5 years; 47.4% male; 73.4% White; 55.8% with obesity), 32.3% had MASLD, 27.4% and 14.1% were classified as active and weekend warriors, respectively. Both the weekend warrior and active groups had significantly lower odds of MASLD [Odds Ratio (OR): 0.34 (95% CI: 0.24–0.50) and OR: 0.48 (95% CI: 0.37–0.63)], type 2 diabetes [OR: 0.43 (95% CI: 0.21–0.90) and OR: 0.34 (95% CI: 0.19–0.61)], and obesity [OR: 0.36 (95% CI: 0.24–0.55) and OR: 0.48 (95% CI: 0.37–0.62)], compared to the inactive group. Among individuals with MASLD, after a median follow-up of 14.3 years (11,242 person-years), mortality rates (per 1,000 person-years) were highest in the inactive group (27.69), compared to active (6.68) and weekend warrior (6.66) groups. Adjusted Cox models demonstrated significantly lower all-cause mortality in the active [Hazard Ratio (HR): 0.48 (95% CI: 0.23–0.98)] and the weekend warrior group [HR: 0.34 (95% CI: 0.13–0.91)] compared to the inactive group ($p < 0.05$).
Conclusion: The weekend warrior pattern of physical activity is equally protective against MASLD and all-cause mortality as the other active pattern. This study supports recommendations for meeting physical activity guidelines to improve long-term outcomes in MASLD and highlights the potential to personalize training programs to fit individual schedules and lifestyles.

OS-019

A large multicentre hepatitis B cohort study in the United Kingdom highlights high rates of comorbidity associated with liver disease outcomes

Email: tingyan.wang@ndm.ox.ac.uk

Background and aims: The chronic hepatitis B (CHB) population is ageing in some countries, with a rising burden of comorbidities reported from multiple settings. This study aims to assess the prevalence of comorbidities in a UK HBV cohort and their impact on liver disease outcomes including development of cirrhosis, decompensation, and hepatocellular carcinoma (HCC).

Method: We analysed an ethnically diverse cohort of >23,800 people living with HBV from nine secondary care centres in England, established by the National Institute for Health and Care Research (NIHR) Health Informatics Collaborative using electronic health records. Comorbidities were identified by ICD-10 codes, and associations with liver-related outcomes were evaluated using univariable and multivariable logistic regression models, adjusting for age, sex, ethnicity, and antiviral treatment.

Results: Among 14,149 adults eligible for analysis (median age: 45 years [IQR: 34–58]; 55.2% male), the most prevalent comorbidities were hypertension (HTN, 27.8%), diabetes mellitus (DM, 16.6%), cardiovascular disease (CVD, 16.0%), chronic kidney disease (14.9%), non-liver malignancy (12.7%), chronic pulmonary disease (12.3%), hyperlipidaemia (11.1%), obesity (10.7%), depression (7.8%), hepatic steatosis (7.0%), HCV coinfection (6.7%), HIV coinfection (3.8%), rheumatic disease (3.3%), alcohol-related liver disease (ArLD, 3.2%), and peptic ulcer disease (PUD, 2.8%). Moderate/severe liver disease and complications were observed in 27.0% of patients, including fibrosis/cirrhosis (10.2%), ascites (5.1%), portal hypertension (4.6%), HCC (4.1%), and varices (4.0%). Males had higher rates of comorbidities and liver complications than females, except for bone-related conditions (all $p < 0.001$). Fibrosis/cirrhosis was significantly associated with HCV coinfection, ArLD, PUD, and hepatic steatosis, with odds ratios (ORs) (95% CIs) of 4.6 (3.9–5.4), 3.0 (2.3–3.7), 2.8 (2.2–3.6), and 2.2 (1.9–2.7), respectively, as well as metabolic conditions including HTN, DM, and obesity (ORs ranging from 1.3 to 1.7). ArLD (OR 18.6, 95%CI 14.8–23.4), PUD (OR 4.0, 95%CI 3.1–5.1), and HCV coinfection (OR 3.1, 95%CI 2.5–3.7) were linked to complications of ascites, varices, or portal hypertension, with HTN, DM, CVD, hepatic steatosis, and obesity also significantly associated (ORs ranging from 1.2 to 1.7). HCC was significantly associated with HCV coinfection, ArLD, obesity, HTN, and DM, with ORs (95% CIs) of 4.4 (3.5–5.6), 3.6 (2.6–4.9), 2.0 (1.4–2.6), 1.5 (1.2–1.6), and 1.4 (1.1–1.7), respectively.

Conclusion: This large multicentre study highlights the prevalence of comorbidities in HBV and their association with liver disease outcomes. The findings emphasise the need for holistic monitoring and intervention strategies, particularly the management of metabolic syndrome and hepatic steatosis in CHB due to their high prevalence and impact.

Rare Liver Diseases

OS-020

Reviewing the utility of genetic cholestasis testing in adults with cholestatic liver disease

Chloe Nguyen[1], Shani Nagler[1], Kristel Leung[1], Aliya Gulamhusein[1], Gideon M. Hirschfield[1], Inbal Houri[1,2]. *[1]The Autoimmune and Rare Liver Disease Programme, Division of Gastroenterology and Hepatology, Toronto General Hospital, Toronto, Canada; [2]Gastroenterology and Hepatology Department, Tel Aviv Medical Center, Israel, Tel Aviv, Israel*
Email: inbalhourio@gmail.com

Background and aims: Cholestatic liver diseases are a wide range of pathologies involving an impairment in the formation or secretion of bile. The more common adult cholestatic diseases are primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC), however a significant portion of patients have an undefined cholestatic disease. In this group, the role of genetic mutations in genes previously thought to be autosomal recessive is being increasingly recognized in the last few years, including but not limited to *ABCB4*, *ABCB11* and

ATP8B1. We sought to review the genetic cholestasis testing experience in our cholestatic liver disease program.
Method: Clinical, demographic and laboratory data were collected retrospectively from patients' medical records attending a tertiary liver programme that had results from a genetic cholestasis panel between 2016–2024. Genetic cholestasis panels were performed by Prevention Genetics or Eurofins Clinical Diagnostics EGL Genetics, with variant screening in a total of 77 different genes.
Results: A total of 166 patients underwent genetic cholestasis testing, with 82 patients (49.4%) found to have variants likely associated with the primary cause of disease. Pathogenic sequence variants were found in *ABCB4* (13.9%), *ATP8B1* (2.4%), and *ABCB11* (0.6%). Additional pathogenic variants were identified in *CFTR* (12.7%), *PKHD1* (4.8%), *HNF1B* (1.8%) and *NOTCH* (1.2%). Of the 82 patients with identified pathogenic variants, 35.4% were tested due to a cholestatic abnormality after ruling out PBC and PSC, 18.3% had cholestatic abnormalities with sclerosing cholangitis visible on MRI, and 14.6% had personal history of intrahepatic cholestasis of pregnancy (ICP). Patients with identified pathogenic variants were 54.3% female, with an average age of 41.6 years at the time of genetic testing; only 16 (19.5%) had a family history of liver disease. At last follow-up, 49 patients (59.8%) were treated with UDCA, and 19 (23%) required an anti-pruritic agent. While most patients had a normal biliary tree or non-specific findings on MRI, 19 patients (23%) had sclerosing cholangitis. Twenty-six patients (31.7%) had undergone cholecystectomy. Ten patients (12%) had evidence of intrahepatic stones, 6 with ABCB4 mutations and 4 with CFTR mutations. Interestingly, 40 patients (49%) had positive immune serology (mostly anti-nuclear antibody or smooth-muscle antibody).
Conclusion: The yield of genetic testing in the appropriate clinical setting is high, reaching approximately 50%. Findings of sclerosing cholangitis on imaging do not preclude genetic mutations and should be considered in the absence of inflammatory bowel disease. Interpretation of the results is still unclear in some of the cases, and further research is required to better understand the clinical impact of various genetic mutations.

OS-021
Fontan-associated liver disease: clinical and epidemiological impact on a large cohort in the UK, a retrospective multicenter study

Eleonora Munaretto[1,2], Hannah Bellsham-Revell[3], Nathalie Dedieu[4], Aaron Bell[3], Mara Cananzi[1], Anil Dhawan[2], Michael Quail[4], Alastair Baker[2]. [1]*Unit of pediatric gastroenterology, digestive endoscopy, hepatology and care of the child with liver transplantation, University Hospital of Padua, Padua, Italy;* [2]*Paediatric liver centre, King's College Hospital, London, United Kingdom;* [3]*Department of paediatric cardiology, Evelina London Children's Hospital, London, United Kingdom;* [4]*Pediatric cardiology, Great Ormond Street Hospital, London, United Kingdom*
Email: eleonoramunaretto92@gmail.com

Background and aims: Fontan-Associated Liver Disease (FALD) is the consequence of liver exposure to the Fontan circulation. As surgical outcomes improve, FALD prevalence is rising. While paediatric FALD onset is increasingly recognized, data remain limited. This study aims to assess FALD prevalence, its impact on survival, and indentify risk factors for disease severity.
Method: This retrospective cohort study included three UK centers: Evelina Children's Hospital, Great Ormond Street Hospital, and King's College Hospital. Patients with univentricular heart who completed the Fontan sequence between 1987 and 2024 were enrolled. MELD-XI and VAST scores assessed the disease severity.
Results: A total of 729 patients underwent Fontan surgery at a median age of 3.9 years (IQR 3.2–4.8). Liver assessment was performed in 390 patients (53.5%). The median follow-up time was 12.8 years (IQR 9.4–18), and the median age was 13.1 years (IQR 8.2–18.06). Liver assessment rates post-Fontan were 32.4% within 5 years, 44.2% at 5–10 years, 73.2% at 10–15 years, rising to 100% beyond 25 years. FALD prevalence increased over time: 10.9% at 0–5 years, 23.3% at 5–10 years, 63.7% at 10–15 years, 82.6% at 15–20 years, 91% at 20–25 years, and 100% at 25–40 years. Radiological findings included hepatomegaly (23.2%), caudate hypertrophy (17.8%), heterogeneous (32.2%) and coarse (44.6%) parenchyma, FNH-like nodules (27.5%), cirrhosis (40.9%), and splenomegaly (28.2%). Hepatocellular carcinoma prevalence was 0.14%. Cirrhosis was present in 18.2% of liver imaging within 5 years, 29.9% at 5–10 years, 37.7% at 10–15 years, and 83.3% beyond 25 years. Liver stiffness (n = 127) showed no significant change over time nor correlation with MELD-XI or VAST. A positive correlation was found between follow-up time and higher VAST and MELD-XI scores ($p < 0.0005$ and 0.0001), both significantly rising from the 10–15 years interval ($p < 0.001$). Older age at Fontan, cardiac isomerism, and male sex correlated with MELD-XI ($p = 0.003$, 0.004 and 0.036). Univariate Cox regression identified liver injury prior to Fontan surgery (HR 3.74, $p = 0.041$), VAST (HR 2.93, $p < 0.0005$) and MELD-XI (HR 1.17, $p = 0.015$) as mortality predictors. Multivariable analysis confirmed VAST (HR 3.15, $p < 0.0005$) and MELD-XI (HR 1.21, $p = 0.013$) independent role. ROC analysis identified VAST ≥ 1 (AUC 0.84) and MELDXI ≥ 10 (AUC 0.92) as mortality predictors.
Conclusion: FALD results in advanced liver disease in nearly all patients over time. MELD-XI and VAST scores predict mortality in FALD. Pre-Fontan liver injury is associated with increased mortality. Liver stiffness is not a reliable marker of FALD progression. Although disease severity increases significantly in the 10–15 years post-Fontan interval, a notable subset of patients develops FALD and cirrhosis earlier, when liver assessment rates are low. We therefore advocate for the initiation of liver assessments in all patients within the first decade post-Fontan to enable timely monitoring and management of hepatic complications.

OS-022
Patient-level analysis of intrahepatic z-alpha-1 antitrypsin burden in patients with alpha-1 antitrypsin deficiency-associated liver disease following fazirsiran treatment

Virginia C. Clark[1], Jen-Chieh Chuang[2], Feng Hong[2], Vandana Gupta[2], Ran Ye[2], Natasha Darras[2], Alexander J. Prokopienko[2], Susana Gonzalez[2], Paresh Thakker[2], Nirav K. Desai[2], Thomas Schluep[3], James Hamilton[4], Pavel Strnad[5], Rohit Loomba[6]. [1]*University of Florida, Gainsville, FL, United States;* [2]*Takeda Development Center Americas, Inc., Cambridge, MA, United States;* [3]*Arrowhead Pharmaceuticals, Inc., Pasedena, CA, United States;* [4]*Arrowhead Pharmaceuticals, Inc., Pasadena, CA, United States;* [5]*University Hospital RWTH Aachen, San Diego, CA, United States;* [6]*University of California San Diego, San Diego, CA, United States*
Email: roloomba@health.ucsd.edu

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disease characterized by Z-alpha-1 antitrypsin (Z-AAT) aggregates in the liver, which may lead to AATD-associated liver disease (AATD-LD). Periodic Acid–Schiff staining with diastase (PAS-D) and liquid chromatography–mass spectrometry (LC–MS) are methods to assess intrahepatic Z-AAT burden, which is a biomarker of AATD-LD. This study aimed to leverage data from two phase 2 trials of fazirsiran (an investigational small interfering RNA therapy for AATD-LD) to understand the onset and magnitude of changes in PAS-D and LC–MS-based Z-AAT burden in patients with AATD-LD, which has not previously been fully characterized.
Method: Baseline and post-baseline (range 24–96 weeks) liver biopsy samples from patients enrolled in the phase 2 AROAAT-2001 (NCT03945292)/-2002 (NCT03946449) trials who received fazirsiran or placebo were included. PAS-D composite score (range: 0–9) and its histologic components were centrally read and adjudicated by three histopathologists. Intrahepatic Z-AAT (total, soluble and insoluble) protein burden was analysed by LC–MS. Further methodological details are described in Strnad *et al. NEJM*, 2022 and Clark *et al. Gastroenterology*, 2024.

Results: Of 41 patients from the AROAAT-2001 (n = 25)/-2002 (n = 16) trials, baseline median (interquartile range) PAS-D composite score was 8.0 (5.0, 8.0), total intrahepatic Z-AAT was 39.4 (26.4, 83.8) nmol/g, soluble intrahepatic Z-AAT was 20.8 (15.9, 28.6) nmol/g and insoluble intrahepatic Z-AAT was 18.4 (8.2, 53.1) nmol/g. Compared with baseline, all patients treated with fazirsiran (n = 32) had markedly reduced intrahepatic Z-AAT burden when measured using PAS-D and LC–MS; reductions occurred as early as Week 24 and were sustained to Week 96. In five patients with two available post-fazirsiran liver-biopsy assessments, there were continuous and sustained reductions in PAS-D score and LC–MS-based total intrahepatic Z-AAT burden; in patients who received placebo (n = 9), intrahepatic Z-AAT burden was largely unchanged after treatment. Overall, 15/19 (78.9%) and 1/9 (11.1%) patients treated with fazirsiran 200 mg or placebo, respectively, had a ≥ 4-point reduction in PAS-D composite score. All patients treated with fazirsiran 200 mg, and no patients treated with placebo, had a ≥ 70% reduction in LC–MS-based total intrahepatic Z-AAT protein burden.
Conclusion: A robust and sustained reduction of intrahepatic Z-AAT burden in patients with AATD-LD following fazirsiran treatment was demonstrated using two independent analytical approaches (PAS-D and LC–MS). Current findings will be validated in an ongoing phase 3 trial (NCT05677971) in which the effect of fazirsiran on the reversal of liver fibrosis in patients with AATD-LD will be evaluated.

OS-023

Single-cell spatial transcriptomic map of biliary atresia

Jake Mann[1,2], Annabelle Schofield[1], Alba Bueno-Jimenez[2], Scott Davies, Girish Gupte[2], Evelyn Ong[2], Khalid Sharif[2], Christopher Shave[1], Hector Vilca-Melendez[2], Ye Htun Oo. [1]*University of Birmingham, Birmingham, United Kingdom;* [2]*Birmingham Children's Hospital, Birmingham, United Kingdom*
Email: j.p.mann@bham.ac.uk

Background and aims: Biliary atresia is characterised by neonatal obliteration of the extrahepatic biliary tree. 50% of children require liver transplantation at under 5 years, despite Kasai portoenterostomy. Multiple aetiological factors are implicated in the initial hit to the biliary system (e.g. polygenic, viral). In the liver, cholangiocytes proliferate in an fibroinflammatory niche known as the 'ductular reaction'. These fibroinflammatory foci may expand to eventually result in end-stage cirrhosis. The epithelial-mesenchymal-immune interactions governing regulation of fibroinflammation across the disease course are not known. It is not clear why some children need early transplant 'rapid progressors' and some remain stable long-term. Here, our overall aim was to understand the interactions governing fibroinflammation across the spectrum of biliary atresia at single-cell resolution. Specifically, we aimed to identify differences at the time of Kasai that predict need for early transplantation.
Method: We performed CosMx single-cell transcriptomic profiling (1000 genes) on liver at time of Kasai from 4 patients with non-syndromic biliary atresia. 2 patients were 'rapid progressors' - transplant under 2 years old; and 2 were 'slow progressors' requiring transplant at 12–15 years old. All patients had moderate (3/6) fibrosis at the time of Kasai. CellChat was used to calculate cell-cell interaction signalling networks. Markers were replicated using a meta-analysis of RNA sequencing data from 182 BA cases, 92 disease-free controls, and 19 cholestatic non-BA controls. Results were validated using multiplex immunofluorescence.
Results: Single-cell spatial profiling identified 269,825 individual cells, after quality-control. Liver at the time of Kasai demonstrated proliferative cholangiocytes, surrounded by portal fibroblasts (expressing IGFBP7, CXCL12, and CD74), accompanied by SPP1 +TREM2+GPNMB+ macrophages. 'Rapid progressors' had more GPNMB+ macrophages, monocytes, and fibroblasts but fewer cholangiocytes. Sinusoidal endothelia from rapid progressors had higher expression of ICAM1 (51% vs. 29%, p.adj= 9.7 × 10–96) and CCL2 (43% vs. 24%, p.adj= 6.2 × 10–78). Cholangiocytes from rapid progressors had higher ANKRD1 expression (36% vs. 21%, p.adj= 3.4 × 10–131), which is down-stream of the pro-fibrotic transcription factor YAP. In addition, CellChat found SPP1-ITGAV/ITGB1, MIF-CD74, CXCL12-CD44/ACKR3, to be key cell- communication factors in the fibroinflammatory niche at Kasai.
Conclusion: At time of Kasai, patients who would go on to need early transplant was predicted by presence of a pro-inflammatory endothelial phenotype with increased monocytes and fewer, but dysfunctional cholangiocytes.

OS-024

Proteomic newborn screening for Wilson disease in Washington state

Sihoun Hahn[1,2,3], Claire Klippel[3], Jiwoon Park[3], Sean Sandin[3], Tara Winstone[4], Xue Chen[4], Dennis Orton[4], John Thompson[5], Brandon Officer[5], Emily Hamacher[5], Tareq Shahbal[5], Jonathan Hill[5], Aranjeet Singh[5], Phi Duong[2], Tim Grotzer[2]. [1]*University of Washington School of Medicne, Seattle Children's Hospital, Seattle, United States;* [2]*Seattle Children's Research Institute, Seattle, United States;* [3]*Key Proteo, Seattle, United States;* [4]*Alberta Precision Laboratories, Calgary, Canada;* [5]*Washington State Department of Health Newborn Screening Laboratories, Seattle, United States*
Email: sihahn@uw.edu

Background and aims: Wilson disease (WD) is an autosomal recessive condition caused by mutations in the *ATP7B* gene, which encodes the copper-transporting ATPase 2 that plays a crucial role in cellular copper homeostasis. The prevalence is widely accepted as 1 in 30,000 individuals in most populations with a carrier frequency of 1 in 90, although variations in the estimation have been reported. While early diagnosis with effective treatment is critical to preventing long-term complications such as liver cirrhosis and permanent brain damages, the wide array of clinical phenotypes and variations of manifestations among patients present significant challenges for early diagnosis. We recently demonstrated that quantification of ATP7B peptide in the dried blood spots (DBS) using LC-MS/MS is a promising methodology for newborn screening (NBS). NBS is considered the most successful public health program to identify infants with treatable disorders for early intervention with favorable outcomes.
Method: A novel proteomic-based multiplex assay to detect two surrogate peptides of ATP7B protein from DBS using high-throughput LC-MS/MS was developed and validated for analytical and clinical precision following the Clinical and Laboratory Standards Institute (CLSI) guidelines. Initial diagnostic cutoffs were set by running 1,056 newborn samples. Additionally, 30,024 newborn samples have been screened using the multiplex analysis from 2022 to 2024. 57 samples with peptide concentrations above but near the cutoff were sent out for sequencing as part of a false negative study to determine if borderline samples were being missed as negative.
Results: The analytical validation study results show that LOB, LOD and LOQ were lower than the diagnostic cutoffs. The reproducibility study results show that our immuno-SRM assay can produce consistent results over days or between different users/instruments. The assay was successfully validated by detecting all 32 genetically confirmed true WD positive blinded samples from a total of 3,294 newborn samples across 3 study sites. One true presumptive positive case of WD has been found along with three false positive cases from the pilot study samples. The positive predictive value was estimated to be 25%, and the false positive rate to be 0.001%. No false negatives were detected from the 57 borderline samples except two samples, each with one pathogenic and one variant of uncertain significance.
Conclusion: Our novel proteomic assay has the sensitivity and precision required to quantify low abundance proteins from dried blood spots. The assay also yields reproducible results in different test sites, making it the appropriate screening candidate for countries across the globe. The pilot study demonstrates the feasibility and

effectiveness of utilizing the proteomic assay for newborn screening of Wilson disease.

Viral hepatitis Basic Science and Liver Immunology

OS-025
Characterizing the molecular mechanism of hepatitis B virus cccDNA loss following mitosis

Gaihong Zhao[1], Yuchen Xia[1]. [1]*Wuhan University, Wuhan, China*
Email: 00032118@whu.edu.cn

Background and aims: The persistence of covalently closed circular DNA (cccDNA) in infected hepatocytes represents the primary barrier to hepatitis B virus (HBV) eradication. Effective elimination of cccDNA is therefore critical for achieving an HBV cure. Recent findings suggest that the proliferation of HBV-infected hepatocytes may lead to cccDNA depletion, but the underlying mechanism remains unclear. We hypothesize that during mitosis, the breakdown of the nuclear envelope exposes cccDNA to cytoplasmic components, leading to its degradation.
Method: Cell division was induced in HBV-infected cells and cells transfected with HBVcircle, a cccDNA mimic, by passaging the cells. cccDNA loss was monitored, and the effect of cell cycle inhibitors on this process was assessed. HBVcircle was incubated with nuclear or cytoplasmic lysates to identify components responsible for cccDNA degradation. The degradation activity was further characterized using heat inactivation, proteinase K, EDTA, EGTA, and nuclease inhibitors. LC-MS analysis was conducted to identify candidate nucleases. siRNA screening and CRISPR-mediated knockout were employed to validate the involvement of a specific cytoplasmic DNA nuclease (CDN). Functional studies included prokaryotic expression and purification of CDN and its overexpression in HBV-infected cells with a nuclear localization sequence (NLS).
Results: cccDNA loss was observed following cell division in both HBV-infected and HBVcircle-transfected cells, and this phenomenon was reversed by cell cycle inhibitors. Incubation of HBVcircle with cytoplasmic lysates, but not nuclear lysates, resulted in its degradation. This activity required metal-ion-dependent nucleases, as it was inhibited by heat inactivation, proteinase K, EDTA, EGTA, and nuclease inhibitors. LC-MS identified nine potential nucleases, and siRNA screening pinpointed one specific CDN. CRISPR-mediated knockout of this gene rescued cccDNA levels in HBV-infected cells following cell division. The purified CDN degraded HBVcircle in a dose-dependent manner in vitro. Notably, overexpressing CDN fused with an NLS in HBV-infected cells led to significant cccDNA loss.
Conclusion: This study uncovers a novel mechanism by which cccDNA is degraded during mitosis via exposure to a cytoplasmic DNA nuclease. The findings highlight a potential therapeutic strategy to target cccDNA for HBV cure by leveraging this mechanism.

Email: venzin.valentina@hsr.it

Background and aims: Efficient priming of $CD8^+$T cell responses against non-cytolytic pathogens like HBV is believed to rely on $CD4^+$T cell help within secondary lymphoid organs. This hypothesis is supported by an observation in experimentally infected chimpanzees, where $CD4^+$T cell depletion prior infection prevents $CD8^+$T cell priming and leads to persistent infection. However, where when and how this issue occurs has never been described or mechanistically elucidated.
Method: We took advantage of unique HBV transgenic mouse models, in which we have demonstrated that adoptive transferred HBV-specific $CD8^+$T cells that recognize hepatocellular viral antigens undergo activation and proliferation but fail to differentiate into antiviral effector cells. To understand the extent to which antigen-specific $CD4^+$T cells help intrahepatic $CD8^+$T cell differentiation, we generated HBV-specific $CD4^+$ TCR transgenic mice (Env126), where all $CD4^+$T cells recognize an I-Ab-restricted T cell epitope of the HBV envelope protein.
Results: Here, we show that the adoptive transfer of T_{H1}-like Env126 effector $CD4^+$T cells in HBV-transgenic mice counteracts the $CD8^+$T cell dysfunction induced by hepatocellular priming, boosts their proliferation and stimulates their production of IFN-γ, TNF-α, and Granzyme-B within the liver. This enhances $CD8^+$T cell-mediated liver immunopathology and suppresses viral replication. Against what the immunological dogma would dictate, our study shows that $CD4^+$T cell help to $CD8^+$T cells occurs locally within the liver, bypassing secondary lymphoid organs. Intriguingly, dendritic cells are dispensable for the observed effects and instead, Kupffer cells (KCs) show enhanced cross-presenting capacity upon Env126 effector $CD4^+$T transfer, emerging as the critical cellular platform for intrahepatic T-cell cooperation. With multiphoton intravital microscopy we indeed reveal that HBV-specific $CD4^+$ and $CD8^+$T cells simultaneously interact with KCs within the liver, and as such, the restorative process of Env126T effector $CD4^+$T cells help is impeded upon KCs depletion. Mechanistically, $CD4^+$T cells engage KCs via CD40-CD40L interactions, leading to the production of IL-12 and IL-27. IL-12 promotes $CD4^+$T cell expansion, whereas IL-27 reinvigorate the $CD8^+$T cell response. Finally, we show that exogenous administration of IL-27 reinvigorates HBV-specific $CD8^+$T cell responses in both HBV-transgenic mice and human T cells isolated from chronic HBV patients.
Conclusion: Our findings reveal a novel mechanism of $CD4^+$T cell help to $CD8^+$T cells that occurs outside secondary lymphoid organs, specifically in the liver, and involves antigen-presenting cells other than conventional dendritic cells. The described cellular and molecular mechanisms offer new insights for immunotherapeutic strategies against chronic hepatic infections and their life-threatening complications.

OS-027-YI
A human cirrhosis single-cell atlas identifies a pro-inflammatory subpopulation of scar-associated macrophages as a therapeutic target for liver fibrosis

Kexin Kong[1], Eleni Papachristoforou[1], Fabio Colella[1], Juliet Luft[1], Jacky Tam[1], Malgorzata Grzelka[1], Max A. Hammer[1], Stefan Veizades[1],

George Finney[2], Ginevra Pistocchi[2], Catalina A. Vallejos[3], Laura J. Pallett[2], Prakash Ramachandran[1]. Email: kexin_2021@163.com

Background and aims: Single-cell RNA sequencing (scRNAseq) is a powerful tool for exploring the cellular mechanisms driving fibrosis in chronic liver disease (CLD). However, the use of small sample sizes in individual scRNAseq studies has hindered comprehensive cellular annotation and accurate definition of pathogenic cell types across multiple patients. To address this, we aimed to develop a human cirrhosis cellular atlas, utilising this resource to better define the specific macrophage subtypes which promote liver inflammation and fibrosis and assess how they could be targeted therapeutically.
Method: Raw human liver scRNAseq data was processed from 81 patients (42 healthy and 39 CLD). Following quality control, 843,457 high quality cells were analysed in depth. The Seurat V5 package was used for integration, clustering and marker gene detection. Iterative subclustering and manual cell type annotation was performed on each cell lineage. Differential abundance and expression analyses were conducted using Milo and MAST respectively. Ligand-receptor interactions between mononuclear phagocytes (MPs) and mesenchymal cells were assessed using CellChat. Validation of human scRNAseq data was performed by multiplex immunofluorescence (IF) and scRNAseq of mouse immune cells from the carbon tetrachloride (CCl_4) model of CLD.
Results: In total we annotated 127 cell states in the cirrhosis atlas, encompassing all major cell lineages and including rare cell types such as neurons, basophils, mast cells and haematopoietic progenitors. Focussing on MPs, analysis of 81,577 cells revealed 14 transcriptionally distinct clusters. Notably, the large cell and patient number enabled the distinction of 2 subpopulations of *TREM2+ CD9+* scar-associated macrophages (SAMacs), termed SAMac1 and SAMac2, both of which expanded significantly in patients with cirrhosis irrespective of sex or CLD aetiology. Differential expression analysis demonstrated that SAMac1 was enriched in anti-inflammatory mediators, whilst SAMac2 expressed higher levels of pro-fibrotic and pro-inflammatory cytokines such as *IL1B* and *IL18* and was predicted to interact with scar-producing myofibroblasts. IF staining confirmed the co-existence of SAMac1 and 2 in the human fibrotic niche, whilst analysis of mouse scRNAseq data demonstrated corollary pro- and anti-inflammatory SAMac subpopulations. Ongoing work aims to modulate targets specifically expressed by the pro-inflammatory SAMac2 subpopulation.
Conclusion: Our human cirrhosis cell atlas demonstrated previously undescribed liver cellular heterogeneity, including the identification of a novel subtype of SAMacs which expands in cirrhosis, has pro-inflammatory and pro-fibrotic properties and is recapitulated in mouse CLD. Specific targeting of this population may therefore inhibit liver fibrogenesis without disrupting anti-inflammatory SAMac properties.

Email: edanur.ates-oz@tum.de

Background and aims: Despite the availability of effective prophylactic vaccines, nearly 4% of the world population is chronically infected with the hepatitis B virus (HBV). Chronic HBV infection is characterized by a lack of neutralizing antibodies and scarce, partially dysfunctional HBV-specific T cells. Restoring virus-specific immune responses by therapeutic vaccination represents a promising treatment option. Our clinical candidate protein-prime/MVA-boost therapeutic vaccine, *TherVacB*, proved efficacious in preclinical mouse models with low-to-intermediate HBV levels; however, in high-titer mice, the vaccine failed to eliminate persistent HBV infection. This study aimed to understand the factors contributing to T-cell responsiveness by comparatively characterizing *TherVacB*-elicited liver-associated CD8 T cells in low and high-titer HBV carrier mice to eventually find potential therapeutic targets to overcome T-cell dysfunctionality in high-titer HBV carriers.
Method: We established low and high levels of persistent HBV infection in C57BL/6J mice using AAV-HBV and then applied *TherVacB*. We isolated liver-associated vaccine-elicited core-specific CD8 T cells at multiple time points and performed comparative transcriptomic and phenotypic analyses in low and high-titer HBV carrier mice.
Results: Transcriptome analysis revealed that *TherVacB* induced comparable numbers of effector CD8 T cells in low and high-titer mice; however, their functionality and long-term survival were determined by hepatic HBV levels. Following the clearance of the infection, long-lasting effector and tissue-resident memory T-cell subsets were established in low-titer mice. In high-titer mice, vaccine-induced CD8 T cells continuously expressed high levels of co-stimulatory molecule 4-1BB together with the well-known exhaustion-related co-inhibitory molecules. Thus, we wondered whether combining *TherVacB* with 4-1BB targeting monoclonal antibodies (mAb) could improve the antiviral efficacy of therapeutic vaccination in high-level HBV infection. We immunized high-titer HBV carrier mice with *TherVacB* with or without *in vivo* 4-1BB mAb treatment and compared HBV-specific immune responses and infection parameters. Co-administration of 4-1BB agonistic mAbs resulted in elevated cytokine production in vaccine-induced CD8 T cells as compared to only vaccinated mice. In addition, combinatorial treatment with 4-1BB mAbs resulted in a significant reduction of serum HBeAg and HBsAg levels accompanied by mild, transient ALT flares and efficient elimination of HBV-infected hepatocytes.
Conclusion: Combining *TherVacB* with 4-1BB stimulation improved HBV-specific CD8 T-cell functionality and enhanced the antiviral efficacy of *TherVacB*. This demonstrates that 4-1BB represents a promising therapeutic target to counteract T-cell dysfunctionality in high-titer HBV carriers.

Background and aims: Chronic hepatitis D is the most severe form of chronic liver disease, with a rapid progression to cirrhosis and hepatocellular carcinoma. Understanding the intricate relationships between HDV, HBV, and liver cells, as well as the host immune response is essential for developing effective prevention and treatment strategies. Our study aimed to characterize the transcriptional landscape of the liver in HBV and HDV infected patients.
Method: We included 5 HBV/HDV coinfected patients (anti-HDV positive), 3 with detectable HDV-RNA (HDV+) and 2 with undetectable HDV-RNA (HDV-), and 3 HBV infected patients (as controls). We used dual chromogenic immunostaining to visualize HBsAg and HDAg in the liver (Bond RX, Leica). Spatial transcriptomics was applied to FFPE liver samples using CosMx Spatial Molecular Imaging (1000-plex RNA, Nanostring). Cell segmentation was performed using morphology visualization markers, including B2M/CD298, PanCK, CD45, CD68 and DAPI.
Results: The analysis of viral antigens revealed that in samples from HDV/HBV coinfected patients, most hepatocytes expressed high levels of HBsAg, but co-expression with HDAg was rare. Specifically, HDAg was restricted to areas with low or undetectable levels of HBsAg. By combining single-cell RNA sequencing (scRNA-seq) data with spatial transcriptomics, we identified over 30 cell types encompassing major populations of the immune system, as well as various subpopulations of hepatocytes, cholangiocytes, and Kupffer cells. Hepatocytes from HDV/HBV coinfected patients exhibited differential gene expression compared to HBV infected patients, characterized by the overexpression of more than 180 genes. Most of these genes were associated with signaling pathways related to the inflammatory response (IL6-JAK-STAT, TNF-NFκB), innate immunity (IFN response), and adaptive immunity (IL2-STAT5). These findings were also confirmed at an intra-patient analysis, where hepatocytes in areas expressing both HDAg and HBsAg showed greater activation than those expressing only HBsAg. Furthermore, in HBV infected patients, HBsAg expression was not only associated with the activation of pro-inflammatory pathways but also with pathways linked to cancer development, such as epithelial-mesenchymal transition.
Conclusion: The expression of viral antigens in the liver is associated with alterations in the host's transcriptome, highlighting the dynamic interplay between viral infection and host responses. Spatial transcriptomics provides a detailed view of the hepatic microenvironment, revealing pathway differences in HBV/HDV coinfection compared to HBV infection, at a cellular level. These findings provide a basis for identifying biomarkers and targets for hepatitis delta treatments.

Email: katrine.tholstrup.bech@rsyd.dk

Background and aims: In the presence of hepatic steatosis and cardiometabolic risk factors, alcohol intake defines the subtypes of steatotic liver disease (SLD). However, self-reported alcohol intake is prone to recall bias and underestimation. The blood-based biomarker phosphatidylethanol (PEth) provides an objective measure of past four weeks' alcohol intake, but has primarily been used to monitor abstinence or heavy drinking in alcohol use disorder studies. We aimed to compare the correlation between PEth and self-reported alcohol intake in a screening cohort of people at risk of SLD.
Method: We conducted a single center, cross-sectional study to screen populations at risk of SLD due to current/prior harmful alcohol intake or metabolic dysfunction. PEth was measured at the time of inclusion. Participants reported their alcohol intake the past week, and average weekly intake over the past three months (hereafter: 'average'). We defined hazardous drinking as an AUDIT-C score ≥3/≥4 (f/m). We used CAP ≥ 248 dB/m to define hepatic steatosis and vibration-controlled transient elastography (VCTE) ≥ 8 kPa to define fibrosis. We divided participants into MASLD, MetALD, ALD or no SLD based on the presence of steatosis, cardiometabolic risk factors and the self-reported average alcohol intake.
Results: We included 2,925 participants distributed into MASLD/MetALD/ALD/no SLD (1,433/409/201/882). Median age was 57 years (IQR 51–64), 51% were males. Median PEth was 40.8 ng/mL (7.0–202.5) and the self-reported alcohol intake was 5 g/day (0–24) the past week, and 9 g/day (2–34) on average. AUDIT-C indicated hazardous drinking in 71% of participants overall. The correlation between PEth and past-week alcohol intake was modest (r = 0.400) and poor between PEth and average intake (r = 0.131). PEth levels increased stepwise from MASLD, to MetALD and ALD (11.2 vs. 246.1 vs. 470.3 ng/mL). In the MASLD group, 8% had a PEth indicative of heavy alcohol intake (≥200 ng/mL), while 31% had levels indicative of a significant intake (>20–199 ng/mL). However, of participants with a significant intake, the majority (22%) exhibited intermediate PEth levels (20–79 ng/mL), which could be within MASLD limits of 1–2 standard drinks per day. In participants with AUDIT-C indicative of hazardous drinking, PEth was higher as compared to those with a normal AUDIT-C (101.9 vs. 5.6 ng/mL, p < 0.001). Finally, VCTE values were independent of both PEth ≥20 ng/mL and high self-reported drinking.
Conclusion: PEth exhibit poor correlation with self-reported average alcohol intake in the population, and only modest correlation with very recent alcohol intake. PEth measurements indicate that more than one-third of MASLD participants may underestimate their alcohol intake and therefore be misclassified. This discrepancy is critical for the patient stratification in clinical trials, potentially affecting study outcomes and generalizability.

OS-031-YI
Hepatocyte-neutrophil interaction in the liver via SAA-FPR2 is key in the pathogenesis of alcohol-associated hepatitis

Email: almartia@recerca.clinic.cat

Background and aims: Alcohol-associated hepatitis (AH) is the most severe form of alcohol-related liver disease (ALD). Using single-cell

RNA sequencing (scRNAseq) data from liver biopsies, we previously identified hepatocyte and neutrophil subpopulations enriched in AH. In this study, we focused on the interplay between hepatocytes and neutrophils subpopulations in AH to gain insight into the pathogenesis, with particular emphasis on the via of serum amiloid A - formyl peptide receptor 2 (SAA-FPR2).
Method: scRNAseq data from liver biopsies of patients with ALD at different stages (healthy n = 3; early ALD n = 3; AH n = 6) were analysed using CellChat to identify cellular interactions. The expression of SAA in liver biopsies was assessed by immunofluorescence (IF). SAA expression was assessed in a previously generated in vitro liver organoid model derived from liver biopsies of ALD patients treated with an AH medium containing a mixture of pro-inflammatory mediators (IL1b, TNFa, LPS, ethanol) using IF. SAA secretion in the liver organoid model was measured by ELISA. Human plasma levels of SAA were measured by ELISA in a cohort of patients with different stages of ALD (healthy n = 9; early ALD (F0/F1, F2, compensated cirrhosis) n = 34; AH n = 43) and the association with disease stage, survival (1, 3 and 12 months) and bacterial infections was analysed.
Results: scRNAseq analysis identified two hepatocyte subpopulations enriched in AH and overexpressing SAA, and a neutrophil subpopulation with high expression of IL1R1 and FPR2, the latter identified as a receptor for SAA. In silico analysis revealed a strong interaction between these subpopulations via SAA-FPR2 axis. IF of liver biopsies showed overexpression of SAA in hepatocytes and of IL1R1 and FPR2 in neutrophils from patients with AH. In liver organoids, SAA expression increased notably at the transcriptomic and protein levels in response to stimuli with AH medium. In human plasma, SAA levels increased significantly with ALD progression (healthy: 8782 ng/mL; early ALD: 19285 ng/mL; severe AH: 37710 ng/mL, p = 0.051). In patients with AH, SAA levels were higher in those who died at 1, 3 and 12 months compared to survivors (1 month: 48703 vs. 34885 ng/mL, p = 0.036; 3 months: 46034 vs. 36924 ng/mL, p = 0.038; 1 year: 53990 vs. 20361 ng/mL, p = 0.009). In addition, plasma SAA levels were increased in patients with active bacterial infections (47061 vs 33195 ng/mL, p = 0.053).
Conclusion: This study highlights the pivotal role of SAA-FPR2 in mediating interactions between hepatocytes and neutrophils, two of the most relevant cell populations in AH pathogenesis. We show how SAA increases its expression in response to inflammation, resulting in an intense interaction with neutrophils in the liver and in secretion into the general circulation, showing its utility as a biomarker of disease progression, patient survival and development bacterial infections.

OS-032

Comparative perioperative morbidity and mortality of transplantation for alcohol-related hepatitis or liver disease: data from the QuickTrans study

Email: alexandre.louvet@chru-lille.fr

Background and aims: Early liver transplantation (LT) improves term survival in patients with severe alcohol-related hepatitis (sAH) who do not respond to medical management, but few perioperative data are available. The aim of this study was to compare the perioperative morbidity outcomes and mortality of patients transplanted for sAH or decompensated alcohol-related cirrhosis.
Method: In the prospective multicenter QuickTrans study (19 centers), perioperative data (up to 90 days post-LT) of patients transplanted for sAH or decompensated alcohol-related cirrhosis were collected retrospectively. Pre-LT, perioperative, postoperative data and survival at 90 days and 2 years were compared between the 2 groups.
Results: Between 2012 and 2016, 68 patients with sAH were transplanted (group A) and 93 patients underwent standard LT for decompensated alcohol-related cirrhosis (group B). The Charlson index (with a median of 4, p = 0.3) and the median age of the donor (61 years in group A *vs.* 59.5 in group B, p = 0.46) were similar. Median cold ischemia time was also similar: 467 (A) *vs.* 465 minutes (B), p = 0.95. Patients transplanted for sAH tended to receive more transfusions during LT (median of 6 vs. 4 packed red blood cells, p = 0.08). During LT, patients with sAH had more often hemodynamic instability or bleeding (39.7 *vs.* 24.7%, p = 0.04). Patients transplanted for sAH had a trend toward being still intubated after 24 hours (79.4 *vs.* 65.9%, p = 0.07) and being on vasopressive support (32.1 vs. 20.2%, p = 0.12). After LT, 31.3% of patients with sAH needed renal replacement therapy *vs.* 19.1% in group B, p = 0.08. The length of stay in ICU after LT was two times longer in group A (10 vs. 5 days, p = 0.0002) and the total length of stay after LT was longer in group A (32 *vs.* 22.5 days, p = 0.0006). In univariate analysis, being transplanted for sAH and the MELD score at LT were associated with the risk of being still hospitalized 30 days after LT. In multivariate analysis, only sAH was independently associated with this risk (p = 0.04), whereas the MELD score was not (p = 0.22). After LT, 80.9% of patients (group A) *vs.* 76.3% (group B) had complications (p = 0.5), with infections or surgical complications being the most frequent, with no difference between the two groups (respectively 35.3 *vs.* 31.2%, p = 0.58 and 36.8 *vs.* 32.3, p = 0.55). Survival in the 2 groups was identical at 90 days (94.1 ± 2.9 *vs.* 94.6 ± 2.4%, p = 0.9) and 2 years after LT (89.6 ± 3.7 *vs.* 88 ± 3.4%, p = 0.77).
Conclusion: While patients transplanted for sAH have similar survival and complication rate after LT as patients transplanted for cirrhosis, their ICU and hospital stays are longer. These patients also have a more frequent need for renal replacement therapy and a trend toward postoperative delayed extubation and discontinuation of vasopressors. These results underline the need for adapting perioperative management of patients transplanted for alcohol-related hepatitis.

OS-033

Liver injury induced by CDK4/6 inhibitors for metastatic breast cancer: characterization and management. Data from a multicenter study

Background and aims: The cyclin-dependent kinase 4/6 inhibitors (CDKi) are the first line therapy for HER2-metastatic breast cancer. Rate of grade 3/4 CDKi-induced liver injury (CDKi-ILI) in the registry studies was 5–9%. However, real-world data on CDKi-ILI characteristics and, specifically management, is scarce.
Method: Multicenter retrospective study that included all patients who started CDKi between 2018 and 2022 and developed CDKi-ILI ≥2 (CTCAE: AST/ALT >3xULN).
Results: A total of 1716 women were identified (861 palbociclib, 504 ribociclib, 351 abemaciclib) and 85 (4.9%) developed CDKi-ILI: 27 (31.8%) grade-2, 46 (54.1%) grade-3, 12(14.1%) grade-4. Rate of CDKi-ILI was higher ($p < 0.001$) among those treated with ribociclib (8.5%) or abemaciclib (8.0%) than palbociclib (1.6%). No differences were observed in severity (CTCAE: grade≥3: 76.7% ribociclib, 57.1% palbociclib, 60.7% abemaciclib, $p = 0.227$; DILI-IEWG ≥ moderate: 14.0% ribociclib, 7.1% palbociclib, 14.3% abemaciclib, $p = 0.778$). DILI-IEWG ≥ moderate was more frequent in those with increased ALT at baseline ($p = 0.089$), or progressive disease at the time of DILI ($p = 0.015$). Pattern of DILI differed according to the CDKi ($p < 0.001$), with hepatocellular as the most common in patients receiving ribocicib (65.1%) and palbociclib (61.5%), and mixed for abemaciclib (59.3%). Five out of 25 (20%) tested for ANAs presented titers ≥1/80. Half of CDKi-ILI cases presented within the first 3 months of therapy (52.9%), with no difference according to the type of CDKi ($p = 0.521$) or severity ($p = 0.516$). Regarding management, 16 (18.8%) were treated with corticosteroids (CS), especially among those with grade-4 CTCAE ($p < 0.001$) or moderate DILI-IEWG ($p = 0.005$). A tendency to higher rate of CS was observed for those on ribociclib ($p = 0.092$). Median duration of CS was 43 days (IQR 26–57). Liver biopsy was performed in 10 (11.8%) patients, more frequent in patients with grade-4 CTCAE ($p = 0.002$), but similar according to the CDKi ($p = 0.794$). The most frequent findings were presence of eosinophils (90%), bridging necrosis (40%), cholestasis (40%), interphase hepatitis (30%), lymphocytic/lymphoplasmacytic infiltrate (50%). After a median of 36 days (IQR, 16–80), 70 (82.4%) patients were rechallenged, rate lower in case of prior DILI-IEWG ≥moderate ($p = 0.022$), but similar regardless of the initial CDKi ($p = 0.287$) or CTCAE ($p = 0.507$). Change on the CDKi was more common among those previously treated with ribociclib ($p = 0.031$), presenting with hepatocellular pattern ($p = 0.039$) and grade 3/4 CTCAE ($p < 0.001$). Recurrence of CDKi-ILI was observed in 19/70 (27.1%) patients, all of them mild.
Conclusion: CDKi-ILI is common, especially within the first months of therapy with ribociclib or abemaciclib. Management of CDKi-ILI is heterogeneous and its standardization a necessity in view of the recent approval of ribociclib and abemaciclib as adjuvant therapy.

Corticosteroids are ineffective in individuals with severe alcohol-associated hepatitis and early spontaneous improvement: a multicenter randomized controlled trial

Christophe Moreno[1], Pierre Deltenre[2], Astrid Marot[3], Hassane Njimi[4], Luc Lasser[5], Delphine Degré[1], Axel Hittelet[6], Jean Delwaide[7], Anja Geerts[8], Silke François[9], Boris Bastens[10], Thierry Gustot[1], Eric Trépo[1]. *[1]Department of Gastroenterology, Hepatopancreatology and Digestive oncology, CUB Hôpital Erasme, Université Libre de Bruxelles, Brussels, Belgium; [2]Department of Gastroenterology and Hepatology, Clinique St Luc, Bouge, Belgium; [3]Department of Gastroenterology and Hepatology, CHU UCL Namur, Université Catholique de Louvain, Yvoir, Belgium; [4]Biomedical Statistics, Université Libre de Bruxelles, Brussels, Belgium; [5]Department of Hepatogastroenterology, CHU Brugmann, Brussels, Belgium; [6]Department of Gastroenterology, Hôpital Ambroise Paré, Mons, Belgium; [7]Department of Hepatogastroenterology, CHU Sart Tilman, Liège, Belgium; [8]Department of Hepatogastroenterology, Ghent University Hospital, Ghent, Belgium; [9]Department of Hepatogastroenterology, UZ Brussel, Brussels, Belgium; [10]Department of Gastroenterology, Hôpital Saint-Joseph, Liège, Belgium*
Email: christophe.moreno@hubruxelles.be

Background and aims: Severe alcohol-associated hepatitis (AH) is a life-threatening disease for which corticosteroid therapy is recommended in the absence of contraindication. A significant proportion of patients with severe AH have a spontaneous serum bilirubin decrease early after admission. Our aim was to determine whether corticosteroid therapy is more effective than placebo in individuals with severe AH and early spontaneous improvement.
Method: In this multicenter, randomized, controlled trial conducted between February 2018 and May 2024 in 10 Belgian hospitals, patients aged 18 or older, who were heavy drinkers, with recent onset of jaundice, with a biopsy-proven severe AH (mDF ≥ 32 at admission), and with a spontaneous early improvement (i.e. serum bilirubin level decrease > 10% at day 5–10 after admission) were randomized to either corticosteroids (CS) (methylprednisolone 32 mg/d) or placebo (P) for 28 days. Primary endpoint was to compare 3-month mortality rate between both groups of treatment. Secondary endpoints were to compare 1-month mortality rate and infection rate during study period between both groups.
Results: A total of 69 patients were randomized, 38 in the corticosteroid group and 31 in the placebo group. Baseline characteristics were not significantly different between the two groups (CS vs P) for age (52 ± 8 vs. 51 ± 10), male gender (76% vs. 63%), total bilirubin (7.4[5.1–10.8] vs. 9.3[6.0–17.6] mg/dL), INR (1.64 [1.48–1.80] vs 1.70 [1.48–1.98]), mDF at admission (44[37–57] vs. 45[40–58]) and MELD score (21[19–23] vs 21[19–24]). Decrease in bilirubin level between admission and screening was not different between both groups (31 ± 15% vs 27 ± 11%). Lille score at day 7 of treatment was 0.18 [0.07–0.30] and 0.18 [0.07–0.40] in CS and P group, respectively ($p > 0.9$). At 3 months, the probability of survival was not different between both groups (83[72–96] vs 82[69–98] % in CS and P groups respectively, $p = 0.88$). There was no difference in the probability of 1-month survival between CS and P groups (95[88–100] vs 94[85–100] %, $p = 0.85$). Probability of infection during the study period was 48% in the CS group and 36% in the P group ($p = 0.41$). Age and Lille score were significantly associated with 3-month survival. The study was prematurely interrupted due to a low recruitment rate.
Conclusion: The present study failed to identify any benefit from corticosteroid therapy in patients with severe AH and early decrease in bilirubin level after admission. Even if the number of included patients initially planned was not reached, it is unlikely that corticosteroids provide a survival benefit when bilirubin level spontaneously decreases by at least 10%. Waiting five days after admission before deciding to start steroids seems to be a reasonable strategy.

Gut colonization guided versus routine empiric antimicrobial therapy to manage infections in patients with cirrhosis: a pragmatic randomized trial

Nipun Verma[1], Jayant Agarwal[2], Samonee Ralmilay[3], Pratibha Garg[3], Archana Angrup[4], Shashi Vig[4], Arka De, Madhumita Premkumar, Sunil Taneja[3], Ajay Kumar Duseja[3], Nusrat Shafiq[5]. *[1]Department of Hepatology, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [2]Department of Internal Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [3]Department of Hepatology, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [4]Department of Medical Microbiology, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [5]Department of Clinical Pharmacology, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India*
Email: nipun29j@gmail.com

Background and aims: Infections in cirrhosis are a major cause of death, and early, effective empirical antimicrobial treatment is critical. However, in high-burden settings like India, where multi-drug-resistant (MDR) infections are prevalent, empirical therapy often fails. Recognizing the strong correlation between rectal colonization and MDR infections, we evaluated whether rapid polymerase chain reaction (PCR) for carbapenemase genes (Xpert Carba-R) and microbial culture of rectal swabs could guide antimicrobial choices and improve outcomes in cirrhosis patients with infections.
Method: This pragmatic, parallel-group, open-label randomized trial [CTRI/2023/02/049479] was conducted at a tertiary-care center from 2023 to 2024. Adult cirrhosis patients hospitalized with bacterial infections (per EASL criteria) were included, excluding those with severe comorbidities, active malignancy, immunosuppression, or recent exposure to polymyxins or ceftazidime/avibactam. Patients were randomized to either an intervention group (rectal swab testing with Xpert Carba-R and microbial culture, followed by antimicrobial adjustments based on detected carbapenemase genes or colonizing bacteria) or a control group (standard empirical treatment per guidelines). Both groups received standard of care. The primary outcome was 28-day overall survival. Secondary outcomes included infection resolution, changes in severity scores, organ failure rates, hospital length of stay, adverse events, and patient costs.
Results: A total of 101 patients (median age 42 years; 90% male; median MELD score 30.1) with predominantly healthcare-associated infections (81.2%), such as pneumonia (46.5%) and spontaneous bacterial peritonitis (35.6%), were randomized (intervention: 51; control: 50). Baseline characteristics were similar between groups. Of 43 carbapenemase-positive patients, 40 in the intervention group received ceftazidime-avibactam plus aztreonam or polymyxin-based therapy. The intervention significantly improved 28-day survival (51% vs. 26%, $p = 0.014$; HR: 0.53, 95% CI: 0.32–0.88; NNT = 4) and led to better resolution of index infections (94.2% vs. 74.1%, $p = 0.011$). MELD and CLIF-C OF scores also improved over time (group time interaction $p = 0.009$ and <0.001). There was no increase in secondary or fungal infections or length of stay ($p > 0.05$). The intervention was cost-effective, with an incremental cost of INR 3,602 (40.5 Euros) per death averted.
Conclusion: This is the first randomized trial to show that Xpert Carba-R and rectal colonization-guided antimicrobials improve survival, infection resolution, and organ function in cirrhosis patients with infections. These findings support integrating gut colonization assessments into the routine care of cirrhosis patients.

OS-036

A multicentre randomised double-blind placebo-controlled phase 1b clinical trial evaluating the safety and mechanism of action of EBX-102, an oral pooled intestinal microbiota product, in liver cirrhosis: the IMPuLCE trial

Laura Craven[1], Michael Smyth[1], Lynsey Howard[1], Lindsey Edwards[2], Debbie L. Shawcross[3], James McIlroy[1], Ewan Forrest[4]. *[1]EnteroBiotix, Glasgow, United Kingdom; [2]Centre for Host-Microbiome Interactions, Faculty of Dentistry, Oral & Craniofacial Sciences, Guy's Tower, Guy's Hospital, Great Maze Pond, London, United Kingdom; [3]Roger Williams Institute of Liver Studies, Faculty of Life Sciences and Medicine, King's College London, Denmark Hill, London, United Kingdom; [4]Department of Gastroenterology, Glasgow Royal Infirmary, Glasgow, UK; University of Glasgow, Glasgow, United Kingdom*
Email: ewan.forrest@nhs.scot

Background and aims: Changes in the intestinal microbiome, its function, and impaired gut barrier integrity contribute to the establishment and progression of cirrhosis. The IMPuLCE (Intestinal Microbiota Product in Liver Cirrhosis and Encephalopathy) study was the first in human study of EBX-102, a novel oral full-spectrum microbiome drug in patients with cirrhosis. The objectives were to evaluate the safety, tolerability and dose of EBX-102 and to assess its effects on the gut microbiota taxonomy. Exploratory objectives assessed the impact of changes to the gut microbiota on clinical assessments and translational biomarkers.
Method: Patients with stable cirrhosis (no previous encephalopathy, not on lactulose or rifaximin and MELD <12) were recruited and randomised 2:1 active to placebo in two cohorts to receive a single dose of either 2 (Cohort 1) or 10 capsules (Cohort 2) of EBX-102 or matching placebo. Safety from Cohort 1 was reviewed before dosing Cohort 2. Follow-up was 12 weeks. Serial stool and blood were collected at Baseline/Day 1, Day 3, Weeks 1, 4, 8 and 12 for next generation sequencing, metabolomics, and lipopolysaccharide binding protein (LBP).
Results: Twenty-four participants were randomised and 96% (23/24) completed follow-up. Seventeen (17/24, 71%) reported 53 adverse events. There were no treatment emergent serious adverse events (TEAEs) reported during the study. The commonest AEs were gastrointestinal, 53% (10/19) in Cohort 1, 32% (6/19) in Cohort 2 and 16% (3/19) in Combined Placebo. They were mainly mild or moderate and self-limiting. The microbiota of Cohort 2 became more similar to the composition of EBX-102 after dosing measured by Aitchison distance (Week 1 $p = 0.022$, Week 4 $p = 0.007$, Week 12 $p = 0.016$), while Cohort 1 did not ($p > 0.05$ at all time points post-dosing). Functional changes with reduced concentrations of total short chain fatty acids, reduced primary to secondary bile acid ratio, and increased faecal ammonia concentrations were observed in the stool of active treatment groups. A decrease in plasma LBP was observed in Cohort 2 at Weeks 1, 4, and 8, however this did not reach statistical significance when compared to LBP at Baseline/Day 1. Scores on the Hospital Anxiety and Depression Scale (HADS) reduced in subjects who received active treatment. The total anxiety score changed −0.2 at Week 12 compared to Baseline in Cohort 1, −1.5 in Cohort 2, and +0.7 in Placebo.
Conclusion: EBX-102 treatment was well tolerated with an acceptable safety profile in stable cirrhosis subjects. There was a significant shift in the microbiota composition in patients who received the higher dose of EBX-102. Changes to the microbiota and their functional outputs appeared to be dose-dependent and were linked to potential clinical benefits. These data support a further study in a larger population of patients with more advanced cirrhosis to measure efficacy and determine the mechanism of action.

OS-037

Prognostic scores and clinical outcomes after covered TIPS placement: analysis of 987 cirrhotic patients from the multicenter international EASL-endorsed EuroTIPS registry

Email: abaigesa@clinic.cat

Background and aims: Covered transjugular intrahepatic portosystemic shunt (TIPS) effectively treats portal hypertension (PH)-related complications such as variceal bleeding and refractory ascites. However, the variability in indication and technical practices across centres may significantly influence outcomes. The EASL-endorsed EuroTIPS registry, established in 2020, collects prospective detailed data from 19 European reference centres. This study aimed to assess the value of various prognostic scores: MELD, Child-Pugh, CLIF-C AD, FIPS, and a composite of bilirubin <3 mg/dL with platelets >75 G/L on ascites resolution, rebleeding rates, overt hepatic encephalopathy (OHE) and survival.

Method: Prospective clinical and technical data of all consecutive TIPS placed since 2020. Patients were followed for 1 year.

Results: Of 1,881 patients enrolled since January 2020, 987 cirrhotic patients had one-year follow-up. Mean age was 56.6 ± 11.3 years, with 71.3% male. The primary aetiologies were ALD (67.3%), MASLD (20.2%) and HCV (8.9%). Baseline MELD was 14.1 ± 5.9, Child-Pugh score 8.1 ± 1.9, CLIF-C AD 48.9 ± 10.9 and FIPS – 1.3 ± 1.1. TIPS was implanted for PH-related bleeding in 465 cases (47%) (pre-emptive: 145; rescue: 159; secondary prophylaxis: 130; ectopic varices: 31), recurrent/refractory ascites in 356 (36%); portal vein thrombosis (n = 55, 5.5%), pre-surgery, (n = 54, 5.5%) and other (n = 57, 5.7%). During follow-up, post-TIPS PH-related bleeding (first episode or rebleeding) occurred in only 61 patients of the full cohort of 987 (6%). 433/987 patients (45%) experienced at least one episode of OHE during follow-up. 185 patients died and 88 were transplanted, yielding a one-year transplant-free survival of 72%. In the 356 patients receiving TIPS for recurrent/refractory ascites, TIPS completely controlled ascites in 244 (69%). All the evaluated scores were independently associated with post-TIPS survival and OHE development, while Child Pugh and MELD also predicted post-TIPS bleeding and ascites control. However, none of them had a strong predictive capacity of neither survival nor clinical outcomes, with all C-index estimates being modest <0.7, both when analysed globally or by TIPS indication.

Conclusion: Current scores have limited accuracy to reliably predict clinically relevant outcomes such as survival, OHE development or post-TIPS ascites control. Future analyses within the EuroTIPS cohort will focus on improving predictive models to address this unmet clinical need.

OS-038-YI

Urinary neutrophil gelatinase-associated lipocalin (NGAL) as a diagnostic and prognostic biomarker of acute kidney injury in patients with decompensated cirrhosis: an individual patient data meta-analysis

María José Moreta[1], Adrià Juanola[1], Andrew S. Allegretti[2], Salvatore Piano[3], Justin Belcher[4], Rohan Yewale[5], David Jaques[6], Jevon Robinson[2], Tianqi Ouyang[2], Carmine Gambino[3], Patricia Huelin[1], Xavier Ariza[1], Paolo Angeli[3], Chirag Parikh[4], Balakrishnan Ramakrishna[5], Belen Ponte[6], Pere Ginès. *[1]Liver Unit, Hospital Clínic of Barcelona, Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Centro de Investigación Biomédica en Red Enfermedades Hepáticas y Digestivas (CIBEREHD), Madrid, Barcelona, Spain; [2]Division of Nephrology, Department of Medicine, Massachusetts General Hospital, Boston, United States; [3]Unit of Internal Medicine and Hepatology (UIMH), Department of Medicine - DIMED, University of Padova, Padova, Italy; [4]Section of Nephrology and Program of Applied Translational Research, Yale University School of Medicine, New Haven, Connecticut, United States; [5]SIMS Institute of Gastroenterology, Hepatobiliary Sciences and Transplantation, SRM Institutes for Medical Science, Chennai, India; [6]Nephrology Division,*

Medicine Specialties Department, Geneva University Hospitals, Geneva, Switzerland
Email: juanola@clinic.cat

Background and aims: Urinary NGAL (uNGAL) has been proposed as a biomarker for classifying acute kidney injury (AKI) phenotypes in patients with decompensated cirrhosis, primarily to differentiate acute tubular necrosis (ATN) from hepatorenal syndrome (HRS). Several studies have shown favorable results, but despite of this its clinical application remains limited. Moreover, it is unknown whether factors such as etiology of cirrhosis or gender affect its accuracy. This study aims to perform an individual patient data meta-analysis to evaluate the diagnostic and prognostic accuracy of uNGAL in patients with decompensated cirrhosis and AKI.
Method: A systematic literature review was conducted to identify studies evaluating uNGAL as a biomarker to identify AKI phenotype in patients with decompensated cirrhosis. Data were obtained from the primary or corresponding authors. An individual patient data meta-analysis was conducted to identify the optimal cut-off point, as well as sensitivity studies to assess confounding factors in the diagnostic and prognostic accuracy of uNGAL.
Results: Data from 7 cohorts from 3 different continents comprising 824 patients were included. No differences were found in the diagnostic accuracy of uNGAL for ATN based on the timing of measurement (at AKI diagnosis or 48–72 hours later) ($p > 0.05$). The uNGAL cut-off for ATN diagnosis was calculated by replicating 20,000 samples using bootstrapping techniques, identifying 232 (163–302) ng/mL as the optimal value, with higher values being indicative of ATN. The pooled area under receiving operating curve (SAUROC) of urinary NGAL for identifying ATN was 0.84 (0.81–0.87), with a sensitivity of 0.73 (0.63–0.81) and a specificity of 0.81 (0.75–0.86). Sensitivity analysis in subgroups (MASLD etiology of cirrhosis and women) ruled out changes in the diagnostic accuracy of uNGAL. The analysis also evaluated the predictive ability of uNGAL for the resolution (total or partial) of AKI, showing uNGAL to be an independent factor of improvement of renal function, regardless of creatinine levels or AKI phenotype. Additionally, uNGAL was predictive of three-month survival, independent of MELD score, sex, or etiology. No evidence of publication bias was identified, and no study was classified as low quality based on the QUADAS-2 assessment.
Conclusion: Urinary NGAL is an excellent biomarker for diagnosis and prognosis in AKI in patients with decompensated cirrhosis. The value of 232 ng/mL correctly classifies up to 80% of patients with decompensated cirrhosis and AKI, maintaining diagnostic accuracy regardless of the timing of its determination, the cause of liver disease, or patient gender. It also predicts the likelihood of AKI resolution and survival status at 3-month follow-up. These results reinforce the idea that determination of uNGAL should be implemented in hospitals managing a high volume of patients with decompensated cirrhosis. *Project PI23/00798", funded by Instituto de Salud Carlos III and co-funded by the European Union.*

OS-039-YI
Effect of albumin treatment duration on response rates and outcomes in patients with cirrhosis and acute kidney injury

Email: eva.schleicher@unimedizin-mainz.de

Background and aims: Current guidelines recommend volume expansion with albumin for 48 hours in patients with cirrhosis and acute kidney injury (AKI) to address hypovolemia and rule out prerenal AKI. Recent updates in the Acute Disease Quality Initiative (ADQI)-International Club of Ascites consensus guidelines suggest shortening this duration to 24 hours, primarily based on expert opinions. This study aimed to evaluate the response rates to albumin treatment at 24 and 48 hours, to compare and assess the prognostic significance of three different definitions of response to albumin therapy and to identify cut-offs.
Method: Data from 214 prospectively recruited patients with cirrhosis and AKI from two German centers were analyzed. After applying inclusion and exclusion criteria (e.g., no ascites, inadequate/no albumin treatment at AKI diagnosis), 127 patients were available for analysis. We examined three response definitions after 24 and 48 hours: (1) serum creatinine (SCr) decrease > 0.3 mg/dl, (2) SCr decrease >25%, and (3) SCr decrease in at least one AKI stage. Follow-up was prolonged until transjugular intrahepatic portosystemic shunt (TIPS) initiation, liver transplantation (LTX), death or hemodialysis (HD).
Results: The median age of the cohort was 60 years, and the median MELD was 22 (Child-Pugh A/B/C: 6%/44%/50%). The stages of AKI at the time of diagnosis were classified as follows: AKI 1A 4%, AKI 1B 37%, AKI 2 34%, AKI 3 25%. Overall, 54.3%, 30.7%, and 46.5% of the patients responded to albumin treatment after 48 hours depending on the applied definition (1–3). Notably, irrespective of the definition, 27.6%, 22.0%, and 18.1% of patients responding after 48 hours did not show a response within the first 24 hours of treatment according to definitions 1, 2, and 3, respectively. 28%, 22%, and 18% of the cohort responded to albumin therapy during the second 24 hours of the treatment. Response according to definition 3 was associated with a better HD- and LTX-free survival in multivariate Cox regression analysis (HR 3.2, 95%CI 1.8, 5.6, $p < 0.001$), while response according to the other two definitions was not. For this definition, at a cut-off of 16% SCr increase at 24 hours, sensitivity was 100% and the negative predictive value was 100%. Subsequently terlipressin treatment could have been initiated in 12% of the patient cohort.
Conclusion: Response to albumin treatment is frequent in the second 24 hours of therapy. Shortening volume expansion therapy may lead to overtreatment with terlipressin. Treatment with albumin should aim for a SCr decrease in at least one AKI stage as this definition is associated with a better prognosis. Finally, one can identify at 24 hours those patients in whom further administration of high dose albumin is futile using a cut-off of 16% SCr increase, so that treatment with terlipressin can be initiated early on.

Background and aims: The presence of chronic kidney disease (CKD) predisposes a patient to the development of acute kidney injury (AKI). While AKI and CKD are well understood in cirrhosis, the entity of acute-on-chronic kidney disease (AoCKD) in cirrhosis is not well defined. To define AoCKD in a global cohort of inpatients with cirrhosis, and its impact on patient outcomes.
Method: AoCKD is defined by AKI superimposed on CKD (GFR<60 ml/min /1.73m^2 for >3months), either as 0.3 mg/dL increase in <48 hours, or a 50% rise from an elevated serum creatinine (sCr) in ≤7 days. The CLEARED consortium enrolled in-patients with cirrhosis worldwide from 127 countries & collected data on demographics, cirrhosis complications, co-morbid conditions, and patient outcomes. The incidence and features of AKI superimposed on CKD (CKD+) were compared to those without (CKD-), and its impact on patient outcomes assessed.
Results: 38% (n = 2733 of 7040) CKD+ patients had a median [interquartile range or IQR] baseline sCr of 1.2 [0.92, 1.70]mg/dL, significantly higher than that in CKD- patients (0.71 [0.60, 0.86]mg/dL, p < 0.001). 63.5% of CKD+ patients developed AKI, with 42%, 28% and 30% being stage 1, 2 and 3 AKI respectively. In contrast, only 12.4% of CKD- patients developed AKI (p < 0.001), who mostly had stage 1 (54%) with less having stage 2 (22%) and stage 3 (24%) AKI (p < 0.001

vs. CKD+ patients). The median [IQR} peak sCr in CKD+ patients were 2.40 [1.76, 3.59] mg/dL, significantly higher than that of 1.52 [1.20, 2.27]mg/dL in CKD- patients ($p < 0.001$). More CKD+ patients (85%) received albumin for their AKI, vs. 72% in CKD- patients ($p < 0.001$). Similar proportions of patients received either norepinephrine or terlipressin as treatment for their AKI ($p > 0.05$), but significantly more CKD+ patients received midodrine (11.9% vs.7.0 in CKD- patients, $p = 0.0018$). 48.3% of CKD- patients recovered from their AKI vs. 41.5% of CKD+ patients, who mostly had a partial resolution of their AKI (30.1% vs. 19.6% in CKD- patients) ($p < 0.001$). The median [IQR] discharge sCr in the CKD+ patients was 1.49 [1.02, 2.40]mg/dL, which was significantly higher than that in CKD- patients (1.10 [0.80, 1.65]mg/dL, $p < 0.001$). Hence more CKD+ patients (15.2%) went onto dialysis compared to CKD- patients (7.3%) ($p = 0.02$). The factors associated with the development of AoCKD were prior AKI/HRS (Odds Ratio or OR: 3.22), infection at admission (OR:1.73) and admission MELD-Na (OR: 1.11), Factors associated with AKI resolution amongst CKD+ patients were a lower peak sCr (OR: 0.70), norepinephrine use (OR: 0.51), living in a high-income country (OR:0.65).

Conclusion: AoCKD is common amongst inpatients with cirrhosis, particularly in those with prior AKI, often associated with lower chance for resolution, especially if admitted with infection. Therefore, it is imperative that prompt treatment, especially in well-resourced countries be provided to improve patient outcomes.

Nutritional therapy prevents overt hepatic encephalopathy (OHE) in patients with cirrhosis after transjugular intrahepatic portosystemic shunt (TIPS): a randomized controlled trial

Ying Li[1], Xin Quan[1], Ou Luo[1], Bo Wei[1], Huan Tong[1], Zhidong Wang[1], Yang Tai[1], Linhao Zhang[1], Can Gan[1], Shuaijie Qian[1], Xu Guo[1], Lei Shi[2], Hao Wu[1]. *[1]Department of Gastroenterology and Hepatology, West China Hospital, Sichuan University, Chengdu, China; [2]Department of clinical nutrition, West China Hospital, Sichuan University, Chengdu, China*
Email: hxxhwh@163.com

Background and aims: Hepatic encephalopathy (HE) is the most common complication following TIPS in patients with cirrhosis. Nutritional status, including sarcopenia, is an important predictor of post-TIPS HE. Efficacy of nutritional therapy in improving minimal HE (MHE) in patients with cirrhosis is well studied. However, its efficacy in preventing the first episode of OHE in patients with cirrhosis after TIPS has not been established. Therefore, we aim to determine whether different nutritional therapies prevent OHE after TIPS.

Method: Patients were randomized into three groups receiving various nutritional therapies (**Gp1**: 35 kcal/kg/d, with the protein intake started at 20 g for the first 3 days, increased by 10 g every 2 days until reaching 1.2–1.5 g/kg/d, then maintained for 24 week; **Gp2**: 35 kcal/kg/d, with the protein intake that started at 20 g for the first 3 days, increased protein by 10 g every 8 days until reaching 1.2–1.5 g/kg/day, then maintained for 24 weeks; **Gp3**: continued their usual dietary habits for 24 weeks without additional nutritional intervention). Prophylactic use of rifaximin or lactulose was not allowed during the 24 weeks. The primary outcome was the incidence of OHE (grades II or higher based on the West Haven criteria) within 24 weeks after TIPS. The secondary outcomes were MHE [defined by number connection test-A (NCT-A) and line-tracing test (LTT)] and sarcopenia [defined by changes in skeletal muscle index (SMI) measured by computed tomography scan at 3rd lumbar spine level (L3-SMI)] at 24 weeks.

Results: 78 participants were randomized into Gp1 (n = 27), Gp2 (n = 26) or Gp3 (n = 25). Baseline characteristics were comparable between three groups. In three groups, HBV infection was the most common etiology of cirrhosis (62.0%). The main indication for TIPS was variceal rebleeding (80.5%) and more than half of patients combined with sarcopenia (59.7%). Our preliminary results indicated that cumulative incidence of OHE at 24 weeks after TIPS was significantly lower in Gp1 patients (18.5% vs 48.0%, log-rank p = 0.034) compared to Gp3 patients. There was no significant difference between Gp2 and Gp3 patients (34.6% vs 48.0%, log-rank p = 0.296). NCT-A and LTT significantly decreased at 24 weeks compared to baseline in Gp1 (NCT-A: 67.01 ± 43.50 vs 40.00 ± 35.87, p = 0.03; LTT: 68.26 ± 23.76 vs 50.13 ± 25.79, p = 0.04). No significant differences were observed in Gp2 or Gp3. L3-SMI increased similarly in three groups ($\Delta 4.6 \pm 2.8$ vs $\Delta 6.7 \pm 1.8$ vs $\Delta 4.4 \pm 1.2$ cm^2/m^2, p = 0.946). There were no significant difference in other cirrhosis-related complications in three groups.

Conclusion: Nutritional therapy can prevent OHE and improve cognitive function in patients with cirrhosis after TIPS. Patients with cirrhosis should restore their daily dietary intake to the target state (35 kcal/kg/d, with 1.2–1.5 g/kg protein intake) as soon as possible after TIPS.

Benchmarking spleen stiffness in assessing response to beta-blocker therapy for secondary prophylaxis of acute variceal bleed-BE-RESPONSE study (NCT05166317)

Akhil Deshmukh[1], Shiv Kumar Sarin, Manoj Sharma[1], Chitranshu Vashitshtha[1], Ankur Jindal[1], Ashok Choudhury[1], Vishnu Girish[1], Rahul Khajuria[1], Tushar Madke[1], Omkar Rudra[1].
[1]Institute of liver and biliary sciences, Department of Hepatology, Delhi, India
Email: shivsarin@gmail.com

Background and aims: Response to non-selective beta-blockers (NSBB) is assessed by measuring hepatic vein pressure gradient (HVPG). Non-invasive tests (NITs) are promising in reflecting response to NSBB for primary prophylaxis. Acute variceal bleed (AVB) poses challenges for NITs due to associated inflammation and splanchnic congestion. We evaluated - efficacy of liver and spleen stiffness measurement (LSM, SSM) post-AVB using transient elastography, as non-invasive correlates of HVPG for NSBB response and rebleed.

Method: This study prospectively assessed 220 cirrhosis patients with g AVB using HVPG, LSM, and SSM within 5 days of bleed, followed by carvedilol therapy. NITs were measured at 0, 3, and 6 weeks, and HVPG at 0 and 6 weeks, with rebleeding followed-up for 90 days. Repeated measures analysis, Cox regression, and Intention-to-Treat (ITT) analysis was used. The primary objective was to determine NIT accuracy in predicting NSBB response at 6 weeks, while secondary goals included correlating NITs with HVPG, rebleeding, and liver related events.

Results: Cirrhosis with AVB [age 49.56 ± 10.34 years, 91.4% male, predominantly ethanol (45%) related cirrhosis] with a mean MELD score of 15.13 ± 2.75, baseline HVPG of 18.66 ± 2.2 mmHg, mean LSM of 59.24 ± 15.44 kPa and SSM of 84.06 ± 15.74 Kpa were included. At 6 weeks, there were 86 (39%) HVPG responders, mean dose of carvedilol used was 11.91 ± 2.03 mg/d. Baseline HVPG, LSM, SSM were comparable between responders and non-responders. NSBB responders compared to non-responders, showed greater reductions in HVPG (24% vs. 8%; $p < 0.05$), LSM (7.4% vs. +1%; $p < 0.05$), and SSM (15.5% vs. 1.6%; $p < 0.05$) at 6 weeks. The predictive accuracy of change in SS (delta SS) for HVPG response at 6 weeks was higher (AUROC 0.85) than change in LS (delta LS; AUROC 0.74). Rebleeding occurred in 31 (14.36%) patients, dominantly in HVPG non-responders (18.6% vs 7.1%; p = 0.027). Importantly, no change in SSM from baseline to week 3, and an increase in SS by 4.18% (3.5 Kpa) from baseline at 6 weeks predicted rebleeding. None of the patients with HVPG ≤12 mmHg at 6weeks rebled within follow-up of 90days.

Conclusion: Lack of reduction in spleen stiffness at week 3is a strong non-invasive predictor of rebleeding risk and non-response to NSBB therapy in patients with AVB. SSM offers a practical alternative to invasive HVPG, allowing timely intervention in high-risk patients with AVB.

OS-043-YI

Clinical impact of non selective beta-blockers in patients with cirrhosis and acute kidney injury: a post hoc analysis of the international club of ascites GLOBAL-AKI study

Email: salvatore.piano@unipd.it

Background and aims: Non-selective beta-blockers (NSBBs) are extensively used for preventing decompensation in patients with cirrhosis. International guidelines recommend NSBBs discontinuation in patients with cirrhosis and acute kidney injury (AKI). However, this recommendation is based on experts' opinion and, few studies have evaluated the effects of NSBBs on AKI outcomes.
Method: Post hoc analysis of ICA GLOBAL-AKI study, a multicenter intercontinental study that prospectively enrolled patients hospitalized for acute decompensation (AD) of cirrhosis from July 2022 to May 2023. AKI outcomes were compared between patients on NSBBs at AKI diagnosis and those who were not. A subgroup analysis further examined outcomes between patients in whom NSBBs were continued during hospitalization and those in whom were tapered/withdrawn within 48–72 hours from AKI diagnosis. Propensity score-matching (PSM, 1:1 ratio) was used to balance age, sex, MELD-Na, mean arterial pressure (MAP), presence of ascites, hepatic encephalopathy, AKI stage, acute on chronic liver failure (ACLF) grade at AKI diagnosis and whether patients were from low or middle-income countries. Main outcome were 28-day mortality and AKI non-resolution.
Results: 503 out of 1,238 patients with AKI were on NSBBs treatment at AKI diagnosis (propranolol 55%; carvedilol 45%). Most of patients were receiving less than 80 mg of propranolol and ≤12,5 mg of carvedilol (89%). Before PSM, patients on NSBBs were older and had significantly lower MAP, MELD-Na score and significantly lower prevalence of grade 2 and 3 ACLF. After PSM, all covariates were balanced between the two groups (standardized mean difference [SMD] <0.1). Patients on treatment with NSBBs had lower white blood cells count than those without (9.2 vs 7.4×10^9/l; $p < 0.001$). In PSM analysis, patients on NSSBs had lower risk of AKI non-resolution (OR = 0.65, p = 0.001) and lower risk of 28-day mortality (sHR = 0.68; p = 0.005). During the first 48/72 hours of hospitalization, NSBBs were continued in 123 patients (26%) and tapered/withdrawn in 350 (76%). Data about NSBBs management were missing in the remaining 37 patients. After PSM, all covariates were balanced between the two groups ([SMD<0.1). Continuation of NSBBs was neither associated with AKI non-resolution (OR = 1.00; p = 0.999) nor with 28-day mortality (sHR = 0.56; p = 0.190). Subgroup analyses in patients with MAP<70 mmHg, serum Na<130 mmol/l and ACLF confirmed the findings.
Conclusion: NSBBs treatment at AKI diagnosis is associated with higher resolution of AKI and lower 28-day mortality in patients with cirrhosis and AKI. Continuation of treatment with NSBBs in patients with cirrhosis and AKI does not seem to be harmful in these patients.

OS-044

Liver sinusoidal endothelial cell BRD4 drives inflammatory angiocrine signaling in liver fibrosis

Can Gan[1], Enjiang Lai[1], Yang Tai[1], Shuai Chen[2], Changqing Yang[2], Chengwei Tang[1], Jinhang Gao[1]. [1]*Department of Gastroenterology, West China Hospital, Sichuan University, Chengdu, China, Lab of Gastroenterology and Hepatology, State Key Laboratory of Biotherapy, West China Hospital, Sichuan University, Chengdu, China, Chengdu, China;* [2]*Department of Gastroenterology and Hepatology Tongji Hospital, School of Medicine, Tongji University, Shanghai, China, Shanghai, China*
Email: gancan_medical@foxmail.com

Background and aims: Chronic liver injury results in inflammation and extracellular matrix deposition, ultimately leading to liver fibrosis. Liver sinusoidal endothelial cells (LSECs) have been shown to initiate liver inflammation through an angiocrine-dependent mechanism in response to injury. The roles of bromodomain-containing protein 4 (BRD4), an epigenetic reader that binds to the super-enhancer (SEs) of active genes, in liver fibrosis are poorly understood. Here, we aimed to investigate the epigenetic regulation of LSECs mediated by SEs in angiocrine signaling during liver fibrosis.
Method: Liver fibrosis was induced in mice with LSEC-specific *Brd4* knockout (*Brd4*$^{fl/fl}$/*Cdh5*^{Cre}) mice and littermate controls (*Brd4*$^{fl/fl}$) by carbon tetrachloride (CCl_4) administration. Following a 6-week treatment, histological and molecular analyses were conducted to assess liver inflammation and fibrosis, and single-cell RNA sequencing (scRNA-seq) was performed to explore communications between LSECs and other cell types. Primary human LSECs were treated with TNFα and BRD4 inhibitor iBET151, with these samples subsequently utilized for ChIP-seq analysis.
Results: In CCl_4 mouse model, collagen I deposition was significantly decreased in *Brd4*$^{fl/fl}$/*Cdh5*^{Cre} mice compared to littermate *Brd4*$^{fl/fl}$ control mice (n = 8/group, $p < 0.001$). Additionally, hepatic stellate cell (HSC) activation marker aSMA and macrophage marker F4/80 were also decreased in *Brd4*$^{fl/fl}$/*Cdh5*^{Cre} mice (n = 8/group, $p < 0.001$). scRNA-seq analysis identified nine different clusters including endothelial cells (ECs), bone marrow-derived macrophages (BMDMs), HSCs and other immune cells (n = 3/group). Subgroup analysis of ECs revealed eight clusters based on marker genes. Pseudotrajectory analysis illustrated a transition from normal to inflammatory gene expression among liver EC subsets, highlighting EC7 as a key player in EC inflammation. Notably, this inflammatory transition was normalized in *Brd4*$^{fl/fl}$/*Cdh5*^{Cre} mice. Ligand-receptor pair analysis showed a strong interaction between *Timp1* in EC7 and *Cd63* in BMDMs. Furthermore, RNA-FISH assays confirmed that TIMP1$^+$ ECs recruit CD63$^+$ BMDMs during liver fibrosis, whereas this interaction was absent in *Brd4*$^{fl/fl}$/*Cdh5*^{Cre} mice. In human LSECs, BRD4 ChIP-seq analysis revealed that SE activity of *TIMP1* was blocked by iBET151, and qPCR analysis confirmed that iBET151 reduced TNFα-induced TIMP1 expression (n = 3, $p < 0.05$).
Conclusion: LSEC-derived TIMP1 facilitates the recruitment of CD63$^+$ BMDMs, thereby promoting liver inflammation. SE-induced TIMP1 expression is dependent on BRD4. Inhibition of the SE activity of TIMP1 by LSEC-BRD4 deletion alleviates liver inflammation and fibrosis.

Fibrosis, Hepatocyte and Liver regeneration

Email: rola.alsayegh@outlook.com

Background and aims: Sustained inflammation is a driving force of chronic liver disease progression to fibrosis and end-stage cirrhosis. A major source of inflammatory and fibrogenic mediators originates from conventional CD4 T cells, in particular the Th17 cell subset. Dysregulation of autophagy in immune cells is associated with an uncontrolled inflammatory response during various inflammatory diseases. Here, we combined studies in human samples and mice models, to evaluate the role of T cell autophagy in liver fibrosis progression.
Method: Autophagy was evaluated in the liver and blood T cells isolated from patients with extended fibrosis or controls by single-cell RNA sequencing (Sc-RNAseq), flow cytometry, immunofluorescence and western blot. Liver fibrosis was induced in mice specifically lacking the autophagy proteins (ATG5)$^{Tlymph-/-}$ or rubicon (RUBCN)$^{Tlymph-/-}$ in T cells, by repeated carbon tetrachloride (CCl_4) injections or by bile duct ligation (BDL). Comparison of genes differentially regulated in CD4 T cells from ATG5$^{Tlymph-/-}$ CCl_4-mice compared to control group was performed by RNA sequencing.
Results: Sc-RNAseq and functional studies indicated that intrahepatic and circulating CD4 T cells from patients with extended fibrosis show defects in the autophagy machinery. Fibrotic (CCl_4 or BDL) mice deficient for autophagy in T cells (ATG5$^{Tlymph-/-}$) displayed reduced CD4 T cell frequency associated with a shift toward an activated glycolytic Th17 phenotype, and with enhanced type 3 cytokine release. These mice exhibited enhanced hepatic inflammation and were more susceptible to liver fibrosis. Co-culture experiments showed that ATG5-deficient CD4 T cells shift hepatic myofibroblasts, hepatocytes and macrophages toward a pro-inflammatory phenotype. As a proof of concept, pharmacological autophagy activation decreased the release of type 3 cytokines in CD4 T cells from patients with extended fibrosis, and mice with specific T cell deletion of the autophagy inhibitory protein Rubicon developed limited fibrosis.
Conclusion: Our findings unravel autophagy in CD4 T cells as a key therapeutic target to control inflammation-driven fibrosis during chronic liver injury.

OS-046

Endothelial Heg1 promotes liver sinusoidal endothelial cells capillarization to aggravate liver fibrosis

Yuting Zhang[1], Xiangjian Zheng[2], Gang Zhao[1], Yuzhen Zhang[1], Jie Liu[1]. [1]*State Key Laboratory of Cardiovascular Diseases and Medical Innovation Center, Shanghai Heart Failure Research Center, Shanghai East Hospital, Tongji University School of Medicine, shanghai, China;* [2]*Department of Pharmacology and Tianjin Key Laboratory of Inflammation Biology, School of Basic Medical Sciences, Tianjin Medical University, Tianjin, China*
Email: kenliujie@126.com

Background and aims: Liver fibrosis represents a global health burden, given the paucity of approved antifibrotic therapies. Liver sinusoidal endothelial cells (LSECs) play a major gatekeeping role in hepatic homeostasis and liver disease pathophysiology. The transmembrane protein heart of glass1 (HEG1) has been proved highly expressed in LSECs and regulates liver vascular/biliary Network patterning and metabolic zonation; however, its function in liver fibrosis in LSECs remains unclear. Here, we investigated the role of LSEC-expressed Heg1 in liver fibrosis.
Method: Hepatic endothelial Heg1 expression was characterized in patients with cirrhosis and chronic carbon tetrachloride (CCl_4) exposure and methionine–choline-deficient (MCD) diet induced liver fibrosis mouse models. Single-cell RNA sequencing (scRNA-seq) and double-immunohistochemistry were employed to explore Heg1 expression patterns in fibrotic livers. The effects of LSECs-specific Heg1 deletion on liver fibrosis were evaluated. Heg1 knockout LSECs were isolated to assess the role of Heg1 in capillarization, fenestration of LSECs were observed via applying two high-resolution microscopy modalities: structured illumination microscopy (SIM) and scanning electron microscopy (SEM). Molecular mechanisms underlying Heg1 function were investigated, while chemical and genetic investigations were performed to assess its potential as a therapeutic target.
Results: Heg1 expression was significantly elevated in LSECs in both patients with cirrhosis and mice. LSECs specific deletion of Heg1 improved liver injury, inhibited LSECs capillarization and attenuated collagen deposition in fibrosis. Furthermore, deletion of Heg1 prevented spontaneous capillarization of isolated LSECs and downregulated capillarization-associated genes, suggesting that Heg1 has critical impact on LSECs capillarization regulating. Mechanistically, Heg1 overexpression promoted phosphorylation of myosin light chain (MLC) via changing intracellular distribution and promoting kinase activity of p21-activated kinase 4 (PAK4) to regulate fenestration. Inhibition of PAK4 by PF-3758309 reversed LSEC capillarization triggered by Heg1 overexpression. Consistently, administration of PF-3758309 alleviated liver fibrosis in mouse model induced by CCl_4 exposure. Finally, a novel nanoparticle carried Heg1 siRNA targeting LSECs was shown to be effective in protecting against liver fibrosis pathology in mice.
Conclusion: In conclusion, our results demonstrate that Heg1 promotes liver fibrosis by inducing LSECs capillarization, underscoring Heg1 as a promising druggable target for liver fibrosis treatment.

Email: gaabruzzese@cicbiogune.es

Background and aims: The liver exhibits metabolic zonation, with gene expression and metabolic functions distributed across specific zones along the lobule radial axis. Disruption of zonation is linked to the initiation and progression of liver pathologies. Neddylation, a post-translational modification essential for metabolism, influences zonal metabolic processes and is associated with liver pathogenesis. However, its relationship with liver zonation remains understudied. This study aims to investigate the connection between neddylation and liver zonation, evaluating its metabolic implications and role in liver diseases.
Method: Spatial transcriptomics was used to assess the localization of neddylation machinery gene expression in mice. Biotinylated Ubiquitin (bioUb) and Biotinylated NEDD8 (bioNEDD8) mice were employed to evaluate post-translational modifications in known zonated proteins. We also utilized different transgenic mouse models to study: 1) the impact of zonation loss on neddylation, using Li-TSC1KO RagAGTP mutants, which exhibit zonation disruption without hepatic disease at early stages, and 2) the role of neddylation modulation on zonation, using models that silence or overexpress NEDD8, overexpress NAE1 (key NEDD8 activator), or silence NEDP1 (a major de-neddylation protease).
Results: Neddylation genes were more highly expressed in pericentral hepatocytes than periportal ones. Proteomic data from bioNEDD8 and bioUb mice revealed neddylation and ubiquitination enrichment on periportal zonation markers (e.g., ALB, ASS, ASL, CYP2F2). In Li-TSC1KO RagAGTP mutant mice, zonation loss altered neddylation mediators' expression. Immunofluorescence showed a decentralized pattern of NEDD8 in the mutants, compared to its periportal localization in controls. Overexpressing NAE1 or silencing NEDP1 disrupted periportal marker gene expression, while NEDD8 modulation also affected central zone markers mRNA levels. Mutant models showed altered expression of genes involved in zonated metabolic processes, with pronounced effects when NEDD8 or NAE1 were manipulated.
Conclusion: Our results demonstrate a significant association between neddylation and liver zonation, suggesting a zonal expression pattern of the neddylation machinery. Genetic manipulation of neddylation mediators influenced zonal markers and altered the expression of genes involved in zonated metabolic processes, reinforcing the link between neddylation and liver zonation. Future research will explore zonal neddylation modulation to elucidate its role in liver metabolism and pathology.

Background and aims: Mucosal-Associated Invariant T (MAIT) cells, which are non-conventional T cells that are restricted by the non-classical MHC class I-related protein MR1, display altered functions during chronic liver diseases. We have previously demonstrated the profibrogenic properties of MAIT cells in the liver and their negative impact in fibrosis regression (1,2). Moreover, recent data demonstrated that MAIT cells have a tissue-repair gene signature and regenerative functions in skin (3) and colon (4). We thus wondered whether MAIT cells might also play a role in liver regeneration.
Method: We analyzed MAIT cell signature from published scRNA-seq data of liver biopsies from patients undergoing portal vein embolization, which induce liver regeneration prior to large hepatectomy (5). Hepatocyte proliferation was measured by Ki-67 immunostaining in human precision cut liver slices (PCLS) that were obtained from liver explants of patients with extended fibrosis. These human PCLS were exposed for 48 hours to the synthetic MAIT cell inhibitor acetyl-6-formylpterin (Ac-6-FP) or its vehicle. We also studied liver regeneration in control B6 mice submitted or not to Ac-6-FP injections, in MAIT cells enriched mice (B6-MAIT^{CAST}) and in mice without MAIT cells (MR1$^{-/-}$ B6-MAIT^{CAST}). Mouse liver regeneration was induced either by 2/3 partial hepatectomy (PHx) or by an acute or chronic intraperitoneal injection of carbon tetrachloride (CCl_4). Hepatocyte proliferation was measured by BrdU incorporation, PHH3 immunostaining and liver cyclin expression at different time points after regeneration stimulus. Finally, co-culture between primary mouse hepatocytes and non-activated or activated MAIT cells (anti-CD3/anti-CD28 antibodies) allowed to determine whether MAIT cells have a direct impact on hepatocyte DNA synthesis.
Results: In humans, (i) MAIT cells from regenerating liver biopsies highly express tissue-repair gene signature compared to healthy liver biopsies; (ii) MAIT cell inhibition by Ac-6-FP blunts hepatocyte proliferation in PCLS from patients with liver extended fibrosis (n = 8). (iii) In mouse models, pharmacological MAIT cell inhibition by Ac-6-FP, or lack of MAIT cells (MR1$^{-/-}$ mice) delays liver regeneration following an acute stimulus (single CCl_4 injection or 2/3 PHx) or a chronic insult (repeated CCl_4 administration) compared to control mice; (iv) in vitro, activated MAIT cells induce hepatocyte proliferation in co-culture experiments.
Conclusion: Using human samples and mouse models, we show that MAIT cells promote liver regeneration. Our in vitro co-culture experiments suggest that this effect could be due, at least partially, to a direct impact of activated MAIT cells on hepatocyte proliferation.

Email: blanca.simon@ub.edu

Background and aims: Macrophages play an essential role in the progression of chronic liver diseases (CLD) by regulating the balance between hepatic fibrogenesis and fibrosis resolution. It is known that systemic therapy with PPAR-alpha agonists inhibits TGF-beta transcription in smooth muscle cells and reduces the production of pro-inflammatory cytokines in macrophages. However, the specific contribution of this pathway on macrophage regulation in liver fibrosis has not been fully elucidated yet. In this study, we evaluate the therapeutic effects of PPAR-alpha activation on macrophages in liver inflammation and fibrosis using macrophage-selective dendrimer-graphite nanoparticles (DGNPs) that deliver the PPAR-alpha agonist GW7647.
Method: DGNPs bound to the GW7647 PPAR-alpha agonist (DGNPs-GW) or to mannitol (DGNPs-Man) as a control were synthesized and characterized. For *in vivo* studies, fibrosis was induced in twelve Balb/c mice with i.p. CCl_4 (1:8 v/v in corn oil) twice a week for 10 weeks. Dispersions of DGNPs-Man or DGNPs-GW were i.v. injected (50 μg/Kg DGNPs and 50 μg/Kg GW7647 or mannitol) to fibrotic mice every 3 days for 10 days. The therapeutic utility of DGNPs-GW on fibrosis, liver function and inflammation was studied via real-time PCR and histological techniques.
Results: Physicochemical characterization of DGNPs-GW and DGNPs-Man revealed a mean nanoparticle size of 270.1 nm and 300.5 nm, respectively, and a negative surface charge of −19 mV and −18 mV, highlighting their suitability for *in vivo* administration. The treatment with DGNPs-GW in fibrotic mice increased the hepatic synthesis and expression of anti-inflammatory markers (MRC: 1.0 ± 0.1 vs. 1.4 ± 0.1 fc, $p < 0.01$ and ARG1: 1.0 ± 0.1 vs. 1.3 ± 0.1 fc, $p < 0.05$) compared to mice receiving DGNS-Man, while no changes were observed in the synthesis and expression of pro-inflammatory markers (NOS2 and COX2). Reduced inflammation was accompanied with a decrease in liver fibrosis (8.3 ± 0.3 vs. 6.8 ± 0.1% fibrosis area, $p < 0.001$) and a lower hepatic stellate cell activation, denoted by a decrease in the hepatic expression of collagen-I (1.0 ± 0.1 vs. 0.7 ± 0.1 fc, $p < 0.05$), TIMP-1 (1.0 ± 0.1 vs. 0.6 ± 0.1 fc, $p < 0.05$) and TIMP-2 (1.0 ± 0.0 vs. 0.9 ± 0.0 fc, $p < 0.05$). These effects were attributed to a reduction in the hepatic expression of macrophage profibrogenic factors TGF-beta (1.0 ± 0.0 vs. 0.8 ± 0.0 fc, $p < 0.01$), PDGFB (1.0 ± 0.0 vs. 0.8 ± 0.0 fc, $p < 0.01$) and OSM (1.0 ± 0.0 vs. 0.8 ± 0.0 fc, $p < 0.05$). The treatment with DGNPs-GW did not affect serum parameters of liver injury, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), albumin, and total protein.
Conclusion: The selective activation of PPAR-alpha in liver macrophages using GW7647 delivered by DGNPs reduces liver fibrosis and stimulates an anti-inflammatory response highlighting the potential of this nanoscale therapy for chronic liver diseases.

Unravelling the therapeutic potential of novel peptides derived from the human gut microbiome in mouse models of MASLD and acute liver injury

Javier Martínez-García[1,2], Mario Fernández-Sanz[1], José Carlos Royo Sanz[1], Álvaro Blanes-Rodríguez[1], Sandra Melitón Barbancho[1], Natalia Sanchez-Romero[1,3], Naiara Beraza[4,5], Pedro Baptista[1,6,7,8]. *[1]Health Research Institute of Aragón (IIS Aragón), Zaragoza, Spain; [2]Multiscale in mechanical and biological engineering (M2BE), Department of Mechanical Engineering, University of Zaragoza, Zaragoza, Spain; [3]Becytes Biotechnologies SL, Barcelona, Spain; [4]Gut Microbes and Health Institute Strategic Programme, Quadram Institute Bioscience, Norwich, United Kingdom; [5]Food, Microbiome and Health Institute Strategic Programme, Quadram Institute Bioscience, Norwich, United Kingdom; [6]Department of Biomedical and Aerospace Engineering, Carlos III University of Madrid, Madrid, Spain; [7]CIBEREHD, Madrid, Spain; [8]ARAID Foundation, Zaragoza, Spain*
Email: pmbaptista@iisaragon.es

Background and aims: The interplay between the liver and human gut microbiome is increasingly recognized as a pivotal factor in liver development, health, and disease. While metabolites from the bacterial secretome, such as secondary bile acids and vitamins, have long been acknowledged for their vital role in liver maturation and function, the impact of peptides derived from microbiome proteins processed by intestinal enzymes remains largely unexplored. Preliminary work showed that four peptides promoted cell survival, enhanced functionality and differentiation of hepatocytes by increasing the expression of liver-specific metabolic genes and albumin secretion. These findings highlight the untapped potential of microbiome-derived peptides in maintaining liver homeostasis, as well as their role in modulating inflammatory and metabolic pathways beneficial for liver disease treatment.
Method: Several synthetic peptides were generated via an *in-silico* digestion of the entire human gut microbiota secretome when exposed to all known intestinal enzymes. Four peptides (B2, B3, B4, and B20) were selected based on their predicted anti-inflammatory properties and ability to ability to enhance hepatocyte function. To assess therapeutic potential, peptides were evaluated in two mouse models of drug-induced acute liver injury (DILI) induced by carbon tetrachloride and acetaminophen. Following the promising outcomes, the peptides were tested in both a disease-established and a preventive protocol in mice with MASLD induced by a choline-deficient, high-fat diet (HF-CDAA).
Results: First, the anti-inflammatory effect of the peptides was demonstrated by reducing TNFa and IL-6 levels in LPS-induced human monocytes. In DILI models, peptide B4 significantly improved inflammation-induced hepatomegaly and liver morphology and reduced serum levels of transaminases and lactate dehydrogenase (LDH), showing comparable or better effects than the standard treatment with N-acetylcysteine. Additionally, B4-treated mice showed significant protection against apoptosis and increased proliferation 48 hours post-injury after histological, immunofluorescence and RT-qPCR analysis. In MASLD-established mice treated daily with peptides for 2 weeks, a significant reduction in liver fibrosis of 30% was observed in mice treated with peptide B2. In a preventive protocol, with mice treated daily during HF-CDAA diet administration, B2-treated mice showed a 66% reduction in fibrosis by histological and RT-qPCR analysis, as well as a reduction in serum levels of transaminases and LDH.
Conclusion: Overall, these findings underscore the therapeutic promise of microbiome-derived peptides in treating liver diseases. Moreover, this is the first study to describe the role of gut microbiota peptides in liver cell proliferation, survival, and function, positioning microbial secretome peptides as a novel and promising therapeutic avenue for the management of liver diseases.

Email: marcos.fernandez.fondevila@gmail.com

Background and aims: Disruption of the gut barrier permits the translocation of microbial products to the liver, driving the progression of liver disease in patients with alcohol-associated hepatitis (AH). We aimed to study the contribution of the faecal proteome to disease progression in patients with AH.
Method: We used high-quantitative fidelity Tandem Mass Tag faecal proteomics analysis with LC/MS in a multicenter cohort of patients with AH (n = 80) or alcohol use disorder (AUD) (n = 21), and controls (n = 19) (InTeam), and a cathepsin B (CTSB) activity assay in a second independent multicenter cohort of patients with AH (n = 67) or AUD (n = 20), and controls (n = 18) (AlcHepNet). Mice lacking *Ctsb* in myeloid cells (LysM-Cre) or Kupffer cells (Clec4f-Cre), and transgenic mice overexpressing occludin in intestinal epithelial cells (occludin-IEC-Tg) were subjected to the chronic-plus-binge ethanol feeding model (NIAAA).
Results: Faecal CTSB levels and activity progressively increased in patients with AUD and AH compared with controls, and were associated with higher 90-day and 180-day mortality in patients with AH in the exploratory and validation cohort. Immunofluorescence analysis in patients with AUD and ethanol-fed mice revealed that CTSB is upregulated and predominantly expressed in macrophages in the intestine. Secretion and release of CTSB into the intestinal lumen are induced by ethanol intake, evidenced by increased CTSB activity in intestinal luminal contents and isolated intestinal cell fractions. Ethanol alone suffices to induce secretion of CTSB in cultured macrophages. Cell-specific deletion of *Ctsb* in myeloid cells, but not in Kupffer cells, stabilized the gut barrier by restoring levels of the intestinal tight junction protein occludin and lowering systemic LPS levels, and reduced ethanol-induced steatohepatitis in mice. Oral administration of the gut-restricted and specific CTSB inhibitor CA074 (5 mg/kg/day) in wildtype mice stabilized occludin levels, restored gut barrier function by reducing systemic LPS levels, and attenuated ethanol-induced steatohepatitis. In contrast, CA074 did not change these parameters in occludin-IEC-Tg mice, indicating that CA074 requires the stabilization of occludin to exert its beneficial actions. Moreover, occludin-IEC-Tg mice were protected against ethanol-induced steatohepatitis. *In vitro*, faecal supernatant from

patients with AH, or conditioned media from macrophages exposed to ethanol, or recombinant CTSB induced barrier disruption independent of cell death and degradation of occludin in Caco2 cell monolayers, mouse and human enteroids; these effects were blocked with CA074. Finally, enzymatic analysis revealed that CTSB directly cleaves occludin.
Conclusion: Intestinal macrophage-derived CTSB promotes intestinal barrier disruption through degradation of occludin, and its inhibition exerts promising beneficial effects in ethanol-induced steatohepatitis.

Chronic exposure to microplastics and nanoplastics exacerbates western diet-induced metabolic dysfunction-associated steatohepatitis: the role of gut microbiota
Dekai Zheng[1,2], Changhao Cheng[1,2], Zhixin Fang, Xuelian Gao[1,2], Kaikai Zhang, Yuchuan Chen, Heqi Zhou[1,2], Xun Wang[1,2], Routing Wang[1,2], Zhixian Lan, Yanhua Tang[3], Jian Sun[1,2]. *[1]State Key Laboratory of Organ Failure Research, Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases, Guangdong Provincial Clinical Research Center for Viral Hepatitis; Guangdong Institute of Hepatology, Guangzhou, China; [2]Key Laboratory of Infectious Diseases Research in South China, Ministry of Education, Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology; Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China; [3]Pulmonary and Critical Care Medicine, The First Affiliated Hospital, Hengyang Medical School, University of South China, Hengyang, China*
Email: doctorsunjian@qq.com

Background and aims: Microplastics (MPs) and nanoplastics (NPs) are ubiquitous pollutants that disturb lipid metabolism and liver function. However, the roles of MPs and NPs in metabolic dysfunction-associated steatohepatitis (MASH) remain unclear. Our study aims to evaluate the role and mechanism of long-term exposure to MPs and NPs in the progression of MASH, and reveal the potential mechanism from the prospective of gut microbiota in this process.
Method: 7-week-old male C57BL/6J mice were fed either a normal chow diet (NCD) or a Western diet (WD) for 18 weeks, with exposure to 5-micrometer MPs or 100-nanometer NPs via drinking water. The liver phenotype was analyzed with regard to steatosis (Oil Red O staining; hepatic TC, TG), inflammation (H&E staining; IL-6, TNF-alpha, IL-1beta) and fibrosis (Sirius red staining; Col1a1, alpha-SMA, expression). Liver transcriptomics and 16S rRNA sequencing were used to evaluate the effects of MPs and NPs on liver gene expression and gut microbiota in MASH mice. Feces were collected from mice exposed to MPs or NPs and transplanted to WD-induced MASH mice after one-week antibiotics administration.
Results: Exposure to MPs and NPs both significantly exacerbated WD-induced MASH and its associated liver fibrosis. MPs mainly promoted MASH-related obesity, hepatic steatosis, and liver injury, whereas NPs exacerbated liver inflammation in mice with MASH. The liver transcriptome suggests that MPs mainly affect gene expression in metabolic pathways, whereas NPs predominantly regulate inflammatory and cancer-related pathways. 16S rRNA sequencing indicated that MPs and NPs had different effects on gut microbiota. MPs upregulated the relative abundance of *Coriobacteriaceae* and *Dubosiella* and downregulated *Ruminococcus* and *Oscillospiraceae*, and NPs increased the relative abundance of potentially pathogenic bacteria such as Staphylococcus and *Muribaculum*. The fecal microbiota transplantation experiment indicated that the gut microbiota of MPs-exposed mice could replicate the aggravating effect of MPs on MASH. However, the gut microbiota of mice exposed to NPs exacerbated liver fibrosis, not inflammation.
Conclusion: MPs and NPs promote the progression of Western diet-induced MASH, with gut microbiota involved and partially driving this process. Our findings provide new evidence for the role of MPs and NPs in MASH and offer new insights into the interactions among environmental pollutants, gut microbiota, and liver diseases.

Background and aims: The global obesity pandemic is paralleled by a surge in metabolic dysfunction-associated steatotic liver disease (MASLD). Intestinal dysbiosis exacerbates hepatic inflammation in MASLD. However, the interplay of environmental and host-derived factors underlying gut-liver crosstalk and its connection to MASLD remains incompletely understood. Here, we aimed to elucidate a molecular link between MASLD and periodontitis, a disease that affects up to 40% of the population.
Method: In a translational approach, we combined population-based data from 500,000 UK Biobank participants, a prospective liver transplant (LTx) cohort, and a mechanistic mouse model. Clinical investigations included pre- and post-LTx assessments of liver and dental health, blood testing, and periodontal examinations. In mice, periodontitis was induced via silk ligatures, coupled with a Western-style diet (WSD) to induce MASLD. Using transcriptomics, protein, and imaging data, we assessed oral and gut microbiome, hepatic inflammation, and liver fibrosis. Finally, mice were treated with proton pump inhibitors (PPI) or underwent microbiome modulation using broad-spectrum antibiotics (ABx) and cohousing experiments.
Results: Patients with periodontitis exhibited elevated liver transaminase levels and a higher prevalence of liver fibrosis compared to controls. In mice, periodontitis caused significant dental bone loss in µCT, hepatic steatosis, fibrosis, and inflammation. This was linked to intestinal dysbiosis and gut microbiome alterations. PPI-mediated disruption of the gastric acidic barrier further aggravated these phenotypes, promoting severe liver fibrosis and gut microbiome shifts. Mechanistically, flow cytometry and immunofluorescence revealed pronounced infiltration of $IL17A^+$ lymphocytes in periodontitis mice. Similarly, serum proteomics in patients with periodontitis demonstrated elevated IL17, IL6, and M-CSF levels and overall enrichment of pathways associated with T-cell activation. This

phenotype was microbiome-dependent in mice, transmissible via cohousing, and reversible with ABx.
Conclusion: Our study highlights periodontitis as a significant risk factor for liver disease progression in MASLD via a microbiome-dependent oral-gut-liver circuit that fuels IL17-mediated hepatic inflammation. Screening and proper management of periodontal disease should be prioritized in MASLD patients to mitigate liver disease progression and improve outcomes.

OS-054
CD8+ tissue-resident memory T cells promotes liver fibrosis resolution and are regulated by intestinal microbiota
Yuzo Koda[1,2], Nobuhiro Nakamoto[1], Takanori Kanai[1]. [1]*Division of Gastroenterology and Hepatology, Department of Internal Medicine, Keio University School of Medicine, Tokyo, Japan;* [2]*Oncology and Immunology Unit, Research Division, Mitsubishi Tanabe Pharma Corporation, Kanagawa, Japan*
Email: kouda.yuuzou@ma.mt-pharma.co.jp

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a major cause of chronic liver disease that can progress to liver fibrosis. Recent clinical advances suggest that liver fibrosis can be reversed, but the cellular and molecular mechanisms behind MASH resolution are not well understood. This study uses a murine diet-induced MASH model to investigate the role of CD8+ tissue-resident memory T cells (CD8+ Trm) and the mechanisms regulating these cells in resolving liver fibrosis.
Method: To study the resolution process in liver fibrosis, we used a murine model where mice were fed a high-fat and high-cholesterol (HFHC) diet for 24 weeks, then switched to a normal diet (RES mice). We examined changes in intrahepatic immune cells during MASH development and resolution using flow cytometry. Additionally, we performed metagenomic analysis and antibiotics treatment to remove intestinal microbiota to examine the effects on immune responses in the liver.
Results: We found that the number of intrahepatic CD8+ T cells remained significantly high in RES mice compared to normal diet-fed (ND) mice, while other cell subsets returned to normal levels with fibrosis regression 8 weeks after the diet switch. Single-cell transcriptome analysis showed that most intrahepatic CD8+ T cells had Cd44+Sell-S1pr1- tissue-resident memory T cell (Trm) phenotypes during MASH resolution. Bulk RNA-seq analysis of isolated CD8+ T cell subsets revealed that both Trm subsets from HFHC and RES mice expressed core Trm signature genes. Depleting CD8+ T cells with a killing antibody during the resolution phase prevented recovery from liver inflammation and fibrosis. During resolution, CD8+ Trm attracted hepatic stellate cells (HSCs) in a CCR5-dependent manner and induced FasL-Fas-mediated apoptosis in activated HSCs. Antibiotic administration during the fibrosis recovery phase further increased CD8+ Trm and promoted fibrosis recovery, indicating that intestinal microflora regulates CD8+ Trm and is involved in fibrosis recovery. Metagenomic analysis suggested that certain bifidobacteria are upregulated during fibrosis recovery and may influence CD8+ Trm differentiation and proliferation.
Conclusion: This study provides new insights into the liver-protective function of CD8+ Trm during the MASH resolution phase. Regulating CD8+ Trm through microbiota manipulation may offer a potential therapeutic option for MASH in the future.

Immune-mediated & Cholestatic Diseases

Novel dual-acting ABCB4/MDR3 and ABCB11/BSEP positive functional modulator demonstrates anti-cholestatic and anti-cholangitis activity in two orthogonal models of hepatobiliary disease
Eric Bell[1], Nathan Fuller[1], Jennifer Truong[1], Youhwa Jo[1], Pui Yee Ng[1], John Miller[1], Alastair Garfield[2], Robert Hughes[1]. [1]*Rectify Pharmaceuticals, Boston, United States;* [2]*Rhythym Pharmaceuticals, Boston, United States*
Email: ebell@rectifypharma.com

Background and aims: ATP binding cassette subfamily B members 4 (ABCB4/MDR3) and 11 (ABCB11/BSEP) facilitate the translocation of phosphatidylcholine (PL) and the efflux of bile acids (BA) from hepatocytes to the canalicular space, respectively. Mutations in these transporters cause monogenic cholestatic diseases (PFIC2 [BSEP deficiency] /PFIC3 [MDR3 deficiency]) and are associated with the hepatobiliary diseases intrahepatic cholestasis of pregnancy (ICP) and low phospholipid-associated cholelithiasis (LPAC), highlighting their critical role in maintaining hepatobiliary health. We have discovered RTY-694, a novel, potent, dual-acting ABCB4/BSEP positive functional modulator (PFM) and characterized it in *in vitro* pharmacology studies.[1] Here we present *in vivo* pharmacology data that RTY-694 demonstrates anti-cholestatic and anti-cholangitis efficacy in animal models of PFIC2 and cholangiopathy.
Method: RTY-694 was evaluated with twice daily oral dosing in; 1) a 2-week model of PFIC2 harboring the pathogenic E297G variant in *Bsep*, and 2) a 6-week model of *Abcb4* heterozygous animals fed a lithogenic diet[2]. Liver function, and biliary endpoints were measured in both models. In addition, gene expression, chemokines, and histology for ductular reaction, cholangitis, and fibrosis were assessed in the *Abcb4* model.
Results: In the PFIC2 model oral RTY-694 led to increased biliary levels of BA, demonstrating Bsep target engagement. Additionally, RTY-694 decreased serum levels of BA, alkaline phosphatase (ALP), alanine transaminase (ALT), liver taurocholic acid (TCA) and liver weight. In the *Abcb4* heterozygous model, oral RTY-694 increased biliary PL levels, demonstrating Abcb4 target engagement. Serum markers of cholestasis and inflammation were reduced by RTY-694, and histology demonstrated a reduction in markers of ductular reaction, cholangitis, and fibrosis.
Conclusion: RTY-694, a first-in-class, orally active dual PFM for ABCB4/BSEP, was characterized in a genetic and a mixed genetic/diet model of hepatobiliary diseases. By enhancing the function of Abcb4 and Bsep, RTY-694 provided a beneficial impact on relevant markers of cholestasis and biliary health. These data demonstrate the promise of our dual BSEP/ABCB4 PFM to provide a benefit for multiple hepatobiliary diseases such as Primary sclerosing cholangitis (PSC) and PFIC2.

Background and aims: Primary sclerosing cholangitis (PSC) is a progressive fibrosing cholangiopathy with no effective therapeutic options. We have previously discovered Claudin-1 (CLDN1) as a therapeutic target for liver and biliary fibrosis in PSC. Here, we aimed to investigate the functional role of CLDN1 in PSC as a therapeutic target using patient liver tissues, monoclonal antibodies (mAbs) and patient-derived mouse models.

Method: CLDN1 expression was investigated in liver tissues from three well characterized PSC cohorts from European tertiary care centers combining integrative scRNA-seq, spatial transcriptomics and proteomics analyses. For proof-of-concept and perturbation studies CLDN1-specific mAbs were applied to bile duct ligation, DDC and MDR2-/- mouse models including human liver chimeric FRG-NOD mice engrafted with human hepatocytes.

Results: CLDN1 expression is significantly upregulated in liver tissues of PSC compared to healthy controls and correlates with serum alkaline phosphatase levels and disease stage. Multi-omics molecular profiling of CLDN1+ cells in PSC liver tissues unraveled high CLDN1 expression in a subset of PSC-cholangiocytes characterized by ductular proliferation, cell plasticity and pro-fibrogenic and pro-carcinogenic signaling. CLDN1+ cholangiocytes and hepatocytes line fibrotic scar lesions, co-expressing TNF-alpha and osteopontin, thus playing a central role in disease progression. Treatment with CLDN1-specific mAbs resulted in a marked reduction of fibrosis and cholestasis across mouse models by inhibition of NFkB, SRC, NOTCH and AKT signaling in cholangiocytes and de-differentiated hepatocytes. In a human liver chimeric mouse model, CLDN1 mAb treatment modulated the cell plasticity of human liver epithelial cells.

Conclusion: CLDN1 expression is a candidate biomarker of PSC progression. Co-expression data in patient cohorts combined with mechanism of action and proof-of-concept studies identify CLDN1 as therapeutic target and open the perspective for the clinical development of CLDN1-specific mAbs to treat PSC.

OS-057-YI

Evaluating the 2023 EASL guidelines for intrahepatic cholestasis of pregnancy: risk stratification and outcomes in 4,000+ U.S. patients

Nina Rodriguez[1], Cecilia Katzenstein[1], Keith Sigel[1], Rhoda Sperling[1], Catherine Williamson[2], Tatyana Kushner[3]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]King's College London, London, United Kingdom; [3]Weill Cornell Medicine, New York, United States*
Email: nina.rodriguez@icahn.mssm.edu

Background and aims: Intrahepatic cholestasis of pregnancy (ICP) is the most common liver disease unique to pregnancy, varying in incidence based on population and associated with adverse fetal outcomes. We assessed the prevalence and outcomes of ICP categories defined by the 2023 European Association for the Study of the Liver (EASL) guidelines in a diverse U.S. population.

Method: We conducted a retrospective cohort study (January 2009-April 2024) using data from our large, ethnically diverse health system. Suspected ICP patients were identified by pregnancy records with total serum bile acids (TSBA) ordered and categorized based on EASL guidelines: Group A (normal TSBA, ALT/AST), B (elevated ALT/AST, normal TSBA), or C (TSBA > 19, normal or elevated ALT/AST). Analyses included first pregnancies, with 76% having obstetric outcome data. Post-pregnancy diagnoses were defined as occurring 6 months after peak TSBA. Multinomial and binary logistic analyses, adjusted for potential confounders, were performed to identify predictors and outcomes of each group.

Results: Among 178,889 pregnancies, we identified 4,764 (2.7%) cases of suspected ICP, involving 4,240 unique patients. Of these, 875 (21%) had TSBA ≥ 10 and 83 (2%) had levels ≥ 100. The cohort (36% White, 23% Hispanic, 12% Asian, 10% Black) was classified as Group A (64%), B (25%), or C (11%). Ursodiol was prescribed to 10% of A, 25% of B, and 67% of C. Mean age (32.5 years) and BMI (29) were similar across groups. Hispanic ethnicity was associated with Group C, compared to A (RRR 1.72, 95% CI: 1.31–2.24) and B (RRR 1.50, 95% CI: 1.12–2.01). Compared to A, pre-existing liver disease was associated with a higher likelihood of being classified in Groups C (RRR 5.12, 95% CI: 3.17–8.26) and B (RRR 1.94, 95% CI: 1.44–2.61). Odds of post-pregnancy liver disease were highest in B (OR 3.24, 95% CI:1.97–5.34) compared to A. Group B showed independent associations with gestational hypertension (OR 2.25, 95% CI: 1.55–3.26), preeclampsia (OR 3.78, 95% CI: 2.46–5.81), and fetal respiratory distress syndrome (OR 2.32, 95% CI: 1.61–3.33), compared to A. Group C had higher odds of preterm birth compared to A (OR 10.93, 95% CI: 8.20–14.56) and B (OR 4.06, 95% CI: 2.99–5.50). Within C, preterm birth rates increased with rising TSBA: 44% with TSBA < 40, 50% with TSBA ≥ 40 and <100, and 69% with TSBA ≥100 (p = 0.003).

Conclusion: This study evaluates the applicability of the 2023 EASL guidelines for suspected ICP, demonstrating how group characteristics can guide risk stratification. Our findings suggest that both elevated TSBA (Group C) and elevated ALT/AST alone (Group B) warrant surveillance. Identifying elevated ALT/AST alone as a potential surveillance indicator has global relevance, offering an accessible screening tool when TSBA may be unavailable. The association of ICP with Hispanic ethnicity and pre-existing liver disease highlights the importance of targeted screening, while post-pregnancy liver disease risk underscores the value of long-term follow-up.

OS-058

Screening for biliary dysplasia using brush cytology in PSC: Accuracy, risk factors and outcomes

Martti Färkkilä[1], Hannu Kautiainen[2], Sonja Boyd[3], Fredrik Åberg[4], Johanna Arola[5]. *[1]Helsinki University, Helsinki University Hospital, Helsinki, Finland; [2]Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland; [3]Diagnostic Center, Department of Pathology, Helsinki University Hospital, Helsinki University, Helsinki, Finland; [4]Helsinki University Hospital, Helsinki, Finland; [5]Helsinki University, Helsinki, Finland*
Email: martti.farkkila@hus.fi

Background and aims: PSC is a chronic inflammatory condition resulting in strictures in bile ducts, leading to cholestasis and cirrhosis. Chronic inflammation significantly increases the risk of biliary dysplasia (BD) and cholangiocarcinoma (CCA), with a relative risk up to 973-fold. The cumulative risk of developing CCA after 10, 20, and 30 years of PSC is 6%, 14%, and 20%, respectively. CCA has a poor prognosis, with a 5-year survival <10%. The optimal screening strategy for CCA remains controversial, but EASL and AASLD guidelines recommend annual surveillance using US and/or MRI/MRCP. Brush cytology (BC) allows for the early detection of BD, potentially identifying malignant transformation before CCA develops. In our unit, BD detected ≥3 times during screening is an indication for transplantation (LTx) evaluation. This study aimed to evaluate the sensitivity and specificity of BC in detecting CCA and assess risk factors for BD in a prospective cohort of patients with PSC undergoing ERCP. Patient outcomes were also analyzed.
Method: We included 989 patients from a prospective registry who underwent ERCP and BC for dysplasia surveillance. Exclusions (n = 102) were age <18 or >65 years, CCA ≤1 year of diagnosis (n = 35), serious concomitant disease or malignancy (n = 1), or LTx (n = 2). We analyzed demographic, laboratory, and imaging data, including liver function tests, ERCP scores, and biliary biomarkers (IL-8 and calprotectin), comparing patients who developed BD≥3 times or CCA (composite endpoint) to those who did not. We calculated optimal cutoff values, time-weighted AUCs, and sensitivity/specificity for potential predictors of the composite endpoint.
Results: Among the cohort, 10% had BD detected once or more, and 43 patients (4.3%) reached the composite endpoint. Median follow-up was 10.6 years (IQR: 5.6–16.6) for patients without BD/CCA and 6.7 y (IQR: 2.4–10.9) for those with dysplasia/CCA. Factors associated with the composite endpoint included intra- and extrahepatic disease, high ERCP scores, elevated AST, bil, IgG4, CA19–9, IL-8, and calpro levels. However, the ERCP score (≥7) was the only significant predictor (AUC 0.87) for composite end point. Only 10 (1,2%) patients with negative BC (n = 884) developed CCA during 25 years f/u. For BD detected ≥1x, sensitivity was 0.61 (95% CI: 0.42–0.78) and specificity 0.92 (95% CI: 0.90–0.93). The negative predictive value was 0.99 (95% CI: 0.98–1.00), and accuracy 0.91 (95% CI: 0.89–0.92). Among 24 patients who underwent LTx for suspected malignancy based on BD in BC≥3 times, explant analysis confirmed dysplasia in all cases: LGD (n = 10), HGD (n = 10), ca in situ (n = 1), and CCA (n = 3).
Conclusion: Brush cytology demonstrates an excellent negative predictive value, effectively excluding CCA development over a 25-year follow-up. Repeated BD is a highly sensitive marker for biliary neoplasia in explant. The ERCP score emerged as the sole significant predictive marker for biliary neoplasia or CCA, underscoring its critical role in PSC surveillance.

Email: michael.heneghan@nhs.net

Background and aims: Cholestatic pruritus (CP) is a debilitating symptom of primary biliary cholangitis (PBC) which greatly impacts overall quality of life. Elevated serum bile acids (sBAs) have been implicated to play a role in CP. Volixibat (VLX) is an ileal bile acid transporter inhibitor (IBATi) which blocks the enterohepatic recirculation of bile acids, leading to reductions in sBA. Here we present the

interim analysis (IA) for VANTAGE which evaluated two doses of VLX for efficacy and safety in PBC.
Method: VANTAGE is a 28-week randomized, multicenter, double-blind, placebo (PBO)-controlled Phase 2b study in adults with PBC and CP. The study has an adaptive design with a dose selection period with an IA (1:1:1 randomization, VLX 20 mg, 80 mg or PBO BID) and a pivotal period (1:1 randomization, selected dose or PBO BID), where efficacy and safety of the selected dose will be confirmed. The primary efficacy endpoint is the mean change in Adult ItchRO score (0–10 pruritus scale) from Baseline through Week 28 in participants with moderate-to-severe pruritus. The PBC-40 assessment scale was a key secondary endpoint. The IA was conducted when approximately 12 participants per treatment arm completed Week 16 or prematurely discontinued study drug. Previously, results were reported through Week 16. Here, we report on data out to 28 weeks of treatment.
Results: A total of 31 participants with moderate-to-severe pruritus were randomized (20 mg VLX = 10; 80 mg VLX = 10; PBO = 11). Mean Baseline ItchRO scores were balanced between groups. Volixibat treatment led to rapid reductions in ItchRO with the VLX combined dose group achieving a statistically significant −3.78-point reduction from Baseline ($p < 0.0001$) and a placebo-adjusted response of −2.51 ($p = 0.0004$). Each VLX dose achieved statistically significant and similar responses. Overall, 70% of participants who received VLX achieved ≥50% reduction in sBA. Improvements in some domains of the PBC-40 were observed with VLX. No new safety signals were observed, with a similar incidence of adverse events between VLX treatment groups. The most common adverse event in the VLX groups was diarrhea; all were mild in severity; 1 patient discontinued therapy due to mild diarrhea.
Conclusion: Volixibat led to early and significant reductions in PBC-associated cholestatic pruritus and fatigue, with no new safety signals observed through 28 weeks of treatment. Given similar results between VLX doses, the 20 mg BID dose was selected for Part 2 of VANTAGE, constituting a new promising therapy to address important symptoms in PBC..

Liver tumours: Clinical aspects except therapy

Email: josep.llovet@mountsinai.org

Background and aims: Immunotherapy has revolutionized the management of hepatocellular carcinoma (HCC), although it has resulted in issues with non-proportional hazards (NPH) in phase III randomized trials (RCTs). Notably, the IMbrave050 study showed a positive interim analysis (IA) followed by a subsequent negative outcome. Our study aims to analyze the presence and impact of NPH in the most relevant RCTs in HCC and to propose strategies to ensure a robust interpretation of both interim and final analyses (FA).
Method: Key phase III RCTs in HCC reported from 2008–2024 were selected. Kaplan-Meier survival curves were reconstructed, and the proportional hazards assumption was evaluated using the Grambsch-Therneau test. For NPH, we proposed optimal timing for IA defined by a minimum follow-up of twice the estimated median of the primary endpoint for the control group or by reaching ≥60% of estimated events. In these RCTs, we assessed efficacy by MaxCombo test and effect size by the ratio of restricted mean survival time (rRMST) and piecewise HR (pHR).
Results: Out of 17 phase III RCTs included, 4 exhibited NPH, all of them assessing immunotherapies. We identified different patterns of NPH: 1) diminishing effects (IMbrave050, recurrence-free survival; and LEAP-012, progression-free survival), 2) delayed effects (HIMALAYA, overall survival) and 3) crossing of curves (CheckMate 9DW, overall survival). All NPH trials showed concordance between the log-rank and MaxCombo tests. In IMbrave050, IA showed a MaxCombo p-value: 0.028, whereas FA showed a p-value: 0.326. Correspondingly, the magnitude of benefit showed rRMST ratios at 12, and 36 months of 0.89 ($p < 0.001$) and 0.93 ($p = 0.08$) and the pHR prior/after 12 months was 0.59 (0.43–0.73) and 1.12 (0.88–1.37). In the LEAP-012 trial, the rRMST were significant at both 12 and 24 months, with 0.83 ($p < 0.001$) and 0.79 ($p < 0.001$) respectively. HIMALAYA displayed a pattern of delayed effects [rRMST at 12 and 36 months: 0.96 ($p = 0.134$) and 0.87 ($p = 0.004$)], whereas CheckMate 9DW displayed one of crossing of curves [rRMST at 12 and 36 months: 1.05 ($p = 0.074$) and 0.93 ($p = 0.003$)]. The pHR in LEAP-012 was 0.55 (0.38–0.69) and 0.83 (0.52–1.13) prior/after 12 months, respectively. In HIMALAYA, the pHR at 12 months was 0.87 (0.69–1.06) and 0.72 (0.57–0.86) thereafter, while in CheckMate 9DW was 1.09 (0.80–1.36) and 0.66 (0.50–0.83).
Conclusion: The inconsistency between interim and subsequent efficacy analysis of IMbrave050 was related to NPH. In cases of NPH at IA, analysis of the significance and magnitude of benefit requires a minimum follow-up duration or number of events prior prematurely stopping an RCT. We propose implementing these criteria in the IA of phase III RCTs in HCC, particularly in the setting of immunotherapy.

OS-061
A holistic approach of systematic tumor and non-tumor biopsy during percutaneous radiofrequency ablation for hepatocellular carcinoma: diagnostic, prognostic and therapeutic impact
Lorraine Blaise[1], Marianne Ziol[2,3], Claudia Campani, Nathalie Ganne-Carrié[1,3], Pierre Nahon[1,3], NKontchou Gisèle[1], Jessica Zucman-Rossi[3], Lucie Del Pozo[4], Nathalie Barget[4], Carina Boros[1], Elvire Desjonqueres[1], Alix Demory[1], Véronique Grando Lemaire[1], Lorenzo Pescatori[5], Olivier Seror[5], Olivier Sutter[5], Jean Charles Nault[1,3]. *[1]Service d'Hépatologie et d'Oncologie Hépatique Hôpital Avicenne AP-HP, Bobigny, France; [2]Service d'anatomopathologie Hôpital Avicenne AP-HP, Centre de Recherche des Cordeliers, Sorbonne Université, Inserm, Université de Paris, team « Functional Genomics of Solid Tumors », F-75006, Bobigny, France; [3]Centre de Recherche des Cordeliers, Sorbonne Université, Inserm, Université de Paris, team « Functional Genomics of Solid Tumors », F-75006, Paris, France; [4]Plateforme de ressources biologiques Hôpital Avicenne AP-HP, Bobigny, France; [5]Service de Radiologie interventionnelle Hôpital Avicenne AP-HP, Bobigny, France*
Email: lorraine.blaise@aphp.fr

Background and aims: We prospectively assess the feasibility, safety, and diagnostic/prognostic value of systematic tumor and non-tumor liver biopsies collected during radiofrequency ablation (RFA) for a first diagnosis of hepatocellular carcinoma (HCC).

Method: We included patients diagnosed with a first diagnosis of HCC between 2015 and 2021, treated with percutaneous RFA and with both tumor and non-tumor biopsies in a tertiary center. We analyzed the percentage of diagnostic tumor biopsies and correlated results of histological findings with prior diagnoses and oncological outcomes. Non-tumor liver biopsy results were compared with multidisciplinary tumor board (MTB) diagnosis of cirrhosis.
Results: 248 patients (86% male, median age 68) with 302 tumors treated by RFA were included. HCC was single in 78%, bifocal in 21%, with a median size of 24 mm. 87% of the patients had cirrhosis (based on the results of the non-tumor liver biopsy done per-procedure). Bleeding occurred in 6 cases (1.9%), requiring intervention in 2, with no death. Nor low platelets-count (<100000/mm^3) nor anticoagulation nor antiplatelet agent were associated with bleeding. Biopsies were diagnostic in 66% with positivity linked to nodule size ($P < 0.0001$), location ($P = 0.04$), and ultrasound visibility ($P = 0.004$). Among the 302 biopsies, 34% were not diagnosis, 61% diagnosed HCC, 3% cholangiocarcinoma (n = 3)/hepatocholangiocarcinoma (n = 6), and 2% dysplastic nodules (n = 7). Discrepancies between MTB and histological diagnosis occurred in 5% of cases. To note, all the cholangiocarcinoma or hepatocholangiocarcinoma diagnosed with the per-ablation biopsy were classified as LIRADS 5 by imagery reviewing. Survival was significantly shorter in patients with cholangiocarcinoma/hepatocholangiocarcinoma ($P < 0.001$). Pathological subtypes of HCC were not otherwise specified HCC in 55%, steatohepatitic-HCC in 19%, macrotrebacular massive-HCC (MTM-HCC) in 15%, scirrhous-HCC in 6.3%, clear cell-HCC in 2.8%, and lympho-epithelioma like-HCC in 2.3%, MTM-HCC was associated with higher rate of tumor recurrence ($P = 0.037$). Presence of more than 30% of tumor cells at formalin-fixed paraffin-embedded samples was associated with expression of cancer-related genes at transcriptomic of the corresponding frozen samples assuring their usefulness for molecular analysis. Among non-tumor biopsies, cirrhosis was histologically confirmed in 82% of cases with a 15% discrepancy between diagnosis of cirrhosis at MTB and biopsy, 10.9% (n = 27) were considered cirrhotic by MTB and identified as non-cirrhotic on the non-tumor biopsy.
Conclusion: Systematic tumor and non-tumor biopsy during RFA for a first diagnosis of HCC is feasible, safe, and has diagnostic, therapeutic, and prognostic value.

Liver transplantation after downstaging of intermediate and advanced HCC with atezolizumab-bevacizumab: a prospective study (ImmunoXXL)

Sherrie Bhoori[1], Licia Rivoltini[2], Valentina Bellia[1], Marianna Maspero[3], Jacopo De Cristofaro[4], Marco Bongini[5], Michela Dosi[2], Elisabetta Vergani[2], Giovanni Di Maio[2], Giuseppe Leoncini[6], Barbara Vergani[7], Nicolò Simonotti[8], Barbara Cappetti[2], Francesca Rini[2], Stefano Bergamini[2], Luca Lalli[2], Carlo Sposito[3], Vincenzo Mazzaferro[3]. *[1]Hepatology, HPB Surgery and Liver Transplantation Unit Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [2]Translational Immunology - Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [3]Department of Oncology and Hemato-Oncology, University of Milan, Hepatology, HPB Surgery and Liver Transplantation Unit, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [4]Internal Medicine, University "Vita e Salute" San Raffaele Hospital, Milan, Hepatology, HPB Surgery and Liver Transplantation Unit, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [5]Hepatology, HPB Surgery and Liver Transplantation Unit, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [6]Pathology - Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy; [7]Department of Medicine, Digital pathology and Immunology, University of Milan-Bicocca, Milano, Italy; [8]Surgery, University of Milan, Hepatology, HPB Surgery and Liver Transplantation Unit, Fondazione IRCCS Istituto Nazionale Tumori, Milano, Italy*
Email: vincenzo.mazzaferro@istitutotumori.mi.it

Background and aims: Tumor downstaging (DS) is an accepted strategy to increase liver transplantation (LT) eligibility in patients with hepatocellular carcinoma (HCC). Given the results of the atezolizumab-bevacizumab (A + B) therapy in advanced HCC, its use within DS protocols should be investigated.
Method: The ImmunoXXL study (NCT05879328) is a phase 2 study investigating LT after successful DS with A + B. Primary endpoint is safety of LT after A + B while secondary endpoint is whether LT can increase progression-free survival (PFS) compared to that reported by the IMbrave150 RCT for patients with advanced HCC in response to A + B. Adverse events (AE) graded ≥3 were recorded throughout and assessed if immune-related (irAE). Spectral quantitative pathology imaging and deconvolution of immune RNA signatures were part of explant pathology analysis.
Results: 16 patients with HCC beyond expanded transplant criteria at presentation obtained a successful DS to within transplant criteria after a minimum of 3 months of A + B (30% PR, 70% CR according to mRECIST). HCC at presentation had median size: 6.5 cm (IQR: 3 - 8), median AFP 283 (IQR: 6 - 1080) portal vein thrombosis (PVT) and multifocality in 50% of cases. 15 (94%) patients had received previous loco-regional therapies (Y^{90} in 9 pts). Median A + B treatment duration was 4.7 months (IQR: 2.4 - 7.6) for 7.5 cycles (IQR: 4 - 9). Interval from last A + B dose to LT (washout period) was 46.5 days. Median follow-up from LT listing was 16 months. Pretransplant irAE occurred in 3 (19%) pts (1 liver decompensation, 2 hypertension) while posttransplant irAE (25%) were 4 acute rejections (RAI > 4) requiring biopsy and steroids boluses. Patients with acute rejection had a significantly larger pre-LT naive T cell pool (null antigen-specificity) with respect to non-rejecting patients. Overall, 90 days morbidity (with 2 reLT) and mortality (1 death) after LT were 62.5% and 6.3% respectively, with12mo. graft survival of 87.5%. Explant pathology revealed 10 complete and 6 partial responses with a concordance between preLT radiology and postLT pathology of 62.5% (Pearson's rho: 0.04 p: 0.883). Tumor microenvironment (TME) of A + B down staged tumor specimens, revealed a composite milieu enriched in tertiary lymphoid structures, trained myeloid effectors and antigen experienced CD8+ T cells. TME changes could be correlated to the duration of pretransplant A + B washout period. As there was 1 HCC recurrence in the lung, the recurrence free survival and overall survival after transplant is 94% and 90% at 2 yrs, respectively.
Conclusion: LT after consistent downstaging with atezolizumab-bevacizumab alone or in combination with loco-regional treatments is safe, effective and competitive strategy for improving outcomes of patients carrying HCC beyond current transplant indications. LT in this contest has implications on HCC control and surveillance.

OS-063
Digital risk stratification management platform improves the early diagnosis and surveillance of liver cancer in china: a real-world study in Zhuhai people's hospital

Qing Yang[1], Manhua Zhong[1], Bing Liu[2], Kee Jit Thye[3], Xiaofeng Wang[1], Yanhong Chen[1], Linfang Li[1], Xiaolei Zhou[1], Cunying Pu[3], Yaoxiang Wu[4], Yong Li[4]. *[1]Department of Infectious Disease and Hepatology, Zhuhai People's Hospital (Zhuhai Hospital Affiliated with Jinan University), Zhuhai, China; [2]Department of Interventional Medicine, Guangzhou First People's Hospital, Guangzhou, China; [3]Roche Diagnostics (Shanghai) Co., Ltd, Shanghai, China; [4]Department of Interventional Medicine, Zhuhai People's Hospital (Zhuhai Hospital Affiliated with Jinan University), Zhuhai, China*
Email: yangqing7007@126.com

Background and aims: Liver cancer imposes a substantial burden on China, with hepatocellular carcinoma (HCC) accounting for 85%-90%. The prognosis for HCC patients remains poor, primarily due to late-stage diagnoses, especially among patients with chronic hepatitis B (CHB). Various diagnostic methodologies demonstrate potential in enhancing early-stage HCC detection rates, including serum

biomarkers such as alpha-fetoprotein (AFP) and PIVKA II, and algorithmic scores such as GAAD, which has been recommended by the latest China Anti-Cancer Association guideline. Zhuhai People's Hospital developed a digital risk stratification platform aimed at facilitating the early screening and diagnosis of HCC, particularly utilizing the GAAD score. This study evaluates the clinical performance of this platform in a real-world setting.

Method: This study included CHB patients without prior diagnoses of HCC who visited the Department of Hepatology and Infectious Disease at Zhuhai Hospital since March 2023. Each patient followed a standardized clinical pathway encompassing screening, diagnosis, treatment, and follow-up management based on individual HCC stages and risk stratification result. The digital platform integrated various HCC risk assessment results, including the GAAD score. Patients were categorized into four distinct risk groups: low, medium, high, and very high risk, with corresponding surveillance intervals of 12, 12, 6, and 3 months, respectively. Total follow-up rate and the rate of early-stage HCC diagnoses (defined as CNLC stage Ia and Ib) were recorded and compared with reported national average value. Receiver-operating characteristic (ROC) curves were plotted to evaluate HCC diagnostic performance, and the area under the ROC curve (AUC) and corresponding sensitivity and specificity of AFP, PIVKA-II, and GAAD were calculated and compared.

Results: From March 2023 to October 2024, a total of 3,958 CHB patients were enrolled, with 3,952 successfully completing the risk assessment. Among these, 32 patients (0.8%) were diagnosed with HCC, predominantly males (81.3%). 30 patients were identified at the early stage of HCC, with a higher early diagnosis rate compared to the national average (93% vs. 30%). Additionally, 2,519 patients attended at least one screening visit, resulting in an enhanced follow-up rate (63.6% vs. 30%). In the subgroup of 1,803 patients with available GAAD scores, 16 HCC cases were detected, with 15 of them identified at an early stage (94%). The ROC curve analysis indicated that the GAAD score exhibited superior performance in detecting HCC compared to AFP and PIVKA II alone (AUC: 0.8426 vs. 0.6558 vs. 0.6674), with a high specificity of 99.22%.

Conclusion: This digital risk stratification platform for standardizing HCC screening and management has improved early diagnosis and follow-up rates relative to national averages. The GAAD score stands out as a reliable tool for early-stage HCC screening, showcasing high diagnostic accuracy performance and specificity.

Email: fabio.piscaglia@unibo.it

Background and aims: This exploratory analysis aimed to assess gut microbiota (GM) composition as a potential predictive biomarker of treatment response in patients with unresectable hepatocellular carcinoma (HCC) treated with atezolizumab plus bevacizumab (AtezoBev) in the multicenter, phase IIIB, single-arm AMETHISTA study.

Method: Fecal specimens were collected from 114 HCC patients at baseline, immediately before starting AtezoBev. We analyzed GM profiles at baseline, and at 3 and 6 weeks (corresponding to immediately before the second and third infusions, respectively). Radiological responses were classified at 6 weeks as progressive disease (PD, n = 18, 15.8%), stable disease (SD, n = 84, 73.7%), or objective response (R, n = 12, 10.5%, none with complete response). Two types of patient grouping were carried out: a) patients were divided into Objective Responders (R) and Non-Responders (NR) to test the prediction of objective response; b) patients with primary PD were separated from those with Disease Control (DC). Predictive models were developed using machine learning (ML) techniques, with class balancing performed by Synthetic Minority Over-sampling Technique (SMOTE). A group of 437 healthy controls from a previous study was used as a comparator at baseline.

Results: At baseline, HCC patients exhibited reduced GM diversity and increased pro-inflammatory taxa compared to healthy controls. Within the HCC group, R patients showed lower levels of inflammatory genera (*Senegalimassilia*, *Eggerthella*, *Turicibacter*) and higher levels of anti-inflammatory taxa (*Dialister*) at baseline compared to NR patients. ML models demonstrated high accuracy in predicting response (Neural Network AUC: 0.998; Random Forest AUC: 1.0). At 3 weeks, NR patients retained higher abundances of pro-inflammatory genera (*Tyzzerella*, *Eggerthella*, *[Ruminococcus] torques*), while R patients showed enrichment in lactic acid bacteria linked to immune support (*Lactobacillus*, *Dialister*). Primary PD patients were enriched in inflammatory taxa (*Senegalimassilia*, *[Eubacterium] hallii*), while DC patients had higher *Bifidobacteriu*m.

Conclusion: Our findings suggest that GM configuration at baseline may serve as a biomarker to predict group-level response to AtezoBev in HCC. Distinct inflammatory taxa associated with NR and PD underscore the role of GM in modulating therapeutic efficacy. These results warrant further studies about GM and microbiome-targeted interventions to enhance treatment outcomes.

Viral Hepatitis B/D Current clinical practice

The multi-center study of functional cure for inactive hepatitis B surface antigen carriers in China: interim analysis of E-cure study

Zhishuo Mo[1], Haifang Cao[2], Yu Zhang[2], Yawen Luo[3], Qingfa Ruan[4], Jianqi Lian[5], Xiulan Xue[6], Xiaobo Lu[7], Xiangyang Ye[8], Rongxian Qiu[8], Xiaoping Wu[9], Xiaorong Mao[10], Qihuan Xu[11], Zhiliang Gao[11]. *[1]The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China; [2]Qinghai Provincial Fourth People's Hospital, Xi ning, China; [3]Affiliated Hospital of Zunyi Medical University, Zunyi, China; [4]Xiamen Hospital of Traditional Chinese Medicine, Xiamen, China; [5]The Second Affiliated Hospital of Air Force Medical University, xi'an, China; [6]The First Affiliated Hospital of Xiamen University, Xiamen, China; [7]The First Affiliated Hospital of Xinjiang Medical University, Urumchi, China; [8]Affiliated Hospital of Putian University, Putian, China; [9]The First Affiliated Hospital Of Nanchang University, Nanchang, China; [10]The First Hospital of Lanzhou University, Lanzhou, China; [11]The third affiliated hospital of Sun Yat-sen university, Guangzhou, China*
Email: mozhsh@mail.sysu.edu.cn

Background and aims: Approximately 30% to 60% of inactive hepatitis B surface antigen carriers (IHCs) exhibit significant liver inflammation (G ≥ 2) or fibrosis (F ≥ 2) on liver biopsy, underscoring the need for therapeutic intervention. This study aimed to investigate the efficacy of different peginterferon alpha (PegIFNα)-based treatment strategies and factors influencing HBsAg clearance for IHCs.
Method: A multi-center real world study (E-cure) started in January 2022. The study enrolled IHCs consistent with the definition of inactive CHB in the guideline of AASLD 2018. The patients received one of the following treatments: Nucleos(t)ide analogues (NAs) monotherapy, PegIFNα monotherapy, Initial combination therapy (PegIFNα-2b with NAs for 12–24w followed by PegIFNα-2b monotherapy), Whole process combination therapy (combination of PegIFNα-2b and NAs for the entire period) and Sequential combination therapy (NAs for 12–24w followed by PegIFNα-2b add-on).
Results: As of November 4, 2024, 7899 individuals were screened and 5328 eligible IHCs were included. Of these, 1038 completed 48 weeks of treatment, with 691 in the PegIFNα monotherapy group, 94 in the Initial combination therapy group, 212 in the Whole process combination therapy group, and 41 in the s Sequential combination therapy group. The median (IQR) age of all patients was 41.0 (34.0–48.0) years, 62.1% were male, 38.2% had a baseline HBsAg < 100 IU/mL, 35.0% had levels between 100 and 1000 IU/mL, 26.8% had levels ≥ 1000 IU/mL, and 90.8% had a baseline HBV DNA < 1000 IU/mL. The HBsAg clearance and seroconversion rates in patients treated with PegIFNα-2b increased as the duration of treatment progressed. By week 48, the cumulative HBsAg clearance rates for the PegIFNα monotherapy, Initial combination therapy, Whole process combination therapy and Sequential combination therapy groups reached 53.3%, 34%, 58% and 65.8%, respectively (P < 0.001), and the cumulative HBsAg seroconversion rates reached 36.8%, 17.6%, 30.1% and 53.3%, respectively (P < 0.001). The cumulative HBsAg clearance rates at 48 weeks for the baseline HBsAg <100 IU/ml, 100–1000 IU/ml, and >1000 IU/ml groups were 72.56%, 42.62%, and 8.89%, respectively. HBV DNA was undetectable in more than 90% of patients in the above 4 groups (92.8%, 95.7%, 97.9% and 95%). Multivariate logistic regression analysis indicated that a lower baseline HBsAg level (OR = 0.220, 95%CI 0.169–0.280, p < 0.001), a higher HBsAg reduction at 24 weeks (OR = 5.168, 95%CI 3.909–7.031, p < 0.001), and the Whole process combination therapy group (OR = 3.064, 95%CI 1.589–6.106, p = 0.001) had a higher likelihood of achieving HBsAg clearance at 48 weeks.
Conclusion: PegIFNα-2b based therapy proved effective for IHCs to pursue functional cure. The efficacy for HBsAg clearance is associated with baseline HBsAg level, HBsAg reduction at 24 weeks, and the treatment regimen.

Email: soo.aleman@ki.se

Background and aims: Bulevirtide (BLV) is approved in Europe for the treatment of compensated chronic hepatitis delta (CHD). In MYR301, a Phase 3 study evaluating BLV monotherapy for 2–3 years, a subset of patients who achieved undetectable HDV RNA by end of treatment (EOT) maintained undetectable viraemia at 48 weeks (W) after EOT (FU48). Here, we present predictors of sustained HDV RNA undetectability through FU48 after 96W or 144W of BLV treatment.
Method: Data were analysed from 149 patients with CHD in MYR301 who were randomised to immediate treatment with BLV 2 or 10 mg/d for 144W, or to 48W of no treatment followed by BLV 10 mg/d for 96W (DT → 10 mg). All patients were to be followed through FU48. Logistic regression modelling (adjusted for treatment group) was performed to examine potential predictors of sustained HDV RNA undetectability (defined as less than the lower limit of quantitation [LLOQ; target not detected at follow-up in patients with available data]) through FU48 in those with undetectable viraemia at EOT.
Results: Baseline (BL) characteristics were similar between all treatment arms. Across all arms, 65/149 (44%) patients achieved HDV RNA undetectability at EOT, of whom 23/64 (36%) with available follow-up HDV RNA data had sustained undetectability through FU48. Rates of sustained undetectability were higher in the immediate treatment arms (2 mg: 7/14, 50%; 10 mg: 10/25, 40%) vs the delayed treatment arm (DT → 10 mg: 6/26, 23%). Undetectability rates at EOT were higher in patients who received BLV 10 mg, but the relapse rate was lower in the few patients with HDV RNA

undetectable in the BLV 2 mg group. BL predictors of sustained undetectability posttreatment included BL HDV RNA less than a median of 4.5 log_{10} IU/mL (odds ratio [OR]: 6.2; 95% CI [1.9, 20.8]; p = .003) and lower BL hepatitis B surface antigen (HBsAg) level (OR: 0.3 per log_{10} IU/mL; 95% CI [0.1, 0.8]; p = .019). On-treatment predictors included greater duration of continuous undetectability at EOT (OR per additional week: 1.0; 95% CI [1.0, 1.1]; p < .0001), HBsAg loss or decrease by ≥ 1 log_{10} IU/mL (OR: 7.2; 95% CI [1.2, 42.3]; p = .030), and W144 antidrug antibody (ADA) incidence (OR: 10.2; 95% CI [1.9, 55.7]; p = .008). The proportion of patients with sustained posttreatment undetectability was 9/10 (90%) in those with ≥ 96W of undetectability at EOT, 11/22 (50%) in those with ≥ 48 to < 96W, and 3/32 (9%) in those with < 48W. Of patients with ADA incidence by W144, 8/10 (80%) had sustained undetectability vs 15/54 (28%) of those without. BL cirrhosis was not a predictor of sustained posttreatment undetectability; 13/32 (41%) with cirrhosis had sustained undetectability vs 10/32 (31%) without cirrhosis.
Conclusion: In patients with CHD treated with BLV monotherapy for 96W or 144W, early and sustained HDV RNA undetectability predicted sustained undetectability during follow-up. Note: PL and HW contributed equally.

OS-067-YI

Long term outcomes after nucleos(t)ide analogue cessation – an extended follow up study from the RETRACT-B cohort

Background and aims: Stopping nucleos(t)ide analogues (NA) in a selected group of patients with chronic hepatitis B (CHB) can result in increased rates of HBsAg loss. However, long-term follow up (FU) data after NA cessation is lacking. This study aimed to assess the long-term outcomes after NA withdrawal in a large global cohort.
Method: Extended FU data were collected from patients previously enrolled in the RETRACT-B cohort. New patients were added if they met the inclusion criteria, i.e. virally suppressed, HBeAg negative and HBsAg positive at end of therapy (EOT). Patients with a history of HCC, co-infection at EOT, Peg-IFN therapy <1 year prior to EOT or ALT≥5xULN at EOT, were excluded. Retreatment criteria were study specific or according to local guidelines.The primary outcome was the 10-year off-treatment (off-Rx) HBsAg loss rate. Secondary outcomes were retreatment- and ALT-flare (≥5xULN) rates. Time to event was defined until HBsAg loss or loss to follow up, censoring if therapy was re-stopped. Cumulative incidences were derived using Aalen-Johansen (AJ) estimators considering retreatment as competing event. Gray's test was used to test equality of these incidences between different groups.
Results: In total, 2029 patients were included. At EOT, mean age was 52 (±11) years, 1647 (81%) were Asian, 299 (15%) Caucasian, and 83 (4%) Black/other. 1464 (72%) were male and 801 (40%) received TDF/TAF and 1094 (54%) ETV. 211 (10%) patients had a history of cirrhosis, 283 (14%) were HBeAg positive at start of therapy and median treatment duration was 3 [IQR 3–5] years. Mean HBsAg at EOT was 2.7 (±0.8) log10 IU/mL (<100/100–1000/>1000: 16/45/38%) and median ALT was 23 [18–32] U/L. Median total and off-Rx FU time after EOT were 65 [36–99] and 28 [10–66] months, respectively. The 10-year cumulative incidence for off-Rx HBsAg loss was 17% (<100/100–1000/>1000: 53/13/6%, p < 0.001) and 4% for HBsAg loss after retreatment. When applying the RETRACT-B stopping criteria, 8-year off-Rx HBsAg loss was 56% for Caucasian <1000 IU/mL vs. 43% for Asian <100 IU/mL, compared to 5% and 5% when not meeting these criteria (p < 0.001). Results were consistent in newly included patients. The 10-year retreatment rate was 59% (<100/100–1000/>1000 IU/mL: 27/62/71%). The 5- and 10-year cumulative incidence for ALT-flares were 29 and 30%, respectively. 55 (3%) patients developed hepatic decompensation, of whom 19 (35%) had clinical symptoms (i.e. jaundice, ascites, hepatic encephalopathy or variceal bleeding). 41 (2%) patients died of whom 16 due to liver related events (e.g. HCC).
Conclusion: The 10-year cumulative off-treatment HBsAg loss rate was 17%, with more than half of the patients being retreated. Patients with HBsAg levels <100 IU/mL seem to benefit the most from NA cessation (HBsAg loss rate 53%), whereas NA withdrawal in patients >1000 IU/mL should be discouraged when aiming for functional cure (HBsAg loss rate 6%).

OS-068

Course and clinical outcomes of chronic hepatitis delta: a longitudinal analysis of 565 patients from the D-Solve consortium and HDV1000 database

Background and aims: Chronic hepatitis Delta (CHD) is considered the most severe viral hepatitis. The predictors of liver disease progression are ill-defined and some studies challenged this accelerated course. Aim of the study was to examine the clinical course and outcomes of CHD patients in a large real-life cohort.
Method: CHD patients with at least 3 years follow-up from the multicenter retrospective D-SOLVE consortium and HDV1000 database (6 European centers) were enrolled. Longitudinal changes in biochemical and laboratory markers were assessed. Time to event analysis was performed and predictors of liver-related events (LREs) were assessed in univariable and multivariable Cox regression analysis.
Results: Among a total of 1004 patients, 565 (56%) with ≥3 years follow-up were included: median (IQR) age was 44 (45–56) years, 55% males, 60% of European origin. 192 patients (34%) had cirrhosis and 55 (10%) history of previous LRE. At study start, median ALT were 57 (36–98) U/L, GGT 35 (23–66) U/L, platelets 170 (115–218) × 10^9/L, liver stiffness measurement (LSM) 8.2 (5.9–13.6) kPa, HBV genotype was D in 62%, HDV genotype 1 in 83%, 86% HBeAg negative, HBsAg 3.7 (3.0–4.1) Log_{10}IU/mL, HDV RNA detectable in 72%; 56% received interferon (IFN), 18% Bulevirtide, 83% were under NUC therapy. During a median follow-up of 55 (46–62) months, patients with normal ALT increased from 31% to 47%, median AST and GGT levels improved. In 264 patients with ≥2 LSM, LSM remained stable in 151 (57%), improved in 75 (28%) and increased in 38 (14%). De-novo cirrhosis was diagnosed in 48 patients; cumulative 1-, 3- and 5-year incidence rates of cirrhosis were 1.3%, 5.1% and 13.1%, respectively. 46 (8%) patients developed a de-novo LRE (HCC n = 21, ascites n = 17, variceal bleeding n = 5, hepatic encephalopathy n = 3). The overall 1-, 3-, and 5-year cumulative rates of LREs were 0.8%, 2.4% and 9.6%, respectively. The corresponding figures were 0.2%, 0.9%, 5.2% for HCC and 0.6%, 1.3% and 4.0% for decompensation, respectively. 14 (2%) patients died and 11 (2%) underwent liver transplantation (LT). The overall LT or death-free survival rates at 1-, 3- and 5-years were 98.9%, 98.6% and 95.3%, respectively. At Cox regression univariate analysis, ALT>ULN and detectable HDV RNA at study start were associated with cirrhosis onset; at multivariate analysis, only ALT>ULN (HR 2.75; 95% CI 1.04–7.28, p = 0.04) remained significant. Age, HBV duration, HDV duration, NUC treatment, ALT>ULN, and detectable HDV RNA at study start predicted LREs at univariate analysis, while at multivariable analysis only age (HR 1.05; 95% CI 1.03–1.07, p < 0.0001) and detectable HDV RNA (HR 5.72, 95% CI 2.25–14.52, p = 0.0002) remained significant.
Conclusion: In a large real-life cohort of CHD patients, cumulative rates of cirrhosis and LREs were lower than expected. ALT, age and detectable HDV RNA were the main determinants of liver-related outcomes.

A Randomised trial of nucleos(t)ide withdrawal vs nucleos(t)ide withdrawal with adjuvant pegylated-interferon in HBeAg-negative hepatitis B virus infection to promote HBsAg clearance (NUC-B)

Email: m.thursz@imperial.ac.uk

Background and aims: Finite therapy resulting in a functional cure (sustained hepatitis B surface antigen (HBsAg) loss) for patients with chronic HBV infection (CHB) is an important therapeutic goal. In patients with HBeAg-negative infection, nucleos(t)ide analogue (NA) withdrawal may achieve HBsAg loss in 5–20% of patients 3 years after cessation of NA therapy depending on duration of NA therapy, HBsAg level, HBV genotype and patient age. Pegylated interferon (pIFN) is a recognized treatment for CHB but is currently under-utilised and simultaneous treatment with pIFN and NA does not enhance rates of HBsAg loss. We hypothesized that sequential NA withdrawal followed by a short course of pIFN might enhance HBsAg clearance.
Method: NUC-B was a randomized, open-label multi-centre UK trial in NA-treated non-cirrhotic HBeAg negative patients with CHB. Patients were allocated to either NA withdrawal alone or NA withdrawal followed by a 16 week course of pIFN 180ug weekly commencing 4 weeks after NA cessation. Randomisation was stratified according to HBsAg quantification. The primary endpoint was HBsAg loss at 3 years. Exaggerated flares were defined according to the following criteria: 1. Bilirubin >35 uMol/l, 2. INR >1.3, 3. ALT > 20 × upper limit of normal, 4. HBV DNA and/or ALT remain persistently elevated for more than 6 months.
Results: 156 patients (82 to NA withdrawal, 74 to NA withdrawal + pIFN) were recruited between 2017 and 2021; median age 45 years, 24% of patients were female, 13.5% were Caucasian, 42% were African and 37% Asian, HBV Genotypes were A 14%, B 4%, C 4%, D 20%, E 15%, other 1%, unknown 42%. HBsAg titre at baseline was 5717 IU/ml in the NA withdrawal group and 4132 IU/ml in the NA withdrawal + pIFN group. HBsAg was < 2000 in 52% of patients in the NA withdrawal group and 51% in the NA withdrawal + pIFN group. In this globally representative group, at 3 years 3% of patients in the NA withdrawal arm and 14% of patients in the NA withdrawal + pIFN arm lost HBsAg (odds ratio 5.39, P = 0.037). In the NA withdrawal arm 34.9% of patients returned to NA therapy compared to 28.4% in the NA withdrawal + Peg-IFN arm. Exaggerated flares occurred in 27.9% of patients in the NA withdrawal arm compared with 13.4% in the NA withdrawal + pIFN arm. Serious adverse events did not differ between the groups.
Conclusion: The use of adjuvant pIFN therapy after withdrawal of NA therapy increases the rate of functional cure of chronic HBV whilst simultaneously reducing the number of exaggerated hepatitis flares thereby improving safety.

Viral Hepatitis B/D – Therapy

OS-070

Achieving undetectable hepatitis delta virus RNA at end of therapy with bulevirtide 10 mg/day with or without with pegylated interferon alpha is strongly associated with post-treatment virologic response in chronic hepatitis delta

Email: renee-claude.mercier@gilead.com

Background and aims: Bulevirtide (BLV) 2 mg is approved for the treatment of chronic hepatitis delta (CHD) in Europe. In an integrated analysis of BLV 10 mg monotherapy or combined with pegylated interferon alpha (PegIFN), we aim to explore whether hepatitis delta virus (HDV) RNA levels undetectable (target not detected; TND) vs below the lower limit of quantification (<LLOQ; target detected [TD]) at end of treatment (EOT) affect post-treatment virologic response.

Method: A pooled analysis of data from patients who completed 2 or 3 years of BLV 10 mg/d with or without PegIFN in the Phase 2 study MYR204 (NCT03852433) and the Phase 3 study MYR301 (NCT03852719) was performed. Patients received (A) BLV 10 mg + PegIFN for 48 weeks (W) followed by 48W of monotherapy with BLV 10 mg (n = 50), (B) BLV 10 mg for 96W (n = 100), or (C) BLV 10 mg for 144W (n = 50). Patients were followed for up to 48W after EOT (FU-48). HDV RNA levels were determined by reverse transcription–quantitative polymerase chain reaction using RoboGene 2.0 (LLOQ 50 IU/mL, limit of detection 6 IU/mL). Virologic response rates at FU-48 were compared between patients with undetectable HDV RNA and those with HDV RNA < LLOQ, TD at EOT.

Results: Demographics were generally similar across groups: male (65%), White (85%), and mean (SD) age 41 (8.2) years. Overall, 41% had compensated cirrhosis, and 53% had prior interferon experience. Mean (SD) HDV RNA, alanine aminotransferase, and liver stiffness were 5.1 (1.38) $\log_{10}$ IU/mL, 109 (88.2) U/L, and 14.0 (9.11) kPa, respectively. At EOT, 48.5% (97/200) overall achieved undetectable HDV RNA: (A) 70% (35/50), (B) 37% (37/100), and (C) 50% (25/50). Additionally, 24% (48/200) had < LLOQ, TD: (A) 16% (8/50), (B) 30% (30/100), and (C) 20% (10/50). At FU-48 in the whole population, undetectable HDV RNA was observed in 24.5% (49/200): 23/50 (46%) of those receiving combination therapy, 14% (14/100) of patients who received BLV monotherapy for 2 years, and 24% (12/50) of those who received 3 years of BLV monotherapy. Of the patients with undetectable HDV RNA at EOT, 46% (45/97) maintained undetectable HDV RNA at FU-48: (A) 60% (21/35), (B) 35% (13/37), and (C) 44% (11/25); 6% (6/97) had < LLOQ, TD at FU-48: (A) 6% (2/35), (B) 9% (3/37), and (C) 4% (1/25). Of those who had < LLOQ, TD at EOT, only 6% (3/48) had undetectable HDV RNA (1 in each group) and 4% (2/48) remained < LLOQ, TD at FU-48, while 71% (34/48) had HDV RNA > LLOQ: (A) 62.5% (5/8), (B) 80% (24/30), and (C) 50% (5/10); during the follow-up period, 9 discontinued the study early.

Conclusion: In patients with compensated CHD, achieving undetectable HDV RNA with TND at EOT is strongly associated with a virologic suppression at 48W post-treatment. Combination therapy with BLV 10 mg/d and PegIFN and longer treatment with BLV monotherapy were associated with higher rates of undetectable HDV RNA at EOT and FU-48. Patients with HDV RNA < LLOQ, TD at EOT are likely to have HDV RNA rebound off therapy.

OS-071

Mitigation of immune dysfunction in patients with sustained suppression of hepatitis B surface antigen after siRNA treatment

Lung Yi Loey Mak[1], Upkar Gill[2], Liqiong Yang[3], Wai-Kay Seto[1], Patrick Kennedy[2], Man-Fung Yuen[1]. *[1]The University of Hong Kong, State Key Laboratory of Liver Research, Hong Kong, China; [2]Queen Mary University of London, London, United Kingdom; [3]The University of Hong Kong, Hong Kong, China*
Email: loeymak@gmail.com

Background and aims: Chronic hepatitis B (CHB) infection is characterized by host immune dysfunction, related to high viral antigen load. Restoration of immune function is critical for achieving and maintaining HBV cure. Novel drugs aiming for finite treatment through achieving functional or partial cure, are in development.[1] We explored the immunological profile of CHB patients who received small interfering RNA (siRNA). (Reference 1: Marc G Ghany et al. Hepatology 2023; 78: 1654–1673.).

Method: CHB patients in our center who received siRNA in clinical trials[2,3] at a median duration of 5.8 years (range 5.0–8.3) from last dose were recruited. We identified 10 patients with sustained HBsAg <100 IU/mL (low HBsAg; median 1.77 log) during long-term follow-up (LTFU), and matched (baseline age and HBeAg) 10 patients with HBsAg ≥100 IU/mL (high HBsAg; median 2.98 log) at LTFU. Peripheral blood mononuclear cells (PBMCs) were evaluated by multicolor flow cytometry characterizing CD4+, CD8+, regulatory (Treg; CD25+CD127^{lo}FoxP3+), T cell subsets, B cells, and markers of exhaustion (PD-1, CTLA-4, TIM-3, LAG-3). Synthetic HBV peptides were co-cultured with PBMCs to assess HBV T cell effector functions including activation (CD38, HLA-DR), proliferation (Ki-67), cytokine production (IFNγ, IL-2) and cytotoxicity (Granzyme B). (References 2–3: Yuen MF et al. J Hepatol 2022; 77:1287–98; Yuen MF et al. Hepatology 2020; 72:19–31).

Results: In the low HBsAg group, the frequency of Treg among CD4+ was significantly lower compared to the high HBsAg group (6.474% vs. 8.646%, p = 0.0006). Expression of LAG-3 and TIM-3 was significantly reduced in CD4+, CD8+, Treg and B cells in the former group (all p < 0.05) along with reduced PD-1 and co-expression of PD-1+CTLA4+ on CD8+ T cells (all p < 0.05). There was a trend for enrichment of central memory (CD45RA-CCR7+CD27+CD28+) among CD4+ T cells (36.6% vs 30.22%, p = 0.056) in the low HBsAg group. Upon HBsAg stimulation, IFNγ production in CD4+ and IL-2 production in CD8+ T cells were markedly increased in the low HBsAg group. No significant differences were observed for the degree of activation, proliferation and cytotoxicity. HBsAg at LTFU, but not at baseline, positively correlated with frequency of Tregs (r = 0.531, p = 0.016), TIM-3 and LAG-3 expression on B and T cells, and negatively correlated with Ki-67 (r = –0.501, p = 0.025) and IFNγ (r = –0.516, p = 0.020) expression on CD4+ T cells.

Conclusion: In patients who received siRNA and achieved sustained low HBsAg <100 IU/mL at >5 years from last dose, the degree of

immune dysfunction in peripheral blood lymphocytes was diminished. Effective siRNA treatment calibrates a new equilibrium between host immunity and the virus.

OS-072-YI

HBV integration can sustain HDV persistence especially in the setting of an absent HBV reservoir and can be a biomarker of response to bulevirtide

Email: stefanodanna26@gmail.com

Background and aims: To elucidate the contribution of HBsAg production from HBV-DNA integration in sustaining HDV replicative activity and the potential role of intrahepatic viral markers and transcriptome profiles in modulating response to bulevirtide (BLV).
Method: 70 liver biopsies from eAg-negative patients (pts) (74% NUC-treated) were included: 35 with CHB and 35 with CHD, 6 of them completed 24 weeks of BLV. Combined response to BLV was defined as >2log HDV-RNA decay plus ALT normalization. Droplet-digital PCR was used to quantify intrahepatic levels of cccDNA, pgRNA, HDV-RNA and HBs transcripts from cccDNA and from integrated HBV-DNA (Grudda, 2022). HBs isoforms were quantified by ELISAs. RNA-Seq by Illumina was applied for transcriptome analysis.
Results: CHD and CHB pts had comparable age and NUC-treatment duration. CHD was characterized by lower cccDNA and pgRNA than CHB (median [IQR]: 1 (0.02–12) vs 24 (8–93) copies (cps)/1000 cells and 8 [1–147] vs 518 [57–3,894] cps/1000 cells, $P < 0.0001$ for both). Despite this, in both CHD and CHB, a comparable production of HBs transcripts was observed with >99% of them from integrated HBV-DNA (median [IQR]: 6,041 [323–29,446] and 12,776 [4,570–55,977] cps/1000 cells). In CHD, cccDNA positively correlated with all HBV intrahepatic markers (Rho from 0.55 to 0.58, $P < 0.01$). Conversely, no correlation was observed between cccDNA and intrahepatic HDV-RNA (Rho = 0.1, $P = 0.6$). Notably, 8 pts, despite having undetectable cccDNA, cccDNA-derived HBs transcripts and serum HBV-DNA, had considerable levels of intrahepatic and serum HDV-RNA (median [IQR]: 5,495 [976–14,946] cps/1000 cells and 6.0 [4.8–6.9] logIU/ml), as well as of integration-derived HBs transcripts (median [IQR]: 3 [1–497] cps/1000 cells) and of all three HBs isoforms (median [IQR] ng/ml: 1,116 [123–3,987] for S-HBs, 368 [8–1,894] for M-HBs and 1.4 [0.2–5.6] ng/ml for L-HBs). Focusing on 6 CHD pts undergoing BLV therapy, 3 achieved combined response at week 12 and 3 at week 24. At baseline, the levels of intrahepatic HDV-RNA and integration-derived HBs transcripts tended to be lower in pts achieving combined response at week 12 (median [IQR]: 2,262 [1,777–2,913] vs 8,760 [4,656–9,046] for HDV-RNA and 12,770 [6,730–22,421] vs 55,417 [30,729–56,982] cps/1000cells for integration-derived HBs transcripts). Notably, in pts achieving an earlier combined BLV response, an upregulation of genes specifically involved in immune responses was observed (CHI3L1, CXCL2, C4B2, FYB2 [log2 fold-change: 1.79, 1.5, 1.25, 1.19, respectively; adjusted $P < 0.02$ for all comparisons]).
Conclusion: HDV persistence is independent from the intrahepatic HBV reservoir and is sustained by HBsAg production from integrated HBV-DNA. Moreover, a reduced intrahepatic HDV reservoir and limited HBV integration may correlate with a rapid control of HDV replication under BLV. The role of the immune system in modulating BLV response deserves further evaluation.

OS-073

Entry inhibitor Hepalatide combined with pegylated interferon-alpha 2a therapy resulted in cccDNA clearance in CHB patients: a phase II randomised, double-blind, placebo-controlled trial

Junliang Fu, Qing Mao[1], Qinglong Jin[2], Hui Chen[3], Yongqian Cheng[4], Xiaolu Tang[5], Hongli Liu[5], Fu-Sheng Wang. *[1]Department of Infectious Diseases, Southwest Hospital, Army Medical University, Chongqing, China; [2]Department of Hepatology, The First Hospital of Jilin University, Jilin University, Changchun, China; [3]Department of hepatitis, Hepatobiliary hospital of Jilin, Changchun, China; [4]Senior Department of Infectious Diseases, The Fifth Medical Center of Chinese PLA General Hospital, National Clinical Research Center for Infectious Diseases, Beijing, China; [5]Shanghai HEP Pharma Co. Ltd., Shanghai, China*
Email: fswang302@163.com

Background and aims: Hepalatide (HLT) is a peptide designed to block the HBV entry receptor sodium-bile acid cotransporter (NTCP). This study aimed to evaluate the efficacy and safety of HLT in combination with pegylated interferon-alpha 2a (PEG-IFN) in patients with chronic hepatitis B (CHB).
Method: This Phase II multicentre, randomised, double-blind, placebo-controlled trial enrolled 96 patients aged 18–60 years with HBV DNA ≥ 20,000 IU/mL (HBeAg-positive) or ≥ 2,000 IU/mL (HBeAg-negative), no cirrhosis, and naïve to interferon treatment (NCT 04426968). Participants were randomly assigned to receive 2.1 mg, 4.2 mg, 6.3 mg of HLT treatment, or placebo for 24 weeks in a 1:1:1:1 ratio. All subjects received PEG-IFN (180 μg/week) foundational treatment for 48 weeks. The primary endpoint was safety and HBV DNA loss (cut-off: 20 IU/mL) at 24 weeks of treatment. HBsAg, Pg RNA, cccDNA and histological response in liver biopsy were also assessed at the end of the 24-week treatment.
Results: A total of 96 subjects (77 HBeAg-positive and 19 HBeAg-negative) were included in the trial, with 24 patients in each group. Two patients withdrew due to interferon-related AEs. A total of 1281 AEs ranging from grade 1 to 3 were recorded, and mainly interferon-related. Only 26 AEs were related to HLT, and all AEs were graded 1 or 2. The proportion of patients with virological response (HBV DNA < 20 IU/mL or a decrease from baseline ≥ 2 $\log_{10}$) at the end of the 24-week HLT treatment in the 2.1 mg, 4.2 mg, or 6.3 mg and placebo group were 78.3%, 87.5%, 70.8% and 58.3%, respectively. The virological response rate in the 4.2 mg group was significantly higher than that in placebo group ($p = 0.0248$). At baseline and the end of 24-week HLT treatment, 21 and 14 liver biopsies were obtained, respectively. All four groups had positive baseline biopsies cccDNA of 3.463 ± 1.03, 2.383 ± 0.97, 3.850 ± 1.08, and 3.018 ± 0.76 $\log_{10}$ copies/μL, respectively. Surprisingly, cccDNA became undetectable (<5 copies/μL by verified PCR assay) in 33.3% (1/3) and 40.0% (2/5) of samples from the 4.2 mg and 6.3 mg groups at the end of the 24-week HLT treatment, while all samples from 2.1 mg and placebo groups remained cccDNA positive. The three subjects with cccDNA clearance remained HBsAg-positive at the end of HLT treatment. Pg RNA levels and HBsAg levels were progressively reduced in all groups during the treatment. The fact that all indicates that this HBsAg may be expressed from integrated HBV DNA.
Conclusion: The combination therapy in the present trial may alter the balance of the HBV reservoir by blocking cccDNA replenishment

through inhibiting HBV entry via HLT and accelerating cccDNA decay via PEG-IFN. This strategy provides great potential to achieve a sterilising cure for patients with CHB.

OS-074

Recombinant polyclonal antibody GIGA-2339 potently neutralizes hepatitis B and hepatitis D virus

Sheila Keating[1], Brett Higgins[2], Ariel Niedecken[1], Yao Chiang[1], Peyton Witte[1], Raina Sharda[2], Yesenia Lopez[2], Julie Lucifora[3], David Durantel[3], Enrikas Vainorius[4], Carl Millward[2], Adam Adler[1].

Email: sheila.keating@grifols.com

Background and aims: While current treatments effectively control viral replication in chronic hepatitis B virus (HBV) infection, hepatitis B surface antigens (HBsAg) are produced at high levels and induce hepatitis B-specific immune tolerance. HBsAg clearance is required to support immune control of viral replication. GIGA-2339 is a first in class recombinant polyclonal antibody therapeutic designed to target the conserved HBsAg to block infection and clear circulating HBsAg in infected individuals.
Method: Memory B cells from HBV vaccinated donors were captured by GigaGen's single cell antibody capture technology to isolate natively paired antibody sequences, which were displayed as single chain variable fragments on yeast to enrich for HBsAg-specific sequences. These antibody sequences were cloned into human IgG1 expression vectors and full-length antibody sequences were transfected *en masse* by single-site integration into a Chinese hamster ovary (CHO) cell line. Recombinant polyclonal antibodies were produced and purified using monoclonal antibody (mAb) production and purification techniques. GIGA-2339 was tested for potency by ELISA, *in vitro* and *in vivo* neutralization, antibody dependent cellular cytotoxicity (ADCC) and antibody dependent cellular phagocytosis (ADCP) immune activation capacity, and cross-mutant binding compared to HBIG and an HBsAg-specific mAb.
Results: GIGA-2339 contains more than 1000 antibodies targeting HBsAg epitopes. Using HBV laboratory strain AD38 genotype D to infect primary hepatocytes, GIGA-2339 demonstrated neutralizing potency greater than 2000x higher than a plasma-derived HBV-specific polyclonal hyperimmune HBIG and 2.5x lower than HBsAg-mAb. Furthermore, GIGA-2339 exhibited neutralization of live HDV-1 expressing each globally circulating HBV genotype (A-H). ADCC (Fc gamma receptor IIIA engagement) and ADCP (Fc gamma receptor IIA engagement) signal activity showed that GIGA-2339 had 10-fold greater potency than HBIG and 2.5x lower potency than HBsAg-mAb; however, GIGA-2339 had the greatest efficacy in signal induction for both ADCC and ADCP. While GIGA-2339 and HBsAg-mAb bound to wild-type HBsAg, GIGA-2339 had enhanced binding to P142L and G145R mutants. In a C57BL/6 mouse model of AAV-HBV infection, treatment with 10 mg/kg or 100 mg/kg of GIGA-2339 induced a dose dependent reduction of serum HBsAg on average by 1.2 and 2.8 log and of HBV DNA on average by 1.5 and 2.2 log, respectively.
Conclusion: GIGA-2339 is a novel antibody therapeutic that captures the HBsAg-specific antibody repertoire and is manufactured using the same production and purification techniques as a mAb. It demonstrated robust activation of cell-mediated immune responses, retained binding to HBsAg mutants commonly found during chronic HBV infection, and exhibited clearance of HBsAg in an animal model. GIGA-2339 is in Phase I clinical studies and adds an important new therapeutic modality to the treatment landscape to achieve HBV functional cure.

Email: chjj@smu.edu.cn

Background and aims: Acute-on-chronic liver failure (ACLF) is a life-threaten syndrome and cause high short-term mortality. Double plasma molecular adsorption system (DPMAS) is one of the available artificial liver support systems which combines plasma filtration and two-specific adsorption membranes. In this study, we aimed to evaluate the real-world use and outcomes of DPMAS for the treatment of ACLF.
Method: A prospective, multicentre and non-randomized cluster-controlled study was conducted (NCT05129904) and 57 tertiary hospitals were recruited and allocated to the DPMAS treatment clusters (n = 28) and standard medical treatment (SMT) clusters (n = 29). Outcomes included disease progression rate, survival, death and liver transplantation and safety of DPMAS therapy. Twelve-months is required for each participant to complete post-discharge follow-up.
Results: In total, 644 patients were enrolled in DPMAS group and 626 patients in SMT group. MELD score was comparable between these two groups (24 ± 5 vs. 24 ± 6, p = 0.128). Totally, 1615 treatment sessions in DPMAS group within 4 weeks and 31.7% patients had 2 DPMAS treatment sessions and 77.1% of the initial DPMAS treatment was with subsequent plasma exchange. Unfractionated heparin was the most common anticoagulants used in DPMAS treatment. The total bilirubin, ALT and CRP levels were all significantly improved after the initial DPAMS therapy. The 4-week and 12-week transplant-free mortality was both lower in DPAMS group than SMT group (4-week: 15.8% vs. 23.1%, p = 0.001; 12-week: 29.5% vs. 38.0%, p = 0.002). For the non-ACLF patients at baseline, no significantly difference was observed in the progression to ACLF within 4 weeks between those two groups (25.2% vs. 29.0%, p = 0.226). Plasma allergy (2.3%) and dialyzer coagulation (3.1%) as well as the arterial hypotension (2.7%) were the common adverse events during DPMAS treatment.
Conclusion: DPMAS treatment for ACLF patients can significantly improve the short-term mortality as well as the liver function markers. DPMAS therapy was associated with few adverse events and its safety is confirmed.

OS-076-YI

Patients with acute decompensation of cirrhosis present a unique methylation signature associated with their outcome

Background and aims: Acute decompensation (AD) of cirrhosis and its progression to acute-on-chronic liver failure (ACLF) are associated with high short-term mortality. There are no therapies due to an incomplete understanding of the pathophysiology and patient heterogeneity. The previous decompensating events are crucial in disease progression and ACLF development. These events may induce changes in DNA methylation, providing insights into the cirrhosis pathophysiology and prognosis.
Method: Prospective clinical and epigenomic data from two well-characterized AD cohorts - the European PREDICT (N = 623) and the Latin American ACLARA (N = 460) - were analyzed to investigate DNA methylation alterations. This study represents a novel epigenetic analysis to characterize AD as part of the H2020-funded DECISION project. A multi-state survival analysis was conducted with four transitions (baseline to ACLF, death, and liver transplant, and ACLF to death), using bootstrapping and permutation test to estimate confidence intervals and permuted p-values. Two complementary analyses were performed per CpG site: (1) without and (2) with clinical covariates associated with each transition (including age and sex).
Results: We observed a significant difference in median global methylation levels between individuals with and without adverse events, suggesting DNA methylation may provide prognostic value in AD. Therefore, we focused on characterizing the predictive value of the CpG sites. Using a multi-state survival model, we identified CpG sites not associated with cell type proportions that showed (1) predictive power (without clinical variables) and (2) added predictive power (including clinical variables). Notable, most significant CpG sites were transition-specific, with some overlap between models for the same transitions. Besides, enrichment in CpG islands and promoter regions suggests functional significance in gene regulation. Validation using the independent ACLARA cohort revealed a global methylation pattern similar to that of the PREDICT cohort. Furthermore, in the ACLAR Caucasian subset, we validated 13 and 14 CpG sites with potential predictive power and added predictive power, respectively.
Conclusion: Our study identified novel blood methylation alterations associated with AD, providing insights into its pathophysiology. Notably, several identified CpG sites are located near genes involved in inflammation, immune response, metabolic regulation, and liver function pathways, including those linked to complications such as septic shock and hepatic steatosis. These findings highlight potential mechanisms underlying disease progression through DNA methylation patterns. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 847949. This reflects only the author's view and the Commission is not responsible for any use that may be made of the information it contains.

OS-077

Single-cell RNA sequencing of peripheral blood mononuclear cells in patients with acutely decompensated cirrhosis reveals a specific monocyte subset associated with an increased risk of progression to ACLF

Email: thwirtz@ukaachen.de

Background and aims: Patients with acute decompensation of cirrhosis (ADC) are at high risk of developing acute-on-chronic liver failure (ACLF), a syndrome characterized by multiple organ failure and high short-term mortality. This study aimed to prospectively analyse alterations in peripheral blood mononuclear cells (PBMCs) in patients with ADC using single-cell technologies and to explore their implications for pathophysiology and prognosis.

Method: 64 patients admitted due to ADC and 15 healthy controls were enrolled in 5 European centres. Blood samples were obtained at hospital admission. Patients were followed up for up to 90 days after study inclusion, and hospital readmission due to ADC or ACLF development was monitored. Cellular indexing of transcriptomes and epitopes by sequencing (CITE-seq) was applied to PBMCs from 16 out of the 64 patients representing different clinical trajectories and 4 healthy controls, to quantify gene expression and targeted surface protein at single-cell resolution. Whole blood for the same 16 patients was assessed by bulk RNA-seq and whole blood transcriptional profiles from two independent prospective multicentre cohorts of patients with ADC (PREDICT (n = 689) and ACLARA (n = 521)) were included as validation cohorts.
Results: Cell proportion analysis revealed a significant increase of classical monocytes in patients with subsequent ACLF development. Notably, classical monocytes represented the cell type with the highest transcriptional alterations. Within the classical monocyte population, a specific subcluster, termed "C2," was identified and found to increase during progression towards ACLF. In addition to reduced expression of *HLA-DR* and upregulation of *MERTK,* this monocytic subpopulation was primarily characterized by decreased expression of genes encoding enzymes relevant to cellular energy supply, such as oxidative phosphorylation and ATP production. Pathway analysis confirmed a marked impairment of energy metabolism pathways as well as a tendency towards reduced inflammatory and bacterial response within the C2 subcluster. Using two independent prospective multicentre cohorts of patients with ADC, we found that a gene signature derived from that monocytic subpopulation was significantly upregulated especially in patients with bacterial infection, ACLF development and non-survivors.
Conclusion: Patients with acute decompensation of cirrhosis who subsequently develop ACLF are characterized by the presence of a subpopulation of classical monocytes with features of impaired energy metabolism pathways.

OS-078-YI

Elevated plasma chenodeoxycholic acid as a prognostic marker and therapeutic target in acute liver failure: role of bacteroides intestinalis AM1 intervention in bile acid modulation and mitigation of liver injury

Sushmita Pandey[1,2], Neha Sharma[1], Nupur Sharma[1], Sadam H. Bhat[1], Manish Kushwaha[3], Anil Kumar[3], Yash Magar[4], Abhishak Gupta[5], Babu Mathew[1], Gaurav Tripathi[1], Vasundhra Bindal[1], Rimsha Rimsha[1], Sanju Yadav[1], Manisha Yadav[1], Anupama Kumari[1], Shvetank Sharma[1], Chhagan Bihari[1], Anju Katyal[2], Shiv Kumar Sarin, Jaswinder Maras[1].

Email: jassi2param@gmail.com

Background and aims: Acute liver failure (ALF) is a life-threatening condition with altered metabolic and microbial profiles contributing to liver disease severity. We studied circulating metabolites, bile acids and microbial signatures to differentiate ALF non-survivors and explored the potential of *Bacteroides intestinalis* AM1 in bile acid modulation and mitigation of liver injury.
Method: Plasma metabolomics and meta-proteomics were conducted in 40 ALF patients and 5 healthy controls (training cohort), with validation in 160 ALF patients (test cohort) using High resolution mass spectrometry (HRMS) and machine learning (ML). A non-survival indicator panel identified chenodeoxycholic acid (CDCA) as a key inflammatory driver (logFC > 10; $p < 0.05$; AUC > 0.95), particularly in non-survivors. Increase in CDCA levels prompted us to explore Bacteroides intestinalis AM1 (10^9 CFU/ml), which successfully reduces CDCA (PMID: 19243441). A therapeutic dose was administered to an APAP-induced mouse model (250 & 500 mg/kg, i.p.), and liver injury and hepatocyte death were analyzed through histological, proteomic, and metabolomic changes in the liver.
Results: ALF non-survivors had distinct metabolomic profile showing increase in CDCA, tryptophan, tyrosine, pathways related to inflammation, cell death and stress response ($p < 0.01$, FDR<0.01, FC>1.5). Plasma of non-survivors showed higher alpha/beta diversity ($p < 0.05$) with increase in Proteobacteria, Firmicutes, Actinobacteria ($p < 0.05$), functionally associated to energy, amino acid and xenobiotic metabolism ($p < 0.05$). In the non-survivors, the increase in bacterial-taxa and functionality correlated with specific increases in CDCA (cell death and inflammation), 4-(2-Amino phenyl)-2,4-dioxobutanoate, L-Tyrosine, other metabolites, clinical parameters and outcome (R^2>0.85, $p < 0.05$). Probability of detection (POD) of non-survival based on these metabolites was >99% with a diagnostic accuracy of 98% (AUC = 0.98(0.92–1.0). Elevated levels of CDCA (logFC>10) correlated with disease severity and mortality in ALF patients and mice model. Using an ALF mouse model, we colonized the mice with *Bacteroides intestinalis AM1* to examine its therapeutic effects on CDCA breakdown. B. intestinalis AM1 colonies reduced CDCA levels, suppressed inflammation, and prevented acute liver injury by reversing necroapoptosis and modulating glutathione (oxidative repair), tryptophan (inflammation), histidine (tissue repair) metabolism.
Conclusion: The plasma microbiome and metabolome of ALF non-survivors exhibits distinct characteristics. Elevated baseline CDCA levels are linked to a higher risk of early mortality. Intervention with *"B intestinalis AM1"* shows promise in lowering CDCA levels, reducing necrosis, and mitigating inflammation in ALF. A clinical trial is needed to validate these findings.

OS-079-YI

Hemodynamic and non-hemodynamic effects of non-selective beta-blockers in experimental and human acute-on-chronic liver failure

Background and aims: The effects of non-selective beta-blocker (NSBB) treatment on hemodynamics (HDs) and systemic inflammation (SI) in acute-on-chronic liver failure (ACLF) remains understudied. This study investigated the impact of NSBBs in experimental and human ACLF.
Method: Cirrhosis was induced in Sprague-Dawley rats by carbon-tetrachloride (CCl4; 12 weeks). In the last induction week, carvedilol (CAR, 5 mg/kg), propranolol (PRO, 15 mg/kg), or vehicle (VEH) was gavaged (2x/day). ACLF was induced by a single i.p. injection of lipopolysaccharide (LPS; 1 mg/kg) 3 hours prior to hemodynamic characterization (portal pressure PP, heart rate HR, mean arterial pressure MAP). Resulting groups were: ACLF+VEH (n = 6), ACLF+CAR (n = 9), ACLF+PRO (n = 8). IL-1β, IL-6, TNF-α, MCP1 and IL-10 were quantified in plasma (ELISA) and liver tissue (RT-qPCR). Patients with ACLF (graded G1-G3 by EASL-CLIF criteria) admitted to the Vienna General Hospital (2003–2022) were characterized for PH severity by

hepatic venous pressure gradient (HVPG), platelet count (PLT) and varices (EV). NSBB intake, liver injury (AST/ALT), SI biomarkers (WBC, CRP, IL-6) were recorded at pre-ACLF, ACLF diagnosis (D0) and ACLF day 7 (D7). Survival was recorded at D28, D90 and D365.
Results: In the animal study, ACLF+CAR and ACLF+PRO had significantly lower HR compared to the ACLF+VEH group (331 ± 15 and 326 ± 10 vs. 410 ± 21 bpm; p = .002), lower MAP (42.4 ± 8.4 and 47.9 ± 5.4 vs. 52.9 ± 7.4 mmHg; p = .437) and similar PP (p = .759). ACLF+CAR group had a trend towards lower AST (797 ± 141 vs. 1341 ± 491 U/L; p = .058) and ALT (491 ± 77 vs. 894 ± 176 U/L; p = .169), and no amelioration of ACLF-induced inflammation as reflected by hepatic inflammatory gene expression and circulating cytokine levels (all p > .05). The clinical study included 189 patients with ACLF (G1: 91 [48.1%], G2: 61 [32.2%], G3: 37 [19.6%]) and 116 [61.4%] patients received NSBB prior to D0 [NSBB(+)]. Before ACLF, NSBB(+) patients showed higher HVPG (p = .006), more EV (p = .019), lower PLT (p = .036), lower WBC (p = .034) but similar SI and MELD (all p > .05) than NSBB(-) patients. At D0, ACLF grade was similar between NSBB groups (p = .831). Significantly lower WBC (7.7 [6.4] vs. 9.1 [6.6], p = .013) but similar CRP (p = .631) and liver injury markers (AST p = .722; ALT p = .969) were noted in NSBB(+) vs. NSBB(-) patients at D0. D90 mortality was similar between groups: 56.6% in NSBB(+) vs. 61.5% in NSBB(-) patients (ACLF grade-adjusted p = .680).
Conclusion: Patients on NSBB prior to ACLF presented more pronounced PH - consistent with NSBB indication. Interestingly, the NSBB+ group had similar short-term ACLF mortality compared to NSBB-naïve patients. In the LPS-induced ACLF rat model, NSBB precipitated the hemodynamic state, while not improving hepatic or systemic inflammation. These results indicate that NSBB treatment may be continued in ACLF patients with PH and HD stability, while non-HD benefits in infection-induced ACLF seem negligible.

Basic Science – MASLD

OS-080-YI
Multimodal single-nuclei atlas of MASLD progression uncovers a link to type 2 diabetes
Laura Pikkupera[1], Rikard Fred[1], Malte Thodberg[1], Thomas Koefoed[1], Benedicte Schultz Kapel[1], Shanshan He[1], Kata Krizic[1], Mikkel Werge[2], Sofie Boesgaard Neestrup Hansen[2], Cesar Medina[3], Elisabeth Galsgaard[4], Lise Lotte Gluud[2], Torben Hansen[1]. Background and aims: The course of metabolic dysfunction-associated steatotic liver disease (MASLD) is highly heterogeneous. MASLD and type 2 diabetes (T2DM) are closely intertwined, and hepatic insulin resistance has been associated with hepatocyte steatosis and inflammation. The cellular and genetic underpinnings for disease heterogeneity are poorly characterised. We hypothesised that joined profiling of gene expression and chromatin accessibility at single cell resolution in patients with MASLD and increasing fibrosis would elucidate the distinct cell populations and processes associated with disease progression.
Method: We therefore generated a large multi-modal single-nuclei atlas of gene regulation with paired snATAC-Seq and snRNA-Seq (10X Multiome) in percutaneous or transjugular liver biopsies. Our analyses included over 300.000 cells from 10 healthy controls and 48 patients with MASLD and F0 to F4 fibrosis (F0 n = 9, F1 n = 10, F2 n = 10, F3 n = 9, and F4 n = 10). Based on the analyses, we evaluated disease progression in terms of changes in cell type abundance, transcription and chromatin landscape. The multimodal RNA expression and chromatin accessibility data allowed us to map the activity and interactions of promoters and enhancers in the individual cell types. Integration of genome-wide association studies (GWASs) of MASLD and T2DM related traits allowed us to identify cell types causally implicated for the different traits.
Results: Our analyses revealed that hepatocytes were most affected by MASLD progression and identified a disease progression gradient perpendicular to the porto-central zonation gradient. In particular, we identified a MASLD-associated subpopulation of hepatocytes that were not present in the healthy controls. These MASLD-associated hepatocytes form a bridge between hepatocytes and cholangiocytes and are enriched for tissue regeneration associated transcription factor motifs and pathways. In comparison to the other hepatocyte populations, the MASLD-associated hepatocytes have distinct signalling and metabolic phenotype. Furthermore, genetic enrichment analysis revealed that the genetic risk of T2DM is enriched in the accessible chromatin of the MASLD-associated hepatocyte subpopulation.
Conclusion: Taken together, our atlas provides a unique resource to study cellular and genetic underpinnings of MASLD progression and highlights the changes in hepatocyte composition underlying heterogeneity among MASLD patients.

Email: a.s.meijnikman@amsterdamumc.nl

Background and aims: Cellular senescence, a stress-induced stable cell-cycle arrest, is a growing focus in metabolic dysfunction-associated steatotic liver disease (MASLD) research. While the gut microbiome is implicated in MASLD development, the role of microbial metabolites in liver senescence and progression to steatohepatitis remains unclear. This study examines liver senescence and the causal impact of gut microbial metabolites on senescence-driven liver disease.
Method: We analysed liver RNA transcriptomics and fasting and post-prandial plasma metabolomics from 300 individuals with severe obesity (median age 48, 76.4% women; median BMI 38 kg/m², 23.9% diabetes, and 60.5% MASLD). Senescent cells were identified through liver transcriptomics (using two senescence signature sets: Sennet and Senmayo and the canonical marker p21), immunohistochemistry, and Western blotting. The cohort was stratified into tertiles based on senescence marker expression (low, medium, high) to calculate odds ratios for MASH and diabetes. Correlations between senescence markers and plasma metabolites were assessed, and candidate metabolites were validated in a Finnish cohort of 10,187 men using Cox regression for liver-related mortality. To explore causality, wild-type mice on a chow diet were administered the candidate metabolite daily, with or without senolytics

(dasatinib and quercetin, D+Q). After 14 days, liver enzymes, liver triglycerides, and senescence markers were measured.
Results: Liver senescence, independent of age, was strongly associated with MASH, with an odds ratio (OR) of 4.75 (95% CI: 2.44–9.51, p < 0.001) in individuals in the highest tertile of senescence. Similarly, the OR for diabetes was 3.95 (95% CI: 1.85–8.92, p < 0.001) for individuals in this tertile. A significant association was observed between senescence markers and the microbial metabolite 3-(4-hydroxyphenyl)lactate (HPLA) in both fasting (R = 0.27, p-FDR < 0.001) and post-prandial conditions (R = 0.39, p-FDR <0.001). In the validation cohort, Cox regression showed that elevated HPLA levels were associated with increased liver-related mortality (HR = 2.14, 95% CI: 1.74–2.62, p < 0.005). In mice, intraperitoneal HPLA administration led to dose-dependent increases in serum ALT, hepatic triglycerides, and senescence marker expression. Senolytic treatment alleviated liver steatosis and reduced serum ALT levels in HPLA-treated mice.
Conclusion: Liver senescence is linked to more severe disease in individuals with obesity. The microbial metabolite HPLA correlates with senescence markers and is associated with liver disease severity and increased liver-related mortality risk. In mice, HPLA induces hepatic injury and steatosis, effects that are mitigated by senolytic treatment. These findings suggest that HPLA drives liver injury through hepatic cellular senescence.

Metabolic molecular subtyping identifies actionable targets in MASLD and hepatocellular carcinoma: an integrative multi-omics and machine learning strategy for precise treatment
Jing Sun[1], Run Shi[2], Xiqiao Zhou[3]. [1]*Affiliated Hospital of Nanjing University of Chinese Medicine, The First Clinical Medical College of Nanjing University of Chinese Medicine, Nanjing, China;* [2]*The First Affiliated Hospital of Nanjing Medical University, Nanjing, China;* [3]*Affiliated Hospital of Nanjing University of Chinese Medicine, Nanjing, China*
Email: zhouxiqiao@njucm.edu.cn

Background and aims: In addition to histological evaluation and pathological classification, a comprehensive analysis of the metabolic landscape and metabolism-related molecular subtyping is urgently needed to categorize Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) patients into distinct subgroups with diverse risks for precise treatment.
Method: A total of 806 MASLD and 267 normal liver samples from 10 public datasets were collected, and alterations in 114 metabolic pathways in MASLD were comprehensively analyzed. Two distinct metabolic clusters exhibiting diverse biological characteristics and fibrotic phenotypes were identified in nonalcoholic steatohepatitis (NASH). Single-cell RNA-sequencing (scRNA-seq) data was analyzed to decipher the metabolic characteristics involved in the microenvironment of MASLD-derived liver cirrhosis. Gaussian Mixture Model (GMM) and logistic regression (LR) analysis were combined to develop a refined fibrotic-prediction model. The multi-omics data and potential therapeutic drugs were comprehensively analyzed in hepatocellular carcinoma (HCC) samples with different metabolic dysfunction scores (MBDS). A total of 78 combinations derived from 9 survival-related machine learning algorithms were applied to MBDS-related genes to select an optimal prognostic model for patients with HCC.
Results: Two distinct metabolic clusters (MBCs) were identified in NASH. The two MBCs exhibited distinct metabolic patterns and immune microenvironment. ScRNA-seq analysis revealed heterogeneous metabolic activities across various cell types and subpopulations in MASLD-derived cirrhosis. The GMM-LR model exhibited its superior capacity in fibrosis discrimination in multiple independent cohorts, including public databases and our in-house cohort. Distinct genomic alterations, immune landscapes, and potential therapeutic drugs were observed in HCC samples with different MBDS levels. Furthermore, MBDS was significantly correlated with EMT in pan-cancer samples, especially in hepatobiliary tumors. Finally, a survival-SVM prognostic model was constructed based on MBDS-related genes and exhibited the best performance across multiple HCC cohorts.
Conclusion: We provide evidence for the necessity of metabolic molecular subtyping and its potential clinical applicability in risk stratification, aiming to facilitate personalized management and treatment strategies for MASLD and HCC individuals.

Email: r.kasuga1017@gmail.com

Background and aims: Obesity, frequently complicated with metabolic-associated steatohepatitis (MASH), is a chronic inflammatory condition involving inter-organ correlations, though many mechanisms remain unclear. We previously reported that CCR9-CCL25 axis inhibition improves the condition of diabetes, but its role in obesity and MASH is unknown. This study aims to investigate the role of CCR9-CCL25 axis in obesity using samples from severely obese patients before and after bariatric surgery and from diet-induced obesity (DIO) mouse.
Method: Serum samples from 32 cases of severely obese (SO) patients who underwent bariatric surgery were subjected to a comprehensive analysis of cytokines and chemokines using a multiplex assay. To investigate the involvement of CCL25, one of the key factors identified from serum analysis, in obesity, wild-type and Ccr9 knockout (Ccr9KO) mice were fed a high-fat diet (HFD) for 12 weeks to induce obesity. Immune cells in white adipose tissues (epididymal: eWAT, inguinal subcutaneous: iWAT, mesenteric: mWAT), small and large intestine, and liver were analyzed longitudinally.
Results: In SO patients, serum CCL25 was significantly higher than in healthy controls and correlated with visceral fat area, while it decreased significantly after surgery. Consistently, increased *Ccl25* expression in small intestinal epithelium was observed in WT-DIO mice. Immunological analysis of the small intestine in WT mice identified type 2 innate lymphoid cells (ILC2s) as CCR9-expressing immune cells whose numbers increased during obesity. The increase in ILC2s during obesity was specific to the small intestine (SI-ILC2), whereas a significant decrease in ILC2s was observed in eWAT and iWAT (WAT-ILC2). RNA-seq analysis of SI-ILC2 showed decreased expression of *Gata3* and *Il5* and increased expression of *Tbx21* and *Ifng* in the obese state compared to that in the steady state. Of note, Ccr9KO mice showed similar weight gain to WT mice on HFD feeding, but showed significantly improved glucose tolerance. Interestingly, Ccr9 deficiency partially cancelled the obesity-induced increase in SI-ILC2 and decrease in WAT-ILC2 demonstrated in WT mice. Histological analysis revealed that intestinal leaky gut, adipose inflammation/fibrosis, and hepatic steatosis/inflammation were significantly improved in Ccr9KO mice compared to WT mice.
Conclusion: In obesity, increased serum CCL25 levels were associated with visceral fat accumulation. Obesity-induced SI-ILC2s exhibited an ILC1-like phenotype, suggesting a pro-inflammatory role that might promote intestinal inflammation and leaky gut. Inhibition of the CCR9-CCL25 axis shifted the inter-organ distribution of ILC2s toward WAT and contributed to the improvement of pathology. These findings highlight the potential for targeting the CCR9-CCL25 axis as a therapeutic approach for obesity and MASH.

OS-084-YI

HSD17B13 loss-of-function protects against steatosis-induced hepatic phosphatidylcholine depletion by promoting polyunsaturated fatty acid retention in humans in vivo and in experimental models

Sami F. Qadri[1,2], Leanne Hodson[3,4], Kimmo Porthan[1,2], Anne Juuti[5], Anne K. Penttilä[5], Tuulia Hyötyläinen[6], Matej Orešič[7,8], Elspeth Johnson[3], Nikola Srnic[3], Sonja Boyd[9], Johanna Arola[9], Michael Carleton[10], Cindy McReynolds[10], Heather Hsu[10], Hannele Yki-Järvinen[1,2]. *[1]Department of Medicine, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [2]Minerva Foundation Institute for Medical Research, Helsinki, Finland; [3]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Oxford, United Kingdom; [4]Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom; [5]Department of Abdominal Surgery, Abdominal Center, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [6]Man-Technology-Environment (MTM) Research Centre, School of Science and Technology, Örebro University, Örebro, Sweden; [7]School of Medical Sciences, Faculty of Medicine and Health, Örebro University, Örebro, Sweden; [8]Turku Bioscience Centre, University of Turku and Åbo Akademi University, Turku, Finland; [9]Diagnostic Center, Department of Pathology, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; [10]Inipharm Inc., Bellevue, Washington, United States*
Email: sami.qadri@helsinki.fi

Background and aims: Phosphatidylcholines (PCs) are a major hepatic reservoir of polyunsaturated fatty acids (PUFAs). In murine models of metabolic dysfunction-associated steatotic liver disease (MASLD), liver injury is induced by PUFA-PC depletion. The lipid droplet enzyme HSD17B13 metabolizes PUFA derivatives, and its loss-of-function variant rs72613567:TA protects against steatohepatitis (MASH) and fibrosis, although the mechanism underlying this protection remains unknown. We investigated whether hepatic PUFA-PC metabolism is influenced by MASLD or the protective *HSD17B13* variant.

Method: Obese patients with a liver biopsy (n = 135) underwent genotyping for *HSD17B13* rs72613567:TA and analysis of the hepatic lipidome by UPLC-MS. A state-of-the-art deep learning image analysis method (Aiforia Technologies) quantified steatosis via the hepatic parenchymal fat fraction. Using a recruit-by-genotype approach, we studied homozygous rs72613567:TA carriers (n = 13) and non-carriers (n = 13) to determine whether the variant affects incorporation of ^{13}C-labeled PUFAs linoleic acid (LA) and alpha-linolenic acid (ALA) into triglycerides (TGs) and phospholipids (PLs) secreted by the liver in very-low-density lipoprotein (VLDL). We tested whether targeting HSD17B13 with a small molecule inhibitor, INI-822, affects PC metabolism using two models: *in vitro*, a primary human liver-on-a-chip system challenged with high-fat media for 20 days; and *in vivo*, Zucker obese rats fed either an atherogenic diet or a choline-deficient, L-amino acid-defined high-fat diet for 21 days.

Results: Human MASLD livers were characterized by a marked depletion of hepatic PUFA-PCs containing 5–8 double bonds. Steatosis had a particularly accentuated effect to lower PUFA-PCs in individuals without the *HSD17B13* rs72613567:TA variant. However, this effect was abolished in variant carriers due to markedly increased concentrations of hepatic PUFA-PCs compared to non-carriers. Homozygous carriers had significantly decreased incorporation of [U-^{13}C]LA into VLDL-TG ($P < 0.001$) and of [U-^{13}C]LA and [U-^{13}C]ALA into VLDL-PL ($P = 0.01$ and 0.05), consistent with retention of these PUFAs in the liver. *In vitro*, inhibition of HSD17B13 by INI-822 in the human liver-on-a-chip system lowered fibrotic markers while stabilizing choline utilization and increasing PC concentrations. *In vivo*, inhibition of HSD17B13 in Zucker obese rats fed MASH-inducing diets reduced liver enzymes and dose-dependently increased hepatic PC concentrations.

Conclusion: In humans, *HSD17B13* rs72613567:TA prevents MASLD-induced hepatic PUFA-PC depletion by retaining PUFAs within the liver. Pharmacological inhibition of HSD17B13 recapitulates the human phenotype *in vitro* and *in vivo*. These findings suggest that hepatic PC enrichment is central to the protective effects associated with HSD17B13 loss-of-function.

Email: c.d.slooter@amsterdamumc.nl

Background and aims: Autoimmune hepatitis (AIH) is a complex condition with various prognostic factors linked to increased mortality risk. To date, only one prediction model for survival in AIH has been developed, which incorporates age, cirrhosis at diagnosis, and non-Caucasian ethnicity. However, this model is based on a relatively small dataset, limited to AIH type 1 without variant syndromes and does not include significant predictors such as achievement of complete biochemical response (CBR). Therefore, our study aims to develop and internally validate a prediction model for transplant-free survival in AIH that incorporates the achievement of CBR at 12 months.

Method: We included all patients with available follow-up data from the International AIH Group Retrospective Registry. The endpoint of the study was overall mortality or liver transplantation. The prediction model was developed using backward selection. We calculated the C-index and plotted the calibration curve. The model was updated after internal validation was performed with 250 bootstrap samples. The coefficients of the model were updated with the slope from internal validation.

Results: With a median follow-up of 8 years, our study encompasses 1139 patients with AIH, of whom 159 died or received a liver transplantation. Among included patients 42.4% did not achieve CBR within 12 months. The prognostic model includes age and cirrhosis at diagnosis, non-Caucasian ethnicity, variant syndrome with PSC, and absence of CBR within 12 months. The model demonstrates C-index of 0.885 with a linear calibration curve. Internal validation yielded a C-index of 0.879 with a slope shrinkage factor of 0.932. This resulted in the following formula: Prognostic index = (0.034 × Age) + (0.960 × Ethnicity) + (1.430 × Cirrhosis) + (1.343 × PSC) + (1.601 × CBR).
Age: age in years at diagnosis of AIH.
Ethnicity: non-Caucasian = 1; Caucasian = 0.
Cirrhosis: cirrhosis at diagnosis = 1; no cirrhosis at diagnosis = 0.
PSC: PSC at diagnosis = 1; no PSC at diagnosis = 0.
CBR: No CBR within 12 months = 1; CBR within 12 months = 0.

Survival(10y) = 1 – exp(–(0.049147616 × exp(PI))).
Conclusion: Our study establishes a predictive model for survival in AIH that incorporates age, cirrhosis at diagnosis, non-Caucasian ethnicity, variant syndrome with PSC, and absence of CBR within 12 months. The model demonstrates robust predictive performance in bootstrap samples and shows promising utility for clinical application.

Email: srodriguez@clinic.cat

Background and aims: Multiple criteria exist to assess the response to ursodeoxycholic acid in primary biliary cholangitis (PBC); however, their efficacy in evaluating the response to second-line (2L) therapy remains undetermined. We aimed to analyze the capacity of response criteria at one year of treatment with bezafibrate (BZF) as 2L to predict event-free survival (EFS) and develop a predictive score for response to BZF.
Method: We conducted a retrospective analysis of 400 patients with PBC with at least one year of treatment with BZF as 2L from 37 centers of the Spanish ColHai registry. EFS was defined as the absence of decompensation, hepatocellular carcinoma (HCC), liver transplantation (LT) or liver-related death (LRD).
Results: Most patients were female (89%), with a median age of 56 years (IQR: 49–64), 45 (11%) had cirrhosis (LC) and in 15.5% obeticholic acid was added as a third line. Median BZF treatment duration was 3.8 (IQR: 1.7–6) years. During follow-up, 51 (14%) patients developed LC, 29 (7%) decompensation, 5 (1%) HCC, 9 (2%)

LRD, and 14 (3.5%) required LT. Of the patients, 11% discontinued BZF due to adverse events or patient´s decision after a median of 25 (3–42) months. According to the Paris II and Poise criteria, 51% and 68% of patients, had a response, respectively, and 53% had ALP < 1xUNL. In LC patients, the response rates were 31% and 61%. To detect SLE, Paris II had an AUC 0.74 with a sensitivity (Se) 91% and specificity (Sp) 56% and an AUC 0.74 (Se 88%, Sp 61%) for developing LC. Poise had lower accuracy for both SLE (AUC 0.68; Se 64%, Sp 71%) and developing LC (AUC 0.66; Se 58%, Sp 74%). Response according to Paris II was associated with improved EFS (HR 9.5; 95%CI 2.2–40.5) and a risk of events of only 1.5%. In non-responders, the Globe-score with a cut-point of 0.35 allowed discrimination of EFS (AUC 0.75; Se 79%, Sp 71%). Thus, only 6% of non-responders according to Paris II and a Globe score ≤ 0.35 presented events vs. 37% with Globe-score >0.35, p < 0.001. ALP normalization vs ALP 1–1.5 xUNL did not improve EFS (HR 1.0; 95%CI 0.3–3.7), However, total bilirubin (TBi) <0.6 mg/dl improved EFS vs TBi 0.6–1.2 (HR 4.4; 95%CI 1.2–15.6) and TBi >1.2 (HR 18.2; 95%CI 4.7–70.9). Variables at baseline of BZF associated with the response were normalized AST, ALT and TBi. Using these variables, we constructed a score for predicting response to BZF (-3.19*Platelets+1.66*BiT+1.35*AST+1.22*ALT-3.27), which obtained an AUC of 0.874 (Se 71%, Sp 86%).

Conclusion: The Paris II has high sensitivity, so patients who respond rarely experience events. In non-responders according to Paris II, those with a Globe-score ≤0.35 have an excellent EFS; therefore, it may not be necessary to add a third-line treatment. Poise criteria had low accuracy to evaluate response after BZF. Variables associated with the response to BZF were AST, ALT, and TBi, but not ALP. We created a score to predict response to BZF, pending further validation.

OS-087

Amongst autoimmune liver diseases, primary sclerosing cholangitis demonstrates distinct methylation profiles on circulating DNA

Soumita Ghosh[1], Cristina Baciu[1], Elisa Pasini[1], Madeline Cameron[2], Shani Nagler[2], Aisha Alawi, Aliya Gulamhusein[2], Gideon M. Hirschfield[3], Mamatha Bhat[4]. *[1]Ajmera Transplant Centre, Toronto General Hospital, University Health Network, Toronto, Canada; [2]The Autoimmune and Rare Liver Disease Programme, Toronto General Hospital, University Health Network, Toronto, Canada; [3]The Autoimmune and Rare Liver Disease Programme, Toronto General Hospital, University Health Network, Division of Gastroenterology & Hepatology, Department of Medicine, University of Toronto, Toronto, Canada; [4]Ajmera Transplant Centre, Toronto General Hospital, University Health Network, Division of Gastroenterology & Hepatology, Department of Medicine, University of Toronto, Toronto, Canada*
Email: soumita.ghosh@uhn.ca

Background and aims: The autoimmune liver diseases— Primary Sclerosing Cholangitis (PSC), Primary Biliary Cholangitis (PBC), and Autoimmune Hepatitis (AIH) —are of unknown aetiology but have overlapping biology despite usually clinically distinct profiles. Methylation patterns on circulating DNA have been shown to be specific to different disease processes before. Our goal was to develop a machine learning biomarker integrating methylation patterns on circulating cell-free DNA (cfDNA) and clinical variables as a means to better understand autoimmune liver disease pathobiology.

Method: This pilot study included 63 patients clinically diagnosed with PSC (n = 21), PBC (n = 21), and AIH (n = 21). Methylation profiles of cfDNA plasma were analyzed using the MEDIPS package, and pairwise comparisons were performed using Quantitative Sequence Enrichment Analysis (QSEA) for MeDIP-seq data (False Discovery Rate, FDR < 0.01, Fold Change > 2). Pathway enrichment was conducted using Ingenuity Pathway Analysis (IPA). We applied the Boruta feature selection algorithm to identify key methylation sites across patient cohorts. A Support Vector Classifier (SVC) with a linear kernel was developed, using 101 bootstrapping iterations to classify patients into AIH, PBC, or PSC groups. SHAP (SHapley Additive exPlanations) analysis was utilized to identify the most significant methylation sites and 24 clinical variables, including age, sex, ALT, AST, ALP, bilirubin, medications, influencing model predictions.

Results: Our findings revealed a distinct separation in methylation patterns in the PSC group compared to AIH and PBC. Pathway analysis highlighted several activated pathways in PSC relative to the other groups, including the Gamma-Glutamyl cycle, NLR Signaling Pathway, JAK-STAT signaling, and IL-8 activation. The Boruta feature selection algorithm identified 182 key methylation sites predictive of disease group classification. By integrating these methylation sites with clinical variables, our Support Vector Classifier achieved a diagnostic accuracy of 90.46% (95% CI: 84.21–94.74%) and an AUROC of 0.9161 (95% CI: 0.9081–0.9167). The methylation patterns alone demonstrated strong classification capability with accuracy of 89.11% (95% CI: 78.95–94.74%) and an AUROC of 0.9131 (95% CI: 0.8974–0.9167), which was further augmented by the inclusion of clinical data. The SHAP analysis identified a locus on KLHL12 as a top predictive methylation site, effectively distinguishing PBC from AIH.

Conclusion: Our systematic investigation of cfDNA methylation profiles sheds light on distinct epigenetic alterations in autoimmune liver diseases. The machine learning diagnostic tool developed in this study, which integrates methylation data with clinical variables, demonstrates significant promise as a means to identify new disease biology for future targeted study.

Email: Vincenzo.ronca@hunimed.eu

Background and aims: The management of Primary Biliary Cholangitis (PBC) has become increasingly complex, with use of obeticholic acid (OCA) and fibrates as second-line therapy. Global practice is heterogeneous, and the lack of survival data on these patients increase the uncertainty in the second-line treatment allocation. Our study aims to compare the transplant-free survival in PBC patients on second-line treatment across the Global PBC cohort.
Method: We conducted a retrospective international cohort study involving PBC patients who initiated second-line treatment with either OCA or fibrates in 40 liver centers across Europe, Japan, South America, and North America. We collected clinical, biochemical, and treatment data at diagnosis and at the initiation of second-line treatment. Only patients exposed to single treatment (either OCA or fibrate) were included in this analysis. The Cox proportional hazards model was used to evaluate the hazard ratio (HR) for transplant-free survival.
Results: We accrued data on 1,333 patients, 646 on OCA and 685 on fibrates. 87.2% were women with an average age at the start of second-line treatment of 57.2 years (SD ± 11.15). Patients on OCA were more frequently cirrhotic (30.5% vs 19.4%, $p < 0.001$). The median alkaline phosphatase (ALP) at the start of second-line treatment was 2.09 times the upper limit of normal (ULN) (IQR 1.66–2.98) in patients on OCA and 1.72 times ULN (IQR 1.15–2.07) in patients on fibrates ($p < 0.001$). The median follow-up time was 30 months (IQR 12–55). The univariable Cox proportional hazards model showed a trend towards reduced survival in patients on OCA compared with fibrates (HR 1.46, 95% CI 0.97–2.20, $p = 0.06$). However, after adjusting for the presence of cirrhosis at the initiation of second-line treatment, no significant difference in survival was observed between the groups (HR 1.01, 95% CI 0.58–2.07, $p = 0.77$). In the multivariable Cox proportional hazards model, the presence of cirrhosis at the start of second-line treatment (HR 2.20, 95% CI 1.19–4.07, $p = 0.01$), higher ALP at second-line treatment (HR 1.23, 95% CI 1.06–1.43, $p < 0.01$), and the number of months before starting second-line treatment after the failure of UDCA (HR 1.01, 95% CI 1.01–1.02, $p = 0.02$) were found to be significantly associated with worse outcomes.
Conclusion: Our study demonstrated no difference in transplant-free survival in patients treated with either fibrates or OCA. The presence of established cirrhosis as well as more aggressive disease, documented by a higher ALP, were independently associated with worse outcomes. We provide further evidence that early access to second-line treatment in patients non-responsive to UDCA might improve outcomes.

Background and aims: Primary sclerosing cholangitis (PSC) is a rare, chronic, cholestatic liver disease characterised by progressive inflammation and fibrosis of the intra- and extra-hepatic bile ducts. The safety and efficacy of elafibranor (ELA), a PPAR alpha/delta agonist, were investigated in adults with PSC in the phase II ELMWOOD trial (NCT05627362).
Method: This 12-week, double-blind trial enrolled patients with large duct PSC and alkaline phosphatase (ALP) ≥ 1.5x the upper limit of normal, randomised 1:1:1 to daily oral ELA 80 mg, ELA 120 mg or placebo (PBO), stratified according to baseline ursodeoxycholic acid (UDCA) use. The primary endpoint was safety and tolerability of ELA vs PBO. Additional endpoints included least squares (LS) mean change from baseline (CfB) in ALP, alanine aminotransferase (ALT), gamma-glutamyl transferase (GGT) values, enhanced liver fibrosis (ELF) score and pro-C3 levels, proportions of patients with ALP normalisation, and LS mean CfB in pruritus according to the Worst Itch Numeric Rating Scale (WI NRS).
Results: In total, 68 patients (male: 54.4%; mean age: 46.3 years) were randomised to ELA 80 mg (n = 22), ELA 120 mg (n = 23) or PBO (n = 23). At baseline, 55.9% had concomitant inflammatory bowel disease, 70.6% of patients were on UDCA, and 23.5% had an ELF score > 10.6. Liver biochemistries were elevated (mean: ALP: 369.5 U/L; ALT: 84.7 U/L; GGT: 447.2 U/L), and the mean (SD) WI NRS score was 1.9 (2.2). Overall, 68.2%, 78.3% and 69.6% of patients on ELA 80 mg, ELA 120 mg and PBO had treatment emergent adverse events (TEAEs), respectively; TEAEs that led to treatment discontinuation occurred in 4.5%, 4.3% and 8.7% of patients, respectively. Serious TEAEs occurred in 4.3% of patients on PBO and none on ELA. Patients on ELA 80 mg and 120 mg had significant reductions in ALP at Week 12 vs PBO (−103.2 U/L and −171.1 U/L vs 32.1 U/L; $p < 0.0001$), with improvements observed as early as Week 4 ($p < 0.0001$). Similar reductions were observed in ALT (−14.1 U/L and −27.4 U/L vs 8.9 U/L; $p < 0.05$) and GGT (−108.1 U/L and −135.2 U/L vs 54.3 U/L; $p < 0.0001$). At Week 12, ALP normalisation occurred in 9.1% and 17.4% of patients on ELA 80 mg and 120 mg, respectively, vs none on PBO. Patients on PBO had a relative increase in non-invasive markers of liver fibrosis vs stabilisation in patients on ELA 80 mg or 120 mg (ELF: 0.30 vs 0.12 and 0.02; pro-C3: 0.2 ng/ml vs −6.2 ng/ml and −2.6 ng/ml, respectively). Greater reductions at Week 12 in WI NRS were observed in patients on ELA 120 mg vs PBO (−0.96 vs −0.28; $p < 0.05$).
Conclusion: In ELMWOOD, ELA 80 mg and 120 mg were well tolerated in patients with PSC. At Week 12, patients on ELA had significant, dose-dependent reductions in biochemical markers of cholestasis. Patients receiving ELA 120 mg had improvements in pruritus. The effects of ELA 120 mg on liver fibrosis will be evaluated in an ongoing, 96-week open-label extension. These findings warrant further investigation of ELA in PSC.

Liver Transplantation

Email: achrafim@hadassah.org.il

Background and aims: Liver transplantation (LTx) is a vital treatment option for patients with end-stage liver diseases. Acute cellular rejection (ACR) is a significant clinical diagnostic and therapeutic challenge at the post-transplant period. The clinical challenge lies in distinguishing ACR from other acute events, such as infections, vascular events, drug toxicity and biliary damage, which necessitates very different therapeutic modalities. Current diagnostic standards require liver biopsy for ACR diagnosis. This leads to a delay in diagnosis, is invasive, and with potentially complications. There is an urgent need for a simple, reliable, and reproducible non-invasive diagnostic test, which could be performed on daily basis, for monitoring post-LTx patients and diagnosing ACR.
Method: We utilized cell-free chromatin immunoprecipitation followed by sequencing (cfChIP-seq), a novel epigenetic-based liquid biopsy assay we recently introduced (Sadeh et al, *Nat. Biotech* 2001), to profile circulating cfDNA originating from active genes in plasma samples. The assay allows for interrogation of gene activity in the cell of origin. It provides insights into the extent of liver damage and the molecular states of dying liver cells and immune cells.
Results: We enrolled a cohort of >150 LTx patients and prospectively collected >4000 blood samples through their post-transplant hospitalization. We collected blood samples during 15 biopsy-verified ACR events and 14 non-ACT acute events for 20 patients. We developed a cfChIP-seq signature of genes that distinguish ACR samples from other acute liver damage events. We show that this signature allows the classification of ACR events with AUC of 0.94. This signature provides superior diagnostic performance compared to blood assay of liver enzymes (AUC of 0.75 for ALT and 0.48 for AST). We validated this signature in a follow-up LTx cohort.
Conclusion: We developed an ACR blood test using a cfDNA signature with high accuracy in patients post-LTx. The assay is highly

reproducible and robust, suggesting a path toward non-invasive detection, monitoring, and diagnosis of post-LTx ACR.

Email: ahn.joseph@mayo.edu

Background and aims: Secure data sharing is crucial for cross-institutional collaboration in hepatology, but often hindered by stringent privacy regulations. Synthetic data—artificially generated datasets that replicate the statistical properties of real data without exposing confidential information—offer a promising solution. We aimed to implement and validate diffusion models, a state-of-the-art generative AI approach, to produce synthetic liver transplant datasets across various liver disease etiologies using the United Network for Organ Sharing (UNOS) database. Our focus was on preserving statistical fidelity, clinical utility, and ensuring robust patient privacy.
Method: We utilized the UNOS liver transplant dataset from 2019 to 2023, encompassing 35,374 patients. Diffusion models were trained to generate synthetic datasets for each liver disease category: alcohol (n = 14,772), metabolic (MASH, n = 10,311), viral (n = 2,545), autoimmune (n = 1,491), biliary (n = 3,350), cryptogenic (n = 2,161), and other (n = 744). We rigorously evaluated the synthetic data against the original using multiple metrics, including statistical fidelity by Wasserstein distances, clinical utility by the MELD score performance, correlation preservation, and privacy protection metrics such as Distance to Closest Record (DCR), Attribute Disclosure Risk, and K-anonymity violation rates.
Results: All synthetic disease subgroups achieved low multivariate Wasserstein distance <1.0, indicating excellent statistical fidelity with the original data. MELD score performance was consistently preserved, with negligible differences in AUC between synthetic and real datasets (0.004 to 0.033): alcohol (synthetic 0.845 vs. original 0.856), MASH (0.794 vs. 0.787), viral (0.814 vs. 0.827), autoimmune (0.814 vs. 0.827), biliary (0.768 vs. 0.800), cryptogenic (0.805 vs. 0.809), and other (0.832 vs. 0.809). Clinically significant correlations were maintained, such as between INR and bilirubin (R = 0.53 vs. 0.55), and the inverse relationship between sodium and creatinine (−0.15 vs. −0.13). In privacy assessments: DCR mean distances ranged from 0.75 to 1.22, ensuring synthetic patients were sufficiently distinct from real patients; Attribute Disclosure Risk was zero, and no K-anonymity violations were detected – meaning no actual patient data was present in the synthetic dataset.
Conclusion: Our study suggests that diffusion models can generate synthetic liver transplant data that retain essential statistical and clinical characteristics while providing strong privacy safeguards. This AI-driven method could enhance hepatology research by enabling more secure, privacy-compliant data sharing and collaboration across institutions. It may facilitate the augmentation of small patient cohorts and enable the use of "digital twins" for control arm simulations in trials. Future research is needed to validate this approach in multicenter studies and to explore its application in diverse clinical datasets.

Background and aims: The diagnosis of graft rejection after liver transplantation (LT) is based on light microscopy. Tissue transcriptomic signatures could help to clarify the alloimmune status of the graft, especially in cases where the diagnosis is unclear, such as chronic antibody mediated rejection (cABMR). CABMR, which leads to shorter graft survival after LT requires histologic criteria, the presence of donor specific antibodies (DSA), and the exclusion of other causes of liver injury. It is noteworthy that not all patients with cABMR fulfill all diagnostic criteria and the absence of DSA (cABMR-DSAneg) has been reported in other solid organ transplants and poses the same risk for adverse outcomes. We aimed to compare the transcriptomic signature of liver biopsies with cABMR and cABMR-DSAneg.
Method: All liver biopsies including surveillance and indication biopsies performed at the Hannover Medical School between 2018 and 2022 were screened. All biopsies with histologic criteria of cABMR (according to Banff 2016 criteria) and 20 liver biopsies with no histologic rejection (NHR) as controls were included. Biopsies with histological criteria for cABMR were divided into those with positive DSA within 3 months of the biopsy and classified as cABMR and those with negative DSA, classified as cABMR-DSAneg. RNA was extracted from paraffin-embedded tissue (FFPE) and sequenced. Downstream analyses explored the unique and shared molecular features of cABMR and cABMR-DSAneg. Differentially expressed genes were analyzed in comparison to biopsies with NHR.
Results: A total of 28 biopsies met the criteria for histologic cABMR, of which 7 (25%) had positive DSA (cABMR) and 21 (75%) had negative DSA (cABMR-DSAneg). Of these biopsies, 21 (6 cABMR and 15 cABMR-DSAneg) had sufficient tissue for RNA extraction. Most cases of cABMR (3/6, 50%) and cABMR-DSAneg (10/15, 66.7%) were found in surveillance biopsies, with no difference between groups (p = 0.83). When comparing the demographics of both groups, both had similar age at LT (47 vs 40 years, p = 0.88) and time after LT (149 vs 158 months, p = 0.88). The transcriptomic profile of cABMR was characterized by fibrogenesis, complement activation and TNF pathways. When comparing differentially expressed genes between cABMR and cABMR-DSAneg, both share the same transcriptomic profile with no up- or down-regulated genes that differ between the groups.
Conclusion: To our knowledge, this is the first report on the transcriptomic profile in liver biopsies with cABMR with and without DSA in the field of LT. Most of the liver biopsies compatible with cABMR do not have DSA, and the presence or absence of DSA does not influence the transcriptomic pathways at the tissue level. This implies that the presence of DSA, as described in other solid organ transplants, is not necessary for the diagnosis of cABMR.

OS-093

Inequalities in liver transplantation: data from the EPA-RITY study

Eloisa Franchi[1], Helen Banks[2], Luca Del Prete[1], Silvia Testa[3], Patrizia Burra[4], Silvia Trapani[3], Giuseppe Feltrin[3], Lucio Caccamo[1], Daniele Dondossola[1]. *[1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]SDA Bocconi School of Management, Milan, Italy; [3]Italian National Transplant Center, Italian National Institute of Health, Rome, Italy; [4]Multivisceral Transplant Unit, Gastroenterology, Department of Surgery, Oncology and Gastroenterology, Padua University Hospital, Padua, Italy*
Email: eloisa.franchi@policlinico.mi.it

Background and aims: Social determinants of health (SDOH) are increasingly recognized as key drivers of health outcomes, including in transplantation medicine. Income inequality, in particular, has emerged as a critical factor influencing access to care and treatment

outcomes. Despite Italy's universal healthcare system, disparities persist, often challenging to quantify due to limited socio-economic data. Liver transplantation (LT) outcomes may be affected by factors such as income, education, and geographic location, influencing waitlist entry and progression. While these disparities are well-documented in countries with private or mixed systems, they remain underexplored in Italy. This study investigates, for the first time, the role of SDOH—particularly income—in shaping LT pathways, from waitlist enrollment to outcomes.

Method: This multicenter, retrospective study analyzed anonymized data from the national transplant database for patients listed for LT between 2010 and 2020. Income data were assigned to geographic areas based on postal codes. Linear and logistic regression models (odds ratios) were used to evaluate associations between income levels and LT outcomes, adjusting for individual and contextual confounders.

Results: We analyzed 9397 patients with complete postal code data from a total of 13947 listed for LT during the study period. Among these, 30.7% were under 50 years old, 40.6% were 51–60, and 28.7% were over 60; 73.6% were male. MELDNa scores at listing were 0–14 in 43.7%, 15–19 in 23.4%, 20–29 in 21.8%, and > 29 in 9.9%. Foreign-born patients were 33% more likely to have a MELDNa > 29 at listing (OR 1.33, p = 0.07). Patients from higher-income areas (> € 20,000) were 20% more likely to have a MELDNa <15. Waitlist durations were longer for women (+ 53 days) and residents of lower-income areas (+ 38–41 days). Organ failure at 6 months and 1 year increased with higher MELDNa scores but unexpectedly also with rising income levels.

Conclusion: Despite Italy's universal healthcare system, SDOH—especially income, gender, and migration status—significantly affect LT access and outcomes. These findings highlight the need for policies that integrate socio-economic factors into transplant planning to ensure equitable care. Addressing disparities through targeted interventions, improved outreach, and resource allocation adjustments is crucial for reducing barriers and achieving fair treatment outcomes.

Donor derived cell free DNA can be used to tailor immunosuppression in liver transplant recipients - results of largest single center experience in the US

Kinnari Modi[1], Kyle Schneider[2], Parvez Mantry[3], Mingyang Cui[4].
[1]*Methodist Dallas Medical Center, Gastroenterology and Hepatology, Dallas, United States;* [2]*Methodist Health System, Internal Medicine, Dallas, United States;* [3]*The Liver Institute at Methodist Dallas, Dallas, United States;* [4]*Methodist Health System, Clinical Research Institute, Dallas, United States*
Email: kmodi1992@gmail.com

Background and aims: Donor-derived cell-free DNA (dd-cfDNA) has emerged as a promising biomarker for detecting graft injury and early rejection in solid organ transplantation. However, data on its clinical utility in liver transplant recipients remains limited. We evaluated dd-cfDNA in liver transplant patients with both normal and abnormal liver function tests (LFTs) and assessed its utility in guiding immunosuppression (IS) titration in stable liver allografts.

Method: We retrospectively analyzed data from 68 liver transplant recipients with dd-cfDNA (AlloSure, CareDx Inc.) measurements from August 2021 to October 2023. The primary cohort included patients with at least one episode of rejection or stable allograft function. For the immunosuppression (IS) titration sub-analysis, we evaluated 13 stable patients who underwent IS modification based on dd-cfDNA levels. The IS regimen consisted of tacrolimus/sirolimus/cyclosporin with mycophenolate mofetil and/or prednisone. Statistical analyses included Wilcoxon rank-sum test for comparing stable versus unstable allografts, and Wilcoxon signed-rank test for evaluating changes after IS modification.

Results: Among 68 patients, 8 demonstrated evidence of rejection while 60 maintained stable allograft function. Median dd-cfDNA levels were significantly higher in unstable versus stable allografts (15% vs 2.8%, p = 0.0012). This correlated with significantly elevated liver enzymes in the unstable group (AST: 120 vs 25 U/L, p < 0.0001; ALT: 161 vs 24 U/L, p < 0.0001; ALP: 253 vs 81 U/L, p = 0.0004). In the IS titration sub-analysis (n = 13), mean initial dd-cfDNA was 3.78 ± 1.14%, with follow-up levels of 5.39 ± 1.42% (p = 0.241) after titration. Despite variable dd-cfDNA changes, LFT stability was maintained in 84.6% of patients after IS modification. Triple immunosuppression was more common in unstable patients (87.50% vs 51.67%).

Conclusion: Our findings demonstrate that in stable patients IS modification guided by dd-cfDNA levels -maintained allograft stability in vast majority of the cases. These results suggest that dd-cfDNA monitoring can effectively help down-titrate IS after liver transplantation while balancing their toxicity with risk of rejection. Larger confirmatory prospective studies are needed.

MASLD: Clinical and therapeutical aspects II

Background and aims: The current regulatory approved surrogate endpoints for drug development in pre-cirrhotic Metabolic-dysfunction Associated Steatohepatitis (MASH) are histologically defined and require accurate measurement of disease activity using the MASLD Activity Score (MAS) and fibrosis stage (F) at trial entry and completion. Histopathologist scoring is subject to both inter- and intra-observer variation however, artificial intelligence (AI) models are a potential aid. The aim of this study was to independently assess performance of the latest iterations of the two best-evidenced quantitative AI approaches (PathAI AIM-MASH™ on H&E/MT stained digital slide images & HistoIndex qFIBS™ on unstained SHG/TPE laser microscopy images) vs. expert histopathologists.
Method: Centrally-evaluated MAS and F by the LITMUS Histopathology Group (LHG) served as the reference standard and were compared with ordinal outputs from each AI tool in 1360 liver biopsies from centres across Europe. Confusion matrices summarised agreement between methods, alongside standard measures of concordance. Accuracy of an AI-assisted histology screening pipeline for "at-risk MASH" (MAS≥4 + F≥2) was assessed.
Results: LHG central scoring (LHG-CS) considered 339/1360 cases to exhibit at-risk MASH and 524/1360 to be F≥3. A significant relationship was observed between LHG-CS and AIM-MASH for F (Kendall's tau 0.52, Cohen's Kappa 0.28) and MAS (0.65, 0.22), with high discriminatory power for diagnosing MAS≥4 (AUROC 0.87, Se/Sp 0.79/0.81), at-risk MASH (AUROC 0.79, Se/Sp 0.76/0.83) and F≥3 (AUROC 0.87, Se/Sp 0.77/0.84) by AIM-NASH. A significant relationship was also observed between LHG-CS and qFIBS for F (Kendall's tau 0.60, Cohen's K 0.29) and MAS (0.47, 0.10) with high discriminatory power for MAS≥4 (AUROC 0.79, Se/Sp 0.83/0.60) and F≥3 (AUROC 0.92, Se/Sp 0.86/0.84) by qFIBS. At-risk MASH performance was lower (AUROC 0.65, Se/Sp 0.36/0.94). Both AI methods showed similar overall concordance with LHG-CS for at-risk MASH (AIM-MASH 1106/1360 (81.3%), qFIBS 1081 (79.5%)), although the two differed in their relative Se/Sp for specific histological features. AIM-MASH considered a greater number of samples as at-risk MASH in disagreement with LHG-CS (172, 12.6% cases) compared to qFIBS (61, 4.5%).
Conclusion: This is the largest head-to-head study comparing the performance of AI digital pathology on MASLD biopsies centrally-scored by expert hepatopathologists. The results demonstrate substantial agreement between methods but highlight relevant differences in performance: AIM-MASH was superior at classifying at-risk MASH (AUROC 0.79 vs 0.65), with greater sensitivity but less specificity. In contrast, qFIBS was superior for staging F≥3 (AUROC 0.92 vs 0.87), due to greater sensitivity. Ongoing analysis with non-invasive biomarkers will examine the potential for AI as a complementary tool in trials.

OS-096

Alignment of response assessed by non-invasive fibrosis biomarkers and HistoIndex AI-based qFibrosis histology in metabolic dysfunction associated steatohepatitis (MASH) clinical trials: a new roadmap for robust drug efficacy assessment demonstrated in the HARMONY trial

Quentin M. Anstee[1,2], Kutbuddin Akbary[3], Yayun Ren[3], Elaine Chng[3], Doreen Chan[4], Erik Tillman[4], Reshma Shringarpure[4], Tim Rolph[4], Kitty Yale[4], Dean Tai[3], Mazen Noureddin[5]. *[1]Translational & Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom; [2]Newcastle NIHR Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, United Kingdom; [3]HistoIndex Pte Ltd, Singapore, Singapore; [4]Akero Therapeutics, South SF, United States; [5]Houston Methodist Hospital and Houston Research Institute, Houston, United States*
Email: quentin.anstee@newcastle.ac.uk

Background and aims: The current regulatory-approved reasonably-likely surrogate endpoints for MASH trials are histologically defined, yet expert hepatopathologist-based scoring is subject to inter- and intra-observer variation. This, combined with the heterogenous nature of liver tissue, potentially inflates placebo response rates, hindering drug development. In the absence of a single "perfect" response biomarker, assessing the extent of concordance of changes in multiple independent biomarkers could be an alternative approach to determine efficacy. Here, utilising the HARMONY Phase 2b trial (NCT04767529) dataset that established efficacy of Efruxifermin (EFX) using traditional histology endpoints, we explore novel response-biomarker strategies that combine non-invasive tests (NITs) and AI-based qFibrosis™ using SHG/TPE laser microscopy on unstained liver biopsies.
Method: This analysis included 104 patients at week 24 (W24: Placebo [PBO] n = 39, EFX = 65) and 76 at week 96 (W96; PBO = 29, EFX = 47). Concordance in fibrosis regression for PBO vs EFX (pooled doses) was assessed using: two NITs (ELF ≥0.5 absolute change and Liver Stiffness Measurement ≥30% change); central pathologist-scored fibrosis ([CPF] ≥1 stage change); categorical qFibrosis ([qF] ≥1 stage change), and continuous qFibrosis ([qFc] ≥ standard error of means).
Results: At W24, at least one NIT improved in 8/39 (20.5%) PBO vs. 47/65 (72.3%) EFX patients; both NITs showed regression in 0/39 (0%) PBO and 20/65 (30.1%) EFX (ChiSq P = 0.0001). At W96, at least one NIT improved in 12/29 (41.4%) PBO vs. 38/47 (80.9%) EFX; both NITs showed regression in 2/29 (6.9%) PBO and 23/47 (48.9%) EFX (ChiSq P = 0.0002). Factoring in liver biopsy assessment, dual-NIT response was concordant with CPF response in 0/39 (0%) PBO and 7/65 (10.7%) EFX cases at W24, and 0/29 (0%) PBO and 15/47 (31.9%) EFX cases (ChiSq P = 0.0007) at W96. Higher rates of dual-NIT concordance were observed with categorical qF response: 0/39 (0%) PBO and 13/65 (20.0%) EFX cases at W24, and 1/29 (3.4%) PBO and 20/47 (42.5%) EFX cases (ChiSq P = 0.0002) at W96. Concordance increased further with qFc response: 0/39 (0%) PBO and 15/65 (23.1%) EFX cases at W24, and 1/29 (3.4%) PBO and 22/47 (46.8%) EFX cases (ChiSq P = 0.0001) at W96.
Conclusion: Combining NITs with CPF appeared to supress PBO response (from 21%/41% at W24/W96 to 0% at both timepoints) whilst preserving clear efficacy signals, as seen by statistically significant superiority of EFX over PBO. Histopathological response as determined by qF/qFc exhibited greater concordance with dual-

NIT response, suggesting these approaches more closely track biological effect. These results demonstrate robustness of combined-NIT/AI-based histopathology and NIT-only biomarker strategies to assess treatment response and, with further validation, support the adoption of more robust reasonably-likely surrogate endpoints.

OS-097

Evaluating noninvasive diagnostic pathways for identifying MASH patients eligible for Resmetirom therapy: a real-world cohort analysis

Winston Dunn[1], Ashwani K. Singal[2], Imad Asaad[3], Edward Mena[4], Amreen Dinani[5], Savannah Nelson[6], Wamda Ahmed[1], Karthikeya Kodali[6], Phuong Nguyen[6], Sonal Kumar[7], Madhavi Rudraraju[8], Mazen Noureddin[9], Naim Alkhouri[6]. [1]*University of Kansas Medical Center, Kansas City, United States;* [2]*University of Louisville School of Medicine, Louisville, United States;* [3]*Firelands Health, Sandusky, United States;* [4]*California Liver Reasearch Institiute, Pasadena, United States;* [5]*Duke University Health System, Durham, United States;* [6]*Arizona Liver Health, Tuscon, United States;* [7]*Cornell University, New York, United States;* [8]*Pinnacle Research, San Antonio, United States;* [9]*Houston Research Institute, Houston, United States*
Email: naim.alkhouri@gmail.com

Background and aims: Resmetirom, the first FDA-approved medication for non-cirrhotic patients with metabolic dysfunction-associated steatohepatitis (MASH) with significant (F2) to advanced (F3) fibrosis, does not require liver biopsy for diagnosis. Current AASLD guidance recommend Vibration-Controlled Transient Elastography (VCTE) liver stiffness measurement (LSM) or the enhanced liver fibrosis (ELF) test for treatment consideration. In the real world, most patients with MASH do not undergo liver biopsy, and the diagnosis is predominantly based on noninvasive tests. This study aims to evaluate the performance of several noninvasive tests (NITs) diagnostic pathways that are proposed to be used in primary care to risk stratify patients with MASLD and determine who needs referral to hepatology care for treatment consideration.
Method: This retrospective study analyzed data from 424 MASLD patients treated with resmetirom at six U.S. tertiary hepatology clinics between March and November 2024. Demographics, laboratory results, liver stiffness measurements, and liver biopsies were recorded at baseline. Patient meeting one of the 3 AASLD guidance proposed criteria (1. LSM 8–20 kPa, or 2. ELF of 9.2–11.3, or 3. Liver biopsy fibrosis stage 2–3) were included in this analysis. The NITs diagnostic pathways that were evaluated included FIB4, SAFE score, Liver Risk Score, and ALADDIN-F2-Lab score.
Results: The cohort consisted of 424 patients with a median age of 58 years (IQR: 49–67), and 42.0% (179) were male. Diagnosis was established through liver biopsy in 20.8% of patients, with 45.5% demonstrating F2 fibrosis and 46.6% F3 fibrosis. Transient elastography was used in 88.9% of cases, with 69.8% of measurements falling within the AASLD-recommended range of 8–20 kPa. ELF testing was performed in 13.2% of patients, and 73.2% had levels between 9.2 and 11.3. A total of 337 patients meeting the AASLD guidance criteria were included in the analysis for NITs. Among the cohort, 45.8% had low-risk FIB-4 scores (<1.3). Results from alternative scoring systems showed varied proportions of patients classified as low risk: 80.2% for the Liver Risk Score, 13.0% for the SAFE score, and 12.5% for the ALADDIN-F2-Lab score.
Conclusion: This real-world analysis highlights the limitations of current AASLD and EASL guidelines, which rely on FIB-4, in identifying MASH patients with significant fibrosis. Nearly half of the eligible cohort would have been excluded from further evaluation based on low-risk classification using these tools. In contrast, novel scoring systems like SAFE and ALADDIN-F2-Lab, leveraging routine laboratory data, identified the majority of patients as intermediate or high risk, supporting the need for confirmatory testing with transient elastography or liver biopsy. These findings underscore the importance of developing alternative diagnostic strategies to optimize the identification and timely treatment of MASH patients.

Email: NoureddinMD@houstonresearchinstitute.com

Background and aims: We evaluated weight-loss direct and indirect effects of survodutide, a glucagon receptor/glucagon-like peptide-1 receptor dual agonist, on liver endpoints in a phase 2 trial in people with biopsy-confirmed metabolic dysfunction-associated steatohepatitis (MASH) and F1 – F3 liver fibrosis.
Method: 295 patients were randomised to once-weekly subcutaneous injections of survodutide 2.4, 4.8, or 6.0 mg or placebo (NCT04771273). Patients with fibrosis stage F2/F3 and paired baseline and end-of-treatment biopsy readings (N = 170) were included, survodutide arms were pooled. Mediation analysis explores how an intermediate variable explains the pathway between an exposure and an outcome; we assessed the proportion of the effect of survodutide on liver endpoints that was attributable to a direct and indirect effect mediated by weight loss (WL). Liver endpoints assessed at Week 48 in this mediation analysis included resolution of MASH without worsening of fibrosis, improvement in fibrosis without worsening of MASH, absolute change in enhanced liver fibrosis (ELF™) score, relative change in propeptide of type III collagen (PRO-C3), FibroScan®-aspartate transaminase (FAST) score, liver stiffness measurement (LSM; FibroScan), and magnetic resonance imaging proton density fat fraction (MRI-PDFF). The model included treatment and percentage change in body weight, with baseline body weight, type 2 diabetes status, and fibrosis stage as covariates. We present the total treatment effect (TE) or total odds ratios (OR) and percentages mediated (% med), i.e., the proportion mediated by WL (the indirect effect of changes in body weight in relation to the total effect). Upper and lower limits presented are 95% confidence intervals.
Results: Changes in liver endpoints were mediated through WL with varying degrees of attribution. Liver endpoints that were highly mediated by WL were resolution of MASH without worsening of fibrosis (% med: 66.7% [41.3, 92.2%]; response rate: 62.9 vs 13.0% for placebo; OR: 14.70), or changes in MRI-PDFF (% med: 58.2% [43.5, 72.8%]; TE: −50.3 [−60.1, −40.5]). Endpoints for which WL had a

lower attribution were improvement in fibrosis without worsening of MASH (% med: 36.3% [−15.0, 87.7%]; response rate: 52.6 vs 25.9% for placebo; OR: 3.68), ELF score (% med: 38.6% [14.4, 62.7%]; TE: −0.64 [−0.83, −0.45]), PRO-C3 (% med: 25.2% [4.3, 46.1%]; TE: −28.63 [−36.38, −20.88]), FAST score (% med: 27.1% [10.6, 43.5%]; TE: −65.16 [−79.13, −51.18]), and LSM (% med: 35.1% [14.6, 55.7%]; TE: −38.78 [−49.08, −28.49]).
Conclusion: The results suggest that MASH resolution induced by survodutide was broadly mediated by WL. However, liver endpoints related to improvement in inflammation and fibrosis were less so, suggesting the reduction in these endpoints can be attributed to a direct effect of survodutide on the liver, likely via direct glucagon effect beyond WL.

OS-099

Personalised prediction of the individual risk of liver-related complications in MASLD using the dynamics of non-invasive tests of liver fibrosis

Email: clemence.moreau@chu-angers.fr

Background and aims: Recent data suggest that monitoring the evolution of non-invasive tests of liver fibrosis helps to refine prognosis assessment in patients with MASLD. However, interpreting the variation of repeated non-invasive tests is challenging in clinical practice. We aimed to develop a model that uses the dynamics of non-invasive tests to provide a personalised prediction of liver-related events (LRE) in MASLD.
Method: We used an international multicentre cohort of MASLD patients with longitudinal follow-up data including liver stiffness measurements (LSM) by vibration-controlled transient elastography. The study outcome was LRE, a composite endpoint including decompensation of cirrhosis and/or hepatocellular carcinoma. Joint latent class modelling (JLCM), taking into account biomarker trajectory (longitudinal part of the model) and LRE occurrence (survival part), was developed to compute dynamic predictions resulting in a personalised prediction of the risk of LRE (0% to 100% at chosen time horizons). As repeated measurements were available during follow-up, JLCM was compared with FIB-4 and LSM at baseline and at each follow-up visit.
Results: 13,627 patients were included in the analysis, with 238 LRE occurring during a median follow-up of 4.0 years (IQR: 2.1–5.9). LSM trajectory adjusted on FIB-4 and gender (longitudinal part) and age with platelets (survival part) were selected by JLCM for LRE prediction. Calibration plots showed very good agreement between the predicted risk of LRE by JLCM and the observed incidence of LRE during follow-up. JLCM provided the highest discrimination for LRE: integrated AUROCs calculated at baseline and the different follow-up visits ranged 0.872–0.888 and were significantly higher than those obtained with LSM alone (0.853–0.864, all $p < 0.034$) or with FIB-4 alone (0.829–0.847, all $p \leq 0.001$). We calculated thresholds to delineate three risk groups according to the 5-year risk of LRE: low risk (≥ 80% sensitivity for LRE), intermediate risk, and high risk (≥ 95% specificity for LRE). These thresholds were 0.45%/1.51% per year for JLCM, 10/17 kPa for LSM, and 1.73/3.35 for FIB-4. At baseline and at each follow-up visit, JLCM included 85–89% of the patients in the low-risk group. 67–72% of the patients who experienced LRE during the follow-up were included in the high-risk group with JLCM, compared to 54–56% with LSM and 46–50% with FIB-4.
Conclusion: By automatically integrating and interpreting the dynamics of non-invasive tests of liver fibrosis, a new model provides an accurate and personalised assessment of the individual risk of liver-related complications in patients with MASLD.

Long term clinical outcomes in patients with chronic hepatitis C after direct-acting antiviral treatment: a prospective study

Riham Soliman[1,2], Ayman Hassan[2], Nabiel Mikhail[3], Nada El-domiaty[4], Ahmed Farahat[5], Gamal Shiha[2,6]. *[1]Tropical Medicine Department, Faculty of Medicine, Port Said University, Egypt, Port Said, Egypt; [2]Egyptian Liver Research Institute and Hospital (ELRIAH), Sherbin, El Mansoura, Egypt, Sherbin, Egypt; [3]Egyptian Liver Research Institute & Hospital (ELRIAH), shirbin, Egypt; [4]Tropical Medicine Dept., Faculty of Medicine, Helwan University, Helwan, Egypt; [5]Egyptian Liver Research Institute and Hospital, Mansoura, Egypt; [6]Hepatology and Gastroenterology Unit, Internal Medicine Department, Faculty of Medicine, Mansoura University, Egypt, Mansoura, Egypt*
Email: rimo1979@gmail.com

Background and aims: The long-term clinical outcome following direct acting antivirals for hepatitis C virus infection has not been yet documented despite the fact that they have been widely used. A total of 14,495 CHC patients received treatment in outreach program "Educate, Test and Treat" among 73 villages in Egypt since 2015. Our aim was to report the incidence of decompensated cirrhosis, hepatocellular cancer, and all-cause mortality in addition to fibrosis changes among patients received direct-acting antiviral therapy over a 10-years period.
Method: We conducted a prospective study including patients who received DAAs since 10 years enrolled from eleven Egyptian villages up till now. Patients with a history of decompensated cirrhosis, hepatocellular cancer, liver transplantation, or chronic hepatitis B were not included in our analysis, nor were those receiving interferon-ribavirin treatment. Our primary aim was to report the incidence of decompensated cirrhosis, hepatocellular cancer, and all-cause mortality. Secondary objective was detection of liver fibrosis changes, by FibroScan or FIB-4 and FIB-6.
Results: 1603 patients were eligible for the study, with available follow-up information and were included in analyses. Median follow-up was 98.0 months (IQR 71.0–105.0). During follow-up, 377 patients

died, 32 reported decompensated cirrhosis and 41 reported hepatocellular carcinoma. Exposure to direct-acting antivirals was associated with all-cause mortality rate of 3.42/100 py (95% CI 3.08–3.77), decompensation of 0.26/100 py (95% CI 0.18–0.36), and hepatocellular carcinoma of 0.51/100 py (95% CI 0.11–0.25). In cirrhotic patients, 17% showed reversal of cirrhosis, 19.1% showed fibrosis regression while 63.8% remained stationary. F3 patients showed reversal of fibrosis in 44.4%, 19.8% showed fibrosis regression and 19.8% remained stationary while 16.0% progressed to F4.
Conclusion: This is the first study to document the long-term outcomes for patients treated with direct-acting antivirals (DAAs) for hepatitis C virus infection in Egyptian patients with genotype 4. Our findings demonstrate that DAAs are associated with a decreased risk of decompensation and hepatocellular carcinoma, and often lead to improvements in liver fibrosis. Further studies involving different ethnicities and genotypes are needed.

OS-101-YI
Concomitant diabetes mellitus in untreated chronic hepatitis B with low-level viremia is associated with increased risk of hepatocellular carcinoma: validating the world health organization 2024 recommendations
Rex Wan-Hin Hui[1], Xianhua Mao[1], Matthew Shing Hin Chung[1], Lu Li[1], Grace Lai-Hung Wong[2], Terry Cheuk-Fung Yip[2], Lung Yi Loey Mak[1], Man-Fung Yuen[1], Wai-Kay Seto[1]. *[1]The University of Hong Kong, Hong Kong, Hong Kong; [2]The Chinese University of Hong Kong, Hong Kong, Hong Kong*
Email: huirex@connect.hku.hk

Background and aims: The World Health Organization (WHO) 2024 guidelines recommended antiviral therapy in chronic hepatitis B (CHB) patients with diabetes mellitus, regardless of hepatitis B virus (HBV) DNA, fibrosis status or alanine aminotransferase (ALT) levels. The benefits of treatment expansion to these patients have not been well defined.
Method: We enrolled CHB patients, defined via hepatitis B surface antigen positivity or ICD-9 coding, who newly presented to a population-wide electronic health registry between 2011 to 2015. Patients with concomitant liver diseases (other than metabolic associated steatotic liver disease), history of hepatocellular carcinoma (HCC), or HCC diagnosed within 6 months after the entry date were excluded. Diabetes mellitus was defined as glycosylated haemoglobin ≥ 6.5%; fasting serum glucose ≥ 7 mmol/L, use of antidiabetic medications or ICD-9 coding. The primary outcome was incident HCC development, and multivariate Cox regression models were applied to calculate adjusted hazard ratio (aHR) and 95% confidence intervals (95%CI).
Results: Among 38979 CHB patients (mean age 47.5 +/− 15.4 years; 41.9% male, 43.3% on antiviral therapy for a median of 5.2 years, 24.3% with newly diagnosed diabetes during study period). Diabetes was an independent predictor of HCC (aHR 1.53, 95%CI 1.29–1.82), and this association remained robust after stratification by age, sex, antiviral treatment, Fibrosis-4 score, AST to platelet ratio index, HBV DNA levels, and alanine aminotransferase levels (aHR: 1.34–4.91). Among the 22096 untreated patients, diabetes was associated with a 1.5-fold increased risk of HCC (aHR 1.50, 95% CI 1.07–2.10), with the association remaining significant in patients with baseline HBV DNA <2000 IU/mL (aHR 1.53, 95%CI 1.09–2.14) or FIB-4 ≤ 3.25 (aHR 1.94, 95%CI 1.24–3.04). When focusing on patients with concomitant CHB and diabetes, antiviral treatment was independently associated with reduced HCC risk (aHR 0.76, 95%CI 0.68–0.84), with more prominent risk reduction in patients < 65 years (aHR 0.64, 95% CI 0.56–0.74); as compared to age ≥ 65 years (aHR 0.91, 95% CI 0.78–1.07) ($P_{interaction}$ for age <0.001).
Conclusion: Concomitant diabetes mellitus was associated with increased HCC risk in CHB, including in untreated patients with low-level viremia or non-advanced liver fibrosis. The risk reduction effects of antiviral treatment were more pronounced in younger patients. These findings support the WHO 2024 recommendations in expanding CHB treatment to patients with concomitant diabetes mellitus.

OS-102
Mortality benefits of a national program of supported, active care in the treatment of marginalised people with chronic HCV infection
Ruth Simmons[1], Monica Desai[1], Sema Mandal[1], Matthew Hickman[2], Ross Harris[1], Mark Gillyon-Powell[3], Beatrice Emmanouil[3], Graham R. Foster[4]. *[1]UKHSA, London, United Kingdom; [2]Bristol University, Bristol, United Kingdom; [3]NHS England, London, United Kingdom; [4]QMUL, London, United Kingdom*
Email: g.r.foster@qmul.ac.uk

Background and aims: Chronic hepatitis C infection is common in marginalised, deprived communities, including those actively using drugs. Given the high mortality in these populations the benefits of treating hepatitis C are unclear. The English Hepatitis C Elimination program focussed on providing holistic care and support to deprived people with hepatitis C and here we report on its impact.
Method: Retrospective review of National Health Service England Hepatitis C Registry data and United Kingdom Health Security Agency mortality data between 2015 and 2022. Standardised mortality ratios (SMR) of the observed number of deaths in people treated and cured of hepatitis C who did not have significant liver disease were compared to the expected number of deaths using general population mortality rates by age, sex, year, and Index of Multiple Deprivation (IMD) were calculated.
Results: Between 2015 and 2022, following the introduction of the comprehensive hepatitis C elimination program 38,429 individuals without evidence of cirrhosis were successfully treated, a large proportion were from deprived communities and 15.7% had a history of homelessness. 1548 (4.0%) died. 23,718 had sufficient data to assign an index of deprivation at diagnosis, of which 67% resided in the 2 most deprived quintiles when first diagnosed. Post treatment mortality, assessed by SMRs, did not differ significantly in affluent cohorts (IMD 4 SMR = 1.2 (1.0–1.5), and 5 (SMR 0.9 (0.6–1.1) and was marginally increased in highly deprived cohorts (IMD 1 = 1.2 (1.1–1.3), IMD 2 = 1.1 (1.0–1.2)). However during the first three years of the program SMRs in the most deprived cohorts were substantially reduced when compared to untreated controls but this benefit reduced with time and, during COVID, SMRs increased, peaking in 2021 before falling again in 2022. The reductions in benefits of the program seen over time may reflect either engagement of a more marginalised cohort in the later years of the program or a reduction in support provided as commitment to the program reduced.
Conclusion: Mortality in people with hepatitis C, who do not have cirrhosis and are effectively treated in a supportive holistic program is not increased compared to appropriate control populations. A comprehensive package of care for people with hepatitis C is associated with beneficial effects on mortality but the impact reduces over time.

Email: f.hinte@uke.de

Background and aims: Hepatitis E virus (HEV) infection has an emerging clinical relevance for patients worldwide, but there is currently no approved antiviral therapy. For immunosuppressed people with chronic hepatitis E, off-label treatment with ribavirin is used in daily clinical practice, but ribavirin can cause serious side effects and resistance does emerge. Therefore, there is an urgent need for new and effective antiviral drugs against HEV infection. The adenosine nucleoside analogue NIDT008 is one such candidate that has been shown to be effective in preclinical studies against a broad range of RNA viruses. The aim of this study was to evaluate the efficacy of NITD008 in vivo in human liver chimeric mice stably infected with HEV.
Method: Immunodeficient human-liver chimeric mice were infected with hepatitis E virus (genotype 1) via the co-housing fecal-oral route. After a stable infection was achieved (6–8 weeks), median HEV RNA viremia was 1.5×10^7 IU/ml, mice received 20 µg/g of NITD008 by oral gavage daily for up to 2 weeks, while a control group received mock treatment. Viral changes were determined by qPCR in faeces and blood. Mice were sacrificed after 1 or 2 weeks of treatment, while a subgroup was observed for a 3-week rebound phase. Intrahepatic analysis including immunohistochemistry, multiplex RNA in situ hybridization (RNA-ISH) and qPCR was performed in all mice at sacrifice.
Results: NITD008 effectively reduced fecal HEV loads by up to 4log already in the first week of treatment, with some mice showing no detectable virus shedding. All mice had undetectable serum HEV titers (LLoQ) after 7 days, while vehicle-only controls showed no decrease in fecal and serum viral titers (median 7.7×10^6 IU/mL and 1×10^6 copies/ml, respectively). Intrahepatic analysis showed a 1.5 log reduction in HEV RNA/human housekeeper levels in treated mice compared to controls after 1 week of treatment and a 2.5 log reduction after 14 days of treatment. Consistent with the qPCR data, RNA-ISH analysis confirmed the presence of only a few weakly HEV-RNA-positive human hepatocytes in treated mice, whereas approximately 95% of human liver cells were strongly positive in control animals. Two weeks of NITD008 administration did not induce ALT elevation or significant weight loss in treated mice. Despite the strong reduction in HEV infection, HEV rebound was observed after 3 weeks of treatment cessation in this immunodeficient system.
Conclusion: This study demonstrates the efficacy and non-toxicity of the adenosine nucleoside analog NITD008 towards human hepatocytes after only 2 weeks of treatment in HEV infected human-chimeric mice. Longer treatment periods and/or combination regimens with ribavirin are needed to further optimize results and eventually achieve complete viral clearance even in the absence of a humoral immune response.

Email: gepapath@med.uoa.gr

Background and aims: There is very few data from trials or real-life cohorts about the long-term outcomes of chronic hepatitis B (CHB) patients treated with a high-genetic barrier nucleos(t)ide analogue (NA). We assessed the incidence of major outcomes in the real-life PAGE-B cohort focusing on patients treated for >10 years.
Method: The PAGE-B cohort included 1951 adult Caucasians with CHB, with or without compensated cirrhosis, who were treated with entecavir/tenofovir being followed at 10 centers. Eight centers which originally included 1644 (84%) of the 1951 patients participated in the follow-up study beyond year 10. Cumulative incidence rates were assessed from both Kaplan-Meier curves and Fine & Gray's models taking into account relevant competing risks.
Results: Of the 1644 patients (baseline age: 53 ± 14 years, 72% males, 17% HBeAg+, 28% cirrhotics), 842 cases (51%) (baseline age: 51 ± 13 years, 71% males, 19.5% HBeAg+, 31% cirrhotics) were followed beyond year 10 for a mean of 14 ± 2 years. Hepatocellular carcinoma (HCC) developed in 174 (10.6%) patients (157 until and 17 after year 10). The 5-, 10- and 15-year cumulative HCC rates (95% CI) were 6.8% (5.6–8.1), 10.8% (9.2–12.5) and 13.7% (11.8–15.8), respectively (Fine-Gray), whereas the HCC incidence rate (95% CI) per 100 patient-years was 1.25 (1.07–1.46) until and 0.83 (0.55–1.23) after year 10 ($p = 0.073$). There were 176 deaths until and 63 deaths after year 10 (liver related deaths: 77 and 19), whereas 18 and 4 patients underwent liver transplantation (LT), respectively. Death/LT incidence rate (95% CI) per 100 patient-years was lower until than after year 10 [1.50 (1.30–1.72) vs 2.21 (1.74–2.80), $p = 0.008$], but liver related death/LT rate did not differ between the two periods [0.73 (0.60–0.90) vs 0.76 (0.50–1.14), $p = 0.872$]. HBsAg loss was observed in 191 (11.6%) patients. The 5-, 10- and 15-year cumulative HBsAg loss rates (95% CI) were 5.0% (4.0–6.1), 9.4% (8.0–11.1) and 17.0% (14.6–19.6), respectively (Fine-Gray), whereas the HBsAg loss incidence rate (95% CI) per 100 patient-years was 1.06 (0.89–1.25) until and 2.04 (1.58–2.64) after year 10 ($p < 0.001$). NA was discontinued in 218 (13.3%) patients [125 (7.6%) before and 93 (5.7%) after HBsAg loss]. NA discontinuation before HBsAg loss was the main factor associated with higher HBsAg loss rates [Crude Hazard Ratio (95% CI) vs patients remaining on NA: 5.58 (3.80–8.28), $p < 0.001$]. The 1-, 3- and 5-year cumulative HBsAg loss rates after NA discontinuation were 5%, 14% and 24%, respectively.
Conclusion: CHB patients remain at risk for HCC after 10 years of NA therapy with a numerical but not significant decline in the annual HCC incidence over time. A small proportion (<10%) of patients who remain HBsAg positive discontinue NA therapy, which is associated with significantly increased HBsAg loss rates.

Abstract LBP-016 is under embargo until Wednesday 7 May 2025, 08:00 CET, after which this abstract will be made publicly available on the congress website and will be released for publication in the supplement issue of the *Journal of Hepatology*.
Industry must not issue press releases – even under embargo – covering the data contained in abstracts selected to be highlighted during official EASL Press Office activities or in official EASL Press Office materials until the individual embargo for each data set lifts.
Media must not issue coverage of the data contained in abstracts selected to be highlighted during official EASL Press Office activities or in official EASL Press Office materials until the individual embargo for each data set lifts.
Journalists, industry, investigators and/or study sponsors must abide by the embargo times set by EASL. Violation of the embargo will be taken seriously. Individuals and/or sponsors who violate EASL's embargo policy may face sanctions relating to current and future abstract submissions, presentations and visibility at EASL Congresses. The EASL Governing Board is at liberty to ban attendance and/or retract data.
Copyright for abstracts (both oral and poster) on the website and as made available during The EASL Congress 2025 resides with the respective authors. No reproduction, re-use or transcription for any commercial purpose or use of the content is permitted without the written permission of the authors. Permission for re-use must be obtained directly from the authors.

Abstract LBP-024 is under embargo until Wednesday 7 May 2025, 08:00 CET, after which this abstract will be made publicly available on the congress website and will be released for publication in the supplement issue of the *Journal of Hepatology*.
Industry must not issue press releases – even under embargo – covering the data contained in abstracts selected to be highlighted during official EASL Press Office activities or in official EASL Press Office materials until the individual embargo for each data set lifts.
Media must not issue coverage of the data contained in abstracts selected to be highlighted during official EASL Press Office activities or in official EASL Press Office materials until the individual embargo for each data set lifts.
Journalists, industry, investigators and/or study sponsors must abide by the embargo times set by EASL. Violation of the embargo will be taken seriously. Individuals and/or sponsors who violate EASL's embargo policy may face sanctions relating to current and future abstract submissions, presentations and visibility at EASL Congresses. The EASL Governing Board is at liberty to ban attendance and/or retract data.

Copyright for abstracts (both oral and poster) on the website and as made available during The EASL Congress 2025 resides with the respective authors. No reproduction, re-use or transcription for any commercial purpose or use of the content is permitted without the written permission of the authors. Permission for re-use must be obtained directly from the authors.

Acute liver failure and drug induced liver injury – Basic

TOP-249

Signaling interaction between TGF-β and EGF controls LPC proliferation and performing liver function in ALF

Chenhao Tong[1], Seddik Hammad[1], Matthias Ebert[2,3,4], Steven Dooley[1], Honglei Weng[1]. *[1]Department of Medicine II, Section Molecular Hepatology, University Medical Center Mannheim, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany; [2]Department of Medicine II, University Medical Center Mannheim, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany; [3]DKFZ-Hector Cancer Institute at the University Medical Center, Mannheim, Germany; [4]Molecular Medicine Partnership Unit, European Molecular Biology Laboratory, Heidelberg, Germany*
Email: chenhao.tong@medma.uni-heidelberg.de

Background and aims: In acute liver failure (ALF), massive hepatic necrosis (MHN) results in severe clinical manifestations and high mortality. Remarkably, liver progenitor cells (LPCs) can rescue ALF in patients through performing vital liver function. To date, key signaling inducing LPC proliferation and initiating liver functional gene expression remains largely unknown. This study aims to investigate how LPCs maintain quiescence under physiological conditions and how they are activated in ALF towards rapid proliferation and taking over liver-specific functions.
Method: SMAD7 transgenic mice were fed with DDC diet to examine the role of TGF-β signaling in LPC proliferation. Spatial transcriptomics was performed on 4 ALF patient liver samples to analyze cell-cell communication between LPCs, hepatocytes and macrophages. Mechanistically, integration of TGF-β and EGF signaling pathways was investigated in the LPC line HepaRG through multiple cellular and molecular approaches, including colony formation, cell cycle analysis, qPCR, immunoblot, immunofluorescence staining, and ChIP-qPCR.
Results: Cytostatic TGF-β signaling maintains LPC quiescence under physiological conditions through impeding G1-S phase transition. Overexpression of SMAD7 increases LPC proliferation in DDC-fed mice by inhibiting TGF-β-induced SMAD3 phosphorylation. In ALF, significant levels of TGF-β are still present, provided from activated macrophages, rather than hepatic stellate cells. Interestingly, despite the presence of TGF-β signaling, in this setting LPCs are proliferating. Mechanistically, EGF signaling effectively inhibits the anti-proliferative TGF-β effect through multiple mechanisms. EGF induces FOXO1 phosphorylation and nuclear exclusion, thereby preventing canonical SMAD-mediated transcription of the cell cycle inhibitors. Additionally, EGF promotes expression of c-MYC, which directly binds to CCND1 gene regulatory regions to drive cyclin D1 expression. Notably, while TGF-β signaling remains active in proliferating LPCs, it avoids the cytostatic outcome while initiating liver-specific gene expression. For example, canonical TGF-β/SMAD signaling and c-MYC synergistically regulate transcription of Apolipoprotein A (APOA) and Transferrin (TF) in LPCs.
Conclusion: Our study provides novel insights into how LPCs remain non-proliferative in healthy liver and how they may rapidly achieve proliferative activity and take over liver-specific functions following MHN. Cytostatic TGF-β-SMAD signaling physiologically keeps LPC quiescent. In ALF, EGF overrides TGF-β's growth-inhibitory effects. However, TGF-β-SMAD signaling is still required for liver functional gene expression in LPCs.

FRIDAY 09 MAY

FRI-136

Biomimetic ceria lipoprotein nanoparticle enable NAC-enhanced macropinocytosis-dependent liver-targeting delivery for the treatment of APAP-induced liver injury

Yaoxing Chen[1], Gan Jiang[2], Yan Huang[1], Shuying Song[1], Haoshuang Fu[1], Bingying Du[1], Xiaoling Gao[2], Qing Xie[1]. *[1]Department of Infectious Diseases, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; [2]Department of Pharmacology and Chemical Biology, State Key Laboratory of Systems Medicine for Cancer, Shanghai Universities Collaborative Innovation Center for Translational Medicine, Shanghai Jiao Tong University School of Medicine, Shanghai, China*
Email: xieqingrjh@163.com

Background and aims: Drug-induced liver injury (DILI) is a severe liver disease mainly caused by the overdosed acetaminophen (APAP), resulting in excessive reactive oxygen species (ROS). N-acetylcysteine (NAC) is the currently only approved drug, but with limited application due to the short therapeutic time window and concentration-related side effects. Therefore, novel strategies to improve the therapeutic effect for DILI need to be explored. Ceria has the antioxidant effect with the potential for the treatment of DILI. Nevertheless, the bare forms tend to agglomerate and thus cause failure of lesion targeting, reduced biological activity, and potential toxicity. Therefore, we developed lipoprotein-based nanoparticle (CeO_2-rHDL) to achieve efficient DILI lesion accumulation of ceria to achieve synergic therapeutic effect.
Method: CeO_2-rHDL were successfully constructed. The electron microscopy and dynamic light scattering detector were utilized for the characterization. The liver-targeting capacity was evaluated via in vivo imaging system and confocal microscope. Therapeutic efficacy to improve the DILI prognosis was evaluated by in vitro studies, survival analysis, serum liver function indicators and immunohistochemical staining.
Results: The average size of CeO_2-rHDL was 32.87 ± 3.39 nm, presenting a spherical morphology. The in vivo distribution showed that the enrichment of CeO_2-rHDL in the liver can augment after APAP-induced liver injury, which was further enhanced by NAC. After the pre-treatment with inhibitors of various uptake pathways, the internalization of CeO_2-rHDL into hepatocytes was only inhibited via the macropinocytosis inhibitor by almost 70%, which can also effectively reduce the in vivo accumulation at the liver by 40%. CeO_2-rHDL was proved to reduce ROS and improve mitochondria function. In the DILI model, CeO_2-rHDL can significantly improve liver function with the reduction of liver necrosis. This therapeutic efficiency can be further improved by the combination with NAC with 100% survival rate for 72 h.
Conclusion: This study has developed CeO_2-rHDL for the treatment of DILI. Double-enhanced macropinocytosis-dependent uptake mediated the efficient liver targeting. CeO_2-rHDL rescued the injured mitochondria by reducing cellular ROS. It could improve the prognosis of DILI-bearing mice with the combination with NAC. Overall, this therapeutic nanoplatform provides a novel strategy for the DILI treatment.

FRI-137

Flavin-containing monooxygenase 3 (Fmo3) knockout mouse reveals the role of Fmo3 in female tolerance to acetaminophen-induced liver injury

Chibuisi Alimba[1], Philipp Gabrys[1], Ahmed Gallab[1], Jörg Reinders[1], Diana Shih[2], Aldons Lusis[3], Jan G. Hengstler[1], Cristina Cadenas[1]. *[1]Leibniz Research Centre for Working Environment and Human Factors, Technical University Dortmund, Dortmund, Germany; [2]Department of*

Medicine, University of California, Los Angeles, United States, [3]University of California, Los Angeles, United States
Email: alimba@ifado.de

Background and aims: Sexual dimorphism causes significant differences in hepatic gene expression that considerably influence drug metabolism. Females are usually more susceptible to drug induced acute liver injury (ALI). Interestingly, female mice are more resistant to acetaminophen (APAP) induced hepatotoxicity. APAP, the most commonly used analgesic and antipyretic drug, causes about 50% of global cases of drug induced ALI. Flavin-containing monooxygenase-3 (Fmo3), predominantly expressed in human and mice female liver, oxygenate some drugs, xenobiotic and endogenous compounds containing nucleophilic heteroatoms. Fmo3 expression in mouse model of APAP autoprotection was associated with tolerance to APAP overdose in female mice. However, unequivocal evidence supporting the role of Fmo3 in protecting against APAP induced hepatotoxicity is unknown. This study explores possible mechanisms underlying Fmo3-mediated resistance to APAP overdose induced hepatotoxicity using Fmo3 knockout (Fmo3KO) mice.
Method: Fmo3KO and wildtype (wt) mice of both sexes were intraperitoneally injected with 250 mg/kg body weight of APAP. Liver tissue and plasma were collected at different time points until 72 h. Plasma aminotransferases (ALT & AST) were quantified using PiccoloXpress® Chemistry analyzed. Bile acids, APAP metabolites and glutathione (GSH) levels in liver were measured using LC/MS. Expression of key detoxification enzymes and transporters was analyzed using quantitative real-time PCR, Western blotting and immunochemistry. Tissue metabolites were investigated using MALDI imaging technique.
Results: Loss of Fmo3 expression was confirmed in Fmo3KO females. Baseline expression of APAP metabolizing enzyme, Cyp2e1 and plasma biochemistry were similar in both genotypes and sexes. Twenty-four hours after APAP injection, centrilobular necrosis was mild in the liver of wt female, but severe in the liver of female Fmo3KO, as well as in wt and Fmo3KO male mice. This was confirmed by ALT and AST plasma levels. Liver GSH levels at different time points after APAP treatment showed that female wt mice replenished GSH faster than female Fmo3KO mice. The upregulation of Fmo3 expression within pericentral region of the centrilobular necrosis correlated with faster GSH recovery. However, no alteration in mRNA expression of the GSH synthetic enzyme (Gclc) was observed. Plasma Bile acid did not differ significantly between groups. However, significant reduction of plasma APAP-GSH and APAP-NAC conjugates in wt female mice, correlated with lower expression of Abcc4 transporter gene.
Conclusion: The findings provide evidence for the role of Fmo3 in quick recovery from APAP-induced hepatotoxicity, via regulation of GSH biosynthesis and expression of detoxification enzymes and transporter molecules that limit intracellular accumulation of APAP toxic metabolites.

FRI-138-YI

Enhanced prediction of drug-induced liver injury in keratinocyte-based high-content single-cell screening integrating machine learning

Email: ang.remesal@gmail.com

Background and aims: Idiosyncratic drug-induced liver injury (DILI) presents challenges for drug safety. A significant issue is the weak correlation between animal studies and clinical DILI, making effective in vitro models crucial for drug development. Although primary human hepatocyte cultures are standard for predicting hepatotoxicity, their extraction and maintenance present challenges limit assay types. Recent findings connect liver and skin, indicating keratinocytes might be a new tool for DILI prediction. This study enhanced a High-Content Single-Cell Screening (HCSCS) assay using keratinocytes with 20 control drugs from the ProEuroDILI Network. We aim to improve the predictive ability of this model through machine learning, enhancing in vitro DILI assessment systems.
Method: The HaCaT keratinocyte cell line was used in all experiments. Cells were seeded in a 96-well plate and, after 24 hours, exposed to 10 positive and 10 negative DILI compounds at varying Cmax concentrations. Cells were stained with fluorescent markers, and parameters such as morphology, cell cycle phase, count, mitochondrial potential, area, and oxidative stress were measured at population and single-cell levels. HCSCS imaging utilized the Operetta CLS system with automated analysis via Harmony 4.9, evaluating morphological, functional, viability, and mitosis endpoints. Additional single-cell analysis employed R, and machine learning algorithms classified DILI+ and DILI- compounds.
Results: DILI-positive drugs showed significant toxicity in HaCaT cells. Chlorpromazine and valproate reduced cell numbers at low concentrations (<30Cmax), increasing cell area and morphology. Tamoxifen had minimal impact on counts but increased ROS and altered mitochondrial potential. At intermediate doses (60–100Cmax), chlorpromazine was the most toxic, drastically lowering cell counts. Valproate caused nuclear enlargement but reversed changes at higher concentrations (>150Cmax). Tamoxifen produced smaller, round cells with increased ROS as mitochondrial function declined. DILI-negative drugs had limited effects; diphenhydramine slightly reduced cell numbers at high doses. Caffeine and lidocaine had mild impacts. These results provided robust datasets for toxicity classification, with machine learning models improving predictions for DILI-positive versus DILI-negative drugs. The SVM model trained on single-cell data at 150Cmax reached an F1-score of 0.813 and ROC-AUC of 0.89, highlighting the importance of morphological and functional parameters in drug toxicity classification.
Conclusion: Integrating keratinocytes with high-content screening and machine learning enhances DILI prediction and drug screening. This approach may significantly impact clinical practices, as keratinocytes are more accessible than hepatocytes, facilitating personalized patient models for disease study.

Lipid metabolites in acute and chronic liver damage: Do N-acyl taurines protect the liver?

Anna Hassing[1], Samuel Trammell[1], Cristina López-Vicario[2], Magnus Grøndahl[3], Nikolaj Rittig[4,5], Lise Lotte Gluud[6,7], Filip Krag Knop[3,7,8], Joan Clària[2], Trisha Grevengoed[1]. *[1]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark; [2]Biochemistry and Molecular Genetics Service, Hospital Clínic, IDIBAPS, Barcelona, Spain; [3]Center for Clinical Metabolic Research, Copenhagen*

University Hospital Herlev and Gentofte, Hellerup, Denmark; [4]Medical/Steno Aarhus Research Laboratory, Aarhus University Hospital, Aarhus University, Aarhus, Denmark; [5]Steno Diabetes Center Aarhus, Aarhus University Hospital, Aarhus, Denmark; [6]Gastro Unit, Medical Unit, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark; [7]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; [8]Novo Nordisk A/S, Søborg, Denmark
Email: anna.hassing@sund.ku.dk

Background and aims: N-acyl taurines (NAT) represent an understudied class of bioactive lipids composed of a fatty acid conjugated to taurine synthetized mainly by the liver and kidney. NATs are found in both plasma and bile, where they accumulate rapidly upon hydrolysis inhibition, a characteristic of many potent signaling molecules. Rodent models have shown promising effects of elevated levels of poly- and monounsaturated fatty acid containing NATs on metabolic health through improved insulin tolerance and resistance to liver steatosis. Interestingly, we observed that plasma NAT concentrations were increased in individuals 3 hours after lipopolysaccharide (LPS) stimulation as well as in non-cirrhotic metabolic dysfunction-associated steatotic liver disease (MASLD), suggesting NAT levels respond to both acute and chronic liver damage.
Method: To investigate if circulating NAT levels were also affected by more severe liver damage, NAT concentrations were measured in plasma from two independent clinical studies. The first study consisted of individuals with all-cause liver cirrhosis (compensated), chronic kidney disease (CKD) and matched controls. The second study consisted of individuals with acute decompensated liver cirrhosis and matched controls. To gain mechanistic insights into the causative role of NATs in liver damage development, *in vivo* rodent models with either elevated or reduced NAT abundance were treated with hepatotoxic doses of LPS or paracetamol and changes in plasma alanine transaminase (ALT) were assessed.
Results: Both compensated and decompensated liver cirrhosis patients had elevated levels of several species of NATs compared to matched controls, while levels were unaffected in CKD patients indicating the increase was specifically associated to damage of the liver. In mice, elevated NAT concentrations prevented LPS- and paracetamol-induced increases in plasma ALT, while reduced hepatic NAT synthesis caused an exaggeration of the response suggesting a protective role of NATs towards liver damage.
Conclusion: Impaired liver function leads to elevation of NAT levels in humans, but not impaired kidney function suggesting NATs are potentially relevant in human liver diseases. The ability of NATs to modulate liver damage severity in mice suggests this elevation potentially occurs as a compensatory mechanism in order to preserve liver function during acute and chronic injury.

FRI-140
Drug-induced hepatic sinusoidal obstruction syndrome: clinical characteristics analysis and preliminary exploration of mechanisms

Mingyan Ji[1], Hong Gao[1]. *[1]Zhongshan Hospital, Fudan University, Shanghai, China*
Email: gao.hong@zs-hospital.sh.cn

Background and aims: Drug-induced hepatic sinusoidal obstruction syndrome (DI-HSOS) refers to HSOS caused by pyrrolizidine alkaloids (PAs) of traditional Chinese medicine, chemotherapy mainly containing oxaliplatin (OX), and other drugs. DI-HSOS is a type of drug-induced liver injury (DILI) primarily characterized by damage to hepatic sinusoids and central veins in the liver. This study aims to analyze the clinical characteristics of DI-HSOS patients, explore characteristic differential genes and their potential regulatory pathways, and preliminarily investigate the mechanisms of DI-HSOS to provide a foundation for clinical diagnosis and treatment improvement.
Method: A retrospective study was performed on patients diagnosed with DI-HSOS and Non-HSOS-DILI at Zhongshan Hospital, Fudan University between January 1, 2014, and December 31, 2023. Clinical data were gathered. High-throughput gene expression analysis using the Gene Expression Omnibus database (GEO) and our model compared sequencing data from PA-HSOS and OX-HSOS mouse models with healthy controls through robust rank aggregation (RRA) analysis and Venn diagrams to identify differentially expressed genes. Enrichment analyses identified potential regulatory pathways. Experiments such as qPCR were conducted to validate main pathway genes, while further validation and mechanism analyses were performed using cell models, mouse models, and patient liver samples.
Results: Data from 54 DI-HSOS and 85 Non-HSOS-DILI cases were analyzed. Clinically, PA-HSOS primarily presented with abdominal distension (100%), while 74.1% of OX-HSOS exhibited no symptoms, contrasting with non-HSOS-DILI's predominant jaundice (57.6%). Laboratory findings showed more significant decreases in platelets, prolonged PT, and elevated D-dimer levels in DI-HSOS compared to Non-HSOS-DILI ($p < 0.05$). Imaging showed heterogeneous density or signal variations on scans, with features like inferior vena cava narrowing assisting differentiation. Pathologically, liver sinusoidal dilation was rare in Non-HSOS-DILI, whereas hepatocyte necrosis and inflammation were more pronounced. Analysis of DI-HSOS mouse models revealed 180 differentially expressed genes, with 62 common across studies. Enrichment analyses indicated roles for cell adhesion and apoptosis pathways. Experimental validation highlighted 4 significant genes, with increased Melanoma Cell Adhesion Molecule (MCAM) protein levels and decreased ST6 Beta-Galactoside Alpha-2,6-Sialyltransferase 1 (ST6GAL1) in DI-HSOS.
Conclusion: PA-HSOS shows prominent abdominal distension alongside platelet and coagulation changes while OX-HSOS often lacks symptoms. Imaging and pathology combined with medication history aid in distinguishing DI-HSOS from Non-HSOS-DILI. Cell adhesion and apoptosis pathways may contribute to both PA-induced and OX induced-HSOS pathogenesis. It shows notable MCAM protein elevation and reduced ST6GAL1 expression in the DI-HSOS model.

FRI-141
A comparison of the protective effects of Rimtoregtide (HTD4010) and DUR-928 on acute liver failure in mice

Ru Bai[1], Junwei Cheng[1], Adrian Di Bisceglie[2], Leigh MacConell[2], Liping Liu[1]. *[1]HighTide Therapeutics, Inc., Shenzhen, China; [2]HighTide Therapeutics, Inc., Rockville, United States*
Email: lmacconell@hightidetx.com

Background and aims: Rimtoregtide (HTD4010) is a new 15 amino acid long synthetic peptide derived from the Reg3a protein with immunomodulatory, anti-inflammatory, and anti-apoptotic effects that was well tolerated in a first-in-human pharmacokinetic and safety study and is now being developed for acute inflammatory-related indications including acute liver failure and alcohol-related hepatitis. The intraperitoneal administration of lipopolysaccharide (LPS) alone or in combination with other hepatotoxins is a widely-used experimental model for inducing systemic and hepatic inflammation in rodents. The purpose of this study was 1) to test the potential protective effects of HTD4010 in an LPS-induced model mimicking acute liver failure in mice and 2) compare these effects to DUR-928, which is currently in late-stage development for the treatment of alcohol-associated hepatitis.
Method: In this study, male C57BL/6 mice were intravenously injected with 40 mg/kg LPS on Day 1 and divided into four groups including a model control (0.9% sodium chloride) group and a HTD4010 10 mg/kg/day group each dosed subcutaneously 1 hour and 8 hours after LPS injection on Day 1 then twice daily thereafter; and two DUR-928 50 mg/kg/dose groups, one dosed intravenously 1 hour after LPS injection; and the other, used to validate the DUR-928 results, was dosed 2 hours before LPS injection.

Results: HTD4010 10 mg/kg/day resulted in significant improvement in (greater than 2-fold) compared to the model control (87% vs 40%, $p < 0.01$). These protective effects of HTD4010 were significantly stronger than DUR-928 which showed some improvement in survival rates when administered 1 hour after the LPS injection (87% vs 53%, $p < 0.05$, respectively) but the fold-increase was less than that achieved with HTD4010. Of note, The protective effects of DUR-928 when treated prior to the LPS injection was consistent with what has been previously reported in the literature.
Conclusion: Treatment with HTD4010 resulted in significant protective effects in an LPS-induced mouse model mimicking acute liver failure. These findings provide evidence that HTD4010 may have a beneficial effect on acute liver conditions including alcohol-related hepatitis and other acute-inflammatory-related conditions.

FRI-142
ECM1 mitigates PAs-induced hepatic sinusoidal obstruction syndrome in mice by interacting with MMP9
Siqi Gao[1], Wanyu Ma[1], Yadong Fu[1], Qun Zhou[1], Wei Liu[1], Ping Liu[1], Jiamei Chen[1]. [1]*Key Laboratory of Liver and Kidney Diseases (Ministry of Education), Institute of Liver Diseases, Shuguang Hospital affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China*
Email: cjm0102@126.com

Background and aims: Hepatic sinusoidal obstruction syndrome (HSOS) is a rare yet life-threatening liver disease caused by pyrrolizidine alkaloids (PAs), hematopoietic stem cell transplantation, or chemotherapy drugs. The increase in hepatic matrix metalloproteinase 9 (MMP9) expression and activity is a significant contributor to the progression of HSOS. Nevertheless, the pathological mechanism and treatment strategies of HSOS remain unclear.
Method: RNA-sequencing analyse of liver samples from senecionine (SEN)-induced HSOS mice was performed. Wide type (WT) mice and hepatocyte-specific knockout of extracellular matrix 1 (ECM1) gene ($ECM1^{\Delta hep}$) mice were induced by SEN or monocrotaline (MCT), the classical PAs to induce HSOS. Furthermore, an adeno-associated virus vector (AAV) over-expressing ECM1 were injected by tail vein in HSOS mice. *In vitro*, SEN-induced AML12 cells injury and hepatic sinusoidal endothelial cells (HHSECs) injury were treated with ECM1 recombinant protein. Subsequently, the interaction between ECM1 and MMP9 was determined.
Results: RNA-sequencing results revealed that the signaling pathways of matrix metalloproteinases, platelet aggregation, inflammatory and immune response were significantly enriched in liver tissue of HSOS mice, whereas a decrease in oxidoreductase activities was noted. *Ecm1* was the most significantly down-regulated common gene in these pathways, along with an increase of *Mmp9* gene, which were further validated by western blot and qRT-PCR in both MCT- and SEN-induced HSOS mice. Moreover, a more severe pathological changes of hepatocyte necrosis, sinusoidal endothelial damage, inflammatory cell infiltration, and erythrocyte stasis was observed in $ECM1^{\Delta hep}$ HSOS mice compared with that in WT HSOS mice. However, hepatic ECM1 over-expression via AAV alleviated HSOS induced by SEN through down-regulating MMP9 expression and inhibiting MMP9 activity. In addition, PPI analysis and molecular docking analysis indicated a high-affinity protein/protein interaction between ECM1(amino acids 236–361) and MMP9 (catalytic domain). We further found that ECM1 bound directly to MMP9 and inhibited MMP9 activity through the experiments of the interaction between ECM1 and MMP9 protein. *In vitro*, the recombinant ECM1 protein enhanced the cellular viability in SEN- or MCT-induced AML12 cells and protected against SEN-induced HHSECs damage. In contact, knockdown of ECM1 in AML12 cells exacerbated SEN- or MCT-induced cell injury.
Conclusion: Hepatocyte ECM1 deletion aggravates the progression of HSOS, while ECM1 over-expression significantly attenuates HSOS induced both by SEN and MCT in mice by directly interacting with MMP9 to suppress MMP9 activity. This study reveals a previously unknown mechanism underlying the progression of HSOS and provides the experimental evidence for HSOS treatment through up-regulating ECM1.

Email: danieldizeo9@hotmail.com

Background and aims: Idiosyncratic drug-induced liver injury (DILI) is an adverse reaction to various drugs. Diagnosing DILI is challenging as it mimics other liver injuries such as autoimmune hepatitis (AIH) and viral hepatitis (VH) and existing biomarkers cannot effectively differentiate it from other diseases. Thus, investigating DILI-specific mechanisms is essential for developing diagnostic tools. Analyzing the circulating metabolome may reveal disease mechanisms for biomarker discovery. This study compares the metabolomes and metabolic pathways in DILI patients with those of other acute liver injuries, and healthy volunteers.
Method: Metabolomic profiling analyzed serum from patients with DILI ($n = 49$), non-DILI acute liver injury (ALI) (AIH $n = 16$; VH $n = 27$; others $n = 11$), and healthy controls ($n = 48$) using ultra-high-performance liquid chromatography with mass spectrometry (UHPLC-MS). 15 machine learning classification models were developed based on the metabolomic dataset, to predict DILI vs. ALI, AIH, or VH. Cross-validation methods were used to mitigate the small sample size typical in low-incidence diseases. Pathway analysis included metabolites with VIP >1 and $p < 0.05$, using MetaboAnalyst 6.0. Spearman correlation determined associations between metabolites and clinical variables.
Results: Metabolomic analysis showed distinct patterns with 27 metabolites differing between DILI and ALI. Changes were more pronounced in DILI vs. AIH than between DILI and VH. Phe-Phe and valine were elevated in DILI vs. AIH, while fatty and bile acids were reduced. Pathway analysis highlighted altered Phe and fatty acid metabolism in DILI vs. AIH, but not with VH. Correlation analysis revealed links between metabolites and liver injury markers: Phe-Phe was negatively correlated with AST and ALT, while glycocholic acid was positively correlated with bilirubin. The full dataset was utilized to develop machine learning models using 10 metabolite panels for cohort differentiation. Phe-Phe and PC(18:3/0:0) were crucial for distinguishing DILI vs. ALI (Random Forest, AUC = 0.70), while serine and glycocholic acid were key for classifying DILI vs. AIH (Logistic Regression, AUC = 0.85). Metabolic similarities between DILI and VH resulted in lower classification performance (Extra Trees Classifier, AUC = 0.65), suggesting shared pathophysiology mechanisms.
Conclusion: Metabolomic analysis highlights relevant metabolic pathways that could be investigated in the search for biomarkers and non-invasive diagnostic tools. Our models were optimized using cross-validation techniques but require further validation. The use of

a reduced panel of metabolites would facilitate potential clinical application.

Abrogation of hepatic TRb action protects the liver from acute liver injury

Denise Zwanziger[1], Manuela Kowalczyk[1], Frédéric Flamant[2], Karine Gauthier[2], Christian Lange[3], Lars Moeller[1]. [1]*University Duisburg-Essen, University Hospital Essen, Department of Endocrinology, Diabetes and Metabolism, Essen, Germany;* [2]*University Lyon, Institut de Génomique Fonctionnelle de Lyon, Lyon, France;* [3]*Ludwig-Maximilian-University Munich, Medical Clinic and Polyclinic II, Munich, Germany*
Email: denise.zwanziger@uk-essen.de

Background and aims: Overdose of acetaminophen (APAP) is a well-known trigger for acute liver failure. Even if the underlying mechanisms of ALF are not yet fully understood, it is well known that triiodothyronine (T3) positively favors hepatocyte proliferation via thyroid hormone receptor β (TRβ) signaling. We observed that abrogation of hepatic TRβ action attenuates APAP-induced acute liver injury and that a crucial time-specific modulation of ALF through TH exists whereas T3 improved hepatocyte proliferation during liver regeneration.
Method: ALF was induced via i.p. injection of 300 mg/kg body weight of APAP (or solvent control) in male C57BL/6J mice w/o hepatocyte specific TRβ knockout. 1–24 h post APAP intoxication, liver function test, liver histology, proliferation and hepatic T3- and APAP-responsive markers were evaluated.
Results: APAP intoxication in hepatocyte-specific TRβ deletion mice (hepTRβKO) resulted in absence of pericentral hepatocellular necrosis and absence of elevated serum transaminases 24 hours post APAP intoxication as compared to WT mice. Interestingly, 12 hours after APAP application injured hepatocytes surrounding central veins could be observed in hepTRβKO mice.
Conclusion: We hypothesize a hepatocyte-intrinsic detrimental TH effect in disease development, whereas TH action during liver regeneration is beneficial. These findings harbor great translational potential for novel therapeutic strategies, e.g. to antagonize or agonize local TH action, depending on the disease status of patients suffering from ALF. It is of high clinical relevance if one could support the so far only therapeutic option NAC in the treatment of APAP-induced ALF, preferably with a prolonged therapeutic window.

miR148a-3p may play a direct role in regulating inflammatory responses in bacterial infection related acute-on-chronic liver injury

Ersin Karatayli[1], Susanne N. Weber[1], Senem Ceren Karatayli[1], Rabea Hall[1], Leonard Kaps[1], Jörn M. Schattenberg[1]. [1]*Saarland University Medical Center, Department of Medicine II, Homburg, Germany*
Email: ersinkaratayli@gmail.com

Background and aims: Given their role as master regulators of many basic cellular processes, dysregulation of miRNAs have been linked to many abnormalities including liver diseases. A distinct expression pattern for miR148a-3p was previously identified in our bacterial infection related acute-on-chronic liver disease (BI-ACLF) mouse model. Herein, we aimed to study the *in vitro* effect of miR148a-3p on hepatic cytokines and chemokines in primary hepatocytes.
Method: Our group has previously established BI-ACLF mouse model using *Abcb4*$^{-/-}$ mice which were intraperitoneally injected with 4 mg/kg LPS. In the current study, mouse primary hepatocytes isolated from Abcb4$^{-/-}$ C57BL/6J mice by perfusion, were stimulated with 50 ng/ml LPS and transfected either with 50 nM miR148a-3p mimic or 50 nM miR-148a-3p inhibitor 6 hours post seeding. miRNA specificity and transfection efficiency was assessed by mock miRNA and GFP expressing plasmid transfections, respectively. Relative expression of *Il-6, Il-2, Il-22, Rantes, il-1β* and *Tnf-α* was determined by qRT-PCR using pre-designed TaqMan gene expression assays 48-hours after transfection. One-way analysis of variance (ANOVA), followed by Bonferroni's *post hoc* tests were applied as statistical tests.
Results: We have previously identified significant upregulation of miR148a-3p in our BI-ACLF model by screening of liver disease-related miRNAs using PCR arrays (miScript, Qiagen) together with differential expressions of *Il-6, Il-2, Il-22, Rantes, il-1β* and *Tnf-α*. Immunohictochemistry revealed a macrophage polarization in these mice with significant upregulation of M1 markers (CD64, CD86 and CCR7) while M2 markers either remained unchanged (CD206 and Arg1) or downregulated (CD163). *In vitro* LPS stimulation on the other hand, resulted in 35-fold overexpression of miR148a-3p. A more profound upregulation (580-fold) was observed after miR148a-3p mimic transfection, while anti-miR repressed the miR148a-3p levels (0.19-fold) *in vitro*. LPS-stimulated expressions before and after miRNA mimic transfection for *Il-6* (40.8-fold vs 13.2-fold), *il-1β* (53.9 fold vs 6.7-fold) and *Tnf-α* (52.2-fold vs 9.2-fold) suggest a significant repression effect of miR-148a-3p on these proinflammatory cytokines. On the other hand, inhibition of miR148a-3p expression by anti-mir transfection resulted in 6.3-fold, 9.2-fold and 4.5-fold upregulation for *Il-6, il-1β* and *Tnf-α* in the absence of LPS stimulation, respectively. Although similar upregulation was observed for *Il-2, il-22* and *Rantes* upon LPS stimulation, their expressions did not differ either by overexpression or inhibition of miR148a-3p.
Conclusion: miR148a-3p might play a direct role in regulating the observed acute inflammatory responses in pre-injured liver, which might lead to the transition from a stable chronic state to progressive liver damage after bacterial infection in BI-ACLF.

FRI-146-YI

Genetic polymorphisms associated with idiosyncratic drug-induced liver injury: a systematic review and bioinformatic analysis

Email: gonzalomatillacabello@gmail.com

Background and aims: Despite being a multifactorial entity, individual genetics plays a crucial role in idiosyncratic drug-induced liver injury (DILI). This study performs a comprehensive systematic review and analysis of DILI and genetics literature, focused on elucidating relevant genes, drugs and functional enrichments.
Method: Using PRISMA 2020 Guidelines, we identified eligible literature published up to June 30, 2023, in four databases (Web of Science, EMBASE, Scopus, PubMed) with a refined search strategy for

liver injury and genetic-related terms. After screening, original articles on human patients with at least one control group, reported statistically significant variants between groups and indicated validated DILI biochemical criteria were included. Data extraction, bioinformatic and statistical analyses were performed using R v4.4.1, RStudio v2024.0 4.2 and Bioconductor v3.19 packages. Functional enrichment analyses were conducted using KEGG and Gene Ontology (GO) databases.

Results: A total of 25,874 records were screened, with 14,931 remaining for further evaluation after duplicate removal. Ultimately, 139 original articles were included: 124 studies involving variants associated to DILI susceptibility (DILI Risk set), 36 involving variants associated to DILI protection (DILI Protective set), and 21 for both. In the DILI Risk set 83 genes were included, being NAT2, HLA-B, HLA-DRB1, HLA-A, and HLA-DQB1 the most frequent. The DILI Protective set comprised 25 genes, of which MAFF, XRCC3, LTA, MTHFD1, UGT1A4, SLC22A2 and MIR1208 appeared exclusive to this set. The most common culprit drugs were antimycobacterials (46.7% for DILI Risk and 44.4% for DILI Protective), antineoplastics (21.0% and 27.8%) and amoxicillin-clavulanate (4.0%) for DILI Risk or systemic antivirals (11.1%) for DILI Protective. Hierarchical analysis performed with KEGG enrichment analysis revealed major pathway clusters in DILI Risk set corresponding to i) regulation of the adaptive immune response and cytotoxicity mediated by T and NK cells (HLA-A, HLA-B, HLA-C, HLA-DRA, HLA-DPB1, HLA-DQA1, HLA-DRB1, HLA-DQB1 and HLA-DRB5); ii) NF-κB pathway, cytokine signaling and general inflammatory response (NFKBIA, NFKB1 and RELA); iii) porphyrin, ascorbate and aldarate metabolism (UGT2B7, UGT1A1 and UGT1A9); iv) drug metabolism pathways mediated by cytochrome P450, in which CYP2E1, CYP3A4, CYP3A5, CYP2B6 and CYP2D6, GSTT1, GSTM1 and GSTP1 genes were involved, and v) biliary secretion and hepatic cellular transport (ABCG2, ABCB11, ABCC2, ABCB1, SLCO1B1 and CYP7A1). GO enrichment analysis showed consistent findings with previous KEGG results.

Conclusion: This work highlights the major role of the immune system and oxidative stress response in DILI, providing a solid basis for further studies focused on most reported genes, as well as on more infrequent genes with strong functional significance in hepatotoxicity.

Funding: PI21/01248; PID2022-140169OB-C21; HORIZON-STAYHLTH-101095679; PT23/00137.

Email: juanpedrotoroortiz@gmail.com

Background and aims: The adaptive immune system seems to play a significant role in the pathogenesis of drug-induced liver injury (DILI) and metabolic dysfunction-associated steatotic liver disease (MASLD). Due to its constant exposure to foreign antigens, the liver has developed a high capacity for immune tolerance. At this point, immune checkpoints control the immune system by preventing T-lymphocyte autoreactivity and promoting self-tolerance. Consequently, any alteration of these immune checkpoints may be related to a modification of immune activation, thus affecting the liver. The objective of this study was to analyse the levels of different immune checkpoints in the serum of control subjects, patients with DILI and patients with MASLD with significant liver fibrosis (MASLD F >2, n = 28) and without significant liver fibrosis (MASDL F ≤2, n = 10).

Method: Blood samples were collected from adjudicated cases of DILI within the first week of symptoms (n = 14), MASLD (n = 38) and healthy-liver controls (n = 28). Transient elastography (FibroScan®) was performed in MASLD and control cases. MASLD cases were divided into two groups according their fibrosis level (F0-F1-F2 (MASDL F ≤2) (n = 19) and F3-F4 (MASLD F >2) (n = 19)). Immune checkpoints were analyzed by ProcartaPlex™ Immunoassays.

Results: A similar profile of immune checkpoints without significant differences was identified between DILI and MASLD F >2 groups: BTLA (312 ± 59 and 250 ± 24 pg/ml), CTLA4 (46 ± 4 and 51 ± 3 pg/ml), CD28 (142 ± 11 and 138 ± 10 pg/ml), CD80 (84 ± 10 and 64 ± 4 pg/ml), PD-1 (24 ± 4 and 17 ± 2 pg/ml) and PD-L2 (1072 ± 102 and 1140 ± 65 pg/ml). However, the levels of these proteins are significantly higher in both groups than in the control and MASLD F ≤2 groups (BTLA: 121 ± 20 and 139 ± 33 pg/ml; CTLA4: 31 ± 2 and 29 ± 4 pg/ml; CD28: 101 ± 9 and 91 ± 9 pg/ml; CD80: 40 ± 4 and 44 ± 4 pg/ml; PD-1: 9 ± 1 and 7 ± 1 pg/ml; PD-L2: 639 ± 49 y 828 ± 87 pg/ml). With regard to PD-L1, significantly elevated levels were observed in the MASLD F >2 group (1.4 ± 0.4 pg/ml) in comparison to the other groups (DILI: 0.7 ± 0.1 pg/ml, MASLD F ≤2 groups: 0.6 ± 0.3 pg/ml, control: 0.1 ± 0.1 pg/ml).

Conclusion: The results indicate that the immune checkpoints under examination are capable of distinguishing between MASDL with or without significant fibrosis. Conversely, these markers are unable to differentiate between chronic liver disease (MASDL with significant fibrosis) and acute liver disease (DILI). The latter two diseases appear to exhibit similar immune tolerance mechanisms.

Dynamic transition of hepatocyte subtypes highlights novel repair pathways in acute liver failure after hBMSC transplantation

Jun Li[1], Heng Yao[1], Jing Zhang[1], Hui Yang[1], Suwan Sun[1], Xi Liang[1], Jing Jiang[1], Jiaojiao Xin[1], Dongyan Shi[1], Xin Chen[2]. *[1]State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, National Clinical Research Center for Infectious Diseases, National Medical Center for Infectious Diseases, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; [2]Institute of Pharmaceutical Biotechnology and the First Affiliated Hospital Department of Radiation Oncology, Zhejiang University School of Medicine, Joint Institute for Genetics and Genome Medicine between Zhejiang University and University of Toronto, Zhejiang University, Hangzhou, China*
Email: lijun2009@zju.edu.cn

Background and aims: Understanding the liver repair mechanisms in acute liver failure (ALF) mouse model following hBMSC transplantation is crucial. This study provides a comprehensive single-cell atlas to explore these regenerative processes.

Method: hBMSCs were transplanted into immunodeficient Fah-/-Rag2-/-IL-2Rγc-/- SCID (FRGS) mice with induced FHF. Single-cell

RNA sequencing (scRNA-Seq) was employed to map hepatic cell types, supplemented by bulk RNA sequencing and immunohistochemistry (IHC) for validation. Pseudotime analysis traced hepatocyte dynamics during regeneration.
Results: Regenerating livers contained two distinct hepatocyte subtypes: type-a and type-b hepatocytes. Type-b hepatocytes, marked by elevated Mlxipl expression, demonstrated superior transporter-like capabilities, particularly in bile acid transport and detoxification, and showed enhanced recovery after transplantation. Pseudotime analysis revealed a trajectory from classic to transporter-like hepatocytes, regulated by hepatic stem/progenitor cells (HsPCs). Multi-color IHC corroborated the existence of Mlxipl-high type-b hepatocytes in regenerating tissues.
Conclusion: This work reveals a dynamic hepatocyte subtype transition as a key driver of liver repair. The transporter-like hepatocytes, pivotal for restoring detoxification and bile acid transport, emerge through transformation from typical hepatocytes, shedding light on the mechanisms of liver regeneration.

FRI-151
Drug-induced liver injury in biopsy-scaled precision-cut liver slices
Milan Lobo[1], Nathalie Eysackers[1], Ayla Smout[1], Stefaan Verhulst[1], Nouredin Messaoudi[1,2], Vincent De Smet[1,2], Leo van Grunsven[1]. *[1]Vrije Universiteit Brussel (VUB), Brussels, Belgium; [2]Universitair Ziekenhuis Brussel (UZ Brussel), Brussels, Belgium*
Email: Milan.Alexandre.G.Lobo@vub.be

Background and aims: Repeated consumption of drugs can lead to drug-induced liver injury (DILI), one of the major safety concerns for pharma companies and clinicians. An important challenge is the lack of methods to predict adverse effects of drugs on the liver. While rodent models are used for pre-clinical tests, these cannot predict DILI risk in humans. Human precision-cut liver slices (PCLS) have emerged as a promising ex-vivo model with great potential to replicate liver functionality. PCLS retains the liver's native micro-architecture and cellular diversity while offering a simpler preparation process than other 3D culture models. However, the usual diameter of PCLS cultures is rather big (5–8 mm) so large liver resections are needed to culture human PCLS which become scarce with the current evolution of parenchyma-sparing liver surgery. We aim to develop biopsy-scaled (1 mm) PCLS cultures for the evaluation of DILI.
Method: Healthy male BALB/c mice (Charles River) were used for baseline studies and an in-house bred BALB/c-Tg(Pdgfrb-GFP) strain for live imaging. Livers of mice were excised, cut in 250 um thick slices using a Leica 1200S vibratome, punched using 1/3 mm biopsy punchers (Kai®), and cultured in 24/96-well plates. Samples were snap-frozen at different times/conditions. RNA extraction was performed using TRIzol® followed by QuantSeq 3′ mRNA-Seq library preparation (Lexogen) and sequencing on a NovaSeq (Illumina). Whole-slice immunostaining was carried out on formalin-fixed samples. Imaging was done using a Zeiss LSM® 800 confocal and an EVOS M7000® microscope.
Results: Comparison of hepatocyte marker expression between 1 mm and 3 mm PCLS over 5 days suggests that a smaller diameter better preserves hepatocyte functionality in mouse cultures. GSEA analysis of RNAseq data on day 0 and 5 slices revealed high enrichment of ECM remodeling pathways and wound healing responses on day 5. Using BALB/c-Tg(Pdgfrb-GFP) mice we confirmed hepatic stellate cell activation over time demonstrated by an increase in the GFP signal. Exposure to pro-inflammatory cytokines further increased the signal showing the responsiveness of the cultures. Finally, 1 mm slices allowed paracetamol-driven liver damage observed on RNA and immunostainings. Optimized 96-well plate cultures of 1 mm PCLS facilitated the determination of IC50 concentrations of APAP and Omeprazole. Part of our findings in mice could be replicated in human 1 mm PCLS cultures.
Conclusion: PCLS of 1 mm diameter from both human and mouse liver samples demonstrated good preservation of hepatocyte functionality in culture compared to larger slices. The use of BALB/c-Tg (Pdgfrb-GFP) mice facilitates the evaluation of DILI drugs and fibrosis-inducing agents. 1 mm slices will allow for testing human liver biopsy-derived slice cultures for DILI and pro- and anti-fibrotic drugs and thus hold promise for personalized medicine approaches.

FRI-152-YI
Validation of markers of hepatocyte senescence for the prognosis of patients with severe acute hepatitis
MohammadMahdi Saeidinejad[1], Andrew Hall[2], Fausto Andreola[1], Alberto Quaglia[2], Cornelius Engelmann[3], Thomas Bird[4], Rajiv Jalan[5]. *[1]University College London, London, United Kingdom; [2]Royal Free Hospital, London, United Kingdom; [3]Charite Hospital, Berlin, Germany; [4]The University of Edinburgh, Edinburgh, United Kingdom; [5]University College London, Royal Free Hospital, EF CLIF, London, United Kingdom*
Email: mohammad.saeidinejad@nhs.net

Background and aims: Severe acute hepatitis is a rare disease that can progress to acute liver failure (ALF) and associated mortality. Biomarkers defining prognosis early in the course of the disease are lacking making drug development and early selection for transplantation difficult. Hepatocyte senescence affects patients with severe acute hepatitis resulting in extrahepatic organ failure and poor survival (Kourtis et al. Nat. Cell Biol. 2024). The aim of this study was to validate these findings in real world clinical practice using traditional histopathological tools.
Method: Patients with severe acute hepatitis, due to autoimmune (AIH), drug-induced (DILI), or indeterminate hepatitis (IAH), presenting to a single centre (2010–2023) and undergoing a liver biopsy were studied. Archived FFPE liver biopsy samples were stained using immunohistochemistry to quantitate hepatocytes (HNF4alpha), senescent cells (P21, P16) and markers of regeneration (Ki67, and CCNA2). Quantifications of the positive cells were made using Image J.
Results: Data from 36-patients (AIH: 16, DILI: 13, DILI, IAH: 7; mean age: 46.9 years, bilirubin at admission: 329 µmol/L; INR at admission: 1.5) were analysed. 24-patients recovered spontaneously (survivors), and 12-patients developed ALF and either died (n = 2) or received transplant (n = 10) (non-survivors). The non-survivor group had higher bilirubin, creatinine, and INR levels at the time of liver biopsy. Hepatocyte expression of markers of senescence was significantly higher in the non-survivors (median p21 and p16 positive hepatocytes per tissue: 2.7% vs 7.5% (p = 0.03) and 24.9% vs 59.0% (p = 0.03) respectively). Regeneration markers were also markedly higher in non-survivors (median Ki67 and CCNA2 positive hepatocytes per tissue: 4.7% vs 14.9% (p = 0.05), and 1.0% vs 2.7% (p = 0.06) respectively), possibly representing ineffective regeneration. The expression of p21 was significantly higher in patients who developed renal dysfunction (median p21: 3.2% vs 10.5%, p = 0.04). In those that developed hepatic encephalopathy (HE), the expression of p21 as well as the markers of regeneration was significantly higher (median p21 3.1% vs 7.5%, p = 0.03; median CCNA2: 1.0% vs 3.7%, p = 0.01; median Ki67: 4.7% vs 11.9%, p = 0.06). Meanwhile p16 was only numerically higher in these groups (renal dysfunction: 28.9% vs 73.8%, p = 0.06; HE: 28.6% vs 71.8%, p = 0.16).
Conclusion: The results of this study validate the previous observations suggesting that expression of markers of hepatocyte senescence could serve as potential histological biomarkers to identify patients at high risk of progression to ALF, need for transplantation and mortality. Further validation and search for liquid biomarkers is underway.

FRI-153

Prognostic significance of very high and towering peak alanine aminotransferase (ALT) values with normal or near normal total bilirubin in patients with idiosyncratic drug-induced liver injury

Naga Chalasani[1], Ismael Alvarez-Alvarez[2], Paul Hayashi[3], Raj Vuppalanchi[1], Marwan Ghabril[1], Jiezhun Gu[4], Huiman Barnhart[4], Jasmine Amirzadegan[3], Hao Niu[2], Maria Isabel Lucena[2], Raul J. Andrade[5]. Email: nchalasa@iu.edu

Background and aims: A high aminotransaminase (AT) level with concomitant jaundice in patients with drug-induced liver injury (DILI) is associated with worse outcomes. However, the prognostic significance of DILI with very high AT values but no jaundice is not known. We examined the prognostic value of a very high or towering alanine aminotransferase (ALT) value with normal or near normal total bilirubin (TBL) in well characterized DILI.
Method: 964 well-phenotyped DILI patients meeting predefined eligibility from the prospective US Drug Induced Liver Injury Network (DILIN) and Spanish DILI Registry were analyzed. We defined ALT 500 to ≤1000 U/L as very high, whereas ALT >1000 U/L as towering ALT. We then investigated five groups based on their peak ALT levels in U/L and serum TBL in mg/dL: Group A: peak ALT < 500 with accompanying TBL ≤1; Group B: very high peak ALT with accompanying TBL ≤1; Group C: very high peak ALT with accompanying TBL 1.1 to ≤2.5; Group D: towering peak ALT with accompanying TBL ≤1 and Group E: towering peak ALT with accompanying TBL 1.1 to ≤2.5. Primary outcome of interest is the number of cases fulfilling Hy's law criteria later in the injury course which was defined as ALT >150 U/L along with TBL >2.5 mg/dL. We also assessed for development of liver-related death or needing a liver transplant among the 5 groups.
Results: 692 patients from DILIN (mean age 49 yrs and 68% female) and 272 from the Spanish DILI Registry (mean age 50 yrs and 55% female) were included. There were 210 patients in Group A, 157 in Group B, 121 in Group C, 67 in Group D, and 137 in Group E from DILIN, while the Spanish Registry had 147, 40, 32, 24, and 29 in Groups A to E, respectively. The incidence of Hy's law in the DILIN cohort was 3.3% in Group A, 4.5% in Group B, 24% in Group C, 10.4% in Group D, and 28.5% in Group E, whereas in the Spanish Registry it was 2%, 5%, 22%, 25%, and 24% in Groups A-E, respectively. Furthermore, the percent of liver-related death or liver transplant in DILIN was 0.5% in Group A, 0% in Group B, 3.3% in Group C, and 1.5% in both Groups D and E, whilst in the Spanish Registry it was 0%, 2.5%, 0%, 8.4%, and 3.5% in Groups A to E, respectively.
Conclusion: In patients with DILI, a very high ALT is associated with poor liver outcomes only when accompanied by at least minimal TBL elevation, but a towering ALT is associated with poor liver outcomes with or without a minimal TBL elevation. These data assist in risk stratifying DILI presenting with very high ALT values without jaundice in clinical care and drug development.

FRI-154

Gadoxetate-enhanced MRI detects acute rifampicin-induced inhibition of hepatocellular transporter function in rats and normalization of function after chronic dosing

Mikael Montelius[1,2], Daniel Scotcher[3], Nicola Melillo[3], Aleksandra Galetin[3], Ebony Gunwhy[4], Gerry Kenna[5], John Waterton[5,6], Steven Sourbron[4], Paul Hockings[1,7]. Email: paul.hockings@antarosmedical.com

Background and aims: Drug-induced liver injury (DILI) can be the result of impaired hepatobiliary transporters, with altered bile formation, flow, and subsequent cholestasis. Gadoxetate (Primovist, Bayer AB) is an hepato-specific paramagnetic gadolinium-based contrast agent. Dynamic gadoxetate MRI can detect acute rifampicin (RIF) induced changes in hepatobiliary transporter function in vivo in rats prior to established biomarkers of liver toxicity. Chronic dosing may lead to indirect changes in transporter function by affecting expression or degradation of transporters. In this study dynamic gadoxetate MRI was used to measure effects of acute and chronic dosing of RIF on hepatic plasma clearance (K^{trans}) and biliary efflux (k_{bh}) in mL/min/100cm3.
Method: All animal experiments were approved by the local animal ethics authorities. Male rats (Wistar Han, ~300 g) were separated in 3 groups (n = 4/group): vehicle, clinical RIF (10 mg/kg) and high RIF (67 mg/kg) and dosed daily. High RIF was designed to be an equivalent clinical dose, i.e. similar relation between the human steady state concentration and Ki for human OATP1/MRP2, and between rat steady state concentrations and rat Ki for Oatp1/Mrp2. Rats were imaged at 7 T on a Bruker Biospec MRI at 4 timepoints. Baseline and acute imaging (D1) were performed 3 h after oral dosing. Day 2 (D2) and Day 5 (D5) follow-up imaging were performed 24 h after the previous RIF dose.
Results: No adverse effects of rifampicin treatment or imaging were detected by clinical observation. At D1, RIF caused K^{trans} to drop by 49% in the clinical group (p = 0.009), and by 78% after the high dose (p = 0.001). This was followed by a gradual return to baseline values on D2 and D5. For k_{bh}, clinical RIF caused a non-significant reduction of 41% (p = 0.10) and high dose RIF caused a 69% reduction on D1 compared with baseline (p = 0.001) and there was a gradual return to baseline on D2 and D5.
Conclusion: Dynamic gadoxetate MRI shows potential as an early non-invasive marker of hepatobiliary transporter functionality. In this work, we found indications for normalized functionality after chronic rifampicin administration. This assay is fully translatable to the clinic as gadoxetate is an approved MRI contrast agent and may improve the risk assessment of DILI in humans.

Background and aims: Dysregulation of PPAR transcription-factors has been implicated with various metabolic disorders. In the context of acetaminophen (APAP)-induced hepatotoxicity, changes in PPAR-alpha(a) activation, fatty acid oxidation (FAO) and related lipophagy have been observed but treatments are still lacking. E2F transcription-factors are key regulators of both metabolism and the cell-cycle. Our preliminary results showed that *E2f1*$^{-/-}$ mice do not survive after APAP-induced liver injury, whereas *E2f2*$^{-/-}$ animals have a higher survival rate with increased FAO, PPARa and PPAR-gamma(g) levels when compared to wild-type (WT) and *E2f1*$^{-/-}$ mice. Therefore, the aim of this study was to investigate whether pharmacological activation of PPARa and PPARg, could improve the response to drug-induced liver injury (DILI) after APAP-induced liver damage.
Method: For this, *E2f1*$^{-/-}$, *E2f2*$^{-/-}$ and WT mice were used. Hepatotoxicity was induced by intraperitoneal injection of 360 mg/kg APAP. Mice were evaluated 6 and 48 h after treatment. Survival, liver-necrosis and proteome analysis were performed. Additionally, PPARg agonist (Rosiglitazone) and the dual PPARa/g agonist (Saroglitazar) were administered before and after APAP treatment.
Results: *E2f1*$^{-/-}$ mice exhibited reduced PPARa and PPARg levels, CREB activation and oxidative stress, which were linked to reduced FAO and levels of autophagy markers 6 hours post-APAP. Conversely, *E2f2*$^{-/-}$ mice had elevated activation of CREB and pathways involved in protection against oxidative stress, together with increased PPARa and PPARg levels. In addition, pretreatment with saroglitazar or rosiglitazone increased survival to 100%, reduced necrosis and normalized transaminase levels in *E2f1*$^{-/-}$ mice 48 h post-APAP, providing almost complete protection against toxicity. The dual agonist saroglitazar led to CREB activation, restored autophagy markers, redox homeostasis and increased FAO 6 h post-APAP. Rosiglitazone did not improve the effect of saroglitazar, but induced similar results in the protection against DILI and CREB activation. Given the importance of finding an antidote to APAP-induced hepatotoxicity, these drugs were also administered 1 and 3 h after APAP treatment. The results showed that after APAP treatment, the PPARa and/or PPARg agonists resulted in a 100% survival rate and were significantly associated with reduced liver damage. This protective effect was supported by a lower transaminase levels and less liver necrosis than in mice treated with APAP alone.
Conclusion: E2F1 deficiency increases hepatic vulnerability by impairing activation of the PPAR-CREB axis, dysregulation of lipid metabolism and increased oxidative stress. However, activation of this axis by PPAR agonists before and even after APAP-induced hepatotoxicity confers protection that may be valuable as a potential treatment in the future.

FRI-156
Coordinated liver tissue regeneration becomes ineffective with increasing injury in patients with acute indeterminate liver failure

Richard Sittner[1], Mohsin Hassan[1], Pavitra Kumar[1], Adrien Guillot[1], Andrew Hall[2], Alberto Quaglia[3], Thomas Bird[4], Mohammad Mahdi[2], Rajiv Jalan[2], Cornelius Engelmann[1]. *[1]Department of Hepatology and Gastroenterology, Charité-Universitaetsmedizin Berlin, Berlin, Germany; [2]Liver failure Group, Institute for Liver and Digestive Health, Division of Medicine, University College London Medical School, Royal Free Hospital, London, United Kingdom; [3]Department of Cellular Pathology, Royal Free London/UCL Cancer Institute, London, United Kingdom; [4]Institute for Regeneration and Repair, Centre for Inflammation Research, The University of Edinburgh, Edinburgh, United Kingdom*
Email: richard.sittner@charite.de

Background and aims: Severe indeterminate acute hepatitis (sIAH) represents a life-threatening condition without clear prognostic criteria or specific therapies, affecting patients without pre-existing liver disease. Recent studies have highlighted the significant role of p21 expression in the liver in driving disease progression and mediating interactions with extrahepatic organs through TGFβ signalling. This study aims to investigate the histopathological features associated with p21-expressing hepatocytes in patients with sIAH, with the goal of deepening our understanding of the disease's pathobiology and identifying potential predictors of patient survival.
Method: 34 patients with sIAH admitted to a single center between 2010 and 2019 that underwent liver biopsy were included. Severity of liver injury was assessed histologically in terms of confluent zonal, or panlobular/multilobular collapse as previously described. A multiplex immunofluorescence staining and an advanced single cell analysis protocol was employed to assess cellular pathomechanisms related to senescence and regeneration. Patients that died or underwent liver transplantation were analysed as non-survivors.
Results: The histopathology of non-survivors revealed more areas of multilobular necrosis with lower rates of hepatocyte proliferation and p62-expression and an increase in p21-expression in preserved hepatocyte islands. Interestingly, neighboring analysis revealed a close proximity of p21^{+} and Ki67^{+} hepatocytes in clusters. With a ratio of 1.59 between Ki67^{+} and p21^{+} hepatocytes compared to 5.76 in survivors, non-survivors showed a strong dysbalance towards p21 expression and lack of regeneration. Furthermore, regenerative dysbalance and p21 overexpression was associated extrahepatic organ failure in the form of renal impairment and hepatic encephalopathy (HE), with the percentage of p21+ hepatocytes positively correlating with serum creatine levels and of the patients developing HE, all showed increases in p21 expression. In the survivors, enhanced Ki67-expression coupled with an increase in p62^{+} hepatocytes hints at an autophagy mediated resolution of tissue injury and compensatory proliferation, notable since p62 expression was found to be distant to p21^{+} hepatocyte clusters. Furthermore, non-survivor patients revealed an elevation in tissue inflammation and damage with increases in yH2Ax and cleaved caspase 3 as well as an increased number of immune cells (IBA1 pos. macrophages, CD8 T-cells, CD45^{+} cells) both in necrotic areas and hepatocyte islands, while TGF-beta levels did not differ. This potentially resembles an exaggerated inflammatory response within the preserved hepatocyte areas in non-survivors.
Conclusion: sIAH non-survivor patients exhibit a regenerative dysbalance in favor of inflammation and hepatocyte senescence, the latter of which is linked to extrahepatic organ injury, underscoring its potential role in disease progression.

FRI-157
Longitudinal assessment of liver stiffness for up to 96 weeks by magnetic resonance elastography and correlation with fibrosis markers in alpha-1 antitrypsin deficiency-associated liver disease: results from phase 2 studies of fazirsiran

Talakad G. Lohith[1], Feng Hong[1], Jen-Chieh Chuang[1], Chien-Lin Yeh[1], Vandana Gupta[1], Jie Cheng[1], Alexander J. Prokopienko[1], Susana Gonzalez[1], Nirav K. Desai[1], Paresh Thakker[1], Thomas Schluep[2], James Hamilton[2], Rohit Loomba[3]. *[1]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [2]Arrowhead Pharmaceuticals, Inc., Pasadena, CA, United States; [3]University of California San Diego, San Diego, CA, United States*
Email: roloomba@health.ucsd.edu

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is a rare genetic disease that may lead to the development of AATD-associated liver disease (AATD-LD). Imaging-based, non-invasive tests for liver fibrosis assessment of patients (pts) with AATD-LD,

including magnetic resonance elastography (MRE) and FibroScan®, are of interest. Cross-sectional and longitudinal analyses of liver stiffness measurement (LSM) via MRE in pts with AATD-LD are limited. Using data from phase 2 clinical trials of fazirsiran (an investigational small interfering RNA therapy for AATD-LD), we aimed to characterize LSM over time via MRE in pts with AATD-LD and to correlate findings with LSM via FibroScan and non-imaging fibrosis-related metrics.

Method: Baseline and post-baseline imaging data (MRE, FibroScan), and serum and histology data from pts with AATD-LD who received fazirsiran/placebo in the AROAAT-2001 (NCT03945292)/-2002 (NCT03946449) trials were included. LSM via MRE was an exploratory endpoint and optional at sites with MRE feasibility. MRE measurements were collected at baseline, and at Week 24/48/72 or Week 96. Change from baseline for MRE, correlation of MRE with FibroScan and correlation of imaging data with serum/tissue fibrosis measures were assessed. Further methodology is described in Strnad *et al. NEJM*, 2022 and Clark *et al. Gastroenterology*, 2024.

Results: Overall, 56 pts received placebo or fazirsiran (25/100/200 mg) in AROAAT-2001/-2002; of those, 22 and 46 pts had available baseline or post-dose MRE or FibroScan data, respectively. In most pts with baseline METAVIR fibrosis stage ≥1, LSM via MRE declined from baseline as early as Week 24 post-fazirsiran treatment; reductions were sustained up to Week 96. Versus baseline, LSM via MRE showed a statistically significant ($p < 0.05$, paired t-test) decrease of 18% with fazirsiran 200 mg at the last data collection; LSM via FibroScan declined by ~18% but changes were not statistically significant. Overall, 7/11 (64%) pts had >19% (cutoff for test-retest repeatability [TST]); range: 22–46%) decrease in LSM via MRE; 6/19 (32%) pts had a >35% (cutoff for TST; range: 36–70%) decrease in LSM via FibroScan. For pts with both MRE and FibroScan data, versus placebo, pts who received fazirsiran 200 mg had a greater decline in LSM via MRE than FibroScan (median change: –28% and –5%, respectively). LSM via MRE and FibroScan showed statistically significant correlations ($p < 0.05$) with most serum and liver histological markers, including serum Z-alpha-1 antitrypsin, Periodic Acid-Schiff stain with diastase globule burden and METAVIR fibrosis stage.

Conclusion: LSM via MRE demonstrated promising utility in monitoring fazirsiran treatment response in a small cohort of pts with AATD-LD. The utility of LSM via MRE and FibroScan will be further evaluated in ongoing phase 3 trials.

Study/writing funding: Takeda Development Center Americas, Inc.

FRI-158

Chronic plus binge ethanol feeding impact on cholesterol metabolism in liver- and intestine-specific Abcg5/g8 knockout mice

Senem Ceren Karatayli[1], Ersin Karatayli[1], Rabea Hall[1], Frank Lammert[2], Jörn M. Schattenberg[1], Susanne N. Weber[1].
[1]*Department of Medicine II, Saarland University Medical Center, Homburg, Germany;* [2]*Hannover Medical School, Hannover, Germany*
Email: senemceren@gmail.com

Background and aims: The ABCG5/G8 heterodimer effluxes sterols including cholesterol from enterocytes and hepatocytes into the intestine and bile, respectively. In this study, we aim to adopt the chronic-plus-binge alcohol feeding diet (NIAAA mouse model) to liver *Abcg5/g8* knock-out (Hep-KO) and the intestinal *Abcbg5/g8* knock-out (Int-KO) mice to investigate the effects of alcohol on cholesterol metabolism.

Method: Total hepatic and ileal RNA was extracted from 15-week-old wild type (WT) C57BL/6J, Hep-KO and Int-KO mice, which were either fed with control diet (WT/Cont, Hep-KO/Cont and Int-KO/Cont groups) or liquid ethanol diet (5% v/v) followed by an acute ethanol binge (5 mg/kg, WT/EtOH, Hep-KO/EtOH and Int-KO/EtOH groups). Hepatic expressions of *Srebf2, Cyp7a1, Cyp8b1, Cyp27a1, Shp, Fxr, Abcg1, Pnpla3, Mboat7, Tm6sf2, Lxr, Acat2, Abca1*, and *Hmgcr* and ileal mRNA levels of *Fgf15, Lxr, Fxr, Shp, Npc1l1, Srebf2, Acat2* and *Abca1* were evaluated. One-way ANOVA test or Kruskal–Wallis test were used for the statistical analysis. $P < 0.05$ was considered as statistically significant. Liver and plasma total cholesterol levels were determined by colorimetric assay. Paraffin-embedded liver sections and frozen liver sections were stained with haematoxylin-eosin and oil red O, respectively.

Results: *Cyp7a1* suppression was observed in both Hep- and Int-KO groups independent of ethanol challenge ($p < 0.05$). Hepatic *Cyp27a1* levels were significantly downregulated in Hep-KO/EtOH compared to Hep-KO/Cont group. Hepatic mRNA levels of *Fxr* showed statistically significant suppression in ethanol challenged Hep- and Int-KO groups compared to WT/Cont group, and significant downregulation in Int-KO/EtOH group compared to others. Significant downregulation of hepatic *Acat2, Lxr* and *Hmgcr* expression in all groups was observed upon EtOH uptake. Among the genes evaluated in ileum, only *Acat2* showed significant downregulation in all KO groups and WT/EtOH group compared to WT/Cont. Among the well-known fatty liver associated genes, alcohol challenge resulted in the repression of *Pnpla3* and upregulation of *Tm6sf2* expression. Hepatic and plasma total cholesterol levels were not different. Histological staining of liver sections showed high numbers of lipid droplets indicating lipid accumulation and increased hepatic steatosis in mice challenged with EtOH regardless of the genotype.

Conclusion: Chronic-plus-binge ethanol-feeding markedly suppressed *Lxr, Acat2* and *Hmgcr* mRNA levels, suggesting its direct effect on cholesterol sensors LXR and ACAT2, and rate-limiting enzyme (HMGCR) for cholesterol synthesis. Moreover, the absence of both liver and intestinal *Abcg5/g8* gene expression resulted in downregulation of *Cyp7a1* expression independent of ethanol challenge, indicating a key role of bile acid synthesis in cholesterol metabolism.

FRI-159-YI

Adrenomedullin as an immunomodulator of CD14+MerTK+ circulating monocytes in liver failure syndromes

Francesca Maria Trovato[1], Florent Artru[2], Roosey Sheth[1], Stephen Atkinson[3], Mark J. W. McPhail[1]. [1]*King's College London, London, United Kingdom;* [2]*Centre Hospitalier Universitaire de Rennes, Rennes, France;* [3]*Imperial College London, London, United Kingdom*
Email: trovatofrancesca@gmail.com

Background and aims: Liver failure syndromes are characterised by dysfunctional immune response. This affects monocyte/macrophage phagocytic capacity and allows circulating microorganisms to disseminate and initiate sepsis. Adrenomedullin (ADM) is a potent vasodilator that contributes to immune regulation. We hypothesised that in liver failure there is a detrimental imbalance between ADM and Adrenomedullin binding protein (AMBP) - 1 that favours a dysfunctional monocyte/macrophage phenotype and function.

Method: Between April 2020 and June 2024, consecutive patients with acute liver failure (ALF = 54), Acute – on - chronic liver failure (ACLF = 25), Decompensated cirrhosis (DC = 9) and healthy controls (HC = 16) were recruited. ADM and AMBP - 1 concentrations were measured by ELISA, peripheral blood mononuclear cells (PBMCs)/monocytes were isolated and used for RNA sequencing and cell culture with ADM, adrenomedullin receptor antagonist (ADM 22–52), AMBP - 1.

Results: In the ALF group, the main aetiology was drug-induced liver injury 78% (n = 42), 43% of patients developed infection during the first 10 days of admission. In the ACLF group, the main cause of liver disease was alcohol-related liver disease in 88% of patients (n = 21) and the main precipitant was infection (n = 20). ADM expression in isolated monocytes was upregulated in ALF (log fold change = 5.88, p = 0.0002) and ACLF (log fold change = 4.62, p = 0.0006) compared to HC. Plasma ADM concentration was increased in ALF (1684 ± 1156 pg/ml) vs ACLF (836.1 ± 765.2 pg/ml) and HC (164.8 ± 62.73 pg/ml), Kruskal Wallis, $p < 0.0001$ (ALF vs HC). AMBP - 1 was decreased in ALF

(59.27 ± 44 ug/ml) vs ACLF (126.3 ± 72.23 ug/ml) and HC (252.8 ± 159.7 ug/ml) ($p < 0.0001$, ALF vs HC). In ALF, ADM was directly correlated with heart rate (HR, $r = 0.273$, $p = 0.04$), lactate, AST ($r = 0.6323$, $p < 0.0001$) concentrations and INR ($r = 0.352$, $p = 0.008$). No difference in ADM and AMBP - 1 concentrations was found between ALF patients who spontaneously survived or died/underwent transplantation. In patients, stimulation with LPS increased ADM production by PBMCs (ALF = 6; 561.4 ± 1038 pg/ml vs 259.2 ± 213.7 pg/ml, ACLF = 4, 3202 ± 491.2 vs 1757 ± 1689, HC = 7; 1920 ± 1184 vs 2299 ± 1188 pg/ml), (2 - way ANOVA $p = 0.0151$). The immunophenotyping of PBMCs after culture (HC n = 6 and ALF n = 6) showed that among CD14 + cells, the percentage of cells expressing MerTk was reduced by LPS (2.077 ± 0.87%) but restored by incubation with ADM 100nM (3.852 ± 1.063).

Conclusion: ADM is increased and AMBP - 1 reduced according to SOFA - defined disease severity in ALF/ACLF. ADM promotes monocyte pro-restorative, anti - inflammatory phenotypes. Intervention on this molecular pathway is indicated to restore vascular resistance and monocyte function in liver failure syndromes.

FRI-160

Targeting cGAS/STING pathway and ferroptosis for protection against hepatic ischemia-reperfusion injury

Rasha Tawfiq[1], Mai Ghoneim[2], Hameis Sleem[3], Doha Nabil[4], Yasmeen Attia[1]. *[1]Department of Pharmacology, Faculty of Pharmacy, The British University in Egypt, Cairo, Egypt; [2]Department of Pharmacology & Toxicology, Faculty of Pharmacy, University of Sadat City, Menofia, Egypt; [3]Department of Biochemistry, Faculty of Pharmacy, The British University in Egypt, Cairo, Egypt; [4]El Demerdash Hospital, Ain Shams University, Cairo, Egypt*
Email: rasha.tawfiq@bue.edu.eg

Background and aims: Hepatic ischemia-reperfusion injury (HIRI) is a critical complication in liver transplantation and surgery, often resulting in liver dysfunction or failure and exacerbating the scarcity of donor organs. Characterized by tissue hypoxia during ischemia and excessive inflammation and oxidative stress upon reperfusion, HIRI leads to regulated cell death through mechanisms such as pyroptosis and ferroptosis. Therapies targeting these pathways, including octreotide (OCT), a somatostatin analogue, and deferoxamine (DFO), an iron chelator that prevents ferroptosis, have shown promise. This study sought to investigate whether combining OCT and DFO can protect against HIRI, providing mechanistic insights into the likely implication of ferroptosis and cGAS/STING pathway.

Method: Male Sprague Dawley rats (12–15 weeks old, 180–220 g) were housed under standard conditions and subjected to 70% partial hepatic ischemia by clamping the left lateral and median lobes, followed by 30 minutes of ischemia and 4 hours of reperfusion. Rats were randomized into five groups: Sham, HIRI, HIRI+OCT (75 μg/kg), HIRI+DFO (200 mg/kg), and HIRI+OCT+DFO. Histopathological examination of liver tissues was performed, alongside immunohistochemical analysis of COX-2 expression. GPX4 levels were assessed using colorimetric analysis, while TLR4 was quantified by ELISA. Gene expression of cGAS and STING was analyzed using qRT-PCR.

Results: Histopathological alterations were notably mitigated in the OCT+DFO+HIRI group. cGAS fold change was significantly reduced in the combination group, whereas STING expression remained unchanged. Additionally, HIRI+OCT+DFO group demonstrated a decrease in COX-2 immunohistochemical expression that parallelled an increase in GPX4 levels indicating a potential modulatory effect on ferroptosis.

Conclusion: The protective effect of the OCT and DFO combination against HIRI is likely driven by a modulation of ferroptosis and a possible interference with the cGAS/STING pathway.

Single-cell RNA sequencing reveals a fundamental role of LCN2+ neutrophils in the innate immune response in drug-induced acute-on-chronic liver failure

Yang Zhi[1], Huimin Wu[2], Xiaochun Huang[2], Yinuo Dong[1], Xiaobo Li[3], Feng Xue[2], Yimin Mao[1]. *[1]Division of Gastroenterology and Hepatology, Renji Hospital, School of Medicine, Shanghai Jiao Tong University, NHC Key Laboratory of Digestive Disease, Shanghai Research Center of Fatty Liver Disease, Shanghai, China; [2]Department of Liver Surgery and Liver Transplantation, Renji Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai Engineering Research Center of Transplantation and Immunology, Shanghai Institute of Transplantation, Shanghai, China; [3]Department of Physiology and Pathophysiology, School of Basic Medical Sciences, Fudan University, Shanghi, China*
Email: maoym11968@163.com

Background and aims: Drug-induced liver injury (DILI) accounts for over 50% of acute liver failure cases in the US and Europe, and often requires liver transplantation. In China, most drug-induced acute liver failure cases occur in patients with chronic liver diseases, such as hepatitis B and metabolic dysfunction-associated steatotic liver disease, due to their high prevalence. Although the pathogenesis of DILI is not fully understood, both innate and adaptive immune responses are believed to play central roles. This study aimed to explore the functions of neutrophils in drug-induced acute-on-chronic liver failure (DI-ACLF) using single-cell RNA sequencing (scRNAseq).

Method: Three patients with DI-ACLF (two with hepatitis B and one with cirrhosis), one patient with liver failure due to hepatitis B, and two liver disease-free healthy controls, were prospectively recruited from the liver surgery department. Single-cell suspensions were prepared from liver tissue and peripheral blood and analyzed using scRNAseq. Additionally, patients from China DILI Registry (DILI-P) were included, with serum samples tested via ELISA for validation. Statistical differences between groups were determined using ANOVA and Tukey's multiple comparisons test.

Results: The causative agents of DILI were chemotherapeutic agents, paracetamol, and herbal medicines in three patients, respectively. ScRNAseq analysis yielded 101,644 cells from liver tissue and 250,106 cells from peripheral blood. Unsupervised clustering revealed an increased proportion of liver neutrophils in the DI-ACLF group compared to other groups. Subclustering of neutrophils highlighted a high abundance of lipocalin-2 positive ($LCN2^+$) neutrophils particularly in the DI-ACLF group, both in liver tissue and peripheral blood. Integrated analysis indicated that liver $LCN2^+$ neutrophils were highly likely to migrate from the peripheral blood. Further pseudotime trajectory analysis suggested that $LCN2^+$ neutrophils were the origin of differentiation and maturation of liver neutrophils. Gene ontology enrichment analysis of differentially expressed genes, particularly those involved in cell-cell interactions, showed significant enrichment in neutrophil activation, leukocyte adhesion, and neutrophil chemotaxis. ELISA assays further demonstrated that serum LCN2 levels (pg/mL) were significantly higher in moderate/severe DILI (n = 8) compared to mild DILI (n = 8; 95% CI: 1210–9714, $p = 0.008$), non-DILI liver injury (n = 7; 95% CI: 3278–12081, $p < 0.001$), and healthy controls (n = 7; 95% CI: 1794–10597, $p = 0.004$).

Conclusion: $LCN2^+$ neutrophils appear to play a fundamental role in the intrahepatic and peripheral innate immune responses in DI-ACLF, highlighting their potential as a therapeutic target to mitigate excessive inflammation. Additionally, elevated expression of serum LCN2 may serve as a valuable biomarker for the early detection of severe DILI.

Brown adipose tissue-derived extracellular vesicles administration alleviates liver injury in mice

Leyu Zhou[1], Li Yang[2]. [1]*Department of Gastroenterology and Hepatology and Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, China;* [2]*Department of Gastroenterology and Hepatology and Laboratory of Gastrointestinal Cancer and Liver Disease, Chengdu, China*
Email: zhouleyu@wchscu.cn

Background and aims: Brown adipose tissue (BAT) not only improves the liver microenvironment through metabolic regulation but also mediates inter-organ signaling via extracellular vesicles (EVs), thereby modulating liver immune response and promoting liver repairment. Previous studies have reported that BAT-derived EVs (BAT-EV) reduce liver fat accumulation and exhibit therapeutic effects in metabolic-associated liver diseases. However, research on the innovative therapeutic role of BAT-EVs in acute liver injury remains limited. This study aimed to explore the therapeutic potential of BAT-EV for acute liver injury.
Method: We conducted experiments using three animal models of liver injury which were induced by concanavalin A (Con A), acetaminophen (APAP) or carbon tetrachloride (CCl_4). First, we validated the BAT-liver axis in vivo through BAT resection and BAT activation. Then we isolated BAT-EVs and cultured primary brown adipocyte in vitro. BAT-EVs or primary brown adipocyte was administrated into Con A, APAP, and CCl_4 mice, with liver function and histology assessed. Inflammatory levels were also analyzed using qPCR and ELISA. Further in vitro experiments were performed to explore the underlying mechanisms.
Results: Our results showed that after BAT removal, liver injury in Con A mice deteriorated, with elevated ALT, AST, and increased hepatic inflammatory cell infiltration. However, activating BAT with the selective β_3-adrenergic receptor agonist CL 316243 reduced CCl_4-induced hepatocyte death. Additionally, both BAT-EVs and primary brown adipocyte administration significantly lowered peripheral ALT and AST levels, reduced liver necrosis area and apoptotic hepatocyte count, decreased inflammatory cell infiltration, and lowered inflammatory cytokine levels, such as interleukin-6 and tumor necrosis factor-alpha. Further in vitro results revealed that brown adipocyte-derived EVs suppressed inflammatory cytokines production in macrophage, potentially by modulating macrophage mitochondrial metabolism through mitochondrial protein transfer.
Conclusion: There is BAT-liver protective axis in vivo. BAT-EVs and brown adipocyte significantly alleviate Con A, APAP, and CCl_4-induced acute liver injury in mice, suggesting a novel therapeutic strategy. Modulating macrophage mitochondrial metabolism may represent a potential therapeutic target. However, the possible mechanism is still under exploration.

Acute liver failure and drug induced liver injury – Clinical

Background and aims: Polyreactivity describes the ability of an antibody to bind multiple molecular structures, thereby increasing flexibility, affinity, and neutralizing potential. Polyreactive immunoglobulin G (pIgG) can be found in every individual, regardless of disease, and play an important role in primary immune defense and the removal of aging or apoptotic cells. Studies on viral influenza show that the majority of monoclonal antibodies are polyreactive after influenza. Recently pIgG was identified as a novel marker for the diagnosis of autoimmune hepatitis (AIH) in multicenter studies in children and adults. However, these studies included only a few AIH cases with acute liver failure (ALF). This retrospective multicenter study aims to evaluate the diagnostic capacity of pIgG to predict AIH in comparison to non-AIH-ALF, sepsis and influenza in an intensive care unit setting in adult patients.
Method: Quantification of human pIgG was done using a "home-made" solid phase ELISA coated with human huntingtin-interacting protein 1-related protein in bovine serum albumin (HIP1R/BSA). Biomaterial was retrieved from local biorepositories.
Results: 165 adult patients (ALF = 42, AIH = 81, influenza = 17, sepsis = 25) were compared from five centers across Europe. All patients in the control groups with viral (influenza) and bacterial infection (sepsis) related hyperinflammation were treated at intensive care units. Every patient in the influenza-group needed artificial respiration. Median age was significantly different between the groups ($p < 0.001$) with the highest age in the influenza group (59 years) and the lowest age in the ALF-group (42 years). Female rate was highest in the AIH group (79%) and significantly lower in the influenza- (12%) and sepsis-group (24%). IgG elevation rate was 60% in the AIH- and 17% in the ALF-group, whereas no elevation could be seen in influenza- and sepsis-groups ($p < 0.001$). 30-days death rate was significantly higher in sepsis (64%) and influenza (47%) compared to ALF (14%) and AIH (0%, $p < 0.001$). 34% in the ALF- and 2% in the AIH-group underwent liver transplantation. ALF due to AIH was 7.1% in the ALF-group (3 cases). 53% in influenza- and 25% in sepsis-group had immunosuppressive medication at sampling (0% in AIH, 2% in ALF). The median pIgG-level was highest in the ALF-group (2.08 normalized arbitrary units, nAU) followed by AIH (1.87 nAU, $p = 0.786$). In the influenza-group, the median pIgG-level (1.01 nAU) was significantly lower compared to ALF and AIH (both $p < 0.001$). The median pIgG-level was 1.39 nAU in the sepsis-group ($p = 0.092$ vs. AIH; $p = 0.070$ vs. ALF). The background of non-AIH liver diseases in previous studies was 1.01 nAU.
Conclusion: Prevalence and concentration of pIgG are similar in AIH (with and without ALF) and ALF suggesting that pIgG are not suited to distinguish between autoimmune and non-autoimmune origin of ALF. However, hyperinflammatory infectious diseases are associated with lower pIgG concentrations than AIH and ALF.

Email: taubert.richard@mh-hannover.de

Background and aims: Amatoxin-related acute liver failure (AT-ALF) is associated with a high mortality rate in the absence of liver transplantation (LTX). The use of therapeutic plasma exchange (PEX) has been demonstrated to improve LTX-free-survival in patients with acute liver failure (ALF) of other etiologies. Nevertheless, it remains unclear whether PEX may also enhance survival in AT-ALF. Additionally, there is considerable variation in the clinical practice of utilizing PEX in AT-ALF across different centers. Given the rarity of this ALF entity, the feasibility of conducting a randomized controlled trial to investigate the use of PEX in AT-ALF remains uncertain. The aim of this study therefore was to record and compare the LTX-free and overall survival within the first 28 days following the fulfillment of ALF criteria (hepatic encephalopathy (HE) and INR >1.5) between patients who received PEX and those who received no PEX.
Method: This is an interim analysis of a multicenter, international, retrospective cohort study (Amanita-PEX study, NCT06187220). The period of inclusion spanned from 2013 to 2024. This report presents the findings for the adult cohort.
Results: A total of 89 adult patients were recruited from 21 centers across eight countries. The median age of the cohort was 58 years (range 18–87 years), and 39 patients (44%) were female, 85 patients (96%) received therapy with silibinin and 83 patients (93%) received additional therapy with N-acetyl cysteine. Twenty-six patients received additional PEX (29%), while 63 received no PEX (71%). Overall, 25 patients (28%) died within the first 28 days, and 26 (29%) required LTX. A multivariate survival analysis was conducted, demonstrating a benefit of LTX-free survival associated with PEX (HR 0.44, CI 0.20–0.94, p = 0.04) when adjusted for age, sex, initial Sequential Organ Failure Assessment (SOFA) score on the first day and HE grade ≥2. The survival curve demonstrated a benefit in LTX-free 28-day survival for PEX when divided into patients with HE = 1 (PEX: 100%; no-PEX: 78%) and HE ≥2 (PEX: 42%; no-PEX: 19%) in comparison with no-PEX with the same grade of HE (log-rank test, p < 0.01). Likewise, there was a benefit in overall survival when divided the patients with HE = 1 (PEX: 100%; no PEX: 87%), and HE ≥2 (PEX: 68%, no-PEX: 52%) in comparison with no-PEX with the same grade of HE (log-rank test, p = 0.01).
Conclusion: In this interim analysis of a multicenter retrospective study, PEX was associated with improved LTX-free survival in patients with AT-ALF.

THU-194

Therapeutic and clinical outcomes of continuous renal replacement therapy and plasma exchange in acute liver failure patients

Anshuman Das[1], Vivekanand Balijepalli[1], Sairam Reddy[2], Anand Gupta[2], R. Sujith Reddy[1], Vinayanand Balijepalli[2], Ushoday Reddy[1], Akash Roy[3], Anand Kulkarni[1]. *[1]AIG Hospitals, Hyderabad, India; [2]AIG Hospitals, Hyderabad, India; [3]Apollo Multispeciality Hospitals, Kolkata, India*
Email: anshuman04@gmail.com

Background and aims: Continuous renal replacement therapy (CRRT) and plasma exchange (PLEX) improve outcomes in Acute liver failure (ALF) as a bridge to liver transplant (LT). Both CRRT and PLEX have been shown to improve outcomes in these sick patients. However, seldom studies have compared these two in the real world scenario, which we aimed to compare.
Method: Single-centre retrospective observational study with 50 patients (≥ 18 years of age) presenting with ALF between 2022 and 2024 were included. We compared the improvement in hepatic encephalopathy grade and organ function, the duration of hospital stay and overall survival rate in patients who underwent CRRT, PLEX and Standard medical therapy (SMT), respectively.

Results: Overall, 50 patients (31.0 ± 13.2 years, 62% females, MELD score (31.4 ± 6.9), 30% satisfying Kings College Criteria), with Hepatitis A virus as the most common (34%), met selection criteria. At admission, infection was present in 50%, 30% had shock and 40% had acute kidney injury. 18 (36%) received CRRT (MELD. 32.3 ± 7.2) or PLEX (MELD, 34.0 ± 5.4), while 14 (28%) were on SMT (MELD, 25.5 ± 4.7). Compared to SMT, using CRRT (p = 0.014) was associated with better improvements in HE grades than PLEX (p = 0.29). CRRT significantly reduced ammonia levels (172 ± 43.6 to 136.44 ± 59.37, p = 0.01) compared to SMT (85.62 ± 24.96 to 74.63 ± 25.76) but PLEX did not (132.27 ± 46.56 to 105.47 ± 39.86, p = 0.31). Similarly, compared to SMT, using CRRT (p = 0.007) significantly improved organ function, and PLEX did not show significant organ improvement (p = 0.32). Overall, 28 day transplant-free survival was 40%. Among those receiving CRRT 6(33%), 11(61.1%) of those on PLEX survived. Only 3 (21.4%) of those on SMT survived. On comparing PLEX with CRRT, there was a trend of better survival with PLEX (p = 0.09).
Conclusion: PLEX and CRRT are associated with better outcomes in ALF than SMT. Future randomized trials comparing PLEX and CRRT for outcomes in ALF are mandated.

THU-195
Haemophagocytic lymphohistiocytosis – a rare but deadly cause of acute liver failure

Esme Gardiner[1], Neil Rajoriya[1], James Ferguson[1], Lindsay George[2], Abhishek Chauhan[1]. [1]*Liver Unit, University Hospital Birmingham NHS Foundation Trust, Birmingham, United Kingdom;* [2]*Centre for Clinical Haematology, University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom*
Email: esmegardiner@btinternet.com

Background and aims: Acute Liver Failure (ALF) is a rare life-threatening clinical syndrome characterized by liver-related coagulopathy and hepatic encephalopathy (HE) with no pre-existing hepatic pathology. Amongst the rare causes of ALF is haemophagocytic lymphohistiocytosis (HLH), a pathology characterised by life-threatening dysregulated immune activity causing pathological inflammation and multi-organ failure. Acute liver injury (ALI), coagulopathy in absence of HE, is recognised as a common bystander of HLH, however ALF secondary to HLH is a rare phenomenon. Treatment is 3-fold; supportive management for ALF, treatment of the underlying trigger and treatment of HLH guided by the HLH-2004 protocol. Super-urgent transplantation is not advised by EASL, with literature describing recurrence of HLH involving the graft and high mortality. The aim of this case series is to review our admissions of patients with ALF secondary to HLH and describe clinical parameters, management and outcomes for this rare group.
Method: This case series describes patients from a quaternary liver transplant unit, all of whom were managed in the intensive care unit. Patients were identified through retrospective review of the hepatology handover archive between January 2010 and October 2024. Electronic and paper hospital records were reviewed to confirm if ALF criteria were met and to collect numerical and descriptive data. 4 cases of ALF secondary to HLH were identified as well as 3 further cases of ALI.
Results: Of the patients with ALF, all 4 were female with a mean age of 35 years (range 17–66). Two of the patients had history of solid organ transplantation (Renal = 1, Liver = 1). Triggers were identified in 3 patients (Herpes Simplex virus 2 (HSV-2) N = 2, Epstein Barr virus (EBV) N = 1). Management of all included corticosteroids. One patient died prior to any further escalation of HLH management. One patient also received etoposide with the addition of anakinra for refractory HLH. One additionally received anakinra and a course of plasmapheresis followed by intravenous immunoglobulin. The final patient also received rituximab. Despite aggressive HLH treatment and multi-organ support, all resulted in critical illness and death. Issues encountered in all patients included balancing the risk of introduction of corticosteroids when viraemia had not been excluded yet and dosing of chemotherapy regimens with liver dysfunction.
Conclusion: This case series explores the varying presentations and management of a rare cause of ALF with high mortality in a large liver transplant center. This rare condition requires a high index of suspicion to allow prompt recognition and treatment to improve outcomes. Further research and guidance for this subsection of ALF is required with focus on the adjustments needed to HLH management with this degree of hepatic dysfunction.

THU-196
Effects of universal early antimicrobial treatment in acute liver failure patients at a large volume transplant centre in the United Kingdom

Gladson Thomas[1], Manan Bajaj[1], Rosemary Worrall[1], Nicholas Murphy[1], Jaimin Patel[1], Abhishek Chauhan[1], Neil Rajoriya[1], Mansoor Bangash[1]. [1]*Queen Elizabeth Hospital, Birmingham, United Kingdom*
Email: Gladson.Thomas@uhb.nhs.uk

Background and aims: We set out to assess clinical consequences of universal early antimicrobial treatment in critically ill acute liver failure (ALF) patients admitted to a tertiary /quaternary liver intensive care unit (ICU).
Method: A retrospective observational study was performed for patients admitted to ICU with ALF between May 2022–April 2024. Electronic patient records were reviewed for microbiologic, radiologic and blood biomarker evidence of infection and resistance. Systemic inflammatory response syndrome (SIRS), non-neurologic sequential organ failure (SOFA) scores and antimicrobial prescriptions were reviewed. Antimicrobial duration as a proportion of ICU length of stay (LoS) was calculated. Data are expressed as median (interquartile range).
Results: There were 37 critically ill ALF admissions with an ICU LoS of 9 (6–16) days, for review. In line with local Liver unit guidelines, all patients received antimicrobials on admission and patients were prescribed fluconazole (100%) alongside either Pipericiliin/Tazobactam (35/37; 94.6%) or meropenem (2/37; 5.4%). On admission, 10/37 (27%) patients already had some evidence of infection (9 radiologic and 1urine culture) – however, pre-ICU LoS was not significantly different between infected and non-infected groups. SOFA scores were significantly higher in infected patients (12 (8.5–14) vs 8 (7–10)) but C-reactive protein (11 (6–25) vs 11 (3–14)), white cell count (14.5 (9.5–19.5) vs 11.5 (7.5–15)) and SIRS scores (2 (1–2) vs 1 (1–2)) were not. Admission blood cultures were negative in all but were only taken in 20% (2/10) infected patients and 30% (8/27) non-infected. Despite universal antimicrobial treatment from the outset, 18/37 (49%) patients required further antimicrobial escalation/extension for presumed infection during their stay and median ICU antibiotic-free days indexed to ICU LoS was 0% (0–26.5). 3 resistant organisms were found in 2/37 (5%) patients (multi-drug resistant (MDR) Pseudomonas, MDR Staphylococcus Haemolyticus and Carbapenemase producing enterococci). Mortality and (6/37 (16%)) transplantation rate (19/37 (51%)) didn't differ according to presence/absence of admission infections, but 2 patients meeting Kings College Criteria with no contra-indications to transplantation succumbed to uncontrolled sepsis at days 4 and 5.
Conclusion: Admission infections were found in nearly 3 in every 10 ALF admissions. SOFA scores were higher in patients with admission infections, but overlap was high and the poor discrimination of traditional infection markers such as CRP, WCC and SIRS scores demonstrates the difficulty of identifying sepsis in this group. Sepsis remains a driver of avoidable ALF deaths, though the association of universal antimicrobial treatment with few antibiotic-free days, antimicrobial escalation in over half of admissions, and the development of resistant organisms highlights the potential harms of over-treatment. Research into better biomarkers of infection in ALF are warranted.

THU-197

Essential: Efficacy and safety of non-transplant therapies for acute liver failure syndromes due to infective etiologies

Ramit Mahajan[1], Saurabh Singhal[2], Ajit Sood[1], Parshotam Gautam[1], Rubina Mahajan[1], Arshdeep Singh[1], Vandana Midha[1]. [1]*Dayanand Medical College and Hospital, Ludhiana, India;* [2]*Akash Healthcare Super Speciality Hospital, Dwarka, New Delhi, India*
Email: mahajan.ramit@gmail.com

Background and aims: Acute liver failure (ALF) in India primarily stems from infective causes, contrasting with drug-induced etiologies prevalent in the West. We investigate non-transplant therapies like plasma exchange (PLEX) and continuous veno-venous hemofiltration (CVVH) as rescue strategies for ALF, addressing high mortality and limited liver transplantation access in resource-constrained settings.
Method: A retrospective analysis of 76 ALF patients from April 2021 to July 2024 at a single center, approved by the Institutional Review Board. Patients were categorized into three management groups: A: CVVH only, B: PLEX [B1: without CVVH, B2: with CVVH], C: standard medical treatment (SMT). Primary outcome was transplant-free survival at discharge or day 21, defined as 'improvement' versus 'worsening' (death, clinical deterioration, or referral for orthotopic liver transplantation [OLT]). Severity indices - Model for End-Stage Liver Disease (MELD), Sequential Organ Failure Assessment (SOFA), Acute Physiology and Chronic Health Evaluation (APACHE), Assessment of Liver Failure (ALFA) Score, and Acute Liver Failure Study Group (ALFSG) index - were evaluated to create a probability score model for individualized treatment prediction.
Results: Groups showed no significant demographic differences except for creatinine levels (group A: 3.1 vs. groups B/C: 1.4, $p = 0.001$). ALFSG Score was highest in groups A and B2, lowest in B1 and C. Group C demonstrated significantly lower bilirubin, ammonia, International Normalized Ratio (INR), and lactate compared to groups A and B. Seven-day improvements were highest in group B (B2 > B1) > A > C ($p < 0.05$). Survival rates were 78.9% vs. 87.8% vs. 85.7%. Clinical improvement: 45% vs. 71% (81% vs. 56%) vs. 86% ($p = 0.031$). Multivariate analysis revealed significant outcomes using ALFA score, ALFSG index, and SOFA score. Regression analysis developed a worsening probability score: 3.2475 + (−1.3688 × ALFSG Index) + (0.0169 × SOFA), with 90.9% accuracy. Multinomial logistic regression probability scores:.

- Group A: −1.3337 + (0.4471 × ALFSG Index) + (0.0507 × SOFA).
- Group B: 1.3571 + (−0.0504 × ALFSG Index) + (−0.0937 × SOFA).
- Group C: −0.0234 + (−0.3967 × ALFSG Index) + (0.0429 × SOFA).

Models showed 90% sensitivity and 72% accuracy when validated at an independent center. Patients with high creatinine (>1.5) and unstable SOFA/ALFSG index benefited most from CVVH, while high ammonia levels responded best to PLEX.
Conclusion: PLEX proves optimal for unstable infective ALF patients, with CVVH as a valuable intervention for acute kidney injury. The predictive models, validated across two centers, demonstrate high accuracy in guiding individualized treatment strategies, offering a promising approach in resource-limited settings.

Combination therapy with plasma exchange and continuous renal replacement therapy improves transplant free outcomes in acute liver failure: a tertiary care center experience

Manasa Alla[1], Anand Kulkarni[1], Anand Gupta[1], Mithun Sharma[1], Sowmya Iyengar[2], Shantan Venishetty[1], Nagaraja Padaki[1], Nageshwar Reddy[1]. [1]*AIG Hospitals, Hyderabad, India;* [2]*AIG Hospitals, Hyderabad, India*
Email: manasa1512@gmail.com

Background and aims: Acute liver failure (ALF) is associated with overall mortality of 30% and mortality without LT being almost 50%. Plasma exchange(PLEX) helps in improved coagulation, and decreases cytokine storm, while continuous renal replacement therapy(CRRT) improves ammonia level and removes various mediators in the formation of cerebral edema. Hence we hypothesized that the combination therapy is associated with better outcomes in ALF patients. Till date, only one retrospective study and one case series available in assessing outcomes of combination therapy in paediatric ALF and no data in adult patients. Our aim was to assess the 28 day transplant free survival in ALF patients undergoing combination therapy (CRRT + PLEX).
Method: It was a retrospective data analysis done at a tertiary care center from October 2022–September 2024 in patients with ALF. All patients underwent standard volume PLEX (arm A) before April 2023 and standard volume PLEX+ CRRT (arm B) thereafter. CRRT was initiated within 24 hours of admission for hyperammonemia (>90 mmol/L) and cerebral edema.
Results: 54 ALF patients (mean age 30.33 ± 12.33 years, females 55.5%, mean MELD 32.1 ± 4.32) were analyzed. Most common etiology was hepatitis A followed by yellow phosphorus poisoning (31.4% {17/54} vs 29.6% {16/54}). All patients received standard medical care, including N-acetyl cysteine and nutritional support. 29 patients underwent only PLEX and 25 underwent combination therapy. 42 (77.7%) patients were in grade 3 or 4 hepatic encephalopathy at presentation. Median sessions of PLEX (2) were similar between the groups. Incidence of sepsis (13.7% {4/29} vs 12%{3/25; $p = 0.85$), pneumonia (6.8% {2/29} vs 4%{1/25}; $p = 0.65$), acute kidney injury (10.3%{3/29} vs 16%{4/25}; $p = 0.53$), seizures (31%{9/29} vs 40% {10/25}; $p = 0.49$) was noted in arm A and B respectively and was comparable between the arms. Day 5 mean MELD scores were 23.22 ± 8.25 vs 19.23 ± 6.3; $p = 0.05$, arterial ammonia was 94.12 ± 34.34 vs 75.32 ± 32.46, $p = 0.04$ in arm A and B respectively. Mean length of ICU stay was 12.92 ± 4.1 vs 13.02 ± 4.58; $p = 0.93$ and mean hospital stay was 18.58 ± 4.24 vs 18.54 ± 4.08; $p = 0.97$ in arm A and B respectively and was similar. 7-day (44.8% {13/29} vs 68% {17/25}; $p = 0.09$) and 30-day (37.9% {11/29} vs 64% {16/25}; $p = 0.058$) transplant free survival in arm A and B respectively and showed a higher transplant free survival at 30 days in the combination arm.
Conclusion: Our study showed that combination therapy with PLEX and CRRT shows promising outcomes and a trend towards improved 30-day transplant free survival compared to PLEX.

THU-199

Evaluation of different large language models' performance in answering common questions from drug-induced liver injury patients

Yinuo Dong[1], Zili Zhang[2], Tengyu Guo[1], Yang Zhi[1], Yimin Mao[1]. [1]*Division of Gastroenterology and Hepatology, Renji Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China;* [2]*Shanghai Jiao Tong University School of Medicine, Shanghai, China*
Email: maoym11968@163.com

Background and aims: Large language models (LLMs) are gaining increasing attention due to their information retrieval capability and ability to generate human-like responses. Drug-induced liver injury (DILI) is a common yet often overlooked disease closely linked to individual medication habits, underscoring the importance of patient education and knowledge support. Therefore, LLMs have the potential to serve as an effective tool for addressing common questions from DILI patients. We evaluated the performance of six major LLMs (LLaMA-3.1, GPT-o1, Claude-3.5, GPT-4.0, Gemini-1.5, GPT-3.5) in delivering accurate responses to common DILI-related queries.
Method: In this study, we collected twenty-eight DILI-related questions frequently asked by patients, which can be categorized into six domains: pathogenesis, risk factors, clinical presentation, diagnosis, treatment and prevention, and prognosis. LLMs were used to generate responses to these questions, which were subsequently evaluated by three consultant-level hepatologists in accuracy,

comprehensiveness, helpfulness and safety. To minimize potential bias, we concealed identifiable features specific to individual LLM-chatbots, randomly shuffled and masked responses before evaluation. Accuracy was graded on a three-point scale (poor, borderline, good), and comprehensiveness, helpfulness and safety were graded on five-point Likert scale. Flesch-Kincaid Grade Level was employed to evaluate the readability.
Results: LLaMA-3.1 demonstrated superior accuracy, with 70.2% of responses graded as 'good', compared to 52.4% in GPT-o1, 31.0% in GPT-4.0, 28.6% in Claude-3.5, 25.0% in Gemini-1.5 and 7.1% in GPT 3.5. (adjusted chi-square, all $p < 0.01$). LLaMA also outperformed others in comprehensiveness (mean score: LLaMA-3.1: 3.86; GPT-o1: 3.49; Claude-3.5: 3.00; GPT-4.0: 2.98; Gemini-1.5: 2.66; GPT-3.5: 2.04, out of a maximum score of 5) and helpfulness (mean score: LLaMA-3.1: 3.92; GPT-o1: 3.71; Claude-3.5: 3.25; GPT-4.0: 3.03; Gemini-1.5: 2.95; GPT-3.5: 2.26, out of a maximum score of 5). All LLMs performed well in safety except for GPT-3.5 (mean score: LLaMA-3.1: 4.02; GPT-o1: 3.80; Claude-3.5: 3.54; GPT-4.0: 3.45; Gemini-1.5: 3.49; GPT-3.5: 2.93, out of a maximum score of 5). As for readability, Gemini-1.5 performed best (mean score: GPT-3.5: 14.16; GPT-o1: 13.91; GPT-4.0: 13.72; LLaMA-3.1: 13.4; Claude 3.5: 12.94; Gemini-1.5: 12.49).
Conclusion: Our study highlights the potential of LLM-chatbots, especially LLaMA-3.1, in delivering accurate, comprehensive, helpful and safe responses to common DILI-related queries. LLMs can serve as effective and safe tools for medical consultation and patient education in DILI.

THU-200
Checkpoint inhibitor-induced liver injury in patients with advanced skin cancer: a single center experience
Antonio Liguori[1,2], Sebastiano Archilei[1,2], Laura Quattrini[1,2], Francesco Brunetti[1,2], Marisa Salvi[1,2], Giuseppe Marrone[1,2], Marco Biolato[1,2], Luca Miele[1,2], Maurizio Pompili[1,2], Alessandro Di Stefani[1,2], Antonio Gasbarrini[1,2], Ketty Peris[1,2], Antonio Grieco[1,2]. [1]*Department of Medical and Surgery Sciences, Fondazione Policlinico Universitario A. Gemelli, IRCCS, Rome, Italy;* [2]*Università Cattolica del Sacro Cuore, Rome, Italy*
Email: lig.antonio91@gmail.com

Background and aims: Today, immune checkpoint inhibitors (ICIs) are first-line therapy for advanced melanoma and non-melanoma skin cancers. Checkpoint inhibitor-induced liver injury (ChILI) is one of the most common adverse effects (AE) widely reported, with an estimated prevalence of around 10% of patients. In patients who develop ChILI it is currently still unclear whether it is needed to discontinue the drug definitely or whether it is possible to safely re-start the same drug after temporary suspension.
Method: By a retrospective study, we enrolled all consecutive patients admitted to the Dermatology Unit at our center, who underwent ICI therapy for advanced melanoma or non-melanoma skin cancer from June 2016 to April 2024. Diagnosis and severity of ChILI were assessed according to CTCAE v5.0, type of liver injury was defined according to international guidelines. Liver function tests (LFTs) at baseline, after three cycles of therapy, and at ChILI suspicion were retrieved. ChILI management and outcome were retrieved.
Results: We enrolled 111 patients (32.4% female, median age 75 years), 70 (63.1%) patients bearing advanced melanoma, and 41 (36.9%) with locally advanced or metastatic skin squamous cell carcinoma. 3 (2.7%) underwent first-line therapy with anti-CTLA4, 106 (95.5%) with anti-PD1, and 2 (1.8%) with a combination of them. Median therapy duration was 10 months (IQR 5–21). 8 (7.2%) patients developed ChILI after a median of 14 infusions (IQR 7–20). 1 presented grade 2, 3 grade 3, and 4 grade 4. Among patients who developed ChILI, 3 showed anti-nuclear antibody positivity (ANA), 1 showed positive extractable nuclear antigen (ENA) test, and in 2 patients an autoimmune disorder was already known at the beginning of ICI's therapy. All patients stopped ICI, in 5 of them we assisted to a spontaneous and complete LFTs normalization, while in 3 of them steroid therapy was added. No patients underwent drug rechallenge. 2 patients started a different class of ICI without evidence of early or late toxic recurrence. Among the more common extrahepatic AE, ChILI patients showed diarrhea and dermatological papular or bullous rash (37.5% and 50% respectively), with a prevalence significantly higher when compared with no-CHILI patients (7.8% and 15.4% respectively, $p < 0.05$). Comparing patients who developed ChILI with patients who did not, baseline and 3rd infusion LFTs were not significantly different ($p > 0.05$).
Conclusion: The median time of ChILI onset, after multiple cycles of treatment, seems to confirm an indirect mechanism of liver damage rather than toxic direct action. Interestingly, we observed that patients who developed ChILI were those at higher risk of dermatological and/or gastrointestinal AE. Although this observation was conducted on a small sample of patients, it may represent a useful tool for clinicians to prevent the possible onset of ChILI, avoid severe clinical scenarios, and provide early treatment.

THU-205
Increased risk of hepatic steatosis in young adults treated for first-episode psychosis; a retrospective study
Tristan Rocheleau[1], Laurent Béchard[1], Olivier Corbeil[1], Nicolas Isabel[1], Maxime Huot-Lavoie[1], Sylvain Iceta[1], Paul Poirier[1], André Tchernof[1], Marie-France Demers[1], Marc-André Roy[1], Fannie Lajeunesse-Trempe[1]. [1]*Laval University, Quebec, Qc, Canada*
Email: tristan.rocheleau.2@ulaval.ca

Background and aims: Psychotic disorders in young adults are associated with an increased risk of cardiometabolic complications, to which exposure to antipsychotics contributes. However, little is known about the evolution of liver health in these young adults. We aim to describe the risk of hepatic steatosis over time in young adults followed in a first-episode psychosis program (FEPP).
Method: This retrospective study included 70 young adults followed in a FEPP. Clinical parameters [weight, height, waist circumference, body mass index (BMI)] and biochemical parameters (lipid profile, blood glucose, hemoglobin A1c, renal and liver function markers, etc.) were measured on admission to the FEPP and during follow-up. Based on the estimated results of the Fatty Liver Index (FLI)–a validated predictive score for hepatic steatosis–young adults were individually classified over time as being at low (<30), moderate (30–59) or high (>60) risk of hepatic steatosis.
Results: On admission, the cohort (36% female, mean age 26 ± 5 years) had a BMI of 26.8 ± 7.4 kg/m^2 and a mean FLI of 44.8 ± 32.2. On average, at 14 months follow-up, the FLI score increased to 61.2 ± 33.0. This deterioration was not detectable nnnby liver enzyme monitoring but was associated with an increase in anthropometric parameters (weight, waist circumference and BMI). Exposition to olanzapine, aripiprazole or quetiapine is associated with a higher FLI and cardiometabolic risk.
Conclusion: These results describe an increase over time in the risk of hepatic steatosis in young people experiencing a first psychotic episode, possibly related to the cardiometabolic deterioration following the introduction of psychiatric pharmacotherapy. Better understanding of the hepatic risks associated with psychotropic medication and of the psychotic disorder itself is essential to minimize possible hepatic complications in young people experiencing a first episode of psychosis.

Plasma exchange to treat severe acute liver injury: opportunity to improve native liver survival
Vijay Alexander[1], Gayathiri Chelliah[1], Gnanadeepam S.[1], Vinoi David[1], Ebor James[1], Subramani Kandasamy[1], Santosh Varughese[1], Sukesh Nair[1], Dolly Daniel[1], Binila Chacko[1], Asisha Janeela M.[1], Santhosh Kumar[1], Uday Zachariah[1], CE Eapen[1], Ashish Goel[1]. [1]*Christian Medical College, Vellore, India*
Email: vijayalexander@cmcvellore.ac.in

Background and aims: Plasma exchange (PLEX) improves survival in patients with phosphorus rodenticidal hepatotoxicity (RH) and paracetamol overdose. In a prior report, no patient with RH who met 'Kochi' criteria (Model for End Stage Liver Disease score ≥36 or baseline International Normalized Ratio ≥6 with hepatic encephalopathy) for urgent liver transplantation survived with medical management alone (PMID: 26310868). Survival benefit with PLEX, reported in a randomized controlled trial from Europe (PMID: 26325537), was not seen in a recent UK study comprising mostly patients with cardio-respiratory failure (PMID: 39362282). In this study, we aim to define an effective window for the utility of PLEX as a stand-alone treatment in patients with RH-induced severe acute liver injury/ failure (sALI/ ALF). We also aim to assess dynamic parameters which can help listing for rescue liver transplant.
Method: Patients with RH from 2014 to 2024 managed in our department were included in this study. We analyzed outcomes in patients (sALI and ALF) who met 'Kochi' criteria, were not on cardio-respiratory support, and were treated with low-volume PLEX earlier in the course of the illness. We also assessed the progression from sALI to ALF. ΔMELD (PMID: 39001974) was calculated as a percentage change from baseline values after the third PLEX session (or last session if < 3 sessions were done). Post–PLEX samples were collected ≥12 hours after completion of each session.
Results: Of 216 consecutive patients with rodenticidal hepatotoxicity managed in our department between January 2014 and August 2024, 130 patients (75 sALI, 55 ALF prior to PLEX) were treated with low-volume PLEX. No patient had liver transplantation. Thirty–three RH patients (age: 21, 7–70 years; F: 64%; sALI: ALF: 19:14; King's College criteria:11/14 ALF patients; 78.6%), who met 'Kochi' criteria and were not on cardio-respiratory support, underwent 3 (2–8) PLEX sessions with 1100 (750–2000) ml volume exchanged per session. In these PLEX–treated patients, 1-month transplant-free survival was 27/ 33 (82%). Patients with ΔMELD decline ≥20% after PLEX had better survival (24/25 v/s 3/8; p-value: 37.5%) and had lesser progression to ALF (2/14 v/s 4/5; p-value: 0.006) vis-à-vis patients who fail to achieve this threshold.
Conclusion: PLEX improves survival in patients with severe RH requiring transplant listing but with preserved cardio-respiratory function. Post-PLEX (day 3) ΔMELD decline < 20% predicts non-response/ worse outcome and can be used to prognosticate/ consider rescue liver transplant.

Alcohol-related liver disease and MetALD – Basic

Bio-molecular characterization of albumin identifies predictors of disease severity and early mortality in severe alcohol associated hepatitis

Sushmita Pandey[1,2], Neha Sharma[1], Gaurav Tripathi[1], Vasundhra Bindal[1], Babu Mathew[1], Nupur Sharma[1], Sadam H Bhat[1], Sanju Yadav[1], Rimsha Rimsha[1], Manisha Yadav[1], Shvetank Sharma[1], Anju Katyal[2], Shiv Kumar Sarin, Jaswinder Maras[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India;* [2]*Dr. B R Ambedkar Center for Biomedical Research, University of Delhi, New Delhi, India*
Email: jassi2param@gmail.com

Background and aims: Albumin modifications are critically linked with the pathophysiology of severe alcohol associated hepatitis (SAH). Bio-molecular and functional characterization of albumin could help in identification of signatures which can predict early mortality in SAH patients.
Method: Purified plasma albumin from SAH patients (n = 351), alcohol associated cirrhosis (AC, n = 11) and healthy controls (n = 20) was analysed for modifications, functionality, and bound multi-omics signatures (proteins, metabolites, lipids and bacterial peptides). Results of training cohort (n = 131; SAH non-survivors, n = 25; SAH survivors, n = 75; AC, n = 11; healthy controls, n = 20) were tested in the validation cohort (n = 251; 147 SAH-Survivors and 104 Non-Survivors) using High Resolution Mass Spectrometry (HRMS) and machine learning (ML) approach.
Results: Bio-molecular signatures of SAH were distinct with high albumin oxidative state and human non mercapto-albumin 2 levels (HNA2, $P < 0.05$). Albumin bound Multiomics signatures of SAH were distinct as compared to other groups. In SAH non-survivors, albumin was linked to hyper-inflammatory proteins and fatty acid beta-oxidation metabolites. Non-survivors had specific increase in bacterial taxa (Nitrospirota, Mycoplasmatota, and others) correlated with lipids (Cer(d17:1/6:0), TG (11:0/10:0/18:0), and others) and metabolites (C04284, C16525,and others, $R^2 > 0.7$). Albumin bound multi-omics signature-based probability of detection (POD) for non-survival was >90% and correlated with functional and clinical parameters ($R^2 > 0.85$). Top albumin-bound metabolome pannel: Eicosanoic acid, Docosahexaenoic acid, Neuraminic acid, Icosadienoic acid and 2-Heptyl-4-hydroxyquinoline-N-oxide had diagnostic accuracy of 98% and segregated SAH patients predisposed to early mortality (log-rank<0.05). On validation (HRMS, 5-ML algorithm) we affirm that SAH patients with greater change in albuminome, specifically with higher binding of metabolome panel had higher probability of early mortality (w > 90% accuracy/sensitivity/p-value).
Conclusion: In SAH, albumin is severely hyper-oxidized and dysfunctional. Our findings show that significant changes in albumin, indicated by elevated metabolome panel interactions, was able to segregate SAH patients predisposed to early mortality.

Email: annabrujats@gmail.com

Background and aims: Plasma exosomes represent an intercellular communication in which the donor cell defines the composition of

the surface antigen. Alcohol-associated hepatitis (AAH) is one of the most severe clinical stages of alcohol-associated liver disease. The characterization of exosome surface antigens may reflect the main immune mechanisms involved in the pathogenesis of AAH. The aim of this study is to characterize the profile of exosomes through the expression of surface antigens in a cohort of patients with AAH and to correlate these values with soluble plasma molecules and clinical events.

Method: Patients with a diagnosis of severe AAH (MELD score > 20) who were admitted to Hospital Santa Creu i Sant Pau, between 2020–2024, were consecutively and prospectively included. Blood samples were collected prior to the initiation of corticosteroid treatment to characterize plasma exosomes. Characterization of surface antigens was performed using conventional flow cytometry with the MACSPlex kit, and soluble plasma molecules were analyzed using ELISA.

Results: A total of 46 patients with AAH were included. Quantification of exosomes was performed by Nanoparticle Tracking Analysis (NTA). The quantity of exosomes by NTA was significantly higher in patients with AAH compared to a control group of 15 healthy donors (HDs). The surface antigen profile expressed by plasmatic exosomes of AAH patients also differed from that of HDs. Patients with AAH exhibited 14 surface antigens with lower expression and 8 with higher expression compared to HDs ($p < 0.05$), and the correlation between these antigens was different between AAH versus HDs. The mean fluorescence intensity (MFI) of CD3 and CD56 was significantly higher in those with AUDIT scores >15 ($p < 0.05$), and the MFI of CD105 was positively correlated with years of alcohol use disorder (r: 0.39, $p = 0.026$). Regarding clinical complications associated to AAH, the MFI of CD20 and CD2 differed between AAH patients with infections and those without an infection. Similarly, the MFI of CD40 and CD146 was correlated with creatinine levels and distinguished between patients who developed acute kidney injury and those who did not. The MFI of CD14, CD25, and CD41b was correlated with systemic inflammatory molecules including interleukin-6 and C-Reactive Protein ($p < 0.05$). The combination of higher levels of CD49e and Ssea4 significantly predicts response to corticosteroid with an AUC 0.847 (CI 0.706–0.988, $p < 0.001$). Combination of CD19 + CD105 + Mcsp significantly predicts mortality in AAH patients with an AUC 0.834 (CI 0.667–1, $p < 0.001$).

Conclusion: Plasma exosomal surface antigens, likely derived from endothelial, monocyte, and platelet activation, are non-invasive markers that could be used to identify those patients with AAH at higher risk of clinical complications, poor response to corticosteroids, and lower survival during follow-up.

Gut microbiota derived immunological signature in metabolic alcohol associated liver disease

Jung A Eom[1], Ki Tae Suk[1], Kyeong Jin Lee[1], Kwon Goo-Hyun[1], In Gyu Park[1], Sung-Min Won[1], Min Ju Kim[1], Younglim Ham[2], Dong Joon Kim[1]. [1]*Hallym University, Institute for Liver and Digestive Diseases, Chuncheon, Korea, Rep. of South;* [2]*Daewon University College, Department of Nursing, Jaecheon, Korea, Rep. of South*
Email: ktsuk@hallym.ac.kr

Background and aims: Liver has been known as an immune organ rich in innate immune cells and exposed to nutrients and endotoxins derived from the gut microbiome. Mucosal-associated invariant T (MAIT) cells are activated and initiate immune responses when their T cell receptor recognizes the riboflavin metabolite (5-OP-RU) derived from bacteria, presented by MR1, under co-stimulatory signals from specific cytokines or toll-like receptors. Although MAIT cells play a central role in various diseases, studies on the gut microbiome related to the function of MAIT cells are still lacking in metabolic alcohol associated liver disease (MetALD). We aimed to demonstrate the role of *Phocaeicola dorei* (with high riboflavin secretion) and *Bifidobacterium breve* (with low riboflavin secretion) in the MetALD model.

Method: A total of 98 human blood samples [healthy control: n = 8, metabolic dysfunction-associated steatotic liver disease (MASLD): n = 19 and MetALD (hepatitis: n = 16 and cirrhosis: n = 55)] were collected for flow cytometry analysis. Six-week-old male C57BL/6J mice were divided into four groups [n = 9 /normal control, n = 12 /group; Western diet (WD)+EtOH, WD+EtOH+*P. dorei*, WD+EtOH+*B. breve* (10^9 CFU/ 100ul by oral gavage 3 times a week for 20 weeks)].

Results: The expression of CD69 and CD25, activation markers of MAIT cells, was significantly increased in MASLD and MetALD patients compared to healthy controls (CD69: 33.3% vs. 30.1% vs. 1.6%, CD25: 5.7% vs. 7% vs. 1.5%). Importantly, the expression was significantly lower in cirrhosis compared to hepatitis (CD69: 24.6% vs. 49.1%, CD25: 6% vs. 10%). In patients with MetALD, serum albumin levels, which decrease with liver damage, showed a positive correlation with the frequency of CD69+ MAIT cells ($r = 0.3683$, $p = 0.0016$). In the MetALD mouse model, *P. dorei* supplementation significantly decreased the frequency of MAIT cells (3.54% vs. 1.95%) and significantly increased the frequency of CD69+ MAIT cells (24.6% vs. 49.6%) compared to the WD+EtOH group. In contrast, *B. breve* supplementation significantly decreased the frequency of CD69+ MAIT cells compared to *P. dorei* (21.1% vs. 49.6%). Furthermore, *P. dorei* or *B. breve* supplementation significantly decreased the expression of CCL5 and CXCR3, which play an important role in immune cell migration and inflammatory response, compared to the WD+EtOH group. The expression of CXCR3, IL-17, and PD-1 was also decreased in CD69+ MAIT cells isolated from mouse liver tissue.

Conclusion: P.dorei suppresses inflammatory responses, alleviates liver damage, and contributes to regulating immune balance in the liver through activation of MAIT cells.

THU-482

Outcomes in a real-world patient group started on Acamprosate for alcohol use disorder (AUD) with co-existent advanced fibrosis: adherence, efficacy and clinical impact over 24 months

Helen White[1], Niamh Forde[1], Lynn Owens[2], Paul Richardson[1]. [1]*Liverpool University Hospitals Foundation Trust, Liverpool, United Kingdom;* [2]*University of Liverpool, Liverpool, United Kingdom*
Email: helen.white3@liverpoolft.nhs.uk

Background and aims: In England, rates of alcohol-associated mortality have been generally increasing in men and women for decades. Despite this, there are no internationally agreed upon guidelines for the conduct of clinical trials in Alcohol Use Disorder (AUD) and the majority of trials for pharmacotherapy in AUD have relatively low patient numbers. We aimed to retrospectively review patients reported to have been started on Acamprosate to report on real-world outcomes at a 2-year time-frame to further develop our understanding of pharmacotherapy use for this complex patient group specifically looking at adherence, efficacy and clinical outcomes including delta change in liver stiffness, GGT and ED attendances. Here we report on a sub-group of patients who were shown to have advanced fibrosis around the time of Acamprosate initiation.

Method: A search tool was used to identify Acamprosate initiation from clinic letters written by the Alcohol Care Team (ACT) at large hospital in England. Electronic patient records were subsequently cross-referenced for serial biomarkers, FibroScan© results and manual review by a clinician and a pharmacist of clinic letters additional systems allowed capture of alcohol status at 3,6,12 and 24 months following the initiation. Additional captured data included; duration of Acamprosate prescription, reason for cessation and additional/alternative pharmacotherapy prescription.

Results: 122/1634 patients had an FibroScan >11.0 kPa. 67 of these FibroScans were performed within 90 days of the initiation of Acamprosate and therefore have been included in this report.

46/67 were male. 40/67 were compliant with pharmacotherapy at 3 months. 32/67 (48%) were abstinent at 3 months, 29 (92%) were adherent to acamprosate. 10/67 had reduced their alcohol consumption, 8 (80%) were adherent to acamprosate, 13/67 reported no reduction in alcohol use but only 4 (30%) were adherent. 12 patients (17%) had already been lost from service by the 3 month mark. Clinical parameters all showed positive delta change over the subsequent 2-year period with acamprosate/alternative pharmacotherapy compliance. Only 9 of the initial 40 patients adherent to acamprosate, and 19/67 (28%) patients in this group reported ongoing abstinence/reduction in alcohol use at 24months.

Conclusion: There is a clear improvement in biochemical markers and liver stiffness if adherent to pharmacotherapy as expected and a reduction in ED attendances. Acamprosate appears to be as well tolerated in advanced liver stiffness as in other groups. Short-term efficacy and safety of acamprosate appears good however reduces over time. The key problems this data presents therefore is 1) how to maximise engagement from the outset and 2) how to maintain patient engagement over time. It is possible this large and chaotic patient group likely demand a higher amount of clinical support than they are currently receiving.

THU-483

Potential therapeutic target for the treatment of alcohol-related liver disease through magnesium homeostasis

Email: irecio@cicbiogune.es

Background and aims: Excessive alcohol consumption represents one of the main causes of chronic liver disease and liver-related mortality in Western countries. It has been reported that prolonged alcohol exposure leads to an impair in Magnesium (Mg^{2+}) homeostasis, decreasing Mg^{2+} serum levels and increasing Mg^{2+} excretion into the urine. This disorder is known as hypomagnesemia and aggravates disease progression. In this study, we investigate the role of Mg^{2+} in alcohol-derived liver disease (ALD), to find a potential therapeutic target.

Method: We have confirmed that ALD patients as well as preclinical mouse model of Chronic and binge ethanol feeding (the NIAAA model) possess a decrease in Mg^{2+} serum levels. Moreover, we have identified that the Mg^{2+} transporter Cyclin M4 (CNNM4) is upregulated under ethanol stimuli in ALD patients and in preclinical NIAAA model, acting as a Mg^{2+} extruder in the liver. For the preclinical studies, WT mice were treated with the NIAAA model for 11 days. At 3rd day, EtOH-fed mice were divided into two groups. One group was injected subcutaneously with GalNAc *Cnnm4* siRNA technology, which silenced *Cnnm4* specifically in the liver. At day 11, EtOH-fed mice and pair-fed mice were gavaged in the early morning with a single dose of EtOH or isocaloric maltose dextrin respectively. Mice were euthanized 9 hours after gavage.

Results: We proposed a new therapeutic target to treat the damage caused by ethanol consumption by specifically modulating the expression of CNNM4 in the liver through GalNAc siRNA technology. The effect of *Cnnm4* silencing was evaluated in primary hepatocytes and in the preclinical mouse NIAAA model. GalNAc si*Cnnm4* restored Mg^{2+} levels to baseline, improving mitochondrial dysfunction and reducing endoplasmic reticulum stress associated with this pathology. On the other hand, silencing *Cnnm4* restored the expression levels of the methyltransferase enzyme Protein L-Isoaspartate O-Methyltransferase (PCMT1), whose main role is the repair of alcohol-induced protein damage. To corroborate this finding, we silenced *Pcmt1 in vitro* and in the NIAAA model in the presence of GalNAc si*Cnnm4*, and we observed that si*Pcmt1* inhibited the therapeutic effect of GalNAc si*Cnnm*4.

Conclusion: Magnesium homeostasis disruption worsens the prognosis of ALD, and the restoration of hepatic Mg^{2+} levels through GalNAc si*Cnnm4* reverses alcohol-induced damage. Furthermore, GalNAc si*Cnnm4* therapy enhances the repair of alcohol-damaged proteins by increasing PCMT1 activity, offering a new therapeutic approach for the treatment of this disease.

THU-484

Digital pathology biomarkers describe fibrosis severity and disease activity in the FAT-MASH murine model and response to preventative treatment with mannose

John Hong[1], Raisa Rasul[2], Joshaya Trotman[1], Nathan Aist[2], Yvette Carbajal[1], Li Chen[2], Charles Derossi[3], Mathieu Petitjean[2], Scott Friedman[1], Jaime Chu[1]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]PharmaNest Inc., Princeton, United States; [3]Icahn School of Medicine at Mount Sinai, New York, United States*
Email: john.hong@mssm.edu

Background and aims: Current histological staging methods used to quantify fibrosis severity and disease activity in metabolic dysfunction-associated steatohepatitis (MASH) are semi-quantitative and subject to poor intra and inter observer variability. We report on use of multiple analogous continuous quantitative digital pathology biomarkers to describe the effects of mannose supplementation on fibrosis and MASH activity.

Method: We used the FAT-MASH model (doi:10.1016/j.jhep.2018.03.011). 43 mouse liver samples were histologically prepared for PSR and H&E and scanned at 40X. Study groups: normal diet (n = 4), MASH diet (high fat, fructose, cholesterol, and low-dose carbon tetrachloride) for 6 weeks (n = 5) or 12 weeks (n = 9); MASH diet for 12 weeks with mannose supplement at 5% (n = 8) or 20% (n = 9) starting at week 0 (prevention arm) or at 5% (n = 4) or 20% (n = 4) starting at week 6 (therapy arm). Development of the Digital Pathology and AI biomarker for fibrosis severity (Ph-FCS), steatosis burden (A%, macro-steatosis area ratio%), hepatocytes with steatosis (SHD, count/mm²), Inflammatory Cells Density (ICD, count/mm²), and Inflammatory Cells Ratio (IC%, % total cells) is described in doi:10.3390/ijms24108494 and doi:10.1101/2024.01.17.576067. The

PT-prefix normalizes biomarkers to the steatosis-free parenchymal tissue area.
Results: During the induction of the 12-week disease stage, the 6-week timepoint was characterized with different relative change (R-Change, 12w change accounting for 100%) showcasing the initial activation of inflammation (PT-ICD, 65.9% R-Change, IC% 79.0% R-Change,) and initial steatotic burden (A%, 59.8%) along with hepatocytes steatotic involvement (SHD, 75.0% R-Change). Fibrosis progression was secondary to these events with a 6-week relative change of 18.2% of Ph-FCS. These different phases were described with other biomarkers in DOI: 10.1016/j.jhep.2018.03.011. The prevention reduced steatosis burden (A%, −43.4% less than the 12-week regimen with 5% and −69.5% for 20% mannose) and for hepatocytes with steatotic involvement (SHD, −20.3% and −64.8% respectively). Inflammatory biomarkers demonstrated opposite behaviors at 5% and 20% mannose (PT-ICD, −36.7 and +11.9%, IC%, −26.7% and +15.2%) showing that mannose supplementation at 20% exacerbated inflammation while significantly reducing steatosis. The 5% mannose supplementation arm was more protected for fibrosis progression than the 20% Arm (PT-FCS, −8.0% and −0.7%).
Conclusion: Digital pathology biomarkers calculated from H&E and PSR digital images provide a holistic quantification of the MASH disease severity and activity and related treatment effects, showcasing only low doses of mannose (5%) dampen inflammation, steatosis and fibrosis severity in a rodent model.

THU-485
Prevalence, genetic risks, and cardiovascular outcomes of Met-ALD in a longitudinal multiethnic U.S. cohort

Jie Yao[1], Xiuqing Guo[1], Jingyi Tan[1], Callie Zaborenko[2], Marco Abreu[2], Tae-Hwi Linus Schwantes-An[2], Matt Budoff[1], Mariana Lazo[3], Jerome Rotter[1], Naga Chalasani[2]. *[1]The Lundquist Institute, Torrance, United States; [2]Indiana University, Indianapolis, United States; [3]Drexel University, Philadelphia, United States*
Email: jyao@lundquist.org

Background and aims: Met-ALD is a newly described entity where steatotic liver disease (SLD) occurs in individuals with both metabolic risk factors and moderate alcohol consumption. Its prevalence, genetic architecture, and outcomes are yet to be fully understood. We compared the prevalence, genetic background, and cardiovascular outcomes of Met-ALD to MASLD in a large multiethnic longitudinal cohort in adults in the United States.
Method: We examined the prevalence of MASLD and Met-ALD in the Multiethnic Study of Atherosclerosis (MESA) cohort at baseline (N = 5182, non-Hispanic White (NHW): 2284. non-Hispanic Black (NHB): 1530, Hispanic: 1368). Hepatic steatosis was defined as liver attenuation < 51 HU and/or liver to spleen < 1 on CT imaging. MASLD and Met-ALD were defined using modified AASLD criteria. We examined the association between 5 selected SLD and cirrhosis polygenic risk scores (PRS) were derived based on recent publications by Chen et al., Emdin et al., Whitfield et al., Schwantes-An et al., and Vujkovic et al. and MASLD and Met-ALD. We also examined the association between MASLD and Met-ALD and prevalent subclinical atherosclerosis measured by coronary artery calcium (CAC) presence and incident cardiovascular events (CVD). We used logistic regression models for the cross-sectional analyses, and cox-proportional hazard models for the longitudinal analyses, controlling for age, gender, and race/ethnicity.
Results: The prevalence of MASLD and Met-ALD WAS 15.1% and 1.3%, respectively. The prevalence of MASLD in NHW, NHB, and Hispanic participants was 11.78%, 11.18%, and 24.8%, whereas the prevalence of Met-ALD among NHW, NHB, and Hispanic participants was respectively. All 5 PRS were significantly associated with MASLD but PRS-Chen (estimate 0.45, p = 7.44E-31) and PRS-Whitfield (estimate 0.39, p = 1.91E-23) had higher estimates than others. Similarly, all 5 PRS were associated with Met-ALD but PRS-Chen (estimate 0.49, p = 3.30E-05) and PRS-Schwantes-An (estimate 0.42, p = 5.28E-04) had higher estimates than others. Both MASLD (OR: 1.58, 95% CI 1.32–1.88, p = 3.55E-07) and Met-ALD (OR: 2.19, 95% CI 1.24–3.84, p = 0.006) were associated with prevalent CAC. MASLD was significantly associated with incident CVD (HR: 1.29, 95% CI: 1.08–1.55, P = 0.0048) whereas Met-ALD had borderline association with incident CVD (HR: 1.56, 95% CI: 0.95–2.57, P = 0.077).
Conclusion: Prevalence of Met-ALT was low in MESA participants, but it appeared to exhibit genetic risks and cardiovascular risks comparable to MASLD.

THU-486
The anticoagulant Edoxaban improves portal hypertension and liver injury in progressive liver disease

Katharina Bonitz[1], Henriette Horstmeier[2], Vlad Taru[3], Thomas Sorz-Nechay[1], Georg Kramer[2], Oleksandr Petrenko[4], Benedikt Simbrunner[2], Kerstin Zinober[2], Hubert Scharnagl[5], Philipp Schwabl[3], Thomas Reiberger[1], Benedikt Hofer[3]. *[1]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, Christian Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria, CeMM Research Center for Molecular Medicine of the Austrian Academy of Sciences, Vienna, Austria, Vienna, Austria; [2]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [3]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, Christian Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [4]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, Department of Laboratory Medicine, Medical University Vienna, Vienna, Austria, Ukrainian Institute for Systems Biology and Medicine, 04119 Kyiv, Ukraine, Vienna, Austria; [5]Clinical Institute of Medical and Chemical Laboratory Diagnostics, University Hospital Graz, Graz, Austria, Graz, Austria*
Email: katharina.bonitz@meduniwien.ac.at

Background and aims: A novel treatment approach in the field of liver disease is the inhibition of protease-activated receptors (PARs). The PAR agonists thrombin and Factor Xa (FXa) can cause liver sinusoidal microthrombosis, activation of hepatic stellate cells, and increased inflammatory cell recruitment. In this study we investigated the effect of the direct oral anticoagulant Edoxaban, which inhibits FXa, in mouse models of progressive and regressive liver disease.
Method: Liver fibrosis was induced in male wildtype C57BL/6 mice by oral gavage of carbon tetrachloride (CCl4, 2 ml/kg, 3x/week) for 12 weeks (Peak). Healthy control animals received olive oil gavage (Ctrl). In the first treatment group, animals were treated with Edoxaban (10 mg/kg) twice daily during the last 2 weeks of CCl4 disease induction (i.e., during disease progression). The second treatment group received Edoxaban for 2 weeks following CCl4 cessation in regressive liver disease. We measured portal pressure (PP), collagen proportionate area (CPA) for fibrosis, and AST/ALT for liver injury severity. Furthermore, bulkRNA-Sequencing of liver tissue was performed and analysed using DESeq2 and GSEA.
Results: Compared to Ctrl, animals at peak disease severity showed significantly higher levels of fibrosis (CPA: 9.36 ± 2.72 vs. 1.54 ± 0.23%), portal hypertension (PP: 9.06 ± 0.89 vs. 5.67 ± 0.89 mmHg) and liver injury (median AST: 1341 vs 17 U/L; median ALT: 1882 vs 12 U/L) (all p < 0.05 vs Ctrl). Administering Edoxaban in disease progression significantly ameliorated portal pressure (7.22 ± 1.23 mmHg) and liver injury (median AST: 343 U/L; median ALT: 637 U/L) when compared to Peak (all p < 0.05 vs. Peak), while CPA remained unaffected. In disease regression, Edoxaban treatment did not induce significant improvements in portal pressure, liver injury or CPA. Differential gene expression analysis confirmed an upregulation of epithelial to mesenchymal transition (EMT) and inflammatory

pathways, including TNFa signaling via NFkB and IL-6/JAK/STAT3 signaling in Peak. Metabolic pathways, such as oxidative phosphorylation, bile- and fatty acid metabolism were downregulated in Peak compared to Ctrl. In animals treated with Edoxaban during disease progression, a downregulation of both EMT and inflammatory signaling could be observed, while metabolic pathways were upregulated compared to Peak.
Conclusion: Edoxaban treatment in progressive liver disease resulted in significantly ameliorated portal hypertension and liver injury. BulkRNA-Seq confirmed the role of Edoxaban in reducing inflammatory and EMT signaling and improving liver function, as indicated by the upregulation of metabolic pathways.

THU-487

Liver-targeted mRNA therapeutics through fibroblast growth factor 21 and apolipoprotein A1 delivery in experimental acute pancreatitis

Amaya Lopez-Pascual[1], Eva Santamaria[2], Nuria Ardaiz[3], Iker Uriarte[2], Tiffany Palmer[4], Anne-Renee Graham[4], Celia Gomar[5], Roberto Barbero[2], Maria U Latasa[6], Maria Arechederra[7], Jesus M Urman[8], Carmen Berasain[9], Antonio Fontanellas[10], Carlos del Rio[4], Maite G Fernandez-Barrena[10], Paolo Martini[4], Joshua R Schultz[4], Pedro Berraondo[11], Matías A Avila[10]. *[1]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Instituto de Investigaciones Sanitarias de Navarra IdiSNA., Pamplona, Spain; [2]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., CIBERehd, Madrid, Spain; [3]Immunology and Immunotherapy Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., Pamplona, Spain; [4]Moderna Inc, Cambridge, Massachusetts, United States., Cambridge, United States; [5]Immunology and Immunotherapy Program, CIMA, CCUN, University of Navarra, Pamplona, Spain; [6]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., Instituto de Investigaciones Sanitarias de Navarra IdiSNA., Pamplona, Spain; [7]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., Instituto de Investigaciones Sanitarias de Navarra IdiSNA, Pamplona, Spain., CIBERehd, Madrid, Spain., Pamplona, Spain; [8]Department of Gastroenterology and Hepatology, Navarra University Hospital, Pamplona, Spain, Instituto de Investigaciones Sanitarias de Navarra IdiSNA., Pamplona, Spain; [9]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., CIBERehd, Pamplona, Spain; [10]Hepatology Laboratory, Solid Tumors Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., Instituto de Investigaciones Sanitarias de Navarra IdiSNA., CIBERehd, Madrid, Spain., Pamplona, Spain; [11]Immunology and Immunotherapy Program, CIMA, CCUN, University of Navarra, Pamplona, Spain., CiberONC, Madrid, Spain, Instituto de Investigaciones Sanitarias de Navarra IdiSNA, Pamplona, Spain*
Email: maavila@unav.es

Background and aims: Acute pancreatitis (AP) presents significant clinical challenges with limited treatment options. Clinical studies suggest that elevated fibroblast growth factor 21 (FGF21) during AP may act as a defense mechanism. Liver-targeted lipid nanoparticles (LNP) delivering mRNA therapy harness the liver's natural protein production capacity. Our study investigates FGF21 and APOA1 mRNA-based therapies, alone and combined, using liver-targeted LNPs to enhance therapeutic efficacy in experimental AP models. Targeting the liver, the main source of circulating APOA1 and nascent HDLs, could restore FGF21 and HDL functionality, often impaired in metabolic and inflammatory conditions, offering a novel therapeutic avenue.
Method: We developed LNP-mRNA formulations encoding FGF21, APOA1, and a chimeric APOA1-FGF21. Protein expression and bioavailability *in vitro* and in high-fat diet-fed mice were assessed. Efficacy was evaluated in the caerulein-induced AP (Cer-AP) model, and the ethanol feeding and binge NIAAA model plus palmitoleic acid administration (EtOH/POA-AP). Serum levels of pancreatic lipase (LIPC), amylase (AMYL), alanine aminotransferase (ALT), and aspartate aminotransferase (AST), along with histopathological analyses, were conducted to assess treatment effects. IL-1β serum levels were determined 12 h post-AP induction by ELISA. Liver *Ho1* and *Ppara* expression were analyzed via qPCR in the EtOH/POA-AP.
Results: In vitro studies demonstrated the translation and secretion of APOA1, FGF21, and APOA1-FGF21 proteins encoded by the LNP-mRNAs. In vivo, LNP-mRNA administration increased serum levels of the respective proteins in metabolically impaired (i.e., high-fat diet-fed) mice. In the Cer-AP model, LIPC and AMYL serum markers of pancreatic injury were similarly reduced when mice were treated with APOA1, FGF21, and APOA1-FGF21 LNP-mRNA; this effect was also observed in the histopathological analyses. In the more aggressive EtOH/POA-AP model, FGF21 and APOA1-FGF21 LNP-mRNAs were protective, as evidenced by lower LIPC and AMYL serum levels, while APOA1 LNP-mRNA had minimal impact. However, histological improvements were more evident in mice receiving APOA1 LNP-mRNA. FGF21 and APOA1-FGF21 LNP-mRNAs reduced serum AST and ALT levels, indicating hepatoprotective activity. In the Cer-AP model, serum IL-1β decreased 12 h post-induction in mice treated with APOA1, FGF21, and APOA1-FGF21 LNP-mRNAs. Finally, EtOH/POA-AP model, FGF21 and APOA1-FGF21 LNP-mRNAs reduced liver Ho1 expression, while APOA1-FGF21 LNP-mRNA increased liver Ppara expression, suggesting enhanced hepatoprotection.
Conclusion: This proof-of-concept study shows the potential of mRNA-based therapies delivering FGF21 and APOA1 in experimental AP. Liver-targeted LNP-mRNA delivery of FGF21 and APOA1 improved experimental AP, underscoring their potential as innovative treatment options for AP.

THU-488

A new translational dietary rat model allows studying MetALD natural history and assesing the efficacy of various therapeutic interventions

María Martínez-Gómez[1,2,3], M Serra Cusidó[1,3], Imma Raurell[1], Sophia C. Parks[1], Joan Genesca[1,2,3,4], María Martell[1,2,3], Meritxell Ventura Cots[1,2,4], Juan Manuel Pericàs. *[1]Advanced Chronic Liver Disease Laboratory, Vall d'Hebron Institute for Research (VHIR), Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain; [2]Spanish Network of Biomedical Research Centers, Liver and Digestive Diseases (CIBERehd), Barcelona, Spain; [3]Universitat Autònoma de Barcelona, Barcelona, Spain; [4]Liver Unit, Digestive Diseases Division, Vall d'Hebron University Hospital, Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain*
Email: juanmanuel.pericas@vallhebron.cat

Background and aims: Metabolic and alcohol-related liver disease (MetALD) was recently proposed as a distinct entity. However, the natural history and optimal therapy for MetALD are still largely unknown. During the last decade, glucagon-like peptide-1 receptor agonists (GLP-1) have been under evaluation for metabolically-induced liver injury, and recently trials have started in ALD. Our primary aim was to test various interventions in a new rat model of MetALD. Secondary objectives included defining the features of MetALD and comparing them to those of MASLD.
Method: To carry out this study, male Sprague Dawley rats were subjected to 20 weeks of dietary intervention consisting of a high-fat diet supplemented with 2% cholesterol and 0.1% cholate, along with a glucose-fructose beverage (HFD/GF) and/or alcohol (HFD/GF+OH). Three different groups were defined: Control group (Chow diet; n = 12), MASLD group (HFD/GF; n = 12) and MetALD group (HFD/GF+OH; n = 96). After 16 weeks, the MetALD group was divided into four subgroups to undergo different interventions for the last 4 weeks consisting on: (1) no intervention (MetALD group; n = 24), (2) dietary intervention (DI; n = 24), (3) alcohol removal (AR; n = 24), (4) combination of both (DI+AR; n = 24). Furthermore, half of the individuals in each of these subgroups (n = 12) underwent

pharmacological treatment with Semaglutide (GLP-1 receptor agonist). The control and MASLD group did not undergo any intervention. By the end of the model, liver hemodynamics, histological staining, metabolic and biochemical evaluation and gene expression analyses were performed.
Results: Compared to controls, individuals in the MetALD group had significantly higher rates of obesity, dyslipidemia, intrahepatic insulin resistance, fibrosis and portal hypertension (PHT). Rates of advanced fibrosis were higher in the MetALD group compared to MASLD (75% vs. 58.3%) but the difference was not statistically significant, nor was it for PHT. Semaglutide (GLP-1) treatment was associated with significant weight loss in all groups. Dietary intervention (DI) and alcohol removal (AR), alone or combined, led to significant fibrosis regression, but no significant improvement of PHT. All interventions except those without DI led to significant improvements of steatohepatitis. Combining DI + AR was not significantly more efficacious that either both alone in improving liver fibrosis. GLP-1 alone did not lead to significantly improve neither fibrosis nor PHT. DI+GLP-1 led to significant reductions in fibrosis and PHT. The most effective treatment was the combination of DI+AR+GLP-1, for fibrosis and PHT.
Conclusion: Our new model of MetALD comprehensively recapitulates both metabolically and alcohol-induced liver injury, leading to advanced fibrosis and PHT. A combined strategy encompassing DI, AR and GLP-1 appears as the most efficacious to treat MetALD. Further investigations are warranted to elucidate whether GLP-1 has weight loss-independent effects on outcomes.

Disruption of receptor-interacting protein kinase 1 post-translational modifications in alcohol-associated liver disease

Uttam Ojha[1], Megan McMullen[1], Vai Pathak[1], Adam Kim[2], Daniel Rotroff[3], Srinivasan Dasarathy[1,4,5], Jaividhya Dasarathy[6], David Streem[7], Nicole Welch[1,5], Laura Nagy[1,4,5]. *[1]Northern Ohio Alcohol Center, Department of Inflammation and Immunity, Cleveland Clinic, Cleveland, United States; [2]UConn Health, Department of Medicine, Division of Gastroenterology and Hepatology, Farmington, United States; [3]Department of Quantitative Health Sciences, Cleveland Clinic, Cleveland, United States; [4]Department of Molecular Medicine, Case Western Reserve University, Cleveland, United States; [5]Department of Gastroenterology and Hepatology, Cleveland Clinic, Cleveland, United States; [6]Department of Family Medicine, Metro Health Medical Center, Cleveland, United States; [7]Department of Psychiatry and Psychology, Cleveland Clinic Lutheran Hospital, Cleveland, United States*
Email: nagyl3@ccf.org

Background and aims: Alcohol-associated liver disease (ALD) is the leading cause of advanced liver disease, with limited therapeutic options currently available. Inflammation and cell death pathways are pivotal to ALD pathogenesis. Receptor-interacting protein kinase 1 (RIP1), a component of the necroptotic pathway of cell death, plays a critical role in determining cellular fate in response to death receptor activation. RIP1 function is tightly regulated by post-translational modifications, especially ubiquitination and phosphorylation; these post-translational modifications regulate the balance between pro-inflammatory, pro-survival, and/or cell death signaling in a cell-specific manner. Notably, RIP1 signaling to activate NFκB in hepatocytes is hepatoprotective, whereas in innate immune cells, it drives pro-inflammatory responses. Given this complexity, we aim to investigate the mechanisms and cell-specific roles of RIP1 post-translational modifications in ALD.
Method: Tandem Ubiquitin Binding Entity (TUBE) pull down assays and western blotting were conducted in livers from murine models of ALD, as well as human livers from patients with alcohol-associated hepatitis (AH) and healthy controls (HC), to assess the ubiquitination and phosphorylation status of RIP1. Bulk RNA-seq and single-cell RNA-seq datasets were analyzed for expression profiles of mRNA for proteins involved in ubiquitination and de-ubiquitination of RIP1 in liver and peripheral blood mononuclear cells (PBMCs) from HC and AH patients challenged with lipopolysaccharide (LPS). THP-1 monocytic cells were challenged with LPS alone or in combination with ethanol.
Results: Ubiquitination of hepatic RIP1 was decreased and phosphorylation of RIP1 increased in patients with AH compared to HC. Similarly, RIP1 ubiquitination was decreased in livers of mice exposed to both acute-on-chronic or chronic ethanol. Bulk RNA-seq meta-analysis revealed significant perturbations in expression of mRNA for proteins involved in ubiquitination/de-ubiquitination of RIP1 in livers of patients with AH. Furthermore, single-cell RNA-seq analysis revealed widespread dysregulation in expression of ubiquitination/de-ubiquitination mRNAs in $CD14^+$ and $CD16^+$ monocytes from AH patients compared to HC both at baseline and in response to LPS. Similar alterations were observed in THP-1 monocytes challenged with either LPS alone or combined with ethanol.
Conclusion: Taken together, these data suggest that ethanol disrupts the post-translational modification of RIP1 in the liver and immune cells. Such disruptions may contribute to dysregulation of the downstream signaling pathways contributing to inflammation and cell death in the pathogenesis of ALD.

Cytokine release assay QuantiFERON Monitor predicts 90-day mortality in patients with severe alcohol-related hepatitis

Paula Boeira[1], Huey Tan[1], Ayesha Sultana[2], Tamar Avades[3], Mark R Thursz[2], Ashwin Dhanda[3]. *[1]University of Plymouth, Plymouth, United Kingdom; [2]Imperial College London, London, United Kingdom; [3]University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom*
Email: paula.boeira@plymouth.ac.uk

Background and aims: Alcohol-related hepatitis (AH), a severe complication of long-term harmful alcohol use, has a 30% 90-day mortality. More accurate predictors of mortality and infection are needed to help guide patient management. QuantiFERON Monitor (QFM) is a commercially available interferon (IFN)-γ release assay that measure global immune function using whole blood stimulation with innate and adaptive immune ligands. A preliminary single-centre study demonstrated that QFM accurately predicted 90-day mortality and incident infection in patients with AH. This study aimed to validate these findings in a multicentre study.
Method: Consecutive patients with AH (bilirubin >50 µmol/L, coagulopathy, and harmful alcohol use [40 g/60 g ethanol/day in females/males]) recruited to the Multicentre Cohort of AH (MICAH) study at Imperial College Healthcare and University Hospitals Plymouth NHS Trusts, took part in this validation study. Outcomes of survival and development of infection were collected up to day 90. Infection was defined according to NACSELD criteria. A sample of blood was obtained at study baseline and QFM was performed according to manufacturer's instructions. Serum Interferon (IFN)-γ concentration was determined by ELISA.
Results: 46 participants were recruited; 61% male, baseline MELD 20.8. IFN-γ release measured by QFM was significantly higher in survivors compared to non-survivors at day 90 (74.1 vs 4.7 IU/mL; $p < 0.0001$). Area under receiver operating characteristic (AUROC) for QFM was 0.85. Positive predictive value of QFM to predict mortality within 90 days was 77% with a threshold of 15.5 IU/mL. Baseline MELD was significantly lower in survivors compared to non-survivors at day 90 (15.2 vs 24.1; $p = 0.0002$; AUROC 0.81). Using a threshold of 30, the positive predictive value of MELD to predict mortality within 90 days was only 50%. Neither QFM nor MELD was able to differentiate patients with incident infection from those without infection.
Conclusion: Assessment of global immune function measured by QFM accurately predicts 90-day mortality in patients with severe AH. It is superior to MELD in predicting patients at high risk of 90-day mortality. However, it is unable to reliably predict incident infection. This study confirms that QFM could be integrated into clinical

management pathways for AH as a decision tool to guide treatment options.

Metabolomic and transcriptomic insights into gender-specific PFAS effects on liver disease

Shashank Gupta[1], Oveis Jamialahmadi[2], Rosellina Mancina[2], Tuulia Hyötyläinen[1], Stefano Romeo[2], Matej Orešič[1]. *[1]Örebro University, Örebro, Sweden; [2]University of Gothenburg, Gothenburg, Sweden*
Email: shashank.gupta@oru.se

Background and aims: Per- and polyfluoroalkyl substances (PFAS) are emerging environmental pollutants linked to metabolic disorders, including metabolic dysfunction-associated steatotic liver disease (MASLD). This study investigates the associations between PFAS exposure and MASLD progression, focusing on lipidomic, metabolomic, and transcriptomic biomarkers, functional pathways, and gender-specific responses.
Method: Metabolomic and lipidomic analyses were performed to examine changes in metabolite and lipid composition across steatosis grades (0–3) and between MASH-positive and MASH-negative samples. Transcriptomic data were analyzed using weighted gene co-expression network analysis (WGCNA), with KEGG pathway enrichment for functional insights. Mediation analysis explored whether specific metabolites mediated the association between PFAS exposure and steatosis.
Results: Lipidomic analysis revealed significant shifts in lipid composition with steatosis severity, including increased TG-SFA and TG-MUFA levels in MASH-positive samples and decreased phosphatidylinositol and phosphatidylcholine levels. Gender-specific transcriptomic analysis using WGCNA identified significant modules in both females and males. These modules were significantly negatively correlated with pathways, including arginine biosynthesis, amino acid metabolism, and other related processes in both genders. Metabolomics analysis supported these findings, identifying metabolites negatively correlated with MASLD progression enriched in similar pathways, implicating a disruption in amino acid metabolism with disease progression. Positively correlated transcriptomic modules in females were linked to cell cycle, steroid biosynthesis, and fatty acid metabolism. Furthermore, significant positive correlations were observed between PFAS compounds (e.g., PFUnDA, PFDoDA) and lipids such as phosphatidylinositol, while acylcarnitines showed negative correlations. Mediation analysis showed that specific metabolites partially mediated the relationship between PFAS exposure and steatosis. Phosphatidylinositol mediated the effect of PFHxA ($p = 0.002$), TG-SFA mediated PFHpA's effect ($p = 0.028$), and lactosylceramide (Laccer) mediated PFHpA's effect ($p = 0.004$).
Conclusion: This study provides insights into the molecular mechanisms linking PFAS exposure to MASLD progression, highlighting disrupted amino acid and lipid metabolism and gender-specific responses. Identifying specific metabolites as mediators highlights new targets for addressing PFAS-related liver diseases.

THU-492-YI

Altered high density lipoprotein 3 and associated proteins signatures contribute to immune dysfunction in alcohol associated liver cirrhosis

Shivani Gautam[1], Sukriti Baweja[2], Vibhuti Jakhmola[2], Harshvardhan Tevethia[2], Guresh Kumar[2], Amar Mukund[3], Shiv Kumar Sarin[4]. *[1]Institute of liver and biliary sciences, Department of molecular and cellular medicine, New Delhi, India; [2]Institute of liver and biliary sciences, New Delhi, India; [3]Institute of liver and biliary sciences, Department of Interventional Radiology, New Delhi, India; [4]Institute of liver and biliary sciences, Department of Hepatology, New Delhi, India*
Email: sukritibiochem@gmail.com.

Background and aims: Alcohol-associated liver cirrhosis (AALC) is associated with high mortality and involves toxins, gut microbiota imbalance, and immune dysfunction. Enteric high-density lipoprotein subtype 3 (HDL3) is known for its immune-protective role, but its impact on AALC remains unclear. This study explores HDL subclasses and associated protein signatures linked to immune dysfunction and disease progression in AALC.
Method: We included 89 cirrhosis patients (Model for End Stage Liver Disease (MELD) 16 ± 8), including AALC (n = 67, age 45 ± 10 years, all male), non alcoholic steatohepatitis (NASH, n = 15, age 52 ± 9 years, 6 females), and hepatitis B/C virus (HBV/HCV, n = 6, age 47 ± 7 years, 1 female). These patients were monitored for three months post TIPS (trans juglar shunt) for infections, bleeding, and mortality. HDL3 and HDL2 levels (mg/dl) in peripheral (PV), portal (POV), and hepatic (HV) venous blood were measured using enzyme linked immunosorbent assay (ELISA) and compared with healthy controls. HDL3 was fractionated for protein analysis via ultracentrifugation and liquid chromatography mass spectrometry (LC-MS). Immune cell functions were evaluated with flow cytometry and validated by quantitative reverse transcription polymerase chain reaction (qRT PCR).
Results: HDL3 levels were significantly lower in the PV of AALC patients compared to healthy controls ($p < 0.001$), but no difference was observed in NASH or viral hepatitis. HDL2 levels did not differ significantly. HDL3 levels in PV (11.3 ± 5), POV (7.6 ± 3), and HV (8.0 ± 3.8) showed strong intraclass correlation (Lin ' s concordance: 86%). The 3 month mortality post TIPS was 28%, with low HDL3 (< 6.6 mg/dl) predicting poor outcomes (AUC: 0.94, specificity 88.6%, sensitivity 88.4%, $p = 0.001$). Proteomics analysis identified 542 associated proteins, including immunoglobulins, apolipoproteins, and complement proteins. Alcoholic HDL3 had reduced levels of paraoxonase 1 (PON1), apolipoprotein A1 (ApoA1), lipopolysaccharide binding protein (LBP), and sphingosine 1 phosphate (S1P) lyases ($p < 0.001$) but increased apolipoprotein C1 (ApoC1), alpha 1 antitrypsin (AAT), and serum amyloid A (SAA). In vitro studies showed that healthy HDL3 with LBP downregulated inflammatory markers (TLR4, TNFalpha, IL1beta) ($p < 0.05$) and increased IL10 production, whereas alcoholic HDL3 had no such effect. Additionally, alcoholic HDL3 activated T cells (CD3 + CD4 + CD38 +; $p = 0.04$), increased dendritic cells (CD11c + CD80 + CD86 +; $p = 0.03$), and upregulated IL-17A. qRT PCR confirmed increased mRNA levels of IL1beta, TNF alpha, and caspase 3, ($p < 0.05$) while decreased SOD2 and eNOS levels were observed after treatment with alcoholic HDL3.
Conclusion: AALC patients show low HDL3 levels and altered protein profiles, indicating HDL3 dysfunction. Alcoholic HDL3 activates T cells and promotes inflammation. These findings suggest that targeting HDL3 could be a therapeutic strategy to address immune complications and improve outcomes in AALC.

Single-cell RNA sequencing and lipidomics identify synergistic effects of alcohol and PNPLA3 I148M on hepatic pathology

Stephen Hoang[1], Hae-Ki Min[2], Mulugeta Seneshaw[1], Faridoddin Mirshahi[1], Arun J. Sanyal[1,2]. *[1]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, Virginia Commonwealth University School of Medicine, Richmond, VA, United States; [2]Division of Gastroenterology, Hepatology and Nutrition, Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, VA, United States*
Email: arun.sanyal@vcuhealth.org

Background and aims: Previous work in the DIAMOND mouse model demonstrated that overexpression of PNPLA3 variant I148M accelerates steatohepatitis through metabolic reprogramming, lipidomic alterations, and inflammation. While its role in diet-induced liver disease has been partly characterized, the interplay between I148M and alcohol exposure remains poorly understood. This study utilized single-cell transcriptomics and lipidomics to investigate the interaction of alcohol with I148M in a mouse model.

Method: MASH was induced in DIAMOND mice via a high-fat diet with ad libitum sugar water (WD). The WD groups were divided into those receiving liver-targeted delivery of luciferase (AAV-luc), AAV-I148M, AAV-luc and alcohol, or AAV-I148M and alcohol. Single-cell RNA sequencing and lipidomic profiling were performed on liver tissues to assess cell type composition, cell type-specific gene expression, and lipid composition. Interaction effects between alcohol and PNPLA3 I148M were identified through differential expression and pathway enrichment analyses. CellPhoneDB was used to assess changes in cell-cell signaling networks.
Results: Alcohol exposure and I148M had synergistic effects on processes linked to cell stress/death, inflammation, steatosis, and fibrosis. These effects were observed as changes in cell type composition, pathway-level gene regulation, lipid profiles, and cell-cell signaling. Together, the two treatments led to a synergistic increase in the Kupffer cell-to-hepatocyte ratio, indicating an increased inflammatory response. Hepatocytes exhibited increased transcriptional regulation of apoptosis and glycogen metabolism pathways, suggesting increased cellular stress. Fibrosis-related cell-cell signaling pathways were also impacted. For instance, collagen-integrin interactions were enhanced between hepatocytes and stellate cells, as well as between cholangiocytes and stellate cells. Lipidomic analysis revealed several lipid species altered by the interaction between alcohol and I148M, including many glycerophospholipids. Notably, an increase in the lipogenic index (the palmitate: linoleate ratio) suggests enhanced de novo lipogenesis.
Conclusion: These findings reveal a critical interaction between alcohol and PNPLA3 I148M, advancing our understanding of the mechanisms driving liver inflammation, metabolic reprogramming, and fibrosis.

THU-494

PNPLA3 risk variant and shortened telomere are independent risk factors for alcohol related liver disease: an indian cohort study

Vaishali Yadav[1], S Muralikrishna Shasthry[1], Kanica Kaushal[1], Mohit Varshney[1], Satender Singh[1], Guresh Kumar[1], Vipin Yadav[1], Khushboo Agrawal[1], Nirupma Trehanpati[1], Shiv Kumar Sarin, Gayatri Ramakrishna[1]. [1]*Institute of liver and Biliary Sciences, New Delhi, India*
Email: vaishalirao199815@gmail.com

Background and aims: Alcohol related liver disease (ALD) is primary cause of cirrhosis and contributes to 5.3% of global deaths. However, only 30% of heavy drinkers develop steatohepatitis, suggesting influence of genetic factors in ALD. Chronic alcohol consumption accelerates cellular function decline, which is a hallmark of aging. This study explores the association of PNPLA3(patatin-like phospholipase domain-containing protein 3) I148M (rs738409) genetic variant and leukocyte telomere length in heavy drinkers, with and without liver disease.
Method: ALD (N = 131) and AUD (Alcohol usage disorder, without any underlying liver disease, N = 54) were enrolled. The PNPLA3 genotype was analysed using PCR-RFLP, with validation by Sanger sequencing. Leukocyte telomere length (TL) was quantified through qPCR, expressed as a T/S ratio relative to a standard reference DNA.
Results: The quantity (140.2 ± 79.12 gm vs. 117.7 ± 42.34 gm, p = 0.595) and duration (13.27 ± 6.99 years vs. 15 ± 9.64 years, p = 0.571) of alcohol consumption were comparable between the ALD and AUD groups. PNPLA3 rs738409 CC, CG, and GG genotypes in ALD patients were 35.88%, 47.33%, and 16.79%, with $\chi^2 = 0.0408$, while in AUD it was 59.26%, 38.89%, and 1.85% with $\chi^2 = 0.4046$. PNPLA3 I148M variants (CG and GG) were significantly more frequent in ALD (q = 0.4046) than AUD (q = 0.213) p < 0.01. Univariate regression showed, genotype CG has OR: 2.013 [95%CI: 1.066–4.151], $p = 0.032$ and genotype GG has OR: 13.422 [95%CI:1.709–105.44], $p = 0.014$. Additionally, the telomere length was significantly shorter in ALD compared to AUD subjects (8.53 ± 1.14 vs. 8.97 ± 1.06, p = 0.031). Further, ROC curve analysis for telomere length between ALD and AUD group with an AUC of 0.60 (p = 0.029) suggests that telomere length decreased with age in AUD (r = -0.3, p = 0.029) but not in ALD (r = -0.01, p = .951). A cut-off value of 8.8 for telomere length was obtained by ROC analysis. Based on this cut-off ALD and AUD patients were divided into two groups, Group 1: RTL ≤8 .8 and Group 2: RTL>8.8. A predictive model was created using age and RTL which shows decrease in RTL with age in both the groups ALD = 0.001*Age +8.533 AUD = -0.025*Age+9.987, also using univariate analysis RTL group 1 has (OR: 2.012 [95%CI: 1.029–3.933], $p = 0.041$).
Conclusion: There are 2-fold odds of disease in CG genotype and it increases to 13-fold with GG Genotype. Also, 2 -fold odds of disease with relative telomere length shorter than 8.8. This shows that PNPLA3 rs738409 risk variant and shorter telomere length are associated with alcohol related liver disease.

THU-495-YI

The role of aryl hydrocarbon receptor across different cellular targets in pectin's improvement of alcohol-associated liver disease

Wanchao Hu[1], Geraldine Schlecht-Louf[1], Nicolas Trainel[1], Aurore Desmons[2], Gerard Eberl[3], Francoise Mercier-Nome[4], Sophie Viel[4], Gabriel Perlemuter[1,5,6], Dragos Ciocan[1,5,6], Anne-Marie Cassard[1,6]. Email: wanchao.hu@universite-paris-saclay.fr

Background and aims: Alcohol-associated liver disease (ALD) is the leading cause of cirrhosis worldwide, with few therapeutic options other than alcohol withdrawal. Intestinal microbiota (IM) plays a causal role in the severity of the disease both in mice and humans. Among metabolites produced by IM, bile acids and tryptophan metabolites are mainly modified in ALD. We previously demonstrated that pectin, a soluble fiber, improves liver and gut injuries in ALD through bile acid metabolism and indoles production acting through the aryl hydrocarbon receptor (AhR) signaling. However, which cellular AhR targets are involved in improving ALD by pectin supplement remains unknown. In this study, we aimed to decipher the role of AhR, specifically in the liver, the intestinal epithelium, myeloid cells, and innate lymphoid cells (ILC).
Method: We established conditional knockout mice models for AhR in hepatocytes ($AhR^{KO\text{-}Alb}$), enterocytes ($AhR^{KO\text{-}villin}$), dendritic cells (DCs), and CD11c expressing macrophages ($AhR^{KO\text{-}CD11c}$), or ILC3 ($AhR^{KO\text{-}Rorgt}$), followed by implementing preventative treatments with pectin in the context of ALD. Then we analyzed liver tissue, ileal and colon tissue, blood, colon, and caecum content samples. Based on metagenomic and metabolomic analyses, we focused on changes in IM, bile acids, and microbiota tryptophan metabolites which are ligands of AhR.
Results: We found that AhR deficiency in hepatocytes or enterocytes worsen the liver injury by increasing the level of alanine transaminase (ALT) and the expressions of inflammation genes, including IL1β, TNFα, CCL2, and CCL3. What's more, pectin reduced liver ALT levels independent of AhR genotypes, but its improvement in hepatic inflammation gene expression was abrogated in mice with $AhR^{KO\text{-}villin}$. Colon flow cytometry showed that pectin reduced cDC2b levels, which was not observed in $AhR^{KO\text{-}villin}$ mice. In $AhR^{KO\text{-}CD11c}$ or $AhR^{KO\text{-}Rorgt}$ mice, they were no worsening of the liver injury in alcohol-treated group, and pectin consistently maintained its protective effect on the liver compared to wild-type littermates. Furthermore, alcohol and pectin supplementation altered the compositions of IM and metabolism independent of genotype.

Conclusion: Our results suggest that AhR expression in enterocytes and hepatocytes plays a protective role in alcohol-induced liver inflammation, conversely to AhR expression in DCs and ILC3. Pectin improves alcohol-induced liver injury in ALD partly through the AhR expression in enterocytes, but the improvement in hepatic steatosis may be also associated with changes in IM and metabolism. These findings unveil the role of AhR in different cellular targets in the improvement of ALD by pectin, that needs to be further explored to propose the AhR pathways activation as an alternative therapeutic approach of pectin. But also raise that other mechanisms are involved.

Alcohol-related liver disease and MetALD – Clinical

TOP-459
MetALD has a higher rate of extrahepatic cancer and cardiovascular events compared to other subtypes of steatotic liver disease

Katrina Pekarska[1,2], Laura Burke[1,2], Ian Rowe[1,2], Richard Parker[1,2].
[1]*Leeds Liver Unit, St James's University Hospital, Leeds, United Kingdom;* [2]*Leeds Institute for Medical Research, University of Leeds, Leeds, United Kingdom*
Email: katrina.pekarska@gmail.com

Background and aims: Steatotic liver disease (SLD) is the most common chronic liver disease worldwide. Research to date suggests that people with metabolic dysfunction associated steatotic liver disease (MASLD) or alcohol-related liver disease (ALD) have a high risk of developing cardiovascular (CV) events or extrahepatic cancers, but little is known about MASLD with increased alcohol intake (MetALD) group. We aimed to investigate the incidence of CV events and extrahepatic cancers in SLD subgroups.
Method: Patients with histologically confirmed SLD at a single tertiary centre were included. During follow up new CV events (heart failure (HF), ischaemic heart disease (IHD), cerebrovascular disease (CVD), peripheral vascular disease (PVD)) and extrahepatic cancers was collected from the electronic patient record. Cumulative incidence (CI) and sub-distribution hazards for CV and extrahepatic events were calculated over a five-year period with mortality or transplantation as competing events. All analyses were done in R.
Results: 726 patients were included**:** 516 (71%) had MASLD, 85 (12%) had MetALD and 125 (17%) – ALD. Median age was 53 (IQR 43–61) and 63% were males. F3 fibrosis was observed in 184 (25%) patients and F4–99 (14%) patients. During a median follow up period of 60.5 (IQR 29–84.5) months 64 (8.8%) patients died (including eight extrahepatic cancer deaths and four CV event deaths), 44 (6.1%) had a decompensating event, 3 (0.4%) had liver transplant and 10 (1.4%) had hepatocellular carcinoma. We observed fifty CV events where IHD (48%) was the most common event. The five-year CI for CV events was 4.9% (3.0%, 7.6%) in MASLD, 8.8% (3.5%, 17.0%) in MetALD and 2.5% (0.68%, 6.7%) in ALD. In total 39 patients were diagnosed with extrahepatic cancers during follow up; the most common sites were skin (18%), prostate (13%) and colorectal cancer (13%). The five-year cumulative incidence of extrahepatic cancers was 3.6% (2.0%, 6.0%) in MASLD, 5.9% (1.9%, 13%) in MetALD and 4.7% (1.7%, 10%) in ALD. Competing risk regression analysis at five years controlling for age, BMI and smoking showed that ALD and MetALD cohorts were associated with higher risk of extrahepatic cancers compared to MASLD: sHR 2.40 (1.20–4.79, p = 0.013) and sHR 2.73 (1.09–6.81, p = 0.031), respectively. However, ALD and MetALD subgroups did not have a significantly higher risk of CV events compared to MASLD.
Conclusion: Patients with MetALD have a higher five-year incidence of CV events and extrahepatic cancers compared to MASLD and ALD groups. This is likely due to synergetic effect of alcohol intake and metabolic risk factors that drives these events and high rates of liver-related events in patients with ALD as a competing risk.

TOP-460
Urinary proteomics identifies complement as potential biomarkers in severe alcohol-associated hepatitis patients

Luan Prado[1], Ryan Musich[1], Laura Nagy[1], for The AlcHepNet Investigators[1]. [1]*Cleveland Clinic, Cleveland, United States*
Email: nagyl3@ccf.org

Background and aims: Alcohol-associated hepatitis (AH) is characterized by sudden onset of uncontrolled liver inflammation. Urine samples can be collected easily and in a non-invasive manner, which makes it a preferred body fluid for biomarker discovery. Complement, a component of the innate immune system, is implicated in the pathogenesis of alcohol-induced liver injury in murine models and complement proteins in plasma are diagnostic and prognostic biomarkers in patients with AH. However, no data is available to the utility of urinary complement signatures as biomarkers in AH. We hypothesize that complement may provide important biomarkers in AH and that urine may be a suitable body fluid for new biomarker discovery.
Method: Baseline urine samples from the AlcHepNet Observational study (27 healthy controls (HC), 25 heavy drinkers (HD) and 27 severe AH (sAH)) were used for global quantitative proteomics using a label free quantitation. Samples were analyzed using a Data Independent Acquisition (DIA) method and searched against an in-house spectral library and SwissProt database.
Results: A total of 2716 proteins were identified in the urine samples. PCA analysis showed a clear segregation of patients with sAH and HC and segregation of sAH and HD, with some overlap of proteins. In the enrichment analysis using gene ontology between sAH and HC, complement activation was upregulated in the biological process sub-ontology. In the molecular function sub-ontology, complement binding was also enriched. These pathways were not enriched in the sAH/HD or HC/HD comparisons. Based on these findings, we then evaluated individual complement components. Multiple complement components were perturbed in sAH compared to HD and HC. C1qb was the most up-regulated protein in sAH and HD compared to HC and Uromodulin and MASP1 the most down-regulated protein found in the urine of sAH compared to HC and HD, respectively. AUC for Uromodulin between HC and sAH was 0.9890 and C1qb was 0.90. The AUC between HD and sAH for C1qb was 0.8948 and for MASP2 was 0.9022.
Conclusion: Urine collection is easy and non-invasive, making it a suitable sample for biomarker discovery. Here we show that urinary proteomics analysis discovered 2716 proteins in the urine of sAH patients and that complement is dysregulated in the urine of those patients. Uromodulin, C1qb and MASP2 are good candidates as biomarkers of AH. More studies are needed to further characterize urinary complement as potential diagnostic and prognostic biomarkers of AH.

Histological features predict response to corticosteroids and short-term survival in severe alcohol-associated hepatitis

Rudolf Stauber[1], Horia Ștefănescu[2], Christophe Moreno[3], Pierre-Emmanuel Rautou[4], Markus Peck-Radosavljevic[5], Gudrun Pregartner[1], Carolin Lackner[1]. [1]*Medical University of Graz, Graz, Austria;* [2]*Regional Institute of Gastroenterology and Hepatology, Cluj-Napoca, Romania;* [3]*Université Libre de Bruxelles, Brussels, Belgium;* [4]*Inserm UMR-1149, Paris, France;* [5]*Klinikum Klagenfurt am Wörthersee, Klagenfurt, Austria*
Email: rudolf.stauber@medunigraz.at

Background and aims: Liver biopsy is useful to confirm alcohol-related steatohepatitis (ASH) in patients with alcohol-associated liver disease (ALD) and clinically suspected alcohol-associated hepatitis (AH). Current clinical practice guidelines recommend prednisolone

for the treatment of severe AH with Maddreýs discriminant function (MDF) ≥ 32 or model for end-stage liver disease (MELD) > 20. However, steroid treatment may lead to severe side effects like sepsis. Therefore, treatment response is assessed at day 7 using the Lille model and steroids are discontinued in non-responders to limit the risk of unnecessary steroid exposure. The aim of our study was to investigate the utility of histologic features of ALD for prediction of response to corticosteroids by Lille score in patients with histologically confirmed ASH.

Method: We analyzed data of a multinational cohort of patients with severe AH and MELD > 20. All patients underwent liver biopsy for confirmation of ASH and were treated with prednisolone. Morphological features of ALD including steatosis, activity (contributed by hepatocellular ballooning and lobular neutrophils), canalicular and ductular cholestasis as well as fibrosis stage were assessed using the ALD-specific SALVE grading and staging system. Logistic regression was performed to evaluate the effects of histological variables on response to steroids by Lille score and on 90-day survival.

Results: A total of 142 patients with MELD > 20 at baseline were enrolled at 5 centers. Out of these, histological ASH was retrospectively confirmed in 114 patients (80%). Response to prednisolone by Lille score < 0.45 was observed in 61 /114 patients (54%). Logistic regression analysis of histologic variables adjusted for age, sex, and center revealed absence of ductular cholestasis as predictor of Lille response (OR 0.38, 95% CI 0.14–0.98, p = 0.046) and presence of SALVE fibrosis stage 4c (severe cirrhosis) as predictor of 90-day mortality (OR 3.93, 95% CI 1.39–11.83, p = 0.010).

Conclusion: Liver biopsy plays an important role to confirm histological ASH in patients with clinically suspected severe AH and was found useful to aid prediction of steroid efficacy and short-term mortality.

A prospective study on hepatic fibrosis evaluation in an alcohol withdrawal unit of an university hospital: role of FIB-4 and elastometry. FIBRADDICT study

Armand Abergel[1], Alexandra Chirvas[1], Benjamin Buchard[1], Leon Muti[1], Dominique Boulier[1], Carine Nicolas[1], Georges Brousse[1].
[1]*CHU Clermont Ferrand, Clermont Ferrand, France*
Email: aabergel@chu-clermontferrand.fr

Background and aims: Excessive alcohol consumption is the major cause of liver-related death and the leading cause of liver transplantation in France. Many patients are seen too late, at a decompensated stage. Early diagnosis of cirrhosis would allow early diagnosis for esophageal varices, screening for hepatocellular carcinoma and reinforcement of addictive behaviour care.

Method: 299 excessive alcohol consumers, defined by the AUDIT-C score, benefited from measurement of liver stiffness (LS) with Fibroscan (Echosesns, France) equipped with two probes M and XL upon entering in the unit (LS1, first measure). LS1>25 kPa ruled in advanced fibrosis (F3F4) and a LS1<10 kPa ruled out advanced fibrosis (F0F1F2) (Legros et al. CGEH 2022). If LS1 was found between 10 and 25 kPa, the status was determined by the second LS (LS2) realised at least two weeks after LS1. If LS2 was >10 kPa, the patient was considered to have advanced fibrosis. A first cohort of 187 patients was included and the second cohort of 112 patients was considered as the internal validation cohort. We have analysed the diagnostic performance of FIB-4, Prothrombin time (PT) and ASAT/ALAT>1. We will present only the results of the FIB-4 as its performance was superior to PT and ASAT/ALAT > 1. The performance of the two cohorts were not significantly different, we will present the results of the whole cohort.

Results: Mean age of the patients was 49 years, sex ratio 2.8, median consumption of alcohol 192 g/day, 11% were obese, 46% had ASAT > ULN, 46% PT < 85% and 13% platelets < 150 G/L. 34 out of 299 patients had severe fibrosis (11%). CAP>248 dB/m was found in 100/299 (33%). The diagnosis performance of the FIB-4 was excellent with an AUC = 0.895. To get a sensitivity higher than 90%, the threshold was 1.45. We used as suggested by the international guidelines, the threshold of 1.3. This threshold had a sensitivity of 91% and a specificity of 67% and could allow to reduce the number of LS measurement in 182 out of 299 patients (60%). In patients with ASAT > 100 IU/L and platelets < 150 G/L, the AUC were respectively 0.73 and 0.62. The sensitivity of the FIB-4 was > 90% in these two subgroups. According to Papatheodoridi et al. (J Hepatol 2021), at least 42 patients were considered to have severe fibrosis (FS1 > 12 kPa).

Conclusion: 1) Eleven percent (34/299) of patients admitted to an addictology unit had an advanced fibrosis, 2) a FIB-4 higher than 1.3 has a sensitivity higher than 90% to rule in severe fibrosis and allow to avoid 60% of Fibroscans, 3) the combination of FIB-4, ELF or Fibrotest and LS should be studied on a larger number of patients to validate this algorithm, 4) the algorithm of Legros should be compared to the Papatheodoridi algorithm (J Hepatol 2021), 5) finally this study suggests that screening for advanced fibrosis should be performed in all hospital units for alcohol withdrawal.

SAT-464

Prospective evaluation of undiagnosed MetALD prevalence in MASLD patients using the ani score

Carlos Alventosa-Mateu[1], Mercedes Latorre Sánchez[1], Inmaculada Castelló Miralles[1], Alejandro Fernández Soro[1], Lara González González[1], José David Prieto Climent[1], Benjamín Climent Díaz[1], Moises Diago[1], Juan José Urquijo Ponce[1].
[1]*Consorcio Hospital General Universitario de Valencia, Valencia, Spain*
Email: almacar84@hotmail.com

Background and aims: The recent EASL-EASD-EASO guidelines differentiate MASLD from MetALD, the latter linked to higher alcohol intake and worse prognosis. However, there is a lack of validated, user-friendly scores or biomarkers for differentiation between both entities. The Alcoholic Liver Disease/Non-Alcoholic Steatohepatitis Index (ANI) score is simple and effective in identifying patients at risk for alcoholic liver disease. Our aim is to assess MetALD presence using the ANI score in MASLD patients and examine their characteristics.

Method: This single-center, prospective study involved MASLD patients attending Digestive Pathology consultations from September to November 2024. MASLD was defined by hepatic steatosis, alcohol intake < 20/30 g/day (women/men), ≥ 1 cardiovascular risk factor, and no other discernible cause, excluding suspected advanced liver disease. MetALD was considered if ANI > 0 (probability of alcoholic liver disease > 50%). Sociodemographic and analytical variables, self-reported alcohol consumption, liver fibrosis, and Controlled Attenuation Parameter (CAP) were assessed using Fibroscan®. Variables were compared between ANI > 0 and ANI < 0 groups, with significance set at p < 0.05.

Results: We included 100 patients, mean age 61.1 ± 9.9 years, 64% men. Fifty-one percent reported no alcohol consumption (0 g/week), and 26% consumed 10–20/30 g/day (women/men). ANI > 0 occurred in 23% (23/100), with 52.2% of them (12/23) having > 90% probability of MetALD/ALD. The ANI > 0 group was exclusively male (100% vs 53.2%, p < 0.001), with lower BMI (29.0 ± 4.4 vs 31.5 ± 4.7, p = 0.03) and CAP (269.7 ± 46.3 vs 305.0 ± 40.8, p = 0.03). Alcohol intake of 10–20/30 g/day was more common in the ANI > 0 group (56.5% vs 16.9%, p < 0.001), as was 30–70 g/week (21.7% vs 5.2%, p < 0.001). No alcohol consumption predominated in the ANI < 0 group (62.3% vs 13%, p < 0.001). The ANI > 0 group showed higher fibrosis (8.1 ± 2.6 vs 5.2 ± 2.1 Kpa, p < 0.001), higher GGT levels (150.5 ± 186.4 vs 67.4 ± 75.4 U/L, p = 0.04), and, although not significant, higher AST levels (43.9 ± 31.2 vs 31.8 ± 14.4 U/L, p = 0.057).

Conclusion: Although the ANI score is not validated to distinguish MASLD from MetALD, our study shows a significant prevalence of potential MetALD in MASLD patients. These findings highlight the need for developing and implementing clinical scores and biomarkers to accurately differentiate alcoholic-associated liver disease, crucial for minimizing the risk of misclassifying MetALD as MASLD.

SAT-465

Performance of MELD 3.0 in predicting 90- and 180-day mortality in alcoholic hepatitis

Ana Suárez-Saro Fernández[1], Mónica Barreales Valbuena[1], Elena Gómez-Domínguez[1], Alvaro Hidalgo[1], Maria Inmaculada Fernández Vázquez[1]. [1]*Hospital Universitario 12 de Octubre, Madrid, Spain*
Email: ana.suarezsaro@salud.madrid.org

Background and aims: Alcohol-associated hepatitis (AH) is a severe condition with high short-term mortality. The MELD (Model for End-Stage Liver Disease) score is commonly used to identify patients with severe AH, aiding in risk stratification and therapeutic decisions. The updated MELD 3.0 score has been proposed to improve prognostic accuracy. This study aims to evaluate the performance of MELD 3.0 compared to MELD, MDF, MELD-Na, ABIC, and GAHS.
Method: We conducted a retrospective analysis of 156 consecutive patients admitted with AH meeting the NIAAA criteria between January 2016 and May 2024. We calculated the area under the curve (AUC) for MELD 3.0, MELD, MDF, MELD-Na, ABIC, and GAHS. DeLong tests were performed to compare AUCs between models. The Reclassification Index (NRI) was calculated to evaluate the improvement in classification provided by MELD 3.0 over MELD. Additionally, we determined the sensitivities (S) and specificities (E) for MELD at the threshold of 21 and compared to MELD 3.0.
Results: The global mortality rates at 90 and 180 days were 16.67% and 19.75%, respectively. MELD 3.0 demonstrated superior AUCs for both time points: 0.879 (90 days) and 0.871 (180 days). These values were higher compared to MELD (0.857 and 0.863), MELD-Na (0.870 and 0.855), MDF (0.821 and 0.816), ABIC (0.747 and 0.729), and GAHS (0.796 and 0.775). The DeLong test showed that MELD 3.0 significantly outperformed ABIC and GAHS ($p < 0.05$), while differences between MELD-Na and MELD were not statistically significant. The optimal threshold for MELD 3.0 was 26 for both 90- and 180-day mortality. At 90 days, MELD 3.0 achieved a S of 84.6% and a E of 80.6%. In comparison, MELD at threshold 21 showed a S of 92.9% but a reduced E of 63.2%. Al 180 days, MELD 3.0 achieved a S of 80.6% and E of 82.3%, compared to MELD, which demonstrated a S of 86.7% but a E of 62.2%. The NRI for MELD 3.0 compared to MELD was 0.124 at 90 days and 0.097 at 180 days, reflecting modest improvements in reclassification.
Conclusion: MELD 3.0 showed comparable predictive performance to MELD for 90- and 180-day mortality but demonstrated greater E and modest reclassification improvements. These findings suggest MELD 3.0 may be a potentially valuable tool for more accurate risk stratification in alcoholic hepatitis. Further studies with larger cohorts are needed to validate these findings.

SAT-466

Plasma exchange as a rescue therapy for patients with severe alcohol-associated hepatitis

Anand Kulkarni[1], Lubomir Skladany[2,3], Svetlana Adamcova Selcanova[4], P Sathwika[1], Kristina Pawelska[2], Daniel Jan Havaj[2], Daniela Žilinčanová[2], Mithun Sharma[1], Karolina Sulejova[2], Shantan Venishetty[1], Manasa Alla[1], Juraj Svac[2], Sowmya Iyengar[1], Nagaraja Padaki[1], Nageshwar Reddy[1]. [1]*AIG Hospitals, Hyderabad, India;* [2]*F. D. Roosevelt University Hospital, Banska Bystrica, Slovakia;* [3]*L. Pasteur University Hospital and PJ Safarik University, Kosice, Slovakia;* [4]*F. D. Roosevelt University Hospital, Banska Bystrica, Slovakia*
Email: anandvk90@gmail.com

Background and aims: Patients with severe alcohol-associated hepatitis (SAH) and advanced liver failure have limited treatment options. Plasma exchange (PLEX) is a bridging modality for such patients with liver failure; the use of which is common in centers with limited access to early liver transplantation. We aimed to assess the outcomes of PLEX in patients with SAH.
Method: In this multicenter retrospective study, we included patients with SAH who underwent PLEX from India and Slovakia. The primary objective was to determine the transplant-free survival (TFS) at 90 days, and the secondary was to assess the change in serum bilirubin levels and model for end-stage liver disease (MELD) score after the last session of PLEX and adverse events related to PLEX. We also compared the outcomes of patients who underwent high volume (HV) and standard volume (SV) PLEX.
Results: We included 128 patients with a mean age of 41 ± 10.3 years. Ninety-three percent of patients were men. The mean MELD score was 32 ± 6, and all these patients met the acute-on-chronic liver failure (ACLF) criteria of APASL. Twenty one percent (27/128) had renal failure and/or underwent renal replacement therapy. TFS was 28.1% (26/128; 95%CI, 20.5–36.7) at day 90. The cumulative change in serum bilirubin levels and MELD score was −10.9 ± 7.4 mg/dl and −6.8 ± 5.8, respectively, after a median PLEX session of 2 (1–5). Seven patients developed adverse events (hypotension-3; fever and rigors-2; hypocalcemia-1 and volume overload-1). Sixty-eight patients underwent HV PLEX, and 60 underwent SV PLEX. The mean change in serum bilirubin (HV: −13.1 ± 8 mg/dl vs. SV: −8.6 ± 5.5 mg/dl; $P < 0.001$) and MELD score (HV: −8.2 ± 6.5 vs. SV: −5.2 ± 4.4; $P = 0.004$) was higher in HV group than SV group. TFS at day 90 was 28% (19/68) in HV PLEX and 28.3% (17/60) in SV group ($P = 1$). On adjusting for age and MELD score, the hazard ratio for survival with HV PLEX was similar to SV PLEX (HR, 0.69 [95%CI, 0.43–1.11]) at day 90.
Conclusion: PLEX provides decent transplant-free survival in patients with advanced liver failure due to SAH. Standard-volume and high-volume PLEX are similar in effectiveness.

SAT-467

Fibroblast activation assessed by PRO-C3 and PRO-C6 is associated to accumulation of key bile acids - A hallmark of fibrosis initiation and mortality in alcohol-related liver disease

Andressa de Zawadzki [1], Maja Thiele, Stine Johansen[2], Peter Andersen[2], Ida Falk Villesen[2], Tommi Suvitaival[3], Morten Karsdal[1], Cristina Legido-Quigly[3], Diana Julie Leeming[1], Aleksander Krag. [1]*Nordic Bioscience, Herlev, Denmark;* [2]*Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark;* [3]*Steno Diabetes Center Copenhagen, Herlev, Denmark*
Email: anza@nordicbio.com

Background and aims: Alcohol-related liver disease (ALD) results from persistent liver damage due to excessive alcohol consumption, often progressing to fibrosis, cirrhosis, and end-stage liver failure. Disrupted bile acid homeostasis is considered a key feature in liver fibrosis development in ALD. Studies in MASH and PSC patients have shown that potent antifibrotic therapy reduces bile acid levels and the fibroblast activity biomarker PRO-C3, hinting at a link between bile acid accumulation and fibrosis induction. However, the role of bile acids as drivers of fibrosis remains unclear. The current study investigates the potential role of bile acids driving fibrogenesis in ALD by exploring associations between fibroblast activity biomarkers, bile acids, and clinical outcomes.
Method: Serum levels of nordicPRO-C3 (N-terminal pro-peptide of type III collagen) and nordicPRO-C6 (endotrophin; type VI collagen formation) obtained by ELISA; and plasma concentrations of bile acids (CA, TCA, GCA, LCA, DCA, TUDCA, GUDCA) obtained by mass-spectrometry were assessed in a cross-sectional cohort of 450 patients with biopsy-proven ALD. Associations between circulating bile acid concentrations and the fibroblast activity biomarkers were

analyzed using Spearman correlation (coefficient r). A Wilcoxon test was applied to compare PRO-C3 and PRO-C6 levels in ALD patients stratified by low and high risk of outcomes over a median follow-up period of five years using Kaplan-Meier survival analysis to obtain survival curves and hazard ratios for mortality and decompensation.
Results: Fibroblast activity markers PRO-C3 and PRO-C6 correlated to glycine conjugated bile acids GCA (r = 0.67 for PRO-C3 and r = 0.45 for PRO-C6) and GUDCA (r = 0.53 for PRO-C3 and r = 0.34 for PRO-C6); taurine conjugated bile acid TCA (r = 0.64 for PRO-C3 and r = 0.46 for PRO-C6) at baseline. The bile acids GCA, GUDCA and TCA were elevated in at-risk ALD patients that developed adverse outcomes such as all-cause mortality and decompensation (GCA, cutoff high/low of 684 ng/mL, $p < 0.001$, $HR_{mortality} = 3.5$ and $HR_{decompensation} = 7.6$; GUDCA, high/low cutoff of 575 ng/mL, $p < 0.001$, $HR_{mortality} = 2.8$ and $HR_{decompensation} = 4.1$; TCA, high/low cutoff of 720 ng/mL, $p < 0.001$, $HR_{mortality} = 2.6$ and $HR_{decompensation} = 3.7$). Baseline levels of the fibroblast activity markers were found to be significantly increased in the high-risk groups stratified according to baseline bile acid concentrations of GCA (PRO-C3, $p = 1.15\ 10^{-28}$; PRO-C6, $p = 8.9\ 10^{-14}$) GUDCA (PRO-C3, $p = 2.67\ 10^{-12}$; PRO-C6, $p = 1.93\ 10^{-5}$) and TCA (PRO-C3, $p = 2.87\ 10^{-20}$; PRO-C6, $p = 5.57\ 10^{-11}$).
Conclusion: Increased circulating levels of toxic hydrophobic bile acids relate to activation of fibroblasts and to poor prognosis in ALD patients, suggesting that bile acids are linked to activation of fibrogenesis, and therefore are key to the induction and development of liver fibrosis in ALD.

SAT-468
Hot & cold fibrosis: fibro-inflammatory biomarkers as prognostic tools in alcohol-related liver disease

Andressa de Zawadzki[1], Maja Thiele, Stine Johansen[2], Peter Andersen[2], Ida Falk Villesen[2], Morten Karsdal[1], Diana Julie Leeming[1], Aleksander Krag. *[1]Nordic Bioscience, Herlev, Denmark; [2]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark*
Email: anza@nordicbio.com

Background and aims: Alcohol-related liver disease (ALD) encompasses a spectrum of liver conditions that begin with inflammation (steatohepatitis) and progress to fibrosis, cirrhosis, and associated complications. In ALD, various fibrotic and inflammatory processes drive disease progression and influence clinical outcomes. The concept of "hot and cold fibrosis" — referring to the presence (hot) or absence (cold) of immune cells in fibrotic tissue — has emerged to help understanding the role of inflammation in liver fibrosis and its impact on ALD progression. This study aims to investigate whether immune cell activity biomarkers can enhance the prognostic performance of established fibrogenesis biomarkers for risk stratification in ALD.
Method: Levels of the fibrogenesis marker nordicPRO-C3 (N-terminal pro-peptide of type III collagen), fibrosis resolution marker nordicCTX-III (MMP degraded fragment of cross-linked type III collagen), neutrophil activity marker nordicCPa9-HNE (calprotectin fragment degraded by neutrophil elastase) and T-cell activity marker C4G (type IV collagen fragment degraded by granzyme-B) were measured in serum from 450 patients with biopsy-proven ALD and 147 matched healthy controls. The prognostic performance of individual and combined biomarkers for the risk of all-cause mortality and decompensation over a median of 6 years was investigated by Kaplan-Meier survival analysis using a time-dependent cox model to obtain survival curves and hazard ratios (HR).
Results: Kaplan-Meier curves stratified by biomarker quartiles were used to determine cut-off values for CTX-III, C4G and CPa9-HNE that better stratify patients into groups with lower or higher risk of events. ALD patients with PRO-C3 levels above 12.6 ng/mL (literature cut-off) exhibited a 4-fold increased risk of mortality ($p < 0.001$; HR = 4.1; 75 events/450 patients) and 10-fold increased risk of decompensation ($p < 0.001$; HR = 10.6; 65 events/450 patients). When combining the PRO-C3 cutoff of 12.6 ng/mL with markers of fibrosis resolution and immune cell activity, the prognostic value of PRO-C3 improved by further stratifying patients by CTX-III levels above or below 15.6 ng/mL ($p < 0.001$; HR = 9.9 and HR = 25.4 in the groups with higher risk of mortality and decompensation, respectively), C4G levels above or below 33 ng/mL ($p < 0.001$; HR = 7.32 and HR = 31.7 in the groups with higher risk of mortality and decompensation, respectively) or by CPa9-HNE levels above or below 60 ng/mL ($p < 0.001$; HR = 12.8 in the group with higher risk of decompensation).
Conclusion: ALD patients at higher risk of adverse clinical outcomes demonstrated a distinct profile of heightened fibrogenesis and inflammation. Integrating biomarkers representing diverse biological processes significantly enhanced the predictive accuracy for clinical outcomes compared to individual biomarkers alone.

SAT-469
Maintaining a low to moderate alcohol consumption over time in MASLD patients increases the risk of fibrosis progression over moderate drinkers and MetALD patients

Ares Villagrasa[1], Anna Aguilar[2], Clara Sabiote[3], Alba Jiménez-Massip[1], Juan Manuel Pericàs[4], Meritxell Ventura Cots[4]. *[1]Liver Unit, Hospital Universitari Vall d'Hebron, Vall d'Hebron Institut de Recerca (VHIR), Universitat Autònoma de Barcelona, Barcelona, Spain., Barcelona, Spain; [2]Liver Unit, Hospital Universitari Vall d'Hebron, Vall d'Hebron Institut de Recerca (VHIR), Universitat Autònoma de Barcelona, Barcelona, Spain, Barcelona, Spain; [3]Vall d'Hebron Institut de Recerca (VHIR), Barcelona, Spain; [4]Liver Unit, Hospital Universitari Vall d'Hebron, Vall d'Hebron Institut de Recerca (VHIR), Universitat Autònoma de Barcelona, Barcelona, Spain., Centro de Investigación Biomédica en Red en Enfermedades Hepáticas y Digestivas, CIBEREHD, Barcelona, Spain*
Email: meritxell.ventura@vallhebron.cat

Background and aims: Metabolic and Alcohol-Related Liver Disease (MetALD) is characterized by the coexistence of metabolic dysfunction and alcohol consumption of 20–50 g/day for women and 30–60 g/day for men. New evidence shows that low to moderate alcohol consumption in patients with Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) significantly increases the risk of liver fibrosis. This study aims to assess the prevalence of MetALD in a cohort of outpatients and to investigate the influence of alcohol consumption and abstinence at the end of follow-up on fibrosis progression and cardiovascular events (CVE).
Method: A retrospective cohort study was conducted using a prospectively collected cohort of MASLD outpatients. Participants were categorized into four groups based on alcohol consumption: very low-risk drinkers (VLD) (0–40 g/week), low-risk drinkers (LD) (41–90 g/week), moderate drinkers (MD) (91–140 g/week women, 91–210 g/week men), and further reclassified as MetALD or Alcohol Related Liver Disease (ArLD). Liver fibrosis was evaluated using non-invasive markers, and data on alcohol abstinence and CVE were recorded throughout the follow-up period.
Results: 482 patients were included for analysis. 77% VLD, 6.75% LD, 7.81% MD, 8.02% MetALD, and 0.42% ArLD. The median follow-up period was 66 months. 52.28% patients were women with a mean age of 59 years. Significant sex differences were observed between groups ($p < 0.0001$), with statistically differences between MetALD vs MD ($p = 0.03$) and VLD groups ($p = 0.01$). No significant age differences were noted ($p = 0.1$). No differences were found at baseline ($p = 0.661$) or at the end of the study in the number of cardiovascular risk factors (CVRF) ($p = 0.7$). At baseline significant differences in liver stiffness (LSF) were only observed within MD vs LD ($p = 0.005$) and MD vs VLD groups ($p = 0.005$). At the end of follow-up, MD group had the highest mean LSF (47.3 KPa), significantly higher than VLD group ($p = 0.008$). This finding may be explained by the difference in alcohol abstinence at the end of the study ($p < 0.0001$) between VLD vs MD and LD groups. No significant differences in overall survival were observed,

including stratified analyses for liver-related complications or CVE. CVE risk during follow-up showed no significant group differences (p = 0.2), though the MD group had the highest risk (HR = 2.3, 95% CI [1.1, 5.1]). For the incidence of the novo CVRF, no significant differences were observed between groups (p = 0.87). The highest risks were seen in the LD (HR = 1.2, 95% CI 0.85–1.8), MD (HR = 1, 95% CI [0.7, 1.4]) and MetALD (HR = 1, 95% CI [0.7, 1.5]) groups.
Conclusion: The prevalence of MetALD in our cohort aligns closely with findings from other recently published studies. Low to moderate alcohol consumption in MASLD patients significantly increases the risk of liver fibrosis, with MD group showing the highest LSF levels during follow up, highlighting the critical role of alcohol abstinence in disease progression.

SAT-470

Impact of diabetes mellitus on mortality in alcohol-related acute-on-chronic liver failure: a study from the AARC database

Ashish Kumar[1], Shiv Kumar Sarin[1], Rakhi Maiwall[1], Ashok Choudhury[1], Vinod Arora[1], Mohamed Rela[1], Dinesh Jothimani[1], Mamun Al-Mahtab[1], Harshad Devarbhavi[1], CE Eapen[1], Ashish Goel[1], Cesar Yaghi[1], Qin Ning[1], Tao Chen[1], Jidong Jia[1], Zhongping Duan[1], Saeed Sadiq Hamid[1], Amna Subhan[1], Wasim Jafri[1], Akash Shukla[1], Soek-Siam Tan[1], Dong Joon Kim[1], Anoop Saraya[1], Jinhua Hu[1], AJIT Sood[1], Omesh Goyal[1], Vandana Midha[1], Manoj Sahoo[1], Guan-Huei Lee[1], Sombat Treeprasertsuk[1], Kessarin Thanapirom[1], Ameet Mandot[1], Samir Shah[1], Ravikiran Maghade[1], Laurentius A. [1]*APASL ACLF Research Consortium (AARC), New Delhi, India*
Email: ashishk10@yahoo.com

Background and aims: Acute-on-Chronic Liver Failure (ACLF) is a life-threatening condition characterized by acute decompensation in patients with chronic liver disease, often resulting in multi-organ failure and high mortality rates. Alcohol is the predominant cause of ACLF worldwide. Although diabetes mellitus is a recognized risk factor for adverse outcomes in chronic liver disease, its role in influencing mortality in alcohol-related ACLF is not well understood. This study evaluates the effect of diabetes mellitus on 90-day mortality in patients with alcohol-related ACLF.
Method: Data were obtained from the APASL ACLF Research Consortium (AARC) registry, including patients diagnosed with alcohol-related ACLF where alcohol was identified as both the cause of chronic liver disease (CLD) and the acute precipitant. Patients with additional etiologies of CLD or alternative precipitants (e.g., HBV, HCV, HEV, DILI) were excluded. Participants were categorized into diabetic and non-diabetic groups. The primary outcome was 90-day mortality, analyzed using baseline clinical and laboratory parameters as well as severity scores.
Results: A total of 2150 patients with alcohol-related ACLF were included: 121 diabetics (median age 45 years; 91.7% male) and 2029 non-diabetics (median age 42 years; 90.9% male). The median MELD-Na score was 31.1 (IQR 27.0–36.0), and the median CTP score was 12.0 (IQR 11.0–12.0) for both groups. Overall, 986 patients (46%) died within 90 days, while 110 (5%) underwent liver transplantation (LT), of whom 12 died post-transplantation. The 90-day mortality rate was significantly higher in diabetics compared to non-diabetics (68.1% vs. 45.4%, $p < 0.05$). Survival analysis revealed a significantly poorer prognosis for diabetic patients, both in overall survival ($p < 0.01$) and transplant-free survival ($p < 0.01$).
Conclusion: Diabetes mellitus significantly exacerbates mortality risk in alcohol-related ACLF. These findings highlight the urgent need for targeted research to unravel the mechanisms behind this association and to develop effective interventions to improve outcomes for diabetic patients with alcohol-related ACLF.

SAT-471-YI

Bacterial infections in patients with severe alcoholic hepatitis: drivers of organ failure and mortality

Laura Buttler[1], Jan Stange[2], Heiner Wedemeyer[1], Benjamin Maasoumy[1], Markus Busch[1]. [1]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany, Hannover, Germany;* [2]*Department of Internal Medicine, University of Rostock, Rostock, Germany, Rostock, Germany*
Email: Buttler.Laura@mh-hannover.de

Background and aims: Severe alcoholic hepatitis (sAH) is a critical condition and treatment remains challenging. Corticosteroids have been associated with an improved short-term survival and therefore play a major role in sAH therapy. However, their safety is still questionable as a linkage with elevated incidences of infections has been suggested by previous studies. We aimed to investigate the impact of steroid use on infections and to analyze the relevance of infections for the clinical outcome of sAH patients.
Method: We performed a post-hoc analysis of the prospective, multicentric VTI-308 trial including 151 consecutive patients with sAH. Competing risk models were used to evaluate the influence of corticosteroids on infection development up to one year of follow-up. To investigate the impact of infections on the risk for multi-organ failure (MOF) and overall mortality, cox proportional hazard regression analyses with time-dependent covariate were performed.
Results: The studied patients had a median baseline MELD of 25, median Maddrey Discriminant Function of 63 and a median age of 40 years. Overall, a number of 35 (23.2%) patients fulfilled the criteria for MOF during one year of follow-up, 4 (2.6%) underwent liver transplantation and 42 (27.8%) patients died. Any bacterial infection was acquired by 90 (59.6%) subjects. Among these, urinary tract infections (n = 31; 34.4%), bloodstream infections (n = 27; 30.0%), and pneumonia (n = 15; 16.7%) were most frequent. In 40 patients, the infection causing pathogen was isolated, with Enterococcus sp. being most common (n = 14; 35.0%). Fungal infections were observed in 19 (12.6%) patients during follow-up. Of note, corticosteroid therapy was neither linked to an increased risk for bacterial (HR = 0.48; p = 0.05) nor to a higher likelihood of fungal infections (HR = 1.74; p = 0.42) within one year. This observation was confirmed in the multivariable competing risk model, adjusted for MELD and previous infections (bacterial infections: HR = 0.48; p = 0.06; fungal infections: HR = 1.77; p = 0.42). Bacterial infections were significant predictors of MOF in the univariate (HR = 2.07; p = 0.04) as well as in the multivariable model, including the components of the Glasgow Alcoholic Hepatitis Score as covariables (HR = 2.54; p = 0.01). In line with this, bacterial infections were strongly linked to mortality, with hazard ratios between 3.54 and 5.14, indicating a four- to five-fold increased mortality. This remained statistically significant in the multivariable model (univariate: HR = 3.54; p < 0.001; multivariable: HR = 5.14; p < 0.001).
Conclusion: Bacterial infections are frequent complications in sAH patients and relevant contributors to MOF, finally leading to a dramatic increase of mortality. However, the use of corticosteroids

was not associated with an aggravated risk for infectious complications, which might ameliorate previous safety concerns.

SAT-472

Misclassification of alcohol use disorder in MASLD and MetALD: prevalence, clinical characteristics, and outcomes

Hyo Young Lee[1], Eileen Yoon[1], Jihyun An[1], Ha Il Kim[1], Joo Hyun Sohn[1], Chul-min Lee[1], Mimi Kim[1], Bo-Kyeong Kang[1], Eun Chul Jang[2], Huiyul Park[3], Hye-Lin Kim[4], Sang Bong Ahn[5], Joo Hyun Oh[5], Hyunwoo Oh[6], Dae Won Jun[7]. *[1]Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [2]Soonchunhyang University College of Medicine, Seoul, Korea, Rep. of South; [3]Myoungji Hospital, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [4]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South; [5]Nowon Eulji Medical Center, Eulji University, Seoul, Korea, Rep. of South; [6]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South; [7]Hanyang University College of Medicine, Seoul, Korea, Rep. of South*
Email: catchhyong@gmail.com

Background and aims: Within MetALD, there exists a continuum where the condition can conceptually shift between being metabolic dysfunction associated steatosis disease (MASLD) or alcoholic liver disease (ALD). However, alcohol use disorder (AUD) is often included in these diagnoses. This study aimed to investigate the prevalence and clinical characteristics of misclassified AUD among patients with MASLD and MetALD.
Method: The study included a total of 3,362,552 participants from the National Health Screening Program. Steatosis was defined as a Hepatic Steatosis Index score of 36 or higher. Significant alcohol intake was calculated based on a self-reported questionnaire. AUD was defined as having received medical care for an alcohol-related condition at least once during the study period. The average follow-up period for participants was 9.8 years.
Results: Among the 3,362,552 participants analyzed, the prevalence of MASLD and MetALD was 23.8% and 1.9%, respectively. Of those classified as MASLD and MetALD, 1.1% (8,481 individuals) and 4.7% (2,989 individuals) had a history of AUD in the index year. MASLD and MetALD with medical records of AUD (AUD misclassified as MASLD or MetALD) in the index year showed higher all-cause mortality compared to MASLD and MetALD without AUD. Liver-related mortality was also significantly elevated in the AUD misclassified as MASLD or MetALD. Adjusted hazard ratios (HRs) of 6.53 for AUD misclassified as MASLD and 6.98 for AUD misclassified as MetALD compare to non-AUD group, respectively. aHR for extrahepatic cancer mortality was 1.33 in the AUD misclassified as MASLD, and 1.44 in AUD misclassified as MetALD groups.
Conclusion: A considerable number of 'AUD' cases were misclassified as MASLD and MetALD in cross-sectional investigations of alcohol consumption. The misclassified AUD as MASLD or MetALD had higher liver-related mortality than the pure MASLD and MetALD groups.

SAT-475

Unemployment and social isolation predict relapse in patients with alcohol related cirrhosis

Christopher Oldroyd[1], Michael Allison[1,2]. *[1]Cambridge Liver Unit, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; [2]NIHR Cambridge Biomedical Research Centre, Cambridge, United Kingdom*
Email: christopher.oldroyd@nhs.net

Background and aims: Abstinence from alcohol is critical for patients with alcohol related cirrhosis (AC). We sought to understand the clinical and psychosocial factors which predict abstinence in patients with AC following admission to hospital.
Method: This was a retrospective single centre study. We reviewed data on all patients admitted to a large tertiary centre in the UK with a diagnosis of AC and/or alcohol-associated hepatitis between Sept 2014 and March 2023. Where there were multiple admissions the first admission on or after the diagnosis of AC was used. We collected a granular dataset which included clinical and psychosocial factors felt to be relevant in predicting abstinence. A hepatologist reviewed all case notes individually. The outcome of interest was abstinence at one year. We used Mann-Whitney U test to compare continuous variables and chi-square test to compare categorical variables. Those variables that were statistically significant ($p \leq 0.05$) on univariate analysis were entered into a backward stepwise elimination variable selection procedure (multivariate logistic regression).
Results: We identified 646 patients who met the inclusion criteria. Median age was 58 (IQR 50–67) and 37% were female. Reasons for admission were: decompensated liver disease 57%; other alcohol related reasons 20%; and other 23%. Median length of stay was 6 days (IQR 3–13). Median MELD score was 14 (IQR 8–21). Median alcohol consumption in units/week was 70 (IQR 14–140). The abstinence rate at one year was 56% and mortality was 29%. Patients who were abstinent at one year were more likely to have been admitted with decompensated liver disease (64% vs 43%, $p < 0.001$); had a higher MELD score at admission (median 14 vs 10 $p = 0.001$); had lower levels of alcohol use at admission (median 50 vs 100 units/week, $p < 0.001$); were more likely to have a partner (64% vs 42% $p < 0.001$); more likely to be in employment (33% vs 22% $p = 0.002$); and were less likely to have a co-morbid psychiatric diagnosis (15% vs 26% $p = 0.01$). After backwards stepwise elimination, co-morbid psychiatric diagnosis was removed from the model. The following categorical variables remained statistically significant on multiple logistic regression: lack of partner (OR 0.55 p 0.03); Unemployment (OR 0.52 p 0.04) and admission with decompensated liver disease (OR 3.65 $p < 0.001$). In addition, for every 10 units additional alcohol consumption/week, likelihood of abstinence decreased by 4% (OR 0.96 p0.002). For each one unit increase in MELD, likelihood of abstinence increased by 6% (OR 1.06 p 0.004).
Conclusion: These predictors highlight potential populations of patients with AC who could be targeted for relapse prevention strategies after a hospital admission. Specific interventions could be designed to target those with the highest levels of alcohol intake, without social support and who have not yet developed decompensated liver disease in order to improve outcomes in this patient group.

SAT-476-YI

Liver death trajectories differ in patients with alcohol consumption and/or metabolic syndrome: a 13-year nationwide study

Claire Delacôte[1], Xavier Lenne[2], Alexandre Louvet[1,3], Line Carolle Ntandja Wandji[1,3], Amelie Bruandet[2], Sylvie Deuffic-Burban[4], Philippe Mathurin[1,3]. *[1]U1286-INFINITE, Univ. Lille - CHU Lille, Inserm, Lille, France; [2]CHU de Lille, Medical Information Department, Lille, France; [3]CHU de Lille, service des maladies de l'appareil digestif, Lille, France; [4]UMR 1137 - IAME, Paris, France*
Email: claire.delacote@inserm.fr

Background and aims: Alcohol-related liver disease (ALD) and metabolic dysfunction-associated steatotic liver disease (MASLD) are 2 main causes of chronic liver disease. Alcohol drinkers are also exposed to metabolic syndrome (MS), requiring investigating trajectories of liver death in those with underlying cirrhosis and/or HCC by comparing ALD with MS (ALD+MS+) to ALD without MS (ALD +MS-) or MASLD alone.
Method: Data of ALD+MS-, ALD+MS+ and MASLD patients hospitalized between 2011 and 2023 with ≥1 ICD-10 code of cirrhosis and/or HCC were extracted from the French national medicalized information system program. Overall and liver-related deaths (HCC or liver decompensation (LD)), age-standardized mortality rates (ASMR, per 100 000), age at death and years of life lost (YLL) over the period were assessed by group.
Results: Death occurred in 176,026 of 376,348 patients with either cirrhosis and/or HCC (ALD+MS-: 44.6%; ALD+MS+: 39.6%; MASLD:

15.8%). Among deaths in ALD groups, MS prevalence was high (47.1%) as was that of severe alcohol use disorder (66.6% in ALD+MS-; 67.0% in ALD+MS-). 63.4% of total deaths were liver-related, with a higher proportion of deaths due to LD in ALD groups (65.9%) and due to HCC in MASLD group (57.9%). The proportion of deaths due to HCC increased in ALD+MS+ (36.6%) compared to ALD+MS- (31.3%, $p < 0.01$). Between 2011 and 2023, liver-related ASMR decreased in ALD +MS- (from 7.9 to 5.0, $p < 0.01$) and increased in ALD+MS+ (from 4.5 to 5.1, $p = 0.01$) and MASLD (from 1.8 to 2.5, $p < 0.01$). In 2023, ALD remained the leading cause of liver-related ASMR (80.2%) but MASLD's contribution increased from 12.7% to 19.8% over the period. Age at death increased in all 3 groups but remained younger in ALD+MS- (from 64.0 to 66.5, $p < 0.01$) and ALD+MS+ (from 67.0 to 68.9, $p < 0.01$) than in MASLD (from 73.9 to 75.1, $p < 0.01$). Knowing 2023 mean age at death in the general population was 79.6, YLL per individual are twice as high in ALD+MS- (15.8 years) and 1.6 times higher in ALD+MS- (12.6 years) than in MASLD (7.8 years, $p < 0.01$).

Conclusion: MS is highly prevalent among deaths in ALD cirrhotic and HCC patients. ALD is associated with an increased risk of LD-related death whereas MS increased HCC risk, the leading cause of death in MASLD. Premature death remains frequent in ALD with high YLL per individual. The paradoxical older age at death in ALD+MS+ and MASLD may be linked to either later onset of MS and/or multidisciplinary management of MS, leading to better access to care.

SAT-477-YI

Feasibility and effectiveness of a liver health check clinic in community alcohol services

Daniel Gutmann[1], Michael Griffiths[1], Susan Kemp[1], Erika Toth-Cserepes[1], Claire St John[1], Douglas Macdonald[1,2], Emmanuel Tsochatzis[1,2]. [1]*Department of Hepatology and Liver Transplantation, Royal Free London NHS Foundation Trust, London, United Kingdom;* [2]*Institute of Liver and Digestive Health, University College London, London, United Kingdom*
Email: daniel.gutmann@nhs.net

Background and aims: Liver cancer affects 6,600 people annually in the UK. As part of an NHS England pilot programme, Liver Health Check Clinics (LHCC) were established within alcohol services across North Central London. Between September 2022 and October 2024, 2,658 liver stiffness measurements (LSM) were conducted to identify individuals at risk of cirrhosis and liver cancer (HCC).

Method: LSM tests were performed by trained clinician assistants during pre-booked and walk-in sessions. Individuals with probable significant fibrosis (LSM 8–11.4 kPa) were offered a repeat scan after 1 year. Those with probable advanced fibrosis/cirrhosis (LSM ≥11.5 kPa) were offered an on-site non-invasive liver screen, referral to hepatology, and a liver ultrasound before their first hepatology appointment. A leaflet with their LSM result and explanation of its significance was provided to all patients.

Results: Of the 2,658 patients, the average age was 46.2 years (±12.1), 64% male; median LSM 5.4 kPa (IQR: 4.3–7.5). Probable significant fibrosis (8–11.4 kPa) in 307 patients (11.5%), probable advanced fibrosis/cirrhosis (LSM >11.5 kPa) in 224 patients (8.4%). 91 of these patients met the Baveno VII criteria for clinically significant portal hypertension with LSM ≥25 kPa. Complete follow up data was available for 101/307 patients. During follow-up, 46 (45%) were diagnosed with cirrhosis, 1 with HCC, 30 (30%) reported abstinence. Complications included 4 admissions with decompensation, 6 alcohol-related admissions, and 4 deaths. There were 5 cases of varices and 11 with portal hypertensive gastropathy. The cumulative non-attendance rate for hepatology clinic appointments was 26%. Retrospective analysis of LSM and FIB-4 scores was conducted for 122 patients who had appropriate blood test results on their electronic patient record to calculate a FIB-4 as well as LSM ≥11.5 kPa. 27 (22.1%) of these patients had FIB-4 scores < 1.3. 109 patients with probable significant fibrosis attended for 1-year follow up scans. 80 LSM values fell below 8 kPa, 17 remained within the significant fibrosis range, and 12 progressed to advanced fibrosis/cirrhosis.

Conclusion: Initial scanning revealed that 20% of patients with a history of alcohol misuse had LSM values indicating at least probable moderate fibrosis, with 8.4% showing probable advanced fibrosis/cirrhosis. This population had not previously undergone liver assessment. The broader impact of LHCCs, including their influence on alcohol use and fibrosis progression, will be further evaluated.

SAT-478

Routine, pre-emptive anti-craving treatment to prevent alcohol relapse after liver transplantation

Pedro de Borba Engster[1], Shirshendu Sinha[1], Julia Lankton[1], Blanca Lizaola-Mayo[1], David M. H. Chascsa[1], Rolland Dickson[1], Channa Jayasekera[1]. [1]*Mayo Clinic Arizona, Phoenix, United States*
Email: jayasekera.channa@mayo.edu

Background and aims: Alcohol-associated liver disease (ALD) is the fastest-rising and leading indication for liver transplantation (LT) in the United States, with acute alcohol-related hepatitis (AAH) and acute-on-chronic ALD with inadequately treated substance use disorder—groups with post-LT alcohol relapse risk 25–50%–representing increasingly-accepted indications. We investigated whether routine, pre-emptive pharmacologic ACT in all such high-risk LT recipients would reduce alcohol relapse rates at 12 months compared to a historical, untreated cohort.

Method: From December 2023, all patients who underwent LT under our Center's Pathways for AAH and ALD with inadequately treated substance use disorder (Exceptions) were initiated on daily acamprosate, topiramate, or naltrexone after LT, with intended treatment of >/ = 12 months. Patients received standard LT care including follow up with addiction psychology and psychiatry teams. Relapse was defined as abnormal serum phosphatidylethanol level when tested per-protocol at 3 weeks, 2, 3, 4, 8, and 12 months after LT, or at any ad-hoc timepoint.

Results: Of 17 LT recipients, 10 were transplanted under Exceptions (median pre-LT sobriety 230 days) and 7 under AAH (median pre-LT sobriety 35 days) Pathways. ACT was initiated at mean 13 days after LT, with 14 receiving acamprosate, 3 receiving topiramate, and 2 transitioned to naltrexone during follow-up. Treatment was well-tolerated, with no serious adverse effects warranting discontinuation. The main adverse effect was diarrhea. Renal impairment was the main reason for agent or dose changes. All patients reported compliance with treatment. Relapse occurred in 2/17 (11.7%) during 12 month follow up: one with a one-time relapse at 3 months, and one with two relapses at 3 and 8 months. In comparison, our 2019–2022 historical cohort of 42 LT recipients who did not receive ACT had an alcohol relapse rate of 22%.

Conclusion: ACT was safe, well-tolerated, and associated with a lower alcohol relapse rate, both absolute and in terms of severity, than previously reported at our center. To our knowledge, these data represent the first assessment of routine, pre-emptive ACT use after LT in patients deemed at high risk of relapsing to alcohol use.

SAT-480

Efficacy and safety of fecal microbiota transplantation in patients with severe alcohol-related hepatitis or decompensated liver cirrhosis: a systematic review and meta-analysis

Nabil El Hage Chehade[1], Tara Alleyasin[1], Adam Deising[1], Paul Pockros[1], Julio Gutierrez[1]. [1]*Scripps Clinic, San Diego, United States*
Email: elhagechehade.nabil@scrippshealth.org

Background and aims: Severe alcohol-related hepatitis (SAH) and acute on chronic liver failure (ACLF) are serious conditions associated with increased mortality. By modifying the liver-gut axis, fecal microbiota transplantation (FMT) has been proposed as a therapeutic option for SAH/decompensated liver cirrhosis with recurrent hepatic encephalopathy (HE). The aim of our systematic review and meta-analysis is to assess the short and long-term efficacy and safety profile

of FMT versus standard of care (SOC) in patients with these conditions.
Method: A thorough search across electronic databases was conducted from inception till November 2024. Included studies involved adult patients with SAH or decompensated liver cirrhosis who received FMT versus SOC (nutritional support, lactulose and rifaximin, pentoxifylline, or corticosteroids). The primary endpoints were short and long-term survival while secondary endpoints were rates of HE, gastrointestinal bleeding (GIB), ascites, infection, and alcohol relapse. Results were pooled together using Reviewer Manager 5.4 software and odds ratios (ORs) with 95% confidence intervals (CI) were calculated.
Results: 13 studies involving 577 patients with either SAH or decompensated liver cirrhosis were included in our pooled analysis, 3 of which were randomized controlled trials. Our findings demonstrate that patients who received FMT had higher survival rates at 1 month (OR = 2.71, 95% CI [1.48, 4.95]), 3 months (OR = 3.15, 95% CI [1.92, 5.17]), 6 months (OR = 2.59, 95% CI [1.45, 4.64]), and 1–3-years (OR = 3.36, 95% CI [2.00, 5.66]) compared to those who received SOC. The rates of HE, ascites, and infection were significantly lower in the FMT group with OR of 0.21 (95% CI [0.10, 0.44]), 0.22 (95% CI [0.11, 0.43]), and 0.24 (95% CI [0.14, 0.42]), respectively. The rate of GIB was similar between both groups (OR = 0.73, 95% CI [0.37, 1.44]). In patients with alcohol use disorder, relapse rates were similar between both groups as well (OR = 0.39, 95% CI [0.15, 1.03]).
Conclusion: In patients with SAH/decompensated liver cirrhosis, FMT demonstrated short and long-term survival benefit over SOC. FMT use was also associated with lower rates of HE, ascites, and infection. To date, this is the most comprehensive systematic review that pooled efficacy and safety data related in FMT use in patients with SAH/chronic liver disease. Additional data regarding changes in gut microbiota following FMT use will be pooled and added to the final report.

SAT-481-YI
Performance of six biomarkers compared to histological fibrosis stage as surrogate markers of clinical endpoints in drug trials of patients with MetALD and ALD - a dual biopsy study
Ellen Lyngbeck Jensen[1,2], Maja Thiele, Nikolaj Torp, Stine Johansen[2,3], Johanne Kragh Hansen[3], Camilla Dalby Hansen[2,3], Mette Lehmann Andersen[3,4], Georg Semmler[3], Katrine Thorhauge[2,3], Helle Schnefeld[3], Ida Falk Villesen[3], Katrine Bech[2,3], Peter Andersen[3], Diana Julie Leeming[5], Morten Karsdal[5], Katrine Lindvig, Sönke Detlefsen[2,6], Aleksander Krag, Mads Israelsen[2,3]. *[1]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense C, Denmark; [2]Institute of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense C, Denmark; [3]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense C, Denmark; [4]Department of Gastroenterology and Hepatology, Herlev Hospital, Herlev, Denmark; [5]Nordic Bioscience, Herlev, Denmark; [6]Department of Pathology, Odense University Hospital, Odense C, Denmark*
Email: ellen.lyngbeck.jensen@rsyd.dk

Background and aims: There is increasing interest in developing therapies for MetALD and ALD with two recently launched phase II trials and several underway. However, no generally accepted endpoints exist. While several non-invasive tests (NITs) show good diagnostic and prognostic accuracy, it remains unclear if changes in these tests predict liver-related outcomes. We compared the predictive performance of changes in six non-invasive tests compared with paired liver biopsies.
Method: We collected data from two RCTs and two prospective studies of participants with MetALD and ALD who underwent baseline and follow-up liver biopsy with concurrent measurement of NITs. Histological fibrosis stage was scored by one pathologist according to NASH CRN and NITs included transient elastography (TE), ELF, PRO-C3, Agile3+, FIB-4 and LiverPRO. We evaluated changes from baseline to follow-up and correlated delta values with Spearman's coefficient. By manual review of electronic medical records, we classified hepatic decompensation per Baveno VII and registered any deaths. To evaluate the six biomarkers as surrogate markers of clinical endpoints, we performed Cox regression models with the delta values adjusted for the baseline value. Model performance for predicting outcomes was compared with Harrell's C.
Results: We included 164 patients with MetALD and ALD, mean age 59 years (±8.5), BMI 30 kg/m² (±6). Alcohol abstinence 1 week prior to inclusion was reported by 42%, while 57% had significant fibrosis (≥F2) and 19% cirrhosis (F4). The median time from baseline to follow-up biopsy was 1.9 (IQR 1.3) years. Referenced to histologic Kleiner fibrosis stage, changes (delta value) in the respective NITs showed the following Spearman's correlation coefficients: Agile3+ (r = 0.80), ELF (r = 0.43), TE (r = 0.27), LIVERPRO (r = 0.26), PRO-C3 (r = 0.20), and FIB-4 (r = 0.08). After follow-up liver biopsy, we further followed patients for a median duration of 2.1 years (range: 0.4–6.0 years). During this period, 13 decompensated and 17 died. Changes (delta value) in histologic fibrosis stage and the six biomarkers were each included in separate Cox regression models, where all predicted hepatic decompensation and death (p-values < 0.01). The performance for predicting outcomes was compared by calculating Harrell's C-index: ELF (0.77), PRO-C3 (0.77), LiverPRO (0.78), Agile3+ (0.75), Kleiner fibrosis stage (0.73), FIB-4 (0.68), to TE (0.66).
Conclusion: In designing clinical trials for MetALD and ALD, it is important to select biomarkers that accurately reflect changes in the risk of liver-related outcomes. ELF, PRO-C3, and LiverPRO demonstrated best predictive performance, warranting greater emphasis in future trial interpretations compared to widely used diagnostic tools such as FIB-4 and TE.

SAT-482-YI
Prospective study of phosphatidylethanol as a quantitative, objective biomarker to detect under-reported alcohol use in steatotic liver disease
Federica Tavaglione[1], Luis Antonio Diaz[1,2], Monica Tincopa[1], Veeral Ajmera[1], Maral Amangurbanova[1], Egbert Madamba[1], Seema Singh[1], Ricki Bettencourt[1], Lisa Richards[1], Claude Sirlin[1], Rohit Loomba[1]. *[1]University of California San Diego, La Jolla, United States; [2]Pontificia Universidad Católica de Chile, Santiago, Chile*
Email: fede.tavaglione@gmail.com

Background and aims: The current subclassification of steatotic liver disease (SLD) strongly relies on using validated questionnaires, such as Alcohol Use Disorders Identification Test (AUDIT) and Lifetime Drinking History (LDH), which, while useful, are impractical and lack precision for their use in routine clinical practice. Indeed, self-reported alcohol use is frequently associated with inaccurate reporting, potentially leading to misclassification. Phosphatidylethanol (PEth) is an abnormal phospholipid formed only in the presence of ethanol and a quantitative, objective biomarker for alcohol use with high sensitivity and specificity. In this study, we aimed to quantify alcohol use and estimate the prevalence of under-reported alcohol use using PEth in a large, population-based cohort of individuals with overweight or obesity in the United States.
Method: This is a cross-sectional analysis of a prospective study including 556 community-dwelling adults with overweight or obesity residing in Southern California, 391 of whom had SLD as defined by MRI-PDFF ≥ 5%. The clinical research visit included medical history, biochemical and PEth testing, standardized validated questionaries for alcohol assessment, physical examination and advanced liver imaging using MRI-PDFF and MRE. Participants were subclassified as having metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic dysfunction and alcohol-associated liver disease (MetALD) or alcohol-associated liver disease (ALD) in accordance with the new nomenclature guidance from AASLD–EASL–ALEH. Under-reported alcohol use was defined as individuals

originally classified as MASLD with PEth ≥ 25 ng/mL or individuals originally classified as MetALD with PEth ≥ 200 ng/mL.
Results: In the overall cohort, the mean (SD) age and BMI were 51 (13) years and 32.4 (5.7) kg/m^2, respectively. As PEth levels increased, body mass index, insulin resistance and hemoglobin A1c decreased, while the prevalence of male sex, blood pressure and HDL cholesterol increased (all $p < 0.05$). In the overall SLD population, under-reporting of alcohol use occurred in 16% of individuals, with 16% misclassified as MASLD having PEth ≥ 25 ng/mL and 29% misclassified as MetALD having PEth ≥ 200 ng/mL. In multivariable logistic regression, male sex (OR 1.11, 95%CI 1.03–1.20, p = 0.005), Caucasian ethnicity (OR 1.08, 95%CI 1.00–1.16, p = 0.047) and the absence of type 2 diabetes (OR 1.12, 95%CI 1.04–1.21, p = 0.005) were the strongest independent factors associated with under-reported alcohol use in this population.
Conclusion: PEth is a precise, direct biomarker that can objectively quantify alcohol use and classify SLD subcategories, bypassing the misclassification bias associated with self-reporting strategies.

SAT-483-YI
Younger, sicker, higher mortality; the burden of alcohol related liver disease in Ireland
Clare Foley[1], Jennifer Russell[1], Stephen Stewart[1], John Ryan[2]. [1]*Mater Misericordiae Hospital, Dublin, Ireland;* [2]*Beaumont Hospital, Dublin, Ireland*
Email: foleyclare123@gmail.com

Background and aims: The burden of liver disease admissions on acute hospitals in Ireland is not clear. This study aimed to examine alcohol related (ARLD) and non-alcohol related (Non-ARLD) liver disease inpatient hospital admissions over a six year period from 2017–2023.
Method: National quality assurance and improvement system (NQAIS) inpatient admission (≥1 day) data was reviewed from 1/1/2017 to 12/12/2023 for all 26 model 3 and 4 general medical hospitals in Ireland. Demographics, inpatient mortality data, average length of stay (LOS), total bed days and total critical care bed days were calculated.
Results: There were a total of 19,298 inpatient hospital admissions as a result of liver disease across the 26 hospitals in 6 years. 54% of these were related to ARLD. ARLD accounted for 135,567 bed days and 8476 critical care bed days. Non-ARLD admissions comprised 92,556 bed days and 4024 critical care bed days. ARLD was associated with longer average LOS (13 days v 10 days for non-ARLD; $p < 0.0001$). Males accounted for 66% of ARLD and 48% of non-ARLD admissions. The median age was 54 years for ARLD and 64 years for non-ARLD ($p < 0.0001$). Patients with a previous diagnosis of cirrhosis had longer average lengths of stay when admitted with UTI (15 days vs 10 days $p < 0.0001$), pneumonia (23 days vs 12 days $p < 0.0001$), TB (58 days vs 20 days $p < 0.0001$), influenza (15 days vs 8 days $p < 0.0068$) or intestinal infection (14 days vs 17 days $p < 0.0001$), when compared to patients without cirrhosis admitted with these conditions. There were a total of 1733 inpatient liver disease deaths over the 6 year period. 63% of these were related to ARLD (1089). ARLD deaths were more likely to be men (66%) and younger than non-ARLD (56 years vs 72 years < 0.0001). Inter-hospital liver related death rates varied significantly between 6 and 13%, whilst ARLD death rates varied between 6 and 18%. Inpatient liver disease death rates were double those of COPD and acute myocardial infarction respectively. Patients with cirrhosis also had statistically significant higher inpatient death rates when admitted with UTI, Pneumonia, TB, Influenza and intestinal compared to those without cirrhosis.
Conclusion: Liver disease poses a huge burden on the acute hospital infrastructure in Ireland, especially ARLD. ARLD patients are younger, more likely to be male, spend longer in hospital including intensive care and are at increased risk of death compared to non-ARLD. Liver disease mortality is higher than other common chronic conditions and appears to vary across hospitals. More effective public health and clinical measures are urgently required to reduce the morbidity and mortality associated with ARLD and its impact on acute hospitals.

SAT-484
Impact of alcohol binge duration and metabolic features on liver stiffness in steatotic liver disease
Lili Liang[1], Frances Lee[2]. [1]*Icahn School of Medicine, Graduate School of Biomedical Sciences, New York, United States;* [2]*Icahn School of Medicine, Division of Liver Diseases, Department of Medicine, New York, United States*
Email: francesyjl@gmail.com

Background and aims: Current screening questions for alcohol related liver disease (ALD) quantify total grams of alcohol intake within a day or week, but the duration of binges is not specified. We sought to understand trends in the impacts of binge drinking during short periods of time and metabolic factors on liver stiffness using transient elastography.
Method: Utilizing the National Health and Nutrition Examination Survey (NHANES) 2017 – March 2020, we included survey respondents with the following inclusion criteria: 1. ages 18 and older, 2. steatotic liver disease, defined as CAP score of at least 285 dB/min, 3. documented liver stiffness measurements (LSM) on transient elastography, 4. responses to alcohol intake questions, 5. presence or absence of metabolic risk factors. Patients not meeting all inclusion criteria were excluded. Using R (version 4.4.1), we applied survey-weighted generalized linear models with a quasibinomial link function to examine the relationship between alcohol intake and significant or advanced fibrosis, adjusting for covariates including gender, age, race, diabetes status, waist circumference, dyslipidemia, hypertension, and obesity.
Results: Of the 15,560 survey responses, 2,902 had steatotic liver disease (SLD). LSM > 8.5 kPa was considered as any fibrosis, and LSM > 13.1 kPa as advanced fibrosis, based on prior studies of SLD. Diabetes, hypertension and obesity remained significant risk factors for advanced fibrosis (OR 1.75, 95% CI 1.05–2.94; OR 2.27, 1.56–3.31, OR 7.36, 2.93–18.4). Non-Hispanic Black race was protective against advanced fibrosis (OR 0.57, 0.33–0.96). Based on documented alcohol intake and gender, 35% of respondents belonged in the MASLD category, 20% met-ALD category, and 11% ALD category. Categorization into either MASLD, Met-ALD, or ALD groups was not associated with fibrosis. To assess the impact of binge drinking, respondents were divided into three categories: excessively (every day to 4 times a week), moderately (twice a week to 2 times a month), rarely (once a month or less). Those with SLD who excessively drank 4–5 drinks within 2 hours had increased risk for both any and advanced fibrosis (OR 15.98, 14.49–17.47; OR 17.26, 15.13–19.38). Those who drank 12 or more alcohol drinks in one day excessively and moderately had increased risk for advanced fibrosis (OR 20.34, 16.96–23.71; OR 19.08, 16.28–21.88).
Conclusion: Our study underscores the impact of both metabolic risk factors and duration of intake periods of large quantities of alcoholic beverages on liver stiffness. Screening for ALD in the future may be enhanced by considering both the duration of alcohol binges and metabolic risk factors to stratify for risk of ALD and fibrosis.

SAT-485
Comorbidities at diagnosis of alcohol-related liver cirrhosis compared to the general population: a population-based case-control study of 11,989 patients

Background and aims: Alcohol-related liver cirrhosis (ARLC) infrequently gives any symptoms before decompensation, leading to patients being diagnosed at a late stage when prognosis is dismal. Patients with ARLC may have a different comorbidity pattern than the general population, allowing for potential screening of pre-cirrhotic disease or high alcohol consumption in specific patient groups. Here, we compare the prevalence of comorbidities at or prior to the time of diagnosis of ARLC, to the prevalence in the general population.
Method: Using national registers, we identified all patients in Sweden with a first diagnosis of ARLC (ICD-10 code: K70.3) from 2006 to 2020 (n = 11 989) with up to 10 controls (n = 113 657), matched on age, sex, and place of residence at the time of ARLC diagnosis. Comorbidities were identified from 1998 to 2020 using ICD-codes from all in- and outpatient contacts with specialized care in Sweden.
Results: At diagnosis of ARLC we found several diagnoses with a significant difference between cases and controls. The comorbidities with the highest prevalence difference were: diseases of the liver (ICD-10 code: K70-K77, excluding K70.3), 48.3% in cases vs 0.3% in controls, mental and behavioral disorders due to psychoactive substance use (F10-F19), 48.8% in cases vs. 3.9% in controls, symptoms and signs involving the digestive system and abdomen (R10-R19), 43.9% in cases vs. 14.5% in controls and diseases of the esophagus, stomach and duodenum (K20-K31), 33.1% in cases vs 8.8% in controls. All differences were significant (p-value< 0.001).
Conclusion: Several comorbidities differ significantly between ARLC patients and controls at diagnosis. Almost 50% of patients later diagnosed with ARLC have diagnoses related to psychoactive substance abuse, suggesting screening in an alcohol use disorder center may be a potential tool to identify pre-cirrhotic disease. These findings may be of importance for early detection of patients at risk for future development of ARLC.

Email: hoferica.jakub@gmail.com

Background and aims: Alcohol-related liver disease (ALRD) affects 4.8% of the global population. Among these patients, 13.4% to 19.6% suffer from alcoholic hepatitis, which carries significant short- and long-term mortality rates. Current therapeutic options are limited, offering only modest short-term survival benefits aside from liver transplantation. Recent studies suggest that microbiota-based therapies may offer a novel therapeutic opportunity for patients with ARLD. In this study, we aim to evaluate and synthesize data from the literature focused on the application of FMT in ARLD.
Method: Databases including Embase, Medline, and CENTRAL were searched up to September 27, 2023. The pre-registered protocol on PROSPERO (CRD42023467455) was followed with no deviations. Studies comparing adult patients with ALRD, treated with fecal microbiota transplantation (FMT) or standard of care (SOC), were included. Investigated outcomes included overall survival, alcoholic recidivism, adverse events, and disease severity scores.
Results: Overall, ten studies were eligible for inclusion, comprising a total of 494 patients, of whom 339 were eligible for synthesis. Nine of ten included publications focused on severe alcoholic hepatitis (SAH). In these patients, FMT was associated with a significantly improved overall survival compared to SOC, with a hazard ratio (HR) of 0.50 (95% CI: 0.35–0.72; p = 0.0002). Survival benefits were most pronounced in patients who were ineligible for corticosteroid therapy. Specifically, when comparing FMT to pentoxifylline, the HR was 0.45 (95% CI: 0.21–0.96; p = 0.0345), and when comparing FMT with nutritional support, the HR was 0.36 (95% CI: 0.19–0.66; p = 0.0001).
Conclusion: FMT is a promising therapeutic option for improving short- and medium-term survival in patients with severe alcoholic hepatitis, particularly for those who are ineligible or unresponsive to corticosteroid therapy.

SAT-487

Disease severity is more important than age and underlying cirrhosis at predicting mortality from alcohol related hepatitis

Email: Huw.Purssell@doctors.org.uk

Background and aims: Alcohol related hepatitis is associated with a high mortality rate. Currently biochemical data is used to determine prognosis however there is a lack of data on the impact of pre-existing liver cirrhosis and age. We therefore analysed a cohort of patients with Alcohol related Hepatitis who had biopsy data to assess the influence that age and the presence of cirrhosis have on outcomes.
Method: The worldwide alcohol liver disease outcomes (WALDO) study is an international collaboration to create a database of patients with biopsy-proven liver disease and follow up information. Baseline information and clinical outcomes are noted from clinical records. Statistical analysis was performed using GraphPad Prism 10.4.
Results: 193 patients (97 (50.3%) males, mean age 47.4 years) with Alcohol related Hepatitis were included of which 116 (60.1%) patients had biopsy proven liver cirrhosis. 108 (56.0%) patients were under the age of 50. There were no significant differences in gender proportions between patients < 50 years and >50 years old (p = 0.082). Patients under 50 years presented with a higher mean white cell count (13.7 vs 10.9 (p = 0.016; 95% CI 2.81–1.15)) than those >50 years however there were no differences in mean bilirubin (259 vs 247 µmol/L; p = 0.661) or creatinine (88.83 vs 84.07 µmol/L; p = 0.521). Male patients

presented with a significantly higher creatinine (96.8 vs 75.4 (p = 0.003, 95% CI 7.32–35.56)). 128 (66.3%) patients died of which 61 (47.7%) deaths were liver related. In patients with cirrhosis, 41 (35.3%) patients died from liver related causes. 25 (19.5%) patients died within 90 days. Patients with underlying cirrhosis did not have a higher likelihood of overall mortality (OR 1.59, p = 0.155) or death within 90 days of biopsy (OR 1.88, p = 0.217). In patients under 50, the presence of cirrhosis did not increase the likelihood of liver related mortality (OR 0.74, p = 0.461). Male patients had a significantly increased risk of death within 90 days (OR 3.13, p = 0.019, 95% CI 1.20–8.15) and this remained significant when adjusted for the presence of cirrhosis (OR 2.91, p = 0.031, 95% CI 1.10–7.68). Age did not impact on 90-day mortality (OR 1.02) or overall liver related mortality (p = 0.350) however patients with a higher MELD score had a higher likelihood of 90-day mortality (OR 1.14, p = 0.021, 95% CI 1.03–1.29).
Conclusion: Liver related mortality is high in alcohol related hepatitis. Disease severity was predictive of death within 90 days however the presence of cirrhosis, age and gender did not impact on overall liver related mortality rates.

SAT-488-YI
Alcohol as a mediator of genetic and metabolic risk for fibrosis and steatosis in SLD

Jan Embacher[1,2], Georg Semmler, Sophie Gensluckner[2], Paul Thöne[1], Lorenz Balcar, Michael Strasser[2], Stephan Zandanell[2], Alexandra Feldman[2], Mattias Mandorfer, Bernhard Wernly[2], Elmar Aigner[2]. *[1]Department of Medicine III, Division of Gastroenterology and Hepatology, Medical University of Vienna, Vienna, Austria; [2]First Department of Medicine, Paracelsus Medical University Salzburg, Salzburg, Austria*
Email: jan.embacher@meduniwien.ac.at

Background and aims: The interplay of alcohol consumption and metabolic dysfunction in steatotic liver disease (SLD) progression is increasingly being acknowledged, e.g., by the novel category of "MetALD." Although genetic risk factors have been identified for both metabolic dysfunction-associated steatotic liver disease and alcohol-related liver disease, their contribution within distinct disease phenotypes is unclear. Thus, we aimed to explore the relationship between alcohol consumption, genetic risk, and metabolic dysfunction.
Method: A cohort of 1,442 patients with suspected SLD referred to a tertiary care center was retrospectively studied. Inclusion criteria were information on insulin resistance (IR) as quantified by the Homeostasis Model Assessment of Insulin Resistance (HOMA-IR), self-reported alcohol consumption classified into three categories - abstinence or low (<20/30 g/day), moderate, and high consumption (>50/60 g/day) - as well as genetic testing of risk-modifying single nucleotide variants (PNPLA3 rs738409, TM6SF2 rs58542926, HSD17B13 rs72613567, and SERPINA1 rs28929474), and reliable liver stiffness measurement (LSM) with controlled attenuation parameter (CAP) using vibration-controlled transient elastography. LSM was used as surrogate for hepatic fibrosis, hepatic steatosis was defined as CAP ≥248 dB/m, IR as HOMA-IR ≥2.5.
Results: Mean age was 51.7 (15.5) years, 780 (54.1%) were male. 1138 (79.6%) patients reported no alcohol consumption, 203 (14.1%) reported moderate consumption, and 91 (6.3%) significant consumption. Mean CAP was 276 (63.1) dB/m, median LSM was 5.4 [4.3–7.1] kPa, 294 (20.4%) patients had suspected advanced fibrosis (LSM ≥8 kPa). 560 (38.8%) had IR. Genetic risk allele prevalence was as follows: PNPLA3 C/G in 561 (38.9%) and G/G in 129 (8.9%), SERPINA1 M/Z & S/Z in 92 (6.4%), TM6SF2 C/T in 243 (16.9%) and T/T in 12 (0.8%), and HSD17B13 T/A in 511 (35.4%) and A/A in 98 (6.8%). Moderate alcohol consumption (regression coefficient β = 0.19, p < 0.001), significant alcohol consumption HOMA-IR (β per log = 0.24, p < 0.001), BMI (β per kg/m² = 0.006, p = 0.003) (β = 0.71, p < 0.001), PNPLA3 G allele (β = 0.10, p < 0.001), and TM6SF2 T-allele (β = 0.08, p = 0.020) were independently associated with LSM (log-transformed). However, when considering interactions with alcohol consumption, a significant amplifying interaction between TM6SF2 T-allele (β for interaction = 0.47, p < 0.001) and PNPLA3 G-allele (β = 0.33, p = 0.001) and significant alcohol consumption was evident. Interestingly, the association of HOMA-IR with LSM was significantly enhanced by moderate alcohol consumption (β = 0.21, p = <0.001). Moderate alcohol consumption potentiated the effect of BMI (β = 2.98, p = 0.002) on hepatic steatosis.
Conclusion: Significant alcohol consumption potentiates the association between PNPLA3 and TM6SF2 risk alleles and hepatic fibrosis. Moderate alcohol consumption appears to accelerate fibrosis and steatosis development through its interaction with IR and BMI.

SAT-489
Monitoring hepatic function at 90 days of abstinence predicts recompensation and reduced liver-related mortality in patients with decompensated alcohol-related cirrhosis

Jan Embacher[1], Lukas Parandian[1], Georg Semmler[1,2], Lorenz Balcar[1,2], Nina Dominik[1,2], Georg Kramer[1,2,3], Christian Sebesta[1,2], Paul Thöne[1,2], Lukas Hartl[1,2], Mathias Jachs[1,2], Benedikt Simbrunner[1,2,3], Michael Trauner[1,2], Mattias Mandorfer[1,2], Thomas Reiberger[1,2,3], Benedikt Hofer[1,2,3]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Clinical Research Group MOTION, Medical University of Vienna, Vienna, Austria; [3]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria*
Email: jan.embacher@meduniwien.ac.at

Background and aims: Alcohol abstinence can facilitate improvements in hepatic synthetic function and improve the prognosis in patients with alcohol-related (ALD) cirrhosis. However, the impact of dynamics in laboratory markers of hepatic function following abstinence on subsequent disease course requires further investigation.
Method: This study analyzed patients with decompensated ALD cirrhosis who achieved abstinence and underwent a paired blood-draw at time of abstinence and after 90 days (±30 days; = M3). The primary events of interest were liver-related death and hepatic recompensation (as defined by Baveno VII). Alcohol relapse and liver transplantation were considered competing events.
Results: 87 patients with decompensated ALD cirrhosis (89.7% ascites, 9.2% bleeding, 21.8% encephalopathy, 48.3% jaundice) were included at time of alcohol abstinence (median age: 52.4 years; 74% male) and followed for a median 31.8 (IQR: 10.9–48.9) months. At time of abstinence, median MELD was 20 (IQR: 16–26) and median albumin was 29.0 (IQR: 26.4–32.3) g/dL. At M3 reassessment under sustained abstinence, MELD decreased by a median 23% (p < 0.001), with 48 patients (55.2%) achieving a decrease >20%, and 16 (18.4%) reverting to MELD<10. Albumin increased by 18% (p < 0.001), with 40 patients (46.0%) achieving an increase >20%, and 40 (46.0%) replenishing to Albumin >35 g/dL. Over the course of the study, 21 patients (24.1%) achieved hepatic recompensation, while 14 patients (16.1%) experienced liver-related death. A decrease in MELD was associated with a significantly higher likelihood of recompensation (subdistribution hazard ratio [SHR] per 10% decrease: 1.19, p = 0.033), yet no association was observed for increased albumin (SHR per 10% increase: 1.07, p = 0.300). Improvements in both MELD and albumin were associated with a significantly decreased risk of liver-related death (MELD - SHR per 10% decrease: 0.85, p = 0.013; Albumin - SHR per 10% increase: 0.72, p = 0.008). In contrast, neither baseline MELD nor albumin alone were linked to hepatic recompensation (MELD - SHR: 1.02, p = 0.420; albumin - SHR per mg/dL: 1.00, p = 0.990) or to liver-related death (MELD - SHR: 1.06, p = 0.110; albumin - SHR per mg/dL: 1.02, p = 0.630). While M3 MELD and albumin as standalone values were significantly associated with liver-related death (MELD-SHR: 1.18, p < 0.001; albumin-SHR per mg/dL: 0.86, p = 0.023) both M3 MELD and M3 albumin were not associated with hepatic

recompensation (MELD-SHR: 0.93, p = 0.110; albumin-SHR per mg/dL: 1.07, p = 0.084; date of second blood draw as baseline).
Conclusion: Longitudinal monitoring of MELD and Albumin at M3 of continued abstinence enables the assessment of clinically meaningful improvements in hepatic synthetic function in ALD cirrhosis. While neither baseline nor M3 values alone predicted hepatic recompensation, improvements in MELD and albumin at M3 of abstinence were associated with a significantly higher probability of hepatic recompensation and a reduced risk of liver-related death.

SAT-490-YI
ALD is diagnosed at more advanced stages of fibrosis as compared to MetALD and MASLD in the general population
Jordi Gratacós-Ginès[1,2], Anna Soria[1,2], Ruth Nadal[3], Guillem Pera[4], Martina Perez-Guasch[1,2,5], Marta Cervera[1,2], Adrià Juanola[1,2], María José Moreta[1,2], Queralt Herms[6], Ingrid Arteaga[4], Carla Chacon[4], Pere Torán[4], Llorenç Caballeria[4], Isabel Graupera[1,2,5], Núria Fabrellas[3,5], Elisa Pose[1,2,5], Pere Ginès. *[1]Liver Unit, Hospital Clínic de Barcelona - Institut d'Investigacions Biomèdiques August Pi i Sunyer, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red en Enfermedades Hepáticas y Digestivas, Madrid, Spain; [3]Institut d'Investigacions Biomèdiques August Pi i Sunyer, Barcelona, Spain; [4]Unitat de Suport a la Recerca Metropolitana Nord, Institut Universitari d'Investigació en Atenció Primària Jordi Gol, Mataró, Spain; [5]Faculty of Medicine and Health Sciences, University of Barcelona, Barcelona, Spain; [6]Liver Unit, Hospital Clínic de Barcelona, Barcelona, Spain*
Email: pgines@clinic.cat

Background and aims: Alcohol-associated liver disease (ALD) is more frequently diagnosed at stages of decompensated cirrhosis as compared to other etiologies of liver disease in tertiary care. However, there is no evidence on the stage of diagnosis of ALD in the general population. The aim of our study was to investigate the stage of fibrosis at diagnosis of ALD as compared to other causes of steatotic liver disease (SLD) in the general population.
Method: Cross-sectional analysis of two prospective cohorts included in screening programs for liver disease with transient elastography (TE) in the general population in Spain. SLD was determined by fatty liver index (FLI)≥60, Controlled Attenuation Parameter (CAP)≥263 dB/m or liver stiffness measurement (LSM) by TE≥10 kPa. Patients were categorized into: 1) ALD; 2) Metabolic dysfunction and alcohol associated liver disease (MetALD); 3) Metabolic dysfunction-associated steatotic liver disease (MASLD); 4) Others. Based on LSM by TE patients were classified in stages of no liver fibrosis (<10 kPa), liver fibrosis without portal hypertension (PHT) (10–25 kPa), fibrosis and PHT (>25 kPa).
Results: Out of 4,198 participants included in the study, 1,930 (46%) had SLD: 64 (3%) ALD, 216 (11%) MetALD, 1,639 (85%) MASLD and 11 (1%) others. The proportion of patients with liver fibrosis without PHT and liver fibrosis with PHT was 23% and 6% in patients with ALD, as compared to 7% and 1% in MetALD and 6% and 1% in MASLD ($p < 0.001$). Median LSM of the different SLD subtypes were 7.1 kPa, 5.6 kPa and 5.3 kPa in ALD, MetALD and MASLD ($p < 0.001$). Additionally, FLI values were highest in patients with ALD as compared to patients with MetALD and MASLD (90 vs 83 vs 78 [$p < 0.001$]); there was also a trend towards higher CAP values in patients with ALD and MetALD (296 vs 299 vs 288 dB/m in MASLD [$p = 0.095$]).
Conclusion: In a population-based setting, patients with ALD are identified and diagnosed at more advanced stages of fibrosis as compared to MetALD and MASLD. This study reinforces the need for developing screening programs specifically in patients with high-risk alcohol consumption.

SAT-491
ELIBIO MRI-based Digital liver biopsy correlates with elastography and blood test in patients with chronic liver diseases (CLD)
Juliette Foucher[1], Panteleimon Papadopoulos[1], Paul Hermabessière[1], Adèle Delamarre[1], Renaud Winzenrieth[2], Chardonnet Benoit[2], Benjamin Leporq[2,3], Simon Lambert[2], Nora Frulio[4]. *[1]Hôpital Haut Lévêque, Bordeaux University Hospital, Bordeaux, France; [2]SoQut-Imaging, Bègles, France; [3]INSA-LYON, Université Claude Bernard1, CNRS, Inserm, CREATIS UMR 5220, U1294, Lyon, France; [4]Hôpital Haut Lévêque, Bordeaux University Hospital, Bordeaux, France*
Email: juliette.foucher@chu-bordeaux.fr

Background and aims: Liver chemical shift-encoded MRI (CSE-MRI) is used for simultaneous fat and iron liver content estimation through PDFF and R2* measurements. However, CLD also requires evaluation of fibrosis severity. Although derived from a standard MRI sequence, CSE-MRI is underexploited. The use of phase CSE-MRI information allows the estimation of the magnetic susceptibility (CHI), a surrogate marker of the liver bulk macromolecule accumulation in the extracellular matrix. Previous work has demonstrated its interest in the diagnostic of MASH among MALFD patients (Leporq et al., NMR Biomed. 2017). This study aims to assess relationships between CHI and standard clinical parameters in a heterogeneous cohort of CLDs.
Method: Between February and November 2024, 106 patients who underwent a 1.5 T MRI CSE-MRI acquisition were retrospectively included. Considering a retrospective delay of 6-month between MRI and blood tests, FibroScan or SWE results, 38 patients were deemed eligible. PDFF, R2* and CHI values were automatically computed using EliBio software (SoQut-imaging, France). Correlations with blood tests, FibroScan LSM and SWE measurements were evaluated using Spearman's correlation test. Patients were stratified considering a LSM cut-off of 8.0 Kpa or 12.0 KPa as defined by the new EASL Clinical Practice Guidelines on MASLD management. Comparisons between stratified patients were performed using Man-Whitney test.
Results: Significant correlations ($p < 0.05$) were obtained between CHI and LSM ($r = -0.55$) or SWE stiffness ($r = -0.47$). Significant correlations ($p < 0.05$) were also obtained between CHI and blood tests: FibroTest ($r = -0.40$), Hepascore ($r = -0.67$), Agile 3+ ($r = -0.66$), Agile 4 ($r = -0.56$), Forns ($r = -0.51$) and FAST ($r = -0.48$). PDFF was significantly correlated ($p < 0.01$) with the controlled attenuation parameters ($r = -0.47$) and BMI ($r = 0.56$). CHI was significantly lower (-0.0272 vs -0.0154 ppm, $p < 0.01$) in patients with LSM lower than 8.0 Kpa ($n = 22$) when compared to those above 8.0 Kpa ($n = 16$) or considering a threshold of 12.0 KPa (-0.02 vs -0.0275, $p < 0.01$).
Conclusion: Due to its sensitivity to bulk macromolecules, magnetic susceptibility parameter CHI has a great potential to assess liver fibrosis. CSE-MRI could be an all-in-one alternative to provide a comprehensive liver analysis including fat, iron and fibrosis assessment using a single 20 s breath-holding acquisition. Further studies in larger cohorts are needed to confirm these preliminary results.

SAT-492
Colorectal cancer incidence in steatotic liver disease (MASLD, MetALD, and ALD)
Takefumi Kimura[1], Nobuharu Tamaki[2], Shun-ichi Wakabayashi[1]. *[1]Shinshu University School of Medicine, Matsumoto, Japan; [2]Musashino Red Cross Hospital, Tokyo, Japan*
Email: kimuratakefumii@yahoo.co.jp

Background and aims: Obesity and alcohol consumption are established risk factors for colorectal cancer (CRC). Recently, a multi-society consensus group has introduced a new classification for steatotic liver disease (SLD), which encompasses metabolic dysfunction-associated SLD (MASLD), MASLD and increased alcohol intake (MetALD), and alcohol-associated liver disease (ALD). However, the risk of developing CRC in each of these SLD subgroups is unknown. This nationwide cohort study investigated the risk of

CRC in MASLD, MetALD, and ALD patients. The primary endpoint was the occurrence of CRC in each SLD subgroup.
Method: We conducted a nationwide, population-based study that included 1,497,813 patients diagnosed with MASLD, MetALD, or ALD, alongside 4,885,536 individuals serving as normal liver control. The ***primary outcome*** was the incidence of CRC and the risk of CRC was compared between MASLD, MetALD and ALD.
Results: The 5- and 10-year cumulative CRC incidence rates were 0.22% and 0.48% for MASLD, 0.32% and 0.73% for MetALD, and 0.43% and 0.97% for ALD, and 0.15% and 0.31% for the normal liver control, respectively. The cumulative incidence of CRC was highest for ALD and significantly greater than that for MetALD, MASLD, and normal liver control (both $p < 0.001$). Using normal liver control as the reference and adjusting for age, sex, smoking habit, number of colonoscopies, diabetes mellitus, dyslipidemia, hypertension, and medication use, the adjusted hazard ratios (95% confidence interval) for CRC were 1.66 (1.54–1.80) for ALD, 1.31 (1.23–1.40) for MetALD, and 1.25 (1.18–1.31) for MASLD.
Conclusion: The risk of CRC differs significantly among patients with SLD, with the highest incidence observed in those with ALD, followed by MetALD and MASLD.

SAT-493-YI
A call to action - shortfalls and variation in care for inpatients with alcohol related liver disease in the UK: results of the ALERT UK national audit
Laura Burke[1], Dianne Backhouse[2], Vikram Bains[3], Keith Bodger[4], Mhairi Donnelly[5], Ewan H Forrest, Roger McCorry[6], Arjuna Singanayagam[7], Richard Parker[8], Ashwin Dhanda[9]. *[1]Leeds Liver Unit, Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom; [2]Hull University Teaching Hospitals NHS Trust, Hull, United Kingdom; [3]Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; [4]Liverpool University Hospitals NHS Foundation Trust, Liverpool, United Kingdom; [5]Scottish Liver Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom; [6]Royal Victoria Hospital Belfast, Belfast, United Kingdom; [7]St Georges University Hospitals NHS Foundation Trust, London, United Kingdom; [8]Leeds Liver Unit, Leeds Teaching Hospitals Trust, Leeds, United Kingdom; [9]University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom*
Email: laura.burke1@nhs.net

Background and aims: Alcohol-related liver disease (ALD) is the leading cause of liver related morbidity and mortality in the United Kingdom (UK). UK professional societies have recently published quality standards and key performance indicators (KPIs) to benchmark care. The Alcohol related LivER disease audit (ALERT- UK) is the first national evaluation of care for patients with ALD. We aimed to assess adherence to quality standards and to explore factors associated with the quality of care.
Method: All UK hospitals treating people with ALD were eligible to participate, with site recruitment facilitated via endorsing national societies, trainee networks and social media. Each site included the first 20 patients admitted with ALD with a discharge date from July 1st 2022–September 30th 2022. Patients were identified from site coding data using the validated Liverpool ALD Algorithm (LAA). Data on patient variables were recorded from the admission episode and at 1 year follow up. Audit compliance was set *a priori* at 90%.
Results: Centre level data were provided by 102 hospitals, with 81 hospitals submitting patient data (specialist centre n = 444, non-specialist centre n = 1078). 1522 individual patients were included (63% male, median age of 54 years (IQR 46,62), median UKELD 57 (IQR 52,62) and median length of stay of 8 days (IQR 4,18)). At admission, 82% of patients were active alcohol users and 27% presented with ALD for the first time. 68% of patients lived in the most deprived areas (index of multiple deprivation 1–5). None of the 7 KPIs met the compliance target. All KPIs were achieved in only 19.8%. Compliance was independently associated with age (0.97 (0.96–0.98, $p < 0.001$)), UKELD (OR 1.05 (1.03–1.07, $p < 0.001$)), region (OR 0.12 (0.01–0.63, $p = 0.044$) and specialist led care (OR 3.23 (2.17–4.95, $p < 0.001$)). Specialty review occurred within 24 hours for 62% of patients, alcohol care team involvement for 52% and dietician review for 44%. Of 149 patients eligible for consideration of liver transplantation, 115 (77%) were referred to a transplant centre. Only 39% of patients discharged had clinic follow up within 6 weeks, 6% received alcohol relapse prevention medications, and 4.8% were enrolled in a research study. Overall, 87% of patients survived to discharge and 62% were alive at 1 year. Survival rates did not differ between specialist and non-specialist centres but varied significantly across regions (admission survival: range: 78.8%–91.7%, p = <0.001); one year survival range: 49.1%–68.4% (p = 0.018)). At 1 year, 50% of surviving patients remained decompensated, 12% were referred to palliative care services and 21% of patients were lost to follow up.
Conclusion: ALERT-UK has revealed suboptimal adherence to quality standards and significant variations in care between centres and regions. Specialist care was associated with better adherence to quality standards. These findings highlight the need to address barriers to care and implement targeted interventions to improve outcomes.

SAT-494
Validating the association between alcohol-related hepatitis and alcohol-related cirrhosis: a population-based study
Lucy Wilson[1], Juan G Abraldes[2], Gilaad Kaplan[1], Abdel-Aziz Shaheen[1]. *[1]University of Calgary, Calgary, Canada; [2]University of Alberta, Edmonton, Canada*
Email: az.shaheen@ucalgary.ca

Background and aims: Patients with alcohol-related hepatitis (AH) may present with features of decompensated cirrhosis. However, the association between the index date of cirrhosis and first admission of AH has not yet been well described. In this study, we identified all index admissions of AH in Alberta. We then described and validated the diagnosis and temporal association between alcohol-related cirrhosis among patients with AH.
Method: We used the national institute on alcohol abuse and alcoholism (NIAAA) criteria to identify index AH admissions in Alberta between 2012 and 2022 (n = 2,158) using the discharge admission database and provincial laboratory database. Validated algorithms of alcohol-related cirrhosis were used to identify the index diagnosis of cirrhosis among the AH cohort. We then selected a systemic random sample of 200 electronic medical records (EMR) for patients with cirrhosis prior to AH index date (n = 1,303, 60.4%) and 100 EMR for patients with cirrhosis after AH index date (n = 587, 27.2%) for validation. We also validated all EMR for patients with a cirrhosis diagnosis on the same AH admission date (n = 211) or no evidence of cirrhosis during the study time (n = 57). Data on ascites and portal hypertensive gastropathy (PHG) or variceal bleeding were obtained.
Results: During the study period, a cirrhosis diagnosis was identified in 97.4% of the whole cohort. The temporal relationship between index AH admission and cirrhosis was 60.4% with cirrhosis diagnosis prior to AH admission, 27.2% with cirrhosis after AH admission, and 9.8% with cirrhosis diagnosed at the same time of AH admission. In our study, 96.3% had validated AH diagnosis. The positive predictive value (PPV) of a cirrhosis diagnosis was 82.6% (422/511). PPV of having cirrhosis did not differ according to sex (male: 253/309 [81.9%] vs female: 169/202 [83.7%], p = 0.87). There was no difference in sex according to timing of cirrhosis (female sex: 41.5% cirrhosis prior to AH, 41.0% cirrhosis after AH and 37.0% cirrhosis at time of AH, p = 0.62). Comparably, age was similar among the groups (median age: 49 years among cirrhosis prior to AH, 45 years among cirrhosis after AH, and 48 years among cirrhosis at time of AH, p = 0.07). Features of decompensated cirrhosis were prevalent in our cohort (ascites 67.2%, variceal bleeding 14.8%, and PHG bleeding 19.4%).
Conclusion: Alcohol-related cirrhosis is more common than previously reported among patients with AH where 60% had cirrhosis

prior to their index presentation of AH. Early diagnosis and preventative measures are warranted among patients with high-risk alcohol consumption.

SAT-495

Stratification of liver fibrosis in individuals at-risk of metabolic dysfunction and alcohol-associated liver disease (MetALD)

Luis Antonio Diaz[1], Federica Tavaglione[1], Nikkita Mittal[1], Ricki Bettencourt[1], Maral Amangurbanova[1], Amy Johnson[2], David Marti-Aguado[3], Monica Tincopa[4], Ria Loomba[4], Asma Khan-Riches[4], Egbert Madamba[4], Harris Siddiqi[4], Lisa Richards[4], Claude Sirlin[5], Veeral Ajmera[4], Rohit Loomba[4]. *[1]MASLD Research Center, Division of Gastroenterology and Hepatology, University of California San Diego, La Jolla, California, United States; [2]Liver Unit, Newcastle Upon Tyne Hospitals NHS Foundation Trust, Newcastle Upon Tyne, United Kingdom; [3]Digestive Disease Department, Clinic University Hospital, INCLIVA Health Research Institute, Valencia, Spain; [4]MASLD Research Center, Division of Gastroenterology and Hepatology, University of California at San Diego, La Jolla, California, United States; [5]Liver Imaging Group, Department of Radiology, University of California at San Diego, La Jolla, California, United States*
Email: luisdiazpiga@gmail.com

Background and aims: Metabolic dysfunction and alcohol-associated liver disease (MetALD) may increase liver fibrosis progression, but data on the optimal screening strategies are limited. We aimed to assess the performance of non-invasive tests (NITs) for detecting significant fibrosis in individuals at risk of MetALD.
Method: Cross-sectional study of prospectively enrolled adults identified as overweight or obese. We included adults at risk of MetALD defined by ≥1 of 5 cardiometabolic risk factors and self-reported alcohol use within MetALD ranges or lower self-reported alcohol use but with phosphatidylethanol (PEth) levels ≥25 ng/mL. Clinical assessment included contemporaneous magnetic resonance elastography (MRE) and vibration-controlled transient elastography (VCTE). Significant fibrosis was defined as MRE ≥3.14 kPa (or VCTE ≥7.6 kPa if MRE was missing). Analyses included area under the receiver-operating curves (AUROCs).
Results: Among 617 individuals screened, we identified 97 (15.7%) at risk of MetALD. The mean age was 50.6 ± 12.8 years, 67% were men, mean body mass index was 31.4 ± 6.5 kg/m2, and 12.4% had diabetes. Eight percent of individuals had significant fibrosis. Fibrosis-4 (FIB-4) ≥1.3 demonstrated good performance for significant fibrosis (AUROC 0.78, 95%CI:0.58–0.98, sensitivity 80%, specificity 76%, positive predictive value [PPV] 17%, and negative predictive value [NPV] 98%). VCTE ≥8 kPa also had good performance (AUROC 0.85, 95% CI:0.66–1.00, sensitivity 80%, specificity 91%, PPV 36%, and NPV 99%). A stepwise approach using FIB-4 followed by VCTE yielded a low false negative rate (2% with significant fibrosis misclassified as low-risk).
Conclusion: A clinical care algorithm utilizing a stepwise approach with FIB-4 and VCTE shows adequate performance in detecting significant fibrosis in individuals with suspected MetALD.

SAT-496

Steatosis independent of fibrosis predict hepatic decompensation and mortality in patients with MetALD and ALD

Mette Lehmann Andersen[1,2], Nikolaj Torp, Stine Johansen[2,3], Camilla Dalby Hansen[2], Ellen Lyngbeck Jensen[2,3], Johanne Kragh Hansen[2,3], Katrine Bech[2,3], Helle Schnefeld[2,3], Georg Semmler[2,3], Peter Andersen[2], Ida Falk Villesen[2], Katrine Thorhauge[2,3], Katrine Lindvig, Maja Thiele, Aleksander Krag, Mads Israelsen[2,3]. *[1]Department of Gastroenterology and Hepatology, Herlev Hospital, Herlev, Denmark; [2]Liver Research Centre, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense C, Denmark; [3]Institute of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense C, Denmark*
Email: mette_98@hotmail.com

Background and aims: Hepatic steatosis define SLD, but steatosis is considered benign in MASLD and is not linked to liver-related outcomes. Alcohol disrupts hepatic lipid metabolism why steatosis may increase the risk of liver-related outcomes in MetALD and ALD. This study investigated the role of steatosis as a predictor of liver-related outcomes in MetALD and ALD.
Method: This prospective cohort recruited individuals aged 18–75 with a current or previous alcohol overuse (>24 g/day for women, >36 g/day for men) > 1 year, and with no history of hepatic decompensation. Participants were categorized based on the grade of steatosis in their biopsy, according to the NAFLD Activity Score and fibrosis stage according to the NASH CRN classification. Patient follow-up was conducted through manual reading of electronic medical records, with hepatic decompensation events defined according to the Baveno VII criteria. We performed Cox regression models for hazard ratio.
Results: We biopsied 341 patients with excessive alcohol intake, with a mean age of 55 years (± 11 years), 256 (75%) were male, with a mean BMI of 28 (± 5) kg/m². At inclusion, 158 patients (47%) reported abstinence the week before inclusion. Histological steatosis was present in 192 (56%) patients. Among patients with histological steatosis, 26% had advanced fibrosis (>F3) while 28% had >F3 in the non-steatosis group. The distribution of steatosis ranged from mild steatosis (S1) in 82 patients (43%), moderate steatosis (S2) in 71 (37%), and severe steatosis (S3) in 39 (20%). During a mean follow-up period of 75 months (IQR 38), 56 patients experienced hepatic decompensation. We recorded 35 (18%) decompensating events in the steatosis group and 21 (14%) events in the non-steatosis group. A total of 84 patients died, hereof 49 patients (26%) with steatosis and 35 (24%) without steatosis. Patients with steatosis had a significantly higher risk of hepatic decompensation and overall mortality than those with non-steatosis, independent of age, sex, histological fibrosis stage and current alcohol intake. With non-steatosis as the reference, the risk of decompensation increased in a stepwise manner from S1 (HR = 0.98, 95% CI: 0.48–1.97) to S2 (HR = 1.62, 95% CI: 0.78–3.36) and S3 (HR = 2.48, 95% CI: 1.07–5.73). Similarly, overall mortality increased from S1 (HR = 1.22, 95% CI: 0.60–2.49) to S2 (HR = 1.63, 95% CI: 0.79–3.39) and S3 (HR = 3.68, 95% CI: 1.55–8.75).
Conclusion: The grade of steatosis is associated with the risk of hepatic decompensation and mortality in patients with MetALD and ALD. This suggests that lipid metabolism is central in MetALD and ALD and disrupted lipid metabolism may be linked to a higher risk of liver-related outcomes.

SAT-497

Predictors of alcohol relapse in patients with alcohol-associated liver disease after liver transplant evaluation

Mohamad Ali Ibrahim[1], Caroline Akua Ankoma-Sey[1], Sherry Fares[1], Islam Mohamed[2], Nagham Ramadan[1], Mazen Elsheikh[1], Megha Bhongade[1], Youseph Karouni[1], Prasun Jalal[1]. *[1]Baylor College of Medicine, Houston, United States; [2]Cleveland Clinic Fairview, Cleveland, United States*
Email: mohamad.ali.ibrahim@hotmail.com

Background and aims: Alcohol-related liver disease (ALD) is a foremost cause of liver transplantation (LT) in the United States, yet alcohol relapse remains a significant concern. Real-world evaluations of relapse prediction scores are limited and focus on relapse post-transplant. To optimize liver transplant outcomes, early identification of individuals at risk for alcohol relapse is crucial. This study primarily aimed to identify risk factors for alcohol relapse after liver transplant evaluation.
Method: Retrospective cohort including patients with ALD and/or alcoholic hepatitis (AH) referred for evaluation for LT from October 2021 to August 2023 at Baylor College of Medicine. ALD was defined as cirrhosis in patients consuming > 3 drinks (40 g) a day for women and > 4 drinks (60 g) for men in the absence of concomitant liver disease. AH was defined according to the NIAAA diagnostic criteria.

Retrospective chart review and collection of data were performed. Patients were divided into two groups: listed or not listed. Patients were categorized into 2 groups: those who relapsed after evaluation and those who did not. Alcohol Relapse was defined as a positive Peth test after evaluation following a period of sobriety.
Results: A total of 158 patients were included in our study (age 52.6 ± 10.8 years, BMI 28.6 ± 6.1 kg/m2, Female 43.7%). Demographics and clinical characteristics were similar between the relapse and non-relapse groups (all $p > 0.05$). When comparing patients who relapsed after liver transplant evaluation to those who did not, the following parameters were associated with a higher risk of relapse on univariable analysis: positive Peth test during the evaluation (OR 5.14; $p < 0.001$), lower age of alcohol consumption start (OR 0.82; $p = 0.015$), previous alcohol-related legal issues (OR 3.67; $p = 0.006$), more than 10 drinks/day during peak of alcohol consumption (OR 3.34; $p = 0.008$), history of bipolar disorder (OR 7.15; $p = 0.014$), and history of anxiety disorders (OR 3.14;$p = 0.019$). Active illicit substance abuse ($p = 0.068$) and shorter time from last drink to the evaluation date ($p = 0.066$) were close to significance. On multivariable analysis, positive Peth test on evaluation (OR 10.20; $p = 0.010$), previous alcohol-related legal issues (OR 14.65; $p = 0.008$), and history of bipolar disorder (OR 49.68; $p = 0.038$) were significantly associated with alcohol relapse after liver transplant evaluation.
Conclusion: Positive Peth test during the evaluation, alcohol legal issues, and a history of bipolar disease are the predictors of alcohol relapse after liver transplant evaluation.

SAT-498-YI
Cause-specific mortality across the spectrum of steatotic liver disease: a nationwide cohort study
Pedro Ochoa-Allemant[1], Rebecca Hubbard[2], David Kaplan[1], Marina Serper[1]. [1]*University of Pennsylvania, Philadelphia, United States;* [2]*Brown University, Providence, United States*
Email: pedro.ochoaallemant@pennmedicine.upenn.edu

Background and aims: Steatotic liver disease (SLD) includes a heterogeneous group of phenotypes, with metabolic dysfunction and harmful alcohol use increasing the risk of liver and non-liver-related death. However, cause-specific death across SLD subtypes remain not well characterized in population-based cohorts, particularly for metabolic and alcohol-associated liver disease (MetALD). This study aimed to determine the risk of cause-specific death across the spectrum of SLD.
Method: We conducted a retrospective cohort study of adult patients with hepatic steatosis identified via natural language processing receiving regular outpatient care between 2010 and 2021 using data from the Veterans Health Administration linked to the National Death Index. The primary exposure was SLD subtype (metabolic dysfunction-associated steatotic liver disease [MASLD], alcohol-related liver disease [ALD], and MetALD) determined using a combination of cardiometabolic risk factors, alcohol use disorder diagnosis, and alcohol use disorders identification test-consumption (AUDIT-C) scores. The primary outcome was cause-specific death. The index date was defined as the first imaging study identifying hepatic steatosis. Follow up started from the index date to the occurrence of the primary outcome, lost to follow-up, or study end date (December 31, 2021). We first estimated incidence rates per 100 person-years and 10-year cumulative incidence within a competing risk framework. We then obtained hazard ratios (HR) using multivariable cause-specific Cox regression models with death from any other cause as the competing risk. Analyses were stratified by baseline cirrhosis status.
Results: Among 387,996 patients with SLD (MASLD 77.1%, MetALD 18.1%, ALD 4.8%), the mean age was 60.4 years, 7.5% were female, 66.8% were non-Hispanic White, and 1.9% had cirrhosis. Over a median follow-up of 5.5 years (IQR, 3.1–8.5), cardiovascular disease (CVD) and extrahepatic cancer were the leading causes of death in non-cirrhotic MASLD (10-year cumulative incidence 8.4% and 7.6%), MetALD (8.0% and 7.6%), and ALD (8.5% and 7.7%). Among those with cirrhosis, liver and CVD death dominated, with 10-year incidences of 9.3% and 10.6% in MASLD, 17.8% and 11.6% in MetALD, and 24.6% and 9.6% in ALD. The risk of HCC-related death was significantly higher in MetALD without cirrhosis (hazard ratio [HR], 1.19; 95% CI, 1.04–1.35) compared to MASLD. The risk of liver-related death was significantly higher in MetALD (HR, 3.38; 95% CI, 3.06–3.72) and ALD (HR, 6.88; 95% CI, 6.10–7.75) compared to MASLD without cirrhosis. Similar results were seen among those with cirrhosis.
Conclusion: CVD and extrahepatic cancer were leading causes of death in MetALD without cirrhosis, whereas liver-related deaths predominated in those with cirrhosis. MetALD showed a significant higher risk of HCC and liver-related death compared to MASLD.

SAT-499
Will individuals with alcohol use disorder participate in screening for chronic liver disease?
Pernille Dahlin[1], Julie Grew[2], Lone Galmstrup Madsen[1,3], Peter Jepsen[4], Jeanette Kirk[5,6], Gro Askgaard[1,2]. [1]*Medical Department, Section of Gastroenterology and Hepatology, Zealand University Hospital, Køge, Denmark;* [2]*Center for Clinical Research and Prevention, Frederiksberg University Hospital, Copenhagen, Denmark;* [3]*Institute for Clinical Medicine, University of Copenhagen, Copenhagen, Denmark;* [4]*Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark;* [5]*Department of Clinical Research, Hvidovre University Hospital, Hvidovre, Denmark, Hvidovre, Denmark;* [6]*Department of Health and Social Context, National Institute of Public Health, University of Southern Denmark, Odense, Denmark*
Email: pernilledahlin@gmail.com

Background and aims: Screening for chronic liver disease with a blood test or transient elastography is recommended in high-risk populations such as individuals with alcohol use disorders (AUD), but less is known about the user's perspective. This study aims to explore attendance and perceptions of screening for chronic liver disease with transient elastography vs. blood test in individuals with AUD.
Method: We used data from an ongoing randomized controlled trial (RCT) of screening for chronic liver disease in individuals attending treatment for AUD, allocating participants 2:1 to a transient elastography or a blood test with FIB-4 measurement, both performed in the nearby hospital clinic. Participants allocated to the blood test were responsible for calling to book their appointment, whereas those allocated to transient elastography were contacted directly by the investigator to plan their screening. We conducted a mixed-methods study. First, we used the exact binomial test to examine whether participation rates depended on screening modality. Then, we conducted semi structured individual interviews with participants of the RCT. Data from the interviews were analyzed using thematic analysis and informants were recruited until data saturation was reached.
Results: Individuals allocated to a transient elastography were much more likely to attend for the screening [115/121 (95%) attended the transient elastography] than were individuals allocated to a blood test [35/59 (59%) attended the blood test], p for a difference in the proportion < 0.00001. Based on interviews with 15 individuals attending the transient elastography, key motivators for attending the transient elastography included contributing to research, receiving a health check not offered by their general practitioner, and feeling privileged to get a free screening. For informants who expected a poor result, a good result brought relief, while some learned about liver health and alcohol's effects. For those with poor results, it was experienced as motivating to reduce alcohol use. Based on interviews with 10 individuals not attending the blood test, the main barriers were personal challenges and the time commitment required. Participants reported that they were not concerned about liver disease but might have been more likely to participate if the blood test could have been performed at the alcohol treatment center.

Conclusion: Attendance in screening for chronic liver disease was much higher for screening with transient elastography than blood test in individuals with AUD. If the blood test is taken at the AUD treatment center, it may increase the attendance for screening by blood test, however, this study revealed that some individuals with AUD might benefit from the conversation they have while having performed a transient elastography.

SAT-500-YI

Augmenter of liver regeneration as a novel biomarker in alcohol-related liver disease: insights into disease progression and prognosis

Pratibha Garg[1], Nipun Verma[1], Parminder Kaur[1], Samonee Ralmilay[1], Arun Valsan[2], Sunil Taneja[1], Ajay Kumar Duseja[1]. *[1]Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [2]Amrita Institute of Medical Sciences, Kochi, India*
Email: nipun29j@gmail.com

Background and aims: Augmenter of Liver Regeneration (ALR) is critically linked to apoptosis and hepatic regeneration. However, its role in alcohol-related liver disease (ALD) remains unexplored. This study investigates the expression of ALR across the spectrum of ALD, its clinical course, and its prognostic significance.
Method: We enrolled 354 patients with ALD, categorized into acute-on-chronic liver failure (ACLF, n = 143), acute decompensation (AD, n = 57), non-acute decompensation (NAD, n = 100), compensated cirrhosis (CC, n = 23), alcohol-use disorder with fatty liver (AUD-FL, n = 20), and healthy controls (n = 10). Plasma levels of ALR and cytokines (IL-6, TNF-α, MCP-1, IL-10) were measured using ELISA. Associations between ALR, clinical parameters, and mortality were analyzed.
Results: Among 354 patients (median age: 45 years; IQR: 14; 97.5% male), ALR levels progressively increased from healthy controls to AUD-FL and CC but significantly declined from NAD to AD and ACLF ($p < 0.001$). ALR further decreased with advancing grades of ACLF ($p < 0.001$). In decompensated ALD (DeALD: NAD, AD, ACLF), ALR levels were lowest in patients with MELD >25 compared to MELD ≤ 25 ($p < 0.001$). ALR was negatively correlated with bilirubin, INR, creatinine, AST, and MELD ($p < 0.001$ each) and positively associated with albumin ($p < 0.001$), while these correlations were absent in non-decompensated ALD (NDALD: AUD-FL, CC). In AD and ACLF patients, higher baseline ALR levels predicted a resolving disease course ($p < 0.001$) and were associated with survival at 30 days, 90 days, and one year ($p < 0.001$ each). Each unit increase in ALR reduced the risk of mortality by 38% at 30 days (HR: 0.62, $p < 0.001$), 35% at 90 days (HR: 0.65, $p < 0.001$), and 32% at one year (HR: 0.68, $p < 0.001$). In DeALD, ALR was negatively associated with pro-inflammatory cytokines IL-6, TNF-α, and MCP-1 ($p < 0.05$ each), while a positive trend between IL-6 and ALR was observed in NDALD ($p = 0.051$), suggesting early regenerative activity.
Conclusion: This study identifies ALR as a novel biomarker reflecting hepatic regeneration, disease severity, and prognosis in ALD. ALR levels increase from fatty liver to CC but decline in decompensated stages, highlighting preserved regeneration in early stages and impaired regeneration in advanced disease. These findings position ALR as a potential therapeutic target to restore hepatic regeneration in advanced ALD.

Email: EPOSE@clinic.cat

Background and aims: Recent studies have shown that alcohol-induced steatosis is associated with increased long-term liver-related mortality. It remains unclear whether this is related to sustained alcohol use during follow-up. This study aimed to evaluate hepatic steatosis, measured by the Controlled Attenuation Parameter (CAP), as a predictor of abstinence in individuals with hazardous alcohol use.
Method: We conducted an analysis of a prospective liver disease screening cohort in patients with alcohol use disorder (AUD) treated at the Addiction Unit of a tertiary hospital between November 2019 and March 2024. Each patient underwent detailed medical history including AUDIT test, laboratory tests, and CAP measurement using transient elastography (TE). All patients were followed in the Addiction Unit for AUD for at least 6 months. Steatosis was defined as CAP ≥ 250 dB/m, and abstinence as no alcohol consumption for at least three consecutive months leading up to the six-month follow-up visit. Predictors of abstinence were evaluated using univariate and multivariate logistic regression.
Results: A total of 400 patients were included, of whom 168 (42%) had steatosis. Patients with steatosis were older, had higher rates of diabetes and dyslipidemia, and had increased body mass index. At six months, 42% of the cohort had achieved alcohol abstinence. Among patients with steatosis, 35% were abstinent, compared with 47% in those without steatosis ($p = 0.018$). Steatosis was independently associated with abstinence (OR 0.49 [95% CI 0.30–0.78]) along with age (OR 1.03 [1.01–1.05]), AUD medication (OR 1.85 [1.09–3.14]) and cholesterol levels (OR 0.99 [0.98–0.99]). Neither the amount or the duration of alcohol consumption, nor the severity of AUD (assessed by AUDIT), were associated with abstinence. In the subgroup analyses, CAP (OR 0.39 [0.21–0.72]) and comorbid substance use disorder (OR 0.53 [0.29–0.99]) were the only factors associated with abstinence in non-obese patients. There was no association between CAP and alcohol abstinence in obese patients.
Conclusion: These findings demonstrate for the first time that the presence of steatosis is linked to lower alcohol abstinence in patients with hazardous alcohol consumption. The difficulty in achieving abstinence during follow-up likely contributes to the poorer prognosis of patients with alcohol-related steatosis.

SAT-502

Prevalence and predictors of early re-hospitalization or death among a national cohort of veterans hospitalized for alcohol-associated hepatitis in the United States

Zeyuan Yang[1], Ramsey C. Cheung[2], Wei Zhang[3], Ashwani K. Singal[4], Michael Ostacher[2], Robert Wong[2]. *[1]VA Palo Alto Health Care System, Palo Alto, United States; [2]Stanford University School of Medicine, Palo Alto, United States; [3]Harvard Medical School - MGH, Boston, United States; [4]University of Louisville, Kentucky, United States*
Email: rwong123@stanford.edu

Background and aims: Pandemic-related surges in unhealthy alcohol use led to increasing incidence of acute hospitalizations due to alcohol-associated hepatitis (AH). High-risk alcohol use is particularly prevalent among U.S. Veterans, further fueling rates of AH in this population. We aim to evaluate prevalence and predictors

of early re-hospitalization or death among a national cohort of U.S. Veterans hospitalized for AH.
Method: Adults without cirrhosis hospitalized for AH from 1/1/2010–6/30/2024 were evaluated using the national Veterans Affairs (VA) database, which captures data for all Veterans utilizing VA healthcare facilities in the U.S. AH was identified using established criteria that incorporate both ICD-9/10 diagnosis codes and supporting laboratory data. The primary outcome was early re-hospitalization or death (reH/D) within 28-days, and the secondary outcome was reH/D within 90-days. Comparisons of reH/D within 28-days or 90-days was compared between groups using chi-square tests. Adjusted multivariable Cox proportional hazards models (adjusted for age, sex, race/ethnicity, ascites, hepatic encephalopathy, number of organ failures, MELD score, steroids or N-acetylcysteine treatment) evaluated for predictors of reH/D within 28-days or 90-days.
Results: Among 1,825 unique patients hospitalized for AH (91.5% men, mean age 51.6 ± 11.3y, 68.1% non-Hispanic white (NHW), 15.9% African American (AA), 8.2% Hispanic, 59.7% MELD > 20), 16.8% had reH/D within 28-days and 27.0% within 90-days. While no sex-specific differences in reH/D were observed, increasing age was associated with higher rates of early reH/D within 28-days (23.3% in age >60 y vs. 10.5% in age 18–39 y; aHR 0.58, 95% CI 0.39–0.86, $p < 0.01$) and 90-days (35.5% in age >60 y vs. 16.7% in age 18–39 y; aHR 2.69, 95% CI 1.90–3.81, $p < 0.01$). When stratified by race/ethnicity, Hispanics (21.2%) had the highest early reH/D and AA (11.0%) had the lowest. Compared to NHW, AA patients had lower risk of early or delayed reH/D (28-day: HR 0.58, 95% CI 0.39–0.86; 90-day: HR 0.72, 95% CI 0.54–0.96). Compared to patients with MELD<20, those with MELD>20 had greater risk of early reH/D (23.3% vs. 8.1%, aHR 2.56, 95% CI 1.83–3.57$p < 0.01$) and within 90-days (37.1% vs. 14.2%; aHR 2.42, 95% CI 1.88–3.11, $p < 0.01$).
Conclusion: Among a national cohort of U.S. Veterans hospitalized for AH, one in six experienced early reH/D, with older age and higher MELD as strong predictors. Timely identification of high-risk alcohol use and linkage to addiction treatment among Veterans is critical, but equally important is close follow-up and referral to alcohol abstinence support and treatment following AH hospitalization.

SAT-503-YI
Cardiac performance is impaired in patients with proven alcohol related hepatitis and and predicts 3-month mortality in this patient population
Hortense Le Bourhis[1], Shantha Valainathan[1], Alexandre Sayadi[2], Audrey Payancé[1], Olivier Roux[1], Lucile Moga[1], Claire Francoz[1], Francois Durand[1], Valérie Paradis[2], Pierre-Emmanuel Rautou[1,3]. *[1]AP-HP, Hôpital Beaujon, Service d'Hépatologie, DMU DIGEST, Centre de Référence des Maladies Vasculaires du Foie, FILFOIE, ERN RARE-LIVER, Clichy, France; [2]AP-HP, Hôpital Beaujon, Service d'Anatomopathologie, Clichy, France; [3]Université Paris-Cité, Inserm, Centre de recherche sur l'inflammation, UMR 1149, Paris, France*
Email: hortense.lebourhis@gmail.com

Background and aims: Cardiac and systemic hemodynamic changes associated with alcohol-related hepatitis (AH) are unknown. This study aimed to assess cardiac and systemic hemodynamic changes in patients with a clinical suspicion of AH, as well as their prognostic value.
Method: We conducted a retrospective analysis of prospectively collected data. All patients referred for transjugular liver biopsy for a clinical suspicion of AH between January 2013 and December 2023 were included and separated into proven and unproven AH based on histology. A group of patients with alcohol-related cirrhosis assessed for liver transplant (LT) and abstinent from alcohol was also included, as a reference group. Serum bilirubin was > 50 µmol/L in all patients. All patients underwent right heart and liver catheterization. Cardiac performance was assessed using the left ventricular stroke work index (LVSWI). Comparisons between groups were unadjusted (Mann-Whitney) and adjusted on MELD and on either leukocyte count or CRP (multivariable logistic regression).
Results: 749 patients were included: 463 with histologically proven AH (median MELD 23), 188 with histologically unproven AH (median MELD 22), and 98 with alcohol-related cirrhosis (median MELD 20). HVPG was not different between the 3 groups. Compared to patients with alcohol-related cirrhosis assessed for LT, those with proven AH had lower LVSWI ($p = 0.001$), cardiac index ($p < 0.001$), and higher diastolic blood pressure ($p = 0.01$) and systemic vascular resistance ($p = 0.001$), when adjusted on MELD and leukocyte count (similar for CRP). Compared to patients with a suspicion of AH ruled out by liver biopsy, those with proven AH had lower LVSWI [median 56.6 g/m2/beat (IQR 47.6–68.9) vs. 50.9 g/m2/beat (IQR 42.9–59.9), respectively; $p < 0.001$], and higher heart rate [median 79 bpm (IQR 68–90) vs. 87 (IQR 75–97), respectively; $p < 0.001$]. Difference of LVSWI remained significant when adjusting on MELD and leukocyte count or CRP ($p < 0.001$). Lower LVSWI was still associated with proven AH, when focusing on patients with or without beta-blockers, analyzed separately. In patients with proven AH, the only hemodynamic values associated with 3-month survival was LVSWI ($p < 0.001$). LVSWI remained associated with survival when adjusting on clinical variables associated with outcome at univariate analysis, i.e. age, sex, hepatic encephalopathy, prothrombin index, leukocyte count, serum bilirubin, creatinine, CRP and AST. Cumulative incidence of death at 90 days was higher (41%) in patients with proven AH with LVSWI < 44.7 g/m2/beat (i.e. the Youden index value), than in patients with proven AH with LVSWI above that threshold (23%) and than in patients with unproven AH with low (29%) or high LVSWI (23%) ($p < 0.001$).
Conclusion: This study showed that proven AH is strongly associated with compromised cardiac performance, a feature associated with impaired 3-month survival.

SAT-504
Rising proportion of young adults and women on the U.S. liver transplant waitlist for end-stage liver disease attributed to rising alcohol-associated liver disease following the COVID-19 pandemic
Shyam Patel[1], Wei Zhang[2], Ashwani K. Singal[3], Ramsey C. Cheung[4], Robert Wong[4]. *[1]Department of Medicine, California Pacific Medical Center, San Francisco, CA, United States; [2]Gastroenterology Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States; [3]Division of Gastroenterology, Hepatology and Nutrition, University of Louisville School of Medicine; Transplant Hepatology, UofL Health Jewish Hospital and Trager Transplant Center; Rob Rexley VA Medical Center, Louisville, KY, United States; [4]Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University, Gastroenterology Section, Veterans Affairs Palo Alto Healthcare System, Palo Alto, CA, United States*
Email: shyampatel7543@gmail.com

Background and aims: Significant increases in high-risk alcohol use among U.S. adults were observed following the onset of the COVID-19 pandemic. This led to a spike in alcohol-associated liver disease (ALD) hospitalizations and liver transplants (LT). We aim to evaluate how LT trends have evolved 4 years following onset of the COVID-19 pandemic in the U.S., with a focus on understanding differences in LT indication by race/ethnicity and other sociodemographic factors.
Method: Adults (≥18 years old) with ESLD without HCC who were listed for LT from 2018 to 2024 were evaluated using data from the United Network for Organ Sharing registry using three time periods corresponding to the period before, during, and following the COVID-19 pandemic: Era 1 (3/1/2018–2/29/2020), Era 2 (3/1/2020–2/28/2022), and Era 3 (3/1/2022–2/29/2024). Trends in new LT waitlist registrants were evaluated by liver disease etiology and patient demographics. Comparisons of trends across aforementioned time periods were evaluated using the z-statistic and trends test.
Results: We identified 49,949 adults with ESLD awaiting LT from 2018–2024 [median age [IQR] 57 years [48–64], 62.6% men, 70.9%

non-Hispanic White, 5.8% African American, 17.8% Hispanic, 4.0% Asian, 1.0% American Indian/Alaska Native. Overall, 45.3% of patients were listed for ALD, of which 10.0% were acute alcohol-associated hepatitis. The proportion of LT waitlist registrants with ALD increased steadily from 38.7% in Era 1 to 46.2% in Era 2, and in Era 3, more than half (50.1%) of all adults ESLD waitlist registrants had ALD. The demographics of waitlist registrants with ALD have demonstrated a growing proportion of young adults (proportion of ALD age 18–39 years old: Era 1–13.6%, Era 2–17.4%, Era 3–17.5%) and women (Era 1–28.8%, Era 2–30.6%, Era 3–31.8%). Similar trends were seen in actual LT performed, with proportion of LT for ALD increasing from 37.8% in Era 1 to 46.8% and 51.2% in Eras 2 and 3, respectively. Rising proportion of young adults age (18–39 years) and women with ALD undergoing LT were also observed, and in Era 3, young adults and women represented 18.5% and 31.8% of adults with ALD receiving LT, respectively ($p < 0.01$ for trend).
Conclusion: ALD contributing to ESLD requiring LT represents more than half of waitlist registrations and LTs performed in the U.S. The rising burden of ALD-related ESLD among young adults and women emphasizes the need for concerted efforts to address unhealthy alcohol use among these at-risk populations.

SAT-514
High-risk PNPLA3 rs738409 genotype is associated with higher CCL2 concentrations in liver transplant candidates with alcohol - related liver disease
Tomislav Kelava[1,2], Ivan Budimir Bekan[3], Dino Šisl[1,2], Alan Šućur[1,2], Ana Bainrauch[4], Valerija Bralić-Lang[5], Pavao Planinić[6], Nataša Kovačić[1,7], Danka Grčević[1,2], Vibor Šeša[8], Anna Mrzljak[8,9].

Email: tkelava@mef.hr

Background and aims: Patients with GG rs738409 patatin-like phospholipase domain-containing protein 3 (PNPLA3) genotype have a greater risk of developing steatotic liver disease and hepatocellular carcinoma (HCC). We aimed to analyze the association between the PNPLA3 genotype and augmented inflammatory response in transplant candidates with alcohol-related liver disease (ALD).
Method: Sera concentrations of 13 cytokines (IL-1, IFN-α, IFN-γ, TNF-α, IL-6, CXCL8, IL-10, IL-12, IL-32 and IL-33, IL-17, IL-18 and CCL2) were measured in 106 ALD liver transplant candidates without HCC (40 with CC, 40 with CG and 26 with GG), 35 with HCC ($n = 35$) and 19 controls by cytometric bead array.
Results: Ten cytokines (IL-1, IFN-α, IFN-γ, TNF-α, IL-6, CXCL8, IL-10, IL-12, IL-32 and IL-33) had significantly higher sera concentrations in ALD patients in comparison to the controls, whereas there was no difference in IL-17 and IL-18 concentrations, and CCL2 concentration was significantly decreased. Patients with HCC had concentrations of all cytokines similar to those of ALD patients without HCC. Concentrations of CCL2 were in a negative correlation with INR ($\rho = -0.412$, $p < 0.001$), while a positive, but weaker, correlation with INR was found for IL-6 ($\rho = 0.278$, $p < 0.01$). Concentrations of CXCL8 ($\rho = 0.248$, $p < 0.05$) and IL-1 ($\rho = 0.232$, $p < 0.05$) correlated with bilirubin concentration. ALD GG carriers had significantly higher concentrations of CCL2 (212.6 (135.9–264.9)) than patients with CC/CG genotype (141.3 (104.1–201.6), $p = 0.002$, Mann-Whitney). We found no significant association for the remaining 12 measured cytokines ($p > 0.05$ for all conducted analyses).GG carriers also had significantly higher levels of AST and ALT and lower platelets.
Conclusion: The risk GG rs738409 PNPLA3 genotype is associated with increased concentration of CCL2 in patients with ALD, suggesting that increased concentration of CCL2 may contribute to the greater risk for development of HCC among the GG carriers.

Cirrhosis and its complications – ACLF and Critical illness

TOP-204
Efficacy of 5% albumin versus plasmalyte in combination with 20% albumin for fluid resuscitation in cirrhosis with sepsis induced hypotension. A randomized controlled trial (ALPS Plus)
Rakhi Maiwall[1], Ayush Jain[1], Vijayraghavan Rajan[1], Harshvardhan Tevethia[1], Satender Singh[1], Chitranshu Vashitshtha[1], Omkar Rudra[1], Mradul Daga[1], Dr. Prashant Mohan Agarwal[1], Shiv Kumar Sarin[1]. *[1]Institute of Liver and Biliary Sciences, New Delhi, India*
Email: rakhi_2011@yahoo.co.in

Background and aims: 5% albumin(5% Alb) is superior to normal saline for reversal of shock in critically ill cirrhosis (CIC) with sepsis induced hypotension (SIH) (FRISC). Plasmalyte was shown to be safer against 20% albumin with reduced incidence of pulmonary complications in CIC with SIH (ALPS trial). The comparison of 5% albumin against plasmalyte has never been studied in CIC.
Method: CIC with SIH underwent open label, 1:1 randomization to receive either 5% Alb alone (5 ml/kg bolus over half hour followed by 50 ml/hr) or plasmalyte (P+Alb20) (30 ml/kg bolus over half hour followed by 100 ml/hr) with 20–40 g of 20% albumin administered over 24 hours. Further, fluid boluses were guided by point of care ultrasound (POCUS) done every hourly for 3 hours. The primary endpoint was attainment of mean arterial pressure (MAP) >65 mm Hg without vasopressor at 3 hours.
Results: Baseline characteristics were comparable in both the groups; MAP (mm Hg) (59.47 ± 4.17 vs 59.90 ± 3.04; $p = 0.58$), arterial lactate (mmol/L) (2.51 ± 1.75 vs 2.60 ± 1.73; p value = 0.79), SOFA score (8.98 ± 2.09 vs 8.94 ± 2.47; $p = 0.93$), MELD score (28.38 ± 9.41 vs 29.43 ± 10.09; p value = 0.60), Inferior vena cava diameter (IVC) (mm) (14.4 ± 3.7 vs 15.2 ± 4.5; $p = 0.379$) with collapsibility index (IVCCI %) >40% and distensibility index (IVCDI %) >18% in all the patients and POCUS showed A pattern in all the patients. Majority of patients were alcohol related liver disease (67.7%), source of sepsis was pulmonary in 47%, Spontaneous bacterial peritonitis in 24% patients. Reversal of shock at 3 hours (45.8% vs 52%; $p = 0.54$) and 24 hours (59.6% vs 63%; $p = 0.73$) was similar in both the groups. The volume of fluid (ml) received at 3 hours was higher in P+Alb20 vs. 5% Alb (605.2 ± 257.2 vs 2248 ± 714.2 ml; $p = 0.0001$) while the dose of albumin per day (g/dl) was higher in 5% Alb (67.7 ± 19.9 vs 35 ± 8.6; $p = 0.0001$). The time to initiation of norepinephrine (hours) was similar 3.4 ± 4.5 vs 3.1 ± 3.6 hours ($p = 0.8$). The change in the IVC diameter, IVCCI and IVCDI was similar ($p = 0.34$, $p = 0.88$, $p = 0.38$), but more patients developed B lines on POCUS at 3 hours in 5% Alb (13.3% vs 2.1%; $p = 0.04$). At 28 days, 71.9% patients in P+Alb20 and 80% in 5% Alb had died (relative risk 0.64; 95% confidence interval [CI], 0.20 to 2.08; $p = 0.55$). The need for dialysis (52.1% vs 51%; $p = 0.91$), serum chloride level at 24 hours (mEq/L) (104.37 ± 9.55 vs 101.28 ± 6.35; $p = 0.161$), hypernatremia (sodium >145 mEq/L) (10.4% vs 9.8%; $p = 0.91$) and respiratory distress (12.5% vs 7.8%; $p = 0.44$) at 24 hours was similar in both groups. No patient developed pulmonary complication at 3 hours.
Conclusion: Plasmalyte with low dose 20% albumin is as effective as 5% albumin for reversal of shock in critically ill patients with SIH. The use of POCUS can reduce the incidence of pulmonary complications

and also guide effective fluid resuscitation. Trial registration - NCT06076330.

Email: julian.pohl@charite.de

Background and aims: ACLF occurs in cirrhosis patients and characterized by multi-organ failure and high mortality. Although inflammation is important in the pathogenesis of ACLF, it is unclear what role circulatory dysfunction plays. The patterns of changes in biomarkers in the two commonest triggers of ACLF; infection (inf) and severe alcohol-related hepatitis (sAH) in patients with cirrhosis are also unknown. To better understand the pathophysiology, we compared a large panel of biomarkers in sAH- and inf-ACLF patients and their association with outcomes.

Method: 1019 patients from CANONIC, PREDICT, ACLARA with either sAH or inf-induced acute decompensation were included (sAH-AD, n = 546), sAH-ACLF (n = 239) or inf-ACLF (n = 234). Biomarkers assessed included those representing systemic inflammation, circulatory dysfunction and albumin function. Uni- and multivariable regression analyses were performed.

Results: IL-6, IL-17A, TNF-alpha, IL-10, IFN-gamma, G-CSF and copeptin were significantly higher in inf-ACLF, while IL-8 and eotaxin was elevated in sAH-ACLF. IL-6 and eotaxin levels independently differentiated sAH-ACLF from inf-ACLF. In univariable regression analyses for 28-day mortality, IL-6, IL-10, IL-1ra, G-CSF, GM-CSF, NGAL, and renin were associated with higher risk of 28-day mortality in both ACLF groups. In multivariate analyses, IL-10 (HR: 1.28; $p < 0.001$) was only predictor of sAH-ACLF mortality, while IL-8 (HR: 1.13; $p < 0.001$) predicted mortality in inf-ACLF. In sAH-AD compared to sAH-ACLF, IL-1 alpha, IL-17A, IFN alpha2 and gamma were significantly higher, whereas levels of IL-6, IL-8, IL-10, TNF alpha, IP 10, NGAL, HNA2 and copeptin were significantly lower. In the group of sAH-AD patients who developed ACLF within 28-days, IL-6, TNF alpha, NGAL, copeptin and HNA2 were significantly higher. IL-8 and HNA2 independently differentiated sAH-AD from sAH-ACLF.

Conclusion: Our study highlights significant differences between sAH-ACLF and inf-ACLF, not only in their clinical presentation but also in their cytokine profiles. In sAH-ACLF, the immunosuppressive cytokine, IL-10 emerged as an independent driver of mortality. In contrast, in inf-ACLF, pro-inflammatory IL-8, was the independent predictor of mortality. Additionally, we show that IL-8 and HNA2 independently differentiated AD from ACLF in patients with severe alcohol-related hepatitis. Our findings suggest that disease driving mechanisms are distinct in different ACLF entities and better characterization and personalized approaches are needed to impact on developing therapeutic strategies.

Background and aims: Yaq-001 is a novel, non-absorbable, gut-restricted nanoporous carbon bead adsorbent. Pre-clinical studies demonstrated its ability to reduce fibrosis, portal hypertension, and organ dysfunction, partially by restoring dysbiotic gut microbiome composition and endotoxemia. A Phase 2 clinical trial confirmed its safety in patients with cirrhosis. The aims of this study were to evaluate the effect of Yaq-001 on the gut microbiome and its association with ammonia metabolism, inflammation and endotoxemia.
Method: 28-patients with compensated cirrhosis were randomized (double-blind) to receive Yaq-001 (4 g once daily) or Placebo. Gut microbiome and biomarker analyses at baseline, after 4-weeks and after 12-weeks were performed. Shotgun sequence reads of the microbiome samples were mapped against the Integrated Gene Catalog of human gut microbiota to generate a gene count table and a species abundance table. Changes in biomarkers and relationship with microbiome composition were assessed.
Results: Yaq-001 was safe and no differences in liver function were observed. Alpha or beta diversity and the distribution distances of the different pairs at different time points were unaltered. Yaq-001 increased the abundance of bacteria associated with improved gut health such as *Adlercreutzia equolifaciens* ($p < 0.05$), a bacterium with anti-inflammatory properties commonly depleted in liver disease and decreased abundance of bacteria associated with infections and poor outcomes such as *Klebsiella pneumonia* and *Streptococcus mutans* ($p < 0.05$ each). Yaq-001 impacted positively and significantly on virulence factors such as siderophores, fimbriae structures and lipopolysaccharides (LPS) that are associated with inflammation and invasion ($p < 0.05$ each). Systemic LPS, NGAL, LBP, creatinine and ammonia showed the highest positive correlations with the virulence factors ($r > 0.28$, $p < 0.025$ each). Antibiotic resistance genes (ARGs) that are linked with negative disease outcomes, decreased in the Yaq-001 group. One gene associated with secondary bile acid metabolism decreased in the Yaq-001 group and showed significant correlations with serum and fecal secondary bile acid concentrations ($r > 0.5$, $p < 0.001$).
Conclusion: The results show that Yaq-001 impacts positively on the composition of the microbiome, significantly reduces its virulence and ARGs resulting on impacts on systemic inflammation and endotoxemia. Late phase clinical trials in cirrhosis are justified.

Human cytomegalovirus reactivation in cirrhotic individuals with acute decompensation

Changze Hong[1], Hai Li[2], Zuxiong Huang[3], Yingli He[4], Rongqi Wang[5], Beiling Li[1], Jinjun Chen. *[1]Hepatology Unit, Department of Infectious Diseases, State Key Laboratory of Organ Failure Research, Guangdong Provincial Key Laboratory of Viral Hepatitis Research, Nanfang Hospital, Southern Medical University, Guangzhou, China; [2]Department of Gastroenterology, Ren Ji Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China; [3]Department of Hepatology, Mengchao Hepatobiliary Hospital of Fujian Medical University, Fuzhou, China; [4]Department of Infectious disease, The First Affiliated Hospital of Xi'an Jiongtong University, Xi'an, China; [5]Department of Traditional and Western Medical Hepatology, Third Hospital of Hebei Medical University, Shijiazhuang, China*
Email: 13528884690@163.com

Background and aims: Human cytomegalovirus (HCMV) reactivation frequently occurs in immunocompromised host and is related to an excess of graft rejection and a major cause of fatal cases during the first year after transplantation. However, information about HCMV reactivation in cirrhotic population is very limited. In this study, we aimed to investigate its incidence and association with hepatic outcomes in acutely decompensation (AD) patients.
Method: Two sets prospective multicenter cohorts (Cohort 1 and Cohort 2, respectively) of AD patients who were HCMV seropositive were investigated. Cohort 1 was conducted from November 2020 to December 2023 in four tertiary hospitals in China. Cohort 2 was selected from the investigation cohort of Chinese Acute-on- Chronic Liver Failure study by using a simple random sampling technique. HCMV reactivation was diagnosed via commercially available real-time polymerase chain reaction with low limit detection at 100 copies/ml.
Results: HCMV reactivation at baseline was diagnosed with both 4.8% patients in Cohort 1 (35/722) and Cohort 2 (14/291). Patients with HCMV reactivation had higher MELD-Na scores than those without reactivation (27 [23–32] vs. 18 [11–26] in Cohort 1, $p < 0.001$; 27 [20–33] vs. 15 [10–23] in Cohort 2, $p = 0.001$) and a higher incidence of acute-on-chronic liver failure (ACLF) (48.6% vs. 16.4% in Cohort 1, $p < 0.001$; 35.7% vs. 9.7% in Cohort 2, $p = 0.011$) and bacterial infection (88.6% vs. 53.3% in Cohort 1, $p < 0.001$; 78.6% vs. 44.8% in Cohort 2, $p = 0.013$). In both cohorts, patients with HCMV reactivation at baseline had increased mortality compared with those without reactivation (49.6% vs. 18.1% in Cohort 1; 57.1% vs. 15.3% in Cohort 2; both $p < 0.001$) and was an independent risk factor for 90-day transplant-free mortality (HR: 1.740 in Cohort 1, $p = 0.038$; HR: 3.148 in Cohort 2, $p = 0.005$). This result appeared to be consistent across different MELD-Na scores and bacterial infection subgroups. As an opportunistic pathogen, patients with HCMV reactivation are both prone to developing ACLF during hospitalization or a 28-day follow-up period compared to non-infection individuals among non-ACLF patients at baseline (38.9% vs. 6.3% in Cohort 1; 33.3% vs. 2.0% in Cohort 2; $p < 0.001$). Among the total of 49 patients with HCMV reactivation in these two cohorts, 9 patients in Cohort1 and none in Cohort 2 had received antiviral therapy (ganciclovir) according to clinicians' decision. Due to the high fatality rate of patients with Grade-3 ACLF, they were excluded from the analysis of impact of anti-HCMV therapy on 90-day mortality. In the multivariable analysis with the inverse probability weighting, there was a significant association between antiviral treatment and death (HR:0.151, 95%CIs: 0.032–0.723).
Conclusion: HCMV reactivation was associated with increased 90-day mortality and development of ACLF. These observations support the use of HCMV reactivation as part of a risk stratification and potential interventional target in the management of AD patients.

FRI-164

Efficacy of Granulocyte Colony-stimulating factor in hepatitis B virus-associated acute-on-chronic liver failure patients: a multicenter study

Jing Yuan[1], Jing Chen[1], Haibin Su[1], Yu Chen[2], Tao Han[3], Tao Chen[4], Xiaoyan Liu[1], Qi Wang[5], Pengbin Gao[6], Jinjun Chen[7], Jingjing Tong[1], Chen Li[1], Jinhua Hu[1]. Background and aims: The role of Granulocyte Colony-stimulating Factor (G-CSF) as a potentially effective drug in acute-on-chronic liver failure (ACLF) is still controversial. The aim of this study was to evaluate the efficacy of G-CSF in the treatment of patients with HBV-ACLF and to assess prognosis by selecting appropriate indicators for monitoring for early intervention.
Method: In this multicenter, nonrandomized, open-label prospective study, 284 patients who met APASL-ACLF criteria were screened and assigned to G-CSF group (300 mg/d G-CSF for the first 6 days and every other day to day 18 thereafter, n = 119) or standard drug therapy group (SMT group, n = 165) based on patient preference at 7 medical facilities in China, from June 2020 to June 2024. We assessed survival until day 90. The delta value (d-value) between each time point and the baseline was used to assess the change in the biomarker. The d-values of the two groups of biomarkers were compared, and the variables with differences were screened out and applied to establish the Cox proportional hazard regression model in G-CSF group, and the specific threshold was determined by X-tile software.
Results: The 90-day transplant-free survival rate was 80.2% in G-CSF treated patients versus 66.3% in the SMT group (p = 0.024).The dMon, dINR in G-CSF group was higher than that in SMT group at day 4,7 (p < 0.05). And the dWBC, dNeu, dGGT in G-CSF group was higher than that in SMT group at day 4,7,14 (p < 0.05). The d-values that differed between the two groups were taken out separately and modeled in the G-CSF group. In the G-CSF group, multivariate Cox regression showed that dMon14 (HR = 16.95, p = 0.021), dNeu14 (HR = 2.12, p = 0.04), dINR4 (HR = 4.92, p = 0.002) were associated with 90-day death. Patients in the high-risk group (dMon14 > 0.07, or dINR4 > 0.03) had worse survival rates, indicating the need for early intervention.
Conclusion: G-CSF can effectively improve the 90-day transplant-free survival of patients with HBV-ACLF (APASL criteria). In the process of G-CSF treatment, blood routine and coagulation should be dynamically monitored. When dMon14 >0.07 and dINR4 >0.03, the patient may have a poor prognosis after treatment with G-CSF, suggesting the need for early intervention.

FRI-165

Prevalence and characteristics of bacterial and fungal infections in end-stage liver disease: a multi-center, cross-sectional study from central China

Wei Liu[1], Lanyue Huang[2], Yuxin Niu[2], Yunhui Liu[2], Tingting Liu[2], QiuYu Cheng[2], Tao Chen[2], Qin Ning[2]. [1]*Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China;* [2]*Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China*
Email: 775018951@qq.com

Background and aims: Patients with end-stage liver disease (ESLD) are at an elevated risk of bacterial and fungal infections due to their weakened immune systems and compromised liver function. This cross-sectional study aims to assess the prevalence, types, and risk factors associated with infections in ESLD patients, providing insights into the clinical characteristics and outcomes of these infections.
Method: A cross-sectional study was conducted, encompassing patients with stable decompensated cirrhosis (SDC), unstable decompensated cirrhosis (UDC), acute on chronic liver failure (ACLF) and Pre-ACLF from multiple tertiary hospitals in central China, spanning from January 2012 to December 2023. Data on demographics, laboratory results, complications, types of infections, identified pathogens, organ failure incidences and mortality were collected at admission and subsequently analyzed.
Results: Out of the 1328 patients enrolled, 935 were classified as SDC&UDC, 121 as Pre-ACLF, and 272 as ACLF, with bacterial infection rates of 38.3%, 52.1%, and 62.1% at admission, respectively. Within the ACLF group, bacterial infection rates for ACLF-1, ACLF-2, and ACLF-3 were 57.5%, 64.8%, and 56.3%, respectively. In each ESLD phenotype, spontaneous bacterial peritonitis (SBP) and pneumonia were the most common types of bacterial infections. Out of 67 identified bacteria, the most prevalent strains were *Enterococcus faecium* among Gram-positive organisms (9/32) and *Escherichia coli* (18/35) among Gram-negative organisms. Ascites was identified to be an independent risk factor for bacterial infections across all ESLD phenotypes (SDC&UDC, Pre-ACLF, and ACLF). SBP shows a moderate positive correlation with ascites (r = 0.675; $P < 0.001$), and pneumonia exhibits a moderate positive correlation with ACLF-2 (r = 0.730; $P = 0.007$). The 90-day mortality rates for patients with bacterial infections at admission in the SDC&UDC (10.4% vs 5.0%; $P = 0.002$) and ACLF-1 (38.6% vs 15.2%; $P = 0.028$) groups were significantly higher than those without infections. Fungal infections were identified in 7 SDC&UDC patients (0.7%), 6 Pre-ACLF patients (5.0%), and 5 ACLF patients (1.8%), with corresponding 90-day mortality rates of 14.3%, 66.7%, and 80%, respectively.
Conclusion: Bacterial infections are highly prevalent in ESLD patients and are associated with significant mortality. Early identification of risk factors and prompt initiation of targeted antimicrobial therapy are crucial for improving outcomes in this vulnerable patient population.

FRI-166

Real-world evidence on clinical outcomes and microbiome changes after healthy donor stool transplantation as palliative therapy compared to best supportive care in patients with unstable decompensations in alcohol-related end-stage liver disease

Cyriac Philips[1,2], Arif Theruvath[3], Rizwan Ahamed[4], Tharun Oommen[4], Nibin Nahaz[4], Ajit Tharakan, Philip Augustine[4]. Email: abbyphilips@theliverinst.in

Background and aims: Alcohol-associated hepatitis (AH) can trigger unstable decompensations in cirrhosis patients. In the absence of curative liver transplantation, they experience high rates of emergency department visits, hospitalization, and life-threatening events. In resource-poor setting, palliative care in such end-stage liver disease (ESLD) patients aims to improve quality of life but not survival. In this real-world experience report, we aimed to study clinical events and overall survival in unstable alcohol-related

cirrhosis (ALC) patients undergoing healthy donor stool transplant (FMT) as an adjunct to standard palliation compared to a control group on best supportive care (BSC).

Method: From July 2021 to April 2024, we enrolled ALC patients with severe unstable decompensations two months post index AH. Twenty-eight patients on palliative FMT along with BSC were compared with 37 patients on BSC. Patients on FMT received 150 ml daily freshly processed healthy donor stool infusion for five days through a nasoduodenal tube. Both groups were treated for symptoms and complications per standard recommendations. Patients were followed up for portal hypertension-related events, infections, hospitalizations, extrahepatic organ failure, as well as 6-, 12-months and overall survival. 16S rRNA sequencing on stool samples were collected at baseline and on follow up to analyze changes in relative abundance (RA) of bacterial communities between groups.

Results: Patients were matched for age, type of decompensation and liver disease severity at enrolment. Among those hospitalized at outset and with infection, septic shock was significantly lower in those receiving FMT (10.7% v 44.4%, P = 0.02). During first 90-days of follow up, hospitalizations (P < 0.001), overt hepatic encephalopathy (HE, 4% v 35.3%, P < 0.001), sepsis (28% v 58.8%, P = 0.02), and worsening ascites (28% v 67.6%) were significantly lower in FMT. Decompensation (90.6% v 58.3%, P = 0.005) beyond 90-days and unstable decompensations (72.7% v 28.6%, P = 0.005), overt HE (57.6% v 4%, P < 0.001) and variceal bleeding (48.5% v 7.7%, P < 0.001) were significantly higher in BSC group. Nonetheless, at median follow-up of 13- in BSC and 16.5-months in FMT, the overall, as well as 6- and 12-months survival were not significantly different between groups. Microbiome analysis revealed progressive expansion of Gram-negative genera in BSC, and beneficial Actinobacteria in FMT-treated patients at 3, 6, and 12 months from baseline.

Conclusion: Healthy donor FMT as an adjunct to palliative care ameliorated adverse clinical events, but not clinical outcomes (long-term survival) in ALC-ESLD compared to BSC. Nonetheless significant reduction in rates of hospitalization, portal hypertension events, HE, and severe infections reveal a strong palliative role for FMT in end-stage liver disease patients, which beckons prospective validation.

FRI-167

AI-AD score: a novel machine learning-based model for predicting acute liver decompensation progression – a prospective observational study

Andrea Dalbeni[1], Marco Vicardi[1], Manuele Bicego[2], Anna Mantovani[1], Filippo Cattazzo[1], Michele Bevilacqua[1], Mirko Zoncapè[3], Leonardo de Marco[1], Katia Donadello[1], Laura Alaimo[1], Rosa Lombardi[4], Donatella Ieluzzi[1], Veronica Paon[1], David Sacerdoti[1]. *[1]University of Verona and University and Hospital Trust (AOUI) of Verona, Verona, Italy; [2]University of Verona, Verona, Italy; [3]University of Verona and University and Hospital Trust (AOUI) of Verona, UCL Royal Free Hospital London, Verona, Italy; [4]University of Milan, Milano, Italy*
Email: andrea.dalbeni@aovr.veneto.it

Background and aims: Patients with advanced chronic liver disease (ACLD), including the new form of non-acute decompensated (NAD), are at risk for acute decompensation (AD) or acute-on-chronic liver failure (ACLF), with an increased risk of mortality. To date, no specific score has been developed for AD onset. The well-known CLIF-C AD score is the only score to predict prognosis in hospitalized cirrhotic patients, but not designed for AD onset. Aim of the study is to develop and validate, using artificial intelligence (AI) techniques, the AI-AD score, a prognostic score for outpatients with ACLD who may develop AD, and to compare its performance with CLIF-C AD, Child-Pugh, and MELD scores.

Method: a single-center cohort study enrolled consecutive ACLD patients, followed at Liver Unit in Verona between January 2017 and December 2022. AI-AD score was developed using machine learning and pattern recognition techniques, focusing on classification and feature selection. AI was able to select the feature most relevant for predicting AD onset and trough a linear classifier to applied it. The score was validated in both an internal and a validation cohort. To assess the performance of the different scores, we used the classic AUC.

Results: 456 patients (70.6% male, mean age 64 ± 11 years) were enrolled for a median follow-up of 43.3 months. Among ACLD patients, 91 developed AD, 62 developed ACLF, while 79 NAD patients progressed to AD. The selected features for AI-AD score were: previous hospital admissions, infection episodes before enrollment, history of ascites and encephalopathy, portal vein thrombosis, serum creatinine and albumin values. AUC for the AI-AD score was 0.80 (CI 95%:0.73–0.86), higher than other scores.

Conclusion: AI-AD score effectively predicts AD onset in ACLD patients. history of infections and PVT, were identified as a crucial complication in cirrhotic patients and may predispose individuals to AD and ACLF.

FRI-170

Acute-on-chronic liver failure in Australia: a non-transplant centre experience

Annie Zhou[1], Ronan O'Connor[1], Leo Wan[1], Jennifer Zhang[1], Stephen Bloom[1,2], Alex Hodge[1,2,3], Rohit Sawhney[1,2]. *[1]Department of Gastroenterology, Eastern Health, Melbourne, Australia; [2]Eastern Health Clinical School, Monash University, Melbourne, Australia; [3]Department of Health and Biomedical Sciences, RMIT University, Melbourne, Australia*
Email: annie.siyuan.zhou@gmail.com

Background and aims: Acute on chronic liver failure (ACLF) is a clinical syndrome distinct from acute decompensation (AD) of cirrhosis characterised by systemic inflammation, organ failures and increased mortality. There is limited reported Australian data on ACLF outside of transplant centres. The aim of this study was to describe the prevalence, characteristics and outcomes of ACLF in a cohort of hospitalised patients at a non-transplant Australian tertiary centre.

Method: Adult patients with cirrhosis admitted acutely with decompensation to a single tertiary non-transplant health service between December 2017 and December 2021 were included for retrospective analysis. Data was collected on patient characteristics, clinical and laboratory parameters. ACLF presence and grades were defined using the European Association for the Study of the Liver-Chronic Liver Failure (EASL-CLIF) Consortium criteria and scored on day of admission, day 3 and day 7.

Results: There were a total of 259 patients with a total of 500 admissions with acute decompensation. On index admissions, 80 patients (30.9%) met the criteria for ACLF (67 at admission and 13 developed during admission). There were no significant differences in basic patient demographics between the ACLF and AD groups. Both groups were predominantly male (66.7% and 72.1% respectively) with a median age at admission of 57 and 59 years respectively and the most common cirrhosis aetiology was alcohol (79.1%). The most common decompensating event was gastrointestinal bleeding for ACLF (30.0%) compared to ascites (48.0%) in AD. Patients with ACLF at index presentation had more severe liver disease than AD, indicated by higher median model for end-stage liver disease scores (23.5 vs 18.0, p < 0.001) and greater proportion with Child-Pugh class C disease (69.6% vs 50.3%, p < 0.004). ACLF patients at day 1 were also characterised by greater inflammation (WCC 9.75 vs 7.3 for AD, p = 0.001) and renal dysfunction (creatinine 90 vs 64 for AD, p < 0.001). The most common organ failure amongst both groups was circulation (26.2%) followed by coagulation (20.5%). Mortality was significantly higher in ACLF vs AD patients at both 30 days (53.2% vs 11.3%, p < 0.001) and 90 days (68.1% vs 28.2%, p < 0.01). The median survival post index admission was 29 days in the ACLF group compared to 257 days in the AD group (p < 0.001). Median survival was also

significantly shorter with progressive grades of ACLF(39.5 days for ACLF1 vs 20–25.5 days for ACLF2/3, $p < 0.001$).
Conclusion: ACLF was present in over a quarter of patients hospitalised with AD in this cohort and is associated with poor survival. The rate of ACLF was similar to previous studies in Europe and Australia with comparable survival rates in a non-transplant centre despite similar severities of liver disease at presentation. Further investigation in and comparison of different cohorts will be important to identify prognostic factors and inform management strategies.

FRI-171-YI
Oral anticoagulants are safe and may reduce risk of hepatic decompensation in patients with cirrhosis and atrial fibrillation
Axel Wester[1], Emilie Toresson Grip[1], Ying Shang[1], Rupesh Rajani[1], Anthony Matthews[2], Hannes Hagström[1]. *[1]Department of medicine Huddinge, Karolinska Institutet, Stockholm, Sweden; [2]Unit of Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden*
Email: axel.wester@ki.se

Background and aims: Intrahepatic microvascular thrombi may elevate the portal pressure and increase the risk of hepatic decompensation in patients with cirrhosis, whereas resolving the thrombi may reduce such risk. Robust evidence from well-powered randomized controlled trials on the effect of anticoagulants on risk of hepatic decompensation is missing and has proven challenging to obtain. Therefore, we designed a hypothetical target trial aiming to estimate the effect of oral anticoagulants on risk of hepatic decompensation in patients with compensated cirrhosis and atrial fibrillation, and then emulated it using observational data. Further, we considered the risk of major bleeding as a potential side effect.
Method: Observational data from Swedish healthcare registers 2011–2022 were used to emulate a target trial of oral anticoagulants in patients with compensated cirrhosis and newly diagnosed atrial fibrillation. Inverse-probability weighted marginal structural models were used to compare 5-year risks of hepatic decompensation and non-portal hypertension-related major bleeding in initiators versus non-initiators of oral anticoagulants.
Results: Baseline characteristics were well balanced between treatment groups after inverse-probability weighting. The 5-year risk of hepatic decompensation was 10.3% (33 of 383) in initiators and 16.6% (112 of 777) in non-initiators in the intention-to-treat (ITT) analysis (risk ratio [RR] = 0.62, 95% confidence interval [CI] = 0.34–0.90). The corresponding per-protocol 5-year risk estimates were 10.2% (17 of 383) versus 16.6% (112 of 777) (RR = 0.62, 95%CI = 0.24–0.99). The effect of oral anticoagulants on the risk of hepatic decompensation was more pronounced in men (ITT RR = 0.53, 95% CI = 0.22–0.85) than in women (ITT RR = 0.85, 95%CI = 0.00–1.72), and primarily driven by a reduced risk of ascites (ITT RR = 0.58, 95%CI = 0.27–0.90). The 5-year risk of major bleeding was 19.3% (63 of 383) in initiators and 19.9% (149 of 777) in non-initiators in the ITT analysis (RR = 0.97, 95%CI = 0.65–1.30), and 14.4% (31 of 383) versus 19.9% (149 of 777) in per-protocol analysis (RR = 0.72, 95%CI = 0.25–1.19). Risks were similar between treatment groups regarding fatal, intracranial, gastrointestinal, and other bleedings.
Conclusion: Patients with compensated cirrhosis who initiated oral anticoagulants after the diagnosis of atrial fibrillation had a lower risk of hepatic decompensation and no increased risk of major bleeding compared to non-initiators. Results suggest oral anticoagulants are safe in compensated cirrhosis and may improve prognosis. Randomized trials are warranted to confirm these results.

FRI-172
Intraperitoneal administration of investigational drug VS-01 captures accumulated metabolites in patients with acutely decompensated liver cirrhosis
Olaf Tyc[1], Berenice Alard[2], Meriam Kabbaj[3], Jeremy Magnanensi[2], Martin Schulz[4], Sabine Klein[4], Robert Schierwagen[4], Sakina Sayah Jeanne[2], Stephanie Ferreira[2], Dean Hum[2], Bart Staels[5], Katharina Staufer[3], Jonel Trebicka[4,6], Frank Erhard Uschner[4]. *[1]Department of Internal Medicine I, Hospital of the Goethe University, Frankfurt, Germany; [2]GENFIT SA, Loos, France; [3]Versantis AG (Genfit Group), Zurich, Switzerland; [4]Department of Internal Medicine B, University Hospital, Münster, Germany; [5]Univ. Lille, INSERM, CHU Lille, Institut Pasteur de Lille, U1011, Lille, France; [6]European foundation for the Study of Chronic Liver Failure, EFCLIF, Barcelona, Spain*
Email: berenice.alard@genfit.com

Background and aims: Metabolites produced by altered gut microbiota may play an important role in acute decompensation (AD) of liver cirrhosis. Investigational drug VS-01 is an intraperitoneal pH-gradient liposomal infusion designed to enhance the clearance of ammonia and further disease-related metabolites. We evaluated the potential of VS-01 to capture gut-derived metabolites in 9 patients with decompensated liver cirrhosis, ascites, and covert hepatic encephalopathy (HE) from the Phase 1b safety clinical trial, EudraCT no.: 2018-004606-25.
Method: Patients received a single dose of either 15, 30 or 45 mL/kg of VS-01 which was administered intraperitoneally to dwell for 2 h following paracentesis. Peritoneal fluid and plasma samples were collected concomitantly at different timepoints: baseline (T0), 1 h (T1), 2 h (T2) and 24 h (T24) after VS-01 infusion start. Metabolomic analyses were first performed on all samples using an untargeted LC/MS approach. Among identified metabolites, we focused on 103 compounds which were described in the Gutsy Atlas as gut-derived metabolites. Fold changes (FC) and t-tests were computed to compare and detect significant differences ($p < 0.05$) in peritoneal samples at T0 vs T2, and in blood samples at T0 vs T24. Statistical analyses were performed using the R package "MetaboAnalyst" on the peak lists containing mass features of identified compounds.
Results: Of the 103 gut-derived metabolites, 64 were associated with a $\log_2(FC) \geq 0$ in the peritoneal fluid between T0 et T2, indicating an increased concentration in presence of VS-01. In particular, 12 of these metabolites showed a significant increase in peritoneal fluid with associated $\log_2(FC)$ ranging 1.12 to 4.47, and none of these metabolites were associated with significant increase in plasma at T24 vs T0. Among these 12 metabolites, 3 were xenobiotics (theophylline, norcotinine, (S)-nicotine) whose degradation occurs mainly in the liver, and 4 were previously described as accumulating in the context of AD (5-methyluridine, allantoin, methionine, formiminoglutamic acid). The remaining 5 included trigonelline, prolylglycine, methionine sulfoxide, carnosine and urocanic acid.
Conclusion: VS-01 appeared to capture gut-derived metabolites including xenobiotics. In the context of acute decompensation with impaired liver clearance, reducing metabolite accumulation may halt progression of AD and ACLF. Further analyses are warranted to confirm our findings.

FRI-173
Severe liver disease patients had dysfunctional platelets hypoergic to adenosine diphosphate
Xiuhua Jiang[1], Xiaoting Tang[1], Weihao Liang[1], Shiqi Chai[1], Jinjun Chen. *[1]Hepatology Unit, Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China*
Email: chjj@smu.edu.cn

Background and aims: Severe liver disease (Liver failure) patients has been documented with multiple organ dysfunctions and always leading to high mortality. Functions of blood cells, such as platelets, and its potential implications in diagnosis and therapy for liver failure patients, has not been widely studied.

Method: A prospective patient set for platelet functions assessment (n = 189) was hired for probing dysfunctional platelets in liver disease patients (n = 26). A prospective cohort was established to validate platelets functions and its prognostic values in liver failure patients (n = 260). The potential therapeutic benefit of platelets transfusion was further explored in liver failure patients (n = 73) from this prospective cohort. Unbiased and target proteomics with platelets concentrates, blood plasma samples from liver failure patients were adopted to explore underlying molecules for platelets dysfunction, respectively. In vitro experiments were further performed to establish the mechanism for dysfunctional platelets in liver failure patients.
Results: Platelets hypoergic to adenosine diphosphate (ADP) and arachidonic acid (AA), two common platelet agonists were found in patients with liver disease patients, tumor or severe infections, all of which were without anti-platelet therapy. With a newly established cohort, platelet hypoergic to ADP was validated in patients with liver disease which was significantly correlated with liver disease severity. Platelets function assessed with responsiveness to ADP (ADP inhibition) had independent impacts on 28-day survival of liver failure patients. Unbiased and target proteomics with platelets concentrates found descending pore-performing protein Orai-1 levels which is responsible for impaired extracellular calcium influx. Meanwhile, decreased calpain-2 level was found and validated in platelets which was responsible for impaired platelet shape changing and adhesion to endothelial cells or collagen. Continuous stimulation with high concentration of collagen, significantly elevated in circulation of liver failure patients was responsible for descending Orai-1 and calpain-2 of platelets. Liver failure patients with platelets highly hypoergic to ADP benefited from platelet transfusion(s) and had a higher 28-day survival than those without platelet transfusion.
Conclusion: Platelets hypoergic to ADP due to descending Oai-1 and Calpain-2 was found and validated in patients with severe liver diseases and manifested potential prognostic values. Platelets transfusions was a potential therapy for liver failure patients highly hypoergic to ADP.

FRI-174

The etiology of chronic liver disease is an independent prognostic factor in patients with acutely deteriorated chronic liver disease

Do Seon Song[1], Hee Yeon Kim[2], Young Kul Jung[3], Tae Hyung Kim[3], Hyung Joon Yim[3], Eileen Yoon[4], Ki Tae Suk[5], Jeong-Ju Yoo[6], Sang Gyune Kim[6], Moon Young Kim[7], Young Chang[8], Soung Won Jeong[8], Jae Young Jang[8], Sung-Eun Kim[5], Jung Hee Kim[5], Jung Gil Park[9], Won Kim[10], Dong Joon Kim[5]. *[1]Department of Internal Medicine, St. Vincent's Hospital, The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Bucheon St. Mary's Hospital, The Catholic University of Korea, Seoul, Korea, Rep. of South; [3]Department of Internal Medicine, Korea University Ansan Hospital, Ansan, Korea, Rep. of South; [4]Department of Internal Medicine, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [5]Department of Internal Medicine, Hallym University College of Medicine, Chuncheon, Korea, Rep. of South; [6]Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South; [7]Department of Internal Medicine, Yonsei University Wonju College of Medicine, Wonju, Korea, Rep. of South; [8]Department of Internal Medicine, Soonchunhyang University College of Medicine, Seoul, Korea, Rep. of South; [9]Department of Internal Medicine, Yeungnam University College of Medicine, Daegu, Korea, Rep. of South; [10]Department of Internal Medicine, Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, Korea, Rep. of South*
Email: dsman@catholic.ac.kr

Background and aims: The prognosis for patients with acutely decompensated chronic liver disease (CLD) is very poor. There is a lack of research on the prognostic impact of underlying CLD in patients with acutely decompensated CLD.
Method: We enrolled a total of 1,352 patients, categorized into three groups: those with viral hepatitis (VH) (n = 206), alcoholic liver disease (ALD) (n = 1,017), and a combination of alcohol and viral hepatitis (Combination) (n = 129) based on etiology of underlying CLD. Subgroups analysis were conducted using Propensity Score matching (PSM). Primary outcome was 28-day liver transplantation free survival (TFS).
Results: The VH group had lower Child-Pugh, MELD, MELD-Na, CLIF-SOFA, and CLIF-C OF scores compared to the ALD and Combination groups, while the ALD and Combination groups had similar scores. The 28-day TFS was similar between the VH and ALD groups (P = 0.661), but significantly lower in the Combination group compared to other groups (P < 0.05). In the subgroup analysis comparing the VH and ALD groups after PSM (Subgroup 1), VH group (n = 193) had significantly lower 28-day TFS than ALD group (n = 197) (P = 0.01). In the subgroup analysis comparing the VH and Combination groups after PSM (Subgroup 2), there was no significant difference in 28-day TFS between VH group (n = 132) and Combination group (n = 90) (P = 0.7). In the subgroup analysis comparing the ALD and Combination groups after PSM (Subgroup 3), ALD group (n = 234) had significantly higher 28-day TFS than Combination group (n = 120) (P = 0.04). When comparing patients with a precipitating event of excessive alcohol consumption in the ALD group (n = 640) to patients with a precipitating event of hepatitis virus in the VH group (n = 52), there was no difference in 28-day TFS between the two groups (P = 1.0). However, after PSM, the patients with a precipitating event of hepatitis virus (n = 32) had significantly lower 28-day TFS than the patients with a precipitating event of excessive alcohol consumption (n = 35) (P = 0.04).
Conclusion: Patients with VH as the etiology of underlying CLD exhibit a poorer prognosis compared to those with ALD. Furthermore, the combined ALD and VH group also demonstrates a worse prognosis than the ALD-only group. Thus, different etiologies require different risk prediction methods.

FRI-175

Loss of hepatic leptin clearance is associated with development of acute-on-chronic liver failure

Frederike Krus[1], Robert Schierwagen[1], Jannik Sonnenberg[1], Simone Anna Keimburg[1], Philipp Wöhler[1], Sabine Klein[1], Maximilian Joseph Brol[1], Sara Noemi Reinartz Groba[1], Michael Praktiknjo[1], Jonel Trebicka[1,2], Julia Fischer[1]. *[1]Internal Medicine B, Uniklinik Münster, Münster, Germany; [2]European Foundation for the Study of Chronic Liver Failure - EF Clif, Barcelona, Spain*
Email: frederike.krus@ukmuenster.de

Background and aims: Bacterial infections (BI) are the most frequent trigger for acute-on-chronic liver failure (ACLF) in patients with liver cirrhosis. Dysregulated systemic inflammation (SI) plays a key role in the development of ACLF. Leptin, a metabolic hormone primarily secreted by white adipose tissue, is critically involved in regulating SI as well as in the immune response to BI. However, the exact role of leptin in the progression to ACLF in patients with liver cirrhosis remains unclear.
Method: In this study, the relationship between leptin levels and liver disease was retrospectively analyzed in a cohort of patients with liver cirrhosis who underwent transjugular intrahepatic portosystemic shunt (TIPS) placement. Leptin concentrations were measured in plasma samples taken from the right atrium, hepatic vein, portal vein, and cubital vein at the time of TIPS implantation using enzyme-linked immunosorbent assay (ELISA). The absolute concentrations in the portal vein and hepatic vein were normalized to the cubital vein.
Results: A total of 180 patients were included in the study (58% male; median age: 58.87 years; 59% with alcohol-related liver cirrhosis; Child-Pugh classification: 17% A, 56% B, 15% C). Leptin concentrations

showed a significant positive correlation with body mass index (BMI) (p < 0.0001) and a negative correlation with the absolute leukocyte count (p = 0.0181). Neither age nor sex had a significant impact on leptin concentrations. Patients with liver cirrhosis (Child-Pugh A, B) exhibited significantly higher leptin concentrations in the portal vein compared to the hepatic vein (p = 0.0018). Interestingly, this difference was no longer detectable in advanced liver cirrhosis (Child-Pugh C) or in the presence of ACLF.
Conclusion: Our findings indicate hepatic uptake of leptin, likely originating from the splanchnic circulation, which may contribute to an attenuation in systemic inflammation (as evidenced by leukocyte counts). As liver cirrhosis progresses, the development of leptin resistance appears to exacerbate systemic inflammation and promote the onset of ACLF.

Background and aims: Acute-on-chronic liver failure (ACLF) is characterized by acute decompensation of chronic liver disease and a proinflammatory state mediating multiorgan failure. While some extrahepatic organ failures have been well characterized, involvement of the pancreas remains poorly understood despite shared risk factors with liver disease such as alcohol abuse. This study aims to determine the prevalence, dynamics, and prognostic significance of elevated lipase (eLIP) and (alpha-)amylase (eAMY) in ACLF.
Method: Patients diagnosed with ACLF, as per EASL-CLIF criteria, were retrospectively identified at the Vienna General Hospital between 11/2003 and 11/2022. eLIP and eAMY were defined as enzyme levels ≥3× the upper limit of normal (ULN). Blood and clinical data were collected at 30–180 days pre-ACLF (pre-ACLF), diagnosis (D0), and days 7 (D7), 28 (D28), and 90 (D90) post-diagnosis. Primary outcomes were post-ACLF survival at D28 and D90. Association with mortality was evaluated by uni- and multivariate Cox proportional hazards models adjusted for Model-of-end stage liver disease (MELD), age, sex, and C-reactive protein (CRP). Adjustments were made for all variables considering the respective values at the D0 and D7 timepoints.
Results: Among 193 ACLF patients (G1: 92 (47.7%), G2: 62 (32.1%), G3: 39 (20.2%) mortality was 39.9% at D28 and 53.9% at D90. No significant differences in pancreatic enzyme levels were observed across ACLF grades. At D0, lipase and (alpha-)amylase levels exceeded the ULN in 82 (43.4%) and 96 (54.5%) ACLF patients, respectively. Further, eAMY was detected in 14 patients (8.0%) at D0 and 14 (9.4%) at D7; while eLIP was found in 17 (9.0%) at D0 and 25 (15.7%) at D7, followed by a significant decline in lipase levels from D7 to D90 (p = 0.029). Lipase and alpha-amylase were strongly correlated (Spearman's rho: 0.687; p < 0.001). Only 2 eLIP patients had clinical and/or radiologic signs of de-novo pancreatitis. While neither D0 levels of lipase/(alpha-)amylase nor eLIP/eAMY at D0 were associated with D28 or D90 mortality (all p-values non-significant), eLIP at D7 emerged as an independent risk factor in univariate and multivariate analyses for both D28 mortality (adjusted hazard ratio [aHR]: 2.009, p = 0.035) and D90 mortality (aHR: 2.115, p = 0.010).
Conclusion: Elevated levels of lipase and (alpha-)amylase were common in ACLF patients - while overt clinical/radiologic signs of pancreatitis were mostly absent. Importantly, lipase levels exceeding ≥ 3x ULN during ACLF (at D7) showed a significant association with ACLF-related mortality, suggesting a potential role in disease progression. Further investigation is warranted to elucidate pathomechanisms linking ACLF with pancreatic inflammation and/or dysfunction in ACLF.

FRI-177
HDL-C, Cholesterol and the ALT/HDL-C ratio are predictors of survival in patients with acute-on-chronic liver failure
Georg Kramer[1,2,3], Vlad Taru[1,4,5], Benedikt Simbrunner[1,2,3,4], Benedikt Hofer[1,2,3,4], Nina Dominik[1,2,3], Lorenz Balcar, Lukas Hartl[1,2,3], Mathias Jachs, Michael Schwarz[1,2], Georg Semmler, Christian Sebesta[1,2,3], Paul Thöne[1,2,3], Philipp Schwabl[1,2,3,4], Michael Trauner, Mattias Mandorfer, Thomas Reiberger. Email: georg.kramer@meduniwien.ac.at

Background and aims: The liver is central to lipid metabolism, with reduced levels of high-density lipoprotein (HDL-C), low-density lipoprotein (LDL-C) and total cholesterol commonly seen in advanced chronic liver disease (ACLD), reflecting disease severity. HDL-C plays a key role in modulating immune responses and neutralizing endotoxins – critical mechanisms in acute-on-chronic liver failure (ACLF). This study investigates the alterations in lipid metabolism (HDL-C, LDL-C, total cholesterol, triglycerides) and their prognostic value in ACLF patients.
Method: Patients with ACLF (EASL-CLIF criteria) were retrospectively identified at the Vienna General Hospital from 11/2003 to 11/2022. Blood and clinical data were collected at multiple timepoints: pre-ACLF (30–180 days before ACLF), at ACLF diagnosis (D0), and at days (D) D7, D28 and D90 after ACLF diagnosis. Primary outcomes were survival at D28 and D90. Predictive performance was evaluated using area under the receiver operating characteristic curves (AUROCs) and compared by DeLong's test. Risk factors were identified by uni- and multivariate Cox proportional hazards models, adjusted for the Model for End-Stage Liver Disease (MELD), age, sex, and C-reactive protein (CRP) at D0. Risk stratification was assessed via Kaplan Mayer survival probabilities and log-rank tests.
Results: 193 patients with ACLF were included (G1: 92 (47.7%), G2: 62 (32.1%), G3: 39 (20.2%)); and 77 (39.9%) and 104 (53.9%) died at D28 and at D90, respectively. HDL-C and total cholesterol levels were higher pre-ACLF compared to D0 (p < 0.001) and replenished by D90 (p < 0.001 vs. D0). A similar pattern was observed for LDL-C (pre-ACLF vs. D0: p = 0.022; D0 vs. D90: p = 0.009), while triglycerides showed no significant dynamic. At D0, HDL-C yielded similar AUROCs as the CLIF-C ACLF score for D28 (0.724 vs. 0.787) and D90 (0.736 vs. 0.752) mortality prediction. Since alanine aminotransferase (ALT) was significantly elevated at D0 in higher ACLF grades (G1: 26 vs. G2: 31 vs. G3: 51 U/L; G1 vs. G3, p < 0.001; G2 vs. G3, p = 0.020), we assessed the D0-ALT/HDL-C ratio, which yielded numerically higher AUROCs than the CLIF-C ACLF score for D28- (0.817) and D90- (0.816) mortality. In multivariate analysis, the ALT/HDL-C ratio was an independent risk factor for D28 (adjusted hazard ratio [aHR]: 1.028,

p < 0.001) and D90 mortality (aHR: 1.030, p < 0.001). Effective stratification in low- and high-risk groups was shown by ALT/HDL-C ratio (<2 vs. ≥2, p = 0.002), HDL-C (<20 vs. ≥20 mg/dL, p < 0.001) and total cholesterol (<80 vs. ≥80 mg/dL, p < 0.001).
Conclusion: Lipid biomarkers such as total cholesterol and HDL-C, particularly when assessed as the ALT/HDL-C ratio are strong predictors of survival in ACLF, offering a straightforward and readily available method to stratify ACLF-related mortality risk based on routine lab values.

FRI-178

Development of an AI-driven predictive model and decision support system for managing acute-on-chronic liver failure: insights from the KACLiF cohort

Seong Hee Kang[1], Hyung Joon Yim[1], Young Kul Jung[1], Do Seon Song[2], Eileen Yoon[3], Won Kim[4], Jae Young Jang[5], Dong Joon Kim[6]. *[1]Korea University College of Medicine, Seoul, Korea, Rep. of South; [2]The Catholic University, Seoul, Korea, Rep. of South; [3]Hanyang University College of MEdicine, Seoul, Korea, Rep. of South; [4]Seoul Metropolitan Government Seoul National University Boramae Medical Center, Seoul, Korea, Rep. of South; [5]Soonchunhyang University College of Medicine, Seoul, Korea, Rep. of South; [6]Hallym University College of Medicine, Chuncheon, Korea, Rep. of South*
Email: gudwns21@korea.ac.kr

Background and aims: Acute-on-Chronic Liver Failure (ACLF) is associated with high mortality due to multisystem organ failure. Accurate prediction of mortality is crucial for guiding dialysis therapies and determining the optimal timing for liver transplantation. We hypothesized that artificial intelligence (AI) models are more precise than standard models in predicting outcomes in ACLF.
Method: A novel AI-based model was developed using data collected from patients with MELD scores ≥21. Data were prospectively collected from July 2015 to August 2018 and retrospectively from January 2013 to December 2013 from the Korean Acute-on-Chronic Liver Failure (KACLiF) cohort. The prospective data were split into training and validation sets in a 7:3 ratio and used as the derivation cohort (n = 294), while the retrospective data served as an independent validation cohort (n = 177). Logistic Regression, Random Forest Classifier, XGBoost Classifier, Decision Tree and Elastic Net were employed to refine the selection of significant features. Random Forest was used to evaluate the selected features' ability to predict survival.
Results: The mean MELD scores for the derivation and validation cohorts were 30.1 and 29.9, respectively. The 30-day mortality rates in the derivation and validation cohorts were 26.2% and 29.4%, while the 90-day mortality rates were 34.0% and 40.7%, respectively. In the validation cohort, XGBoost demonstrated the highest AUC of 0.82 for predicting 30-day mortality, and Logistic Regression achieved the highest AUC of 0.84 for predicting 90-day mortality. Baseline international normalized ratio (INR), prior acute deterioration events, circulatory failure, respiratory failure, ascites, hepatic encephalopathy, albumin levels, and systemic inflammatory response syndrome (SIRS) were identified as the top features influencing 30- and 90-day outcomes. The model demonstrated relatively high predictive power and outperformed previously reported models, including MELD (0.74 and 0.67), MELD-Na (0.62 and 0.68), MELD 3.0 (0.69 and 0.65), CLIF-ACLF score (0.63 and 0.63), and CLIF-SOFA score (0.74 and 0.74), in predicting 30- and 90-day mortality.
Conclusion: The AI-based model outperformed previously established models in predicting mortality among patients with severe ACLF, providing a more accurate tool for clinical decision-making.

FRI-179

Integrated analyses of cytokine and metabolomics profiles uncover pathways regulating acute-on-chronic liver failure induced mortality

Yuexiang Bian[1], Jinjun Chen[2], Guohong Deng[3], Xin Zheng[4], Yan Huang[5], Xian-Bo Wang[6], Peixuan Ji[1], Jianyi Wei[1], Yan Zhang[1], Wenyi Gu[1], Adila Abuduaini[1], Kai He[1], Yawen Lu[1], Lining Guo[7], Hai Li[1]. *[1]Department of Gastroenterology, Ren Ji Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai Institute of Digestive Diseases, Shanghai, China; [2]Hepatology Unit, Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China; [3]Department of Infectious Diseases, Southwest Hospital, Third Military Medical University (Army Medical University), Chongqing, China; [4]Department of Infectious Diseases, Institute of Infection and Immunology, Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China; [5]Department of Infectious Diseases, Hunan Key Laboratory of Viral Hepatitis, Xiangya Hospital, Central South University, Changsha, China; [6]Center of Integrative Medicine, Beijing Ditan Hospital, Capital Medical University, Beijing, China; [7]Shanghai Gan Ning Medical Technology Inc., Shanghai, China*
Email: haili_17@126.com

Background and aims: Acute-on-chronic liver failure (ACLF) is a high mortality clinical syndrome of acute hepatic dysfunction in patients with chronic liver diseases. Aside from liver transplantation, the treatment options for ACLF are limited. To develop new therapeutics, it is necessary to gain mechanistic understanding on ACLF pathogenesis. Impaired immunity and dysregulated metabolism are central to ACLF pathogenesis. However, there is lack of comprehensive and integrated analyses in cytokine profiles and metabolomics data to understand key alternations associated with ACLF clinical outcomes.
Method: Using an antibody array for 151 cytokines (covering chemokines, interleukins, tumor necrosis factors, colony-stimulating factors, and transforming growth factors) and a broad-spectrum metabolomics platform measuring over 1,000 annotated metabolites, we analyzed a cohort of 388 plasma samples collected from patients with chronic liver disease at hospital admission due to acute exacerbation. We classified the samples into three groups: non-ACLF (n = 239), ACLF survivor (at 90-day, n = 102), and ACLF non-survivor (n = 47). We used statistical analyses and machine learning methods to identify cytokines and metabolites associated ACLF mortality. We further performed correlation analysis between the cytokine and metabolomic profiles.
Results: Majority of the cytokines were altered between non-ACLF and ACLF survivor group, with intriguing interactions between pro- and anti-inflammatory cytokines. Among the most significant changes were cytokines in the interleukin-1 (IL-1) family, IL-6 family, chemokines, and death receptors in the TNF family. A number of these cytokines were further up-regulated in the ACLF non-survivor group, particularly death receptors TRAILR1, TNFR1 and DR6, 4-1BB, CCL20, CCL21, IL-6, IL18, IL36, IL37, IFN-beta, TGFbeta-2. We found that mitochondrial dysfunction, sphingomyelin metabolism, and polyamine metabolism were high correlated with IL-18 and death receptors, suggesting that these pathways may participate ACLF associated mortality.
Conclusion: Our analyses generated a comprehensive picture of cytokine cascade through ACLF pathogenesis and potential molecular mediators for ACLF pathogenesis. The findings may have therapeutic and diagnostic implications on ACLF patients.

FRI-180

Establishment of a sarcopenia decline curve for patients with liver cirrhosis to develop hepatic rehabilitation medicine

Hiroteru Kamimura[1], Shuji Terai[1], Miida Suguru[1], Hiroki Maruyama[1], Hiroyuki Abe[1], Saori Endo[1], Hitoshi Yoshiji[2], Masahito Shimizu[3], Takumi Kawaguchi[4], Tetsuya Tsuji[5]. *[1]Niigata University, Niigata, Japan; [2]Nara medical University, Nara, Japan; [3]Gifu University, Gifu, Japan; [4]Kurume University, Fukuoka, Japan; [5]Keio University, Tokyo, Japan*
Email: hiroteruk@med.niigata-u.ac.jp

Background and aims: Liver disease is a representative cause of secondary sarcopenia, and liver cirrhosis (LC) complicated by sarcopenia is associated with poor prognosis. Therefore, controlling sarcopenia progression is crucial. This study aimed to analyze factors related to muscle mass decline using the skeletal muscle index at the third lumbar vertebra (L3-SMI; cm^2/m^2), a representative indicator of sarcopenia. Furthermore, we sought to establish and validate a predictive model for muscle mass decline in LC patients.
Method: This multicentred retrospective study included 612 LC patients (375 males; mean age: 70 years) from four facilities who underwent annual CT imaging, including the pelvis, over five years. L3-SMI was measured annually, and factors related to muscle mass decline were analysed. A linear regression model predicting L3-SMI at year five (SMI_5) based on L3-SMI at year one (SMI_1) was developed using our institution's data and validated using external data from three other facilities.
Results: Patients were categorized by Child-Pugh score (A: n = 98, B: n = 75, C: n = 26). The average annual decline rates in L3-SMI were significantly steeper in Child C patients (-1.79 ± 1.92 cm^2/m^2/year) than in Child A (-0.99 ± 0.70 cm^2/m^2/year, p = 0.002). A multiple regression analysis yielded the following predictive formula: $SMI_5 = -1.194 + 0.731SMI_1$ - 2.609 (male) + 0.081BMI - 0.033*age - 4.077 (Child B) - 23.085 (Child C). Validation with data from 343 external patients demonstrated high accuracy ($R^2 = 0.8786$; root mean squared error [RMSE] = 5.39).
Conclusion: This study identified a significant correlation between liver functional reserve (Child-Pugh score) and the rate of muscle mass decline, with worse liver reserve associated with accelerated muscle loss. The developed model accurately predicts future L3-SMI values based on current L3-SMI, age, BMI, and Child-Pugh score. These findings support the potential for personalized hepatic rehabilitation protocols targeting sarcopenia in LC patients. This predictive model lays the foundation for establishing evidence-based hepatic rehabilitation strategies, potentially improving patient outcomes in the field of liver cirrhosis management.

Plasma interleukin-33 as a novel diagnostic marker for invasive pulmonary aspergillosis in patients with acute-on-chronic liver failure: a prospective study

Lanyue Huang[1], Wei Liu[1], Yunhui Liu[1], Liang Chen[1], Meng Zhang[1], Yuxin Niu[1], Yuzhao Feng[1], QiuYu Cheng[1], Tingting Liu[1], Mi Song[1], Qin Ning[1], Tao Chen[1]. *[1]Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China*
Email: hlyue2000@163.com

Background and aims: Invasive pulmonary aspergillosis (IPA) represents a critical and life-threatening complication in patients with acute-on-chronic liver failure (ACLF), characterized by a high rate of short-term mortality. Cytokines play a pivotal role in the pathogenesis of IPA and have been implicated as potential diagnostic biomarkers. The objective of this study is to conduct a comprehensive evaluation of the diagnostic efficacy of cytokines in the context of IPA among ACLF patients.
Method: In this single-center, proof-of-concept and prospective study, we enrolled 216 ACLF patients. Plasma samples and corresponding clinical data were collected throughout their hospitalization. Based on established diagnostic criteria for IPA, 16 patients were designated as the IPA group. For comparative analysis, 32 patients with bacterial pneumonia without IPA (BP group) and 32 patients without any infectious complications (non-infection group) were matched as controls based on gender, age and the severity of liver decompensation. Plasma levels of a panel of cytokines, including including interleukin (IL)-33, IL-17A, IL-23, IL-31, IL-1beta, IL-2, IL-4, IL-6, IL-10, IL-12p70, IL-13, interferon (IFN)-gamma, tumor necrosis factor (TNF)-alpha and soluble IL-2 receptor (sIL-2r), were quantified at the time of IPA diagnosis. The diagnostic performance of these cytokines for IPA was evaluated using receiver operating characteristic (ROC) curve analysis.
Results: No significant difference was observed for patients baseline characteristics among IPA, BP and non-infection groups. Among the three groups, significant differences were observed in IL-33 levels (163.07 [IQR 108.30; 211.22] vs 12.82 [IQR 0.00; 50.55] vs 0.00 [IQR 0.00; 52.51] pg/ml, p = 0.033), IL-6 levels (33.82 [IQR 5.87; 50.04] vs 12.09 [IQR 5.56; 21.32] vs 7.67 [IQR 2.58; 11.47] pg/ml, p = 0.004), IL-4 levels (0.16 [IQR 0.11; 0.27] vs 0.11 [IQR 0.10; 4.92] vs 0.11 [IQR 0.10; 0.12] pg/ml, p = 0.025) and IL-23 levels (10.14 [IQR 9.03; 11.09] vs 10.95 [IQR 10.05; 12.87] vs 11.28 [IQR 9.67; 12.46] pg/ml, p = 0.033), in which only plasma IL-33 level (163.07 [IQR 108.30; 211.22] vs 12.82 [IQR 0.00; 50.55] pg/ml, p < 0.001) was significantly higher in the IPA group, when compared with BP group. ROC curve analysis and determination of cut-off values revealed that IL-33 (AUC = 0.871, cut-off = 66.97 pg/ml, p < 0.001) effectively discriminated between IPA and pulmonary bacterial infections, with a sensitivity of 93.80% and a specificity of 84.40%. Furthermore, IL-33 levels were significantly higher at the time of IPA infection compared to 5–7 days before infection (154.86 vs 2.01 pg/ml, p = 0.003) and 5–7 days after antifungal treatment (154.86 vs 28.01 pg/ml, p = 0.042).
Conclusion: Plasma IL-33 levels demonstrate robust diagnostic potential for IPA in ACLF patients, particularly in distinguishing aspergillus from bacterial infections.

FRI-182

Prediction of circulatory failure in patients with liver cirrhosis and acute-on-chronic liver failure on the intensive care unit

Hendrik Matthias Rogge[1], Martin Schulz[1,2], Kai-Henrik Peiffer[1,2], Maximilian Joseph Brol[1,2], Michael Praktiknjo[1], Stefan Zeuzem[2], Jonel Trebicka[1,2], Frank Erhard Uschner[1,2]. *[1]Department of Internal Medicine B, University Hospital Münster, Münster, Germany; [2]Department of Internal Medicine I, Hospital of the Goethe University Frankfurt, Frankfurt, Germany*
Email: frankerhard.uschner@ukmuenster.de

Background and aims: Acute-on-chronic liver failure (ACLF) classification is based on the modified sepsis-related organ failure (SOFA) score, called CLIF-SOFA. Circulatory status is evaluated utilizing mean arterial pressure (MAP) and need of vasopressor therapy to define organ failure and predict outcome. Previous research failed to identify an optimal MAP target for critically ill patients with ACLF. Nevertheless, early detection of patients at risk for circulatory failure might improve survival. This study aimed to identify predictors of circulatory failure in patients with acute decompensation (AD) or ACLF on the intensive care unit (ICU).
Method: In this cohort study, we analyzed data from 498 cirrhotic patients with AD and/or ACLF admitted to the ICU between March 2015 and June 2019 at the Hospital of the Goethe University Frankfurt. Patients were stratified by presence or absence of circulatory failure according to CLIF-SOFA criteria using (i) a MAP threshold of 70 mmHg and (ii) vasopressor treatment at admission and on day 7. Logistic regression was used to test the predictive value of selected laboratory parameters and outcome measures for circulatory failure on day 7. An algorithm for an alternative circulation score was then developed and integrated into a modified ACLF grading and a recalibrated CLIF-C ACLF score to compare prognostic

precision of the original and modified CLIF-C ACLF scores regarding 28-day mortality.
Results: A MAP threshold < 70 mmHg could not discriminate patients with increased mortality on the ICU in absence of vasopressor treatment (p = 0.5). Lactate dehydrogenase (LDH) and lactate at admission were significantly associated with circulatory failure on day 7, as confirmed by logistic regression analysis. Using LDH and lactate, an algorithm for prediction of circulatory failure during follow-up was developed and aligned with CLIF-C organ failure (OF) score: (i) LDH < 400 U/l *and* lactate < 35 mg/dl (1 point), (ii) LDH ≥400 U/l *or* lactate ≥35 mg/dl (2 points) and (iii) LDH ≥400 U/l *and* lactate ≥35 mg/dl (3 points). Patients with circulatory failure at admission gained an additional point, with a maximum CLIF-C-OF score of 3. The predicted-to-observed mortality alignment within CLIF-C ACLF categories showed improved performance of the modified scores between 60–64 points (65% to 64% vs. 71% to 62%) and ≥65 points (81% to 84% vs. 72% to 85%), while performance in other ranges was comparable (<40, 50–59) or slightly lower (40–49) than original CLIF-C ACLF score.
Conclusion: In our study, MAP was not useful for the prediction of short-term mortality in patients with liver cirrhosis on the ICU. Instead, surrogates of tissue hypoxia, such as lactate and LDH at admission might be suitable to predict circulatory failure and optimize risk stratification in severely diseased patients.

FRI-183
Supporting unified management for patients with prior or first decompensation: evidence from three ACLF criteria
Meiqian Hu[1], Jinjin Luo[1], Yu Wu[2], Jing Zhang[1], Jiaojiao Xin[1], Jing Jiang[1], Dongyan Shi[1], Yu Chen[2], Jun Li[1]. *[1]State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, National Clinical Research Center for Infectious Diseases, National Medical Center for Infectious Diseases, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China; [2]Beijing Municipal Key Laboratory of Liver Failure and Artificial Liver Treatment Research, Fourth Department of Liver Disease, Beijing Youan Hospital, Capital Medical University, Beijing, China*
Email: lijun2009@zju.edu.cn

Background and aims: Acute-on-chronic liver failure (ACLF) is a complicated syndrome associated with a high short-term mortality and reversibility. Whether the prior decompensation should be included in the definition of ACLF is controversial.
Method: A total of 532 patients with prior or first decompensation of chronic liver disease were retrospectively enrolled and analyzed from two Chinese tertiary hospitals from January 2018 to June 2023. Clinical data were used to identify the characteristics and determine prognosis.
Results: Of the 532 patients, 99 patients didn't meet APASL-ACLF criteria due to the exist of prior decompensation and 433 patients met the Asian Pacific Association for the Study of the Liver (APASL)-ACLF criteria. 442 patients met (Chinese Group on the Study of Severe Hepatitis B (COSSH)-ACLF criteria (73 prior decompensation and 369 first decompensation), and 217 patients met Chronic Liver Failure (CLIF)-ACLF criteria (47 prior decompensation and 170 first decompensation). Under three criteria, the two groups had similar characteristics including prognosis scores (APASL/COSSH/CLIF criteria: AARC score, p = 0.033/0.425/0.077; COSSH-ACLF II score, p = 0.934/0.310/0.898; CLIF Consortium ACLF score, p = 0.273/0.635/0.839) and the 28-/90-day mortality rates (APASL/COSSH/CLIF criteria: 28 days, p = 0.267/0.641/0.093; 90 days, p = 0.978/0.709/0.101). In all integrated ACLF patients, Receiver Operating Characteristic (ROC) curve analysis and decision curve analysis (DCA) showed that COSSH-ACLF IIs had higher prognostic efficiency and clinical net benefit than AARC score and CLIF-C ACLFs for 28-/90-day mortality under three criteria.
Conclusion: Prior decompensated patients exhibited clinical characteristics and high short-term mortality similar to those of first decompensated patients. The COSSH-ACLF IIs demonstrated the highest prognostic efficiency for all integrated ACLF patients. Including prior decompensation in the ACLF definition can help to simplify and improve clinical management.

FRI-184
Multidrug-resistant organism colonization and outcomes in critically Ill patients with cirrhosis: evidence from a tertiary care center
Iva Košuta[1], Laura Peretin[2], Frano Šušak[3], Maja Sremac[4], Vibor Šeša[4], Viktor Domislovic[4], Jaksa Babel[1], Dijana Varda Brkić[5], Anna Mrzljak[6]. *[1]Division of Intensive Care Medicine, Department of Internal Medicine, University Hospital Centre Zagreb, Zagreb, Croatia; [2]Gastroenterology Division, Department of Internal Medicine, General Hospital Varaždin, Varaždin, Croatia; [3]Division of Intensive Care Medicine, Department of Internal Medicine, University Hospital Centre Zagreb, Zagreb 10000, Croatia, Zagreb, Croatia; [4]Department of Gastroenterology and Hepatology, Liver Transplant Center, University Hospital Centre Zagreb, Zagreb, Croatia; [5]Department of Clinical and Molecular Microbiology, University Hospital Centre Zagreb, Zagreb, Croatia; [6]Department of Gastroenterology and Hepatology, Liver Transplant Center, University Hospital Centre Zagreb, School of Medicine, University of Zagreb, Zagreb, Croatia*
Email: ivakosuta@gmail.com

Background and aims: Patients with liver cirrhosis are highly susceptible to multidrug-resistant organism (MDRO) colonization, which can influence clinical outcomes. This study evaluated the impact of MDRO colonization on survival and described MDRO prevalence and risk factors for colonization and MDRO infection in critically ill patients with cirrhosis.
Method: This retrospective cohort study included critically ill patients with cirrhosis admitted to a tertiary centre in Zagreb, Croatia (2018–2024). MDRO colonization was assessed via nasal, pharingeal, and rectal swabs at ICU admission and within 5 days. Data collected included clinical, demographic, and laboratory parameters, as well as severity (MELD) and organ failure (SOFA, CLIF-ACLF) scores.
Results: The cohort included 101 patients (median age 56.5 years, 69.3% male), with alcohol-related liver disease as the leading etiology (83.2%). Median MELD score was 14, and 75.2% presented with ACLF (median CLIF-ACLF score 60). MDRO colonization was found in 28.7% at admission and was not associated with 28-day survival (44.8% vs. 52.4%, p = 0.396), though it significantly increased the risk of MDRO infections (75.9% vs. 15.3%, p < 0.001). Risk factors for colonization included lower platelets (OR = 0.985, p = 0.024), diabetes (OR = 4.522, p = 0.011), lower PaO2/FiO2 (OR = 0.995, p = 0.018), and prolonged pre-ICU hospitalization (OR = 1.048, p = 0.049). MDRO infection was linked to prior colonization (OR = 17.604, p < 0.001) and lactulose use (OR = 4.334, p = 0.014). Predictors of mortality included MELD-Na (p = 0.001) and respiratory dysfunction (p = 0.014) in the whole cohort, and CLIF-ACLF score (p = 0.024) in the ACLF subgroup, with neither colonization nor infection affecting mortality.
Conclusion: MDRO colonization and infection were prevalent but did not affect mortality, which was primarily determined by disease severity markers such as MELD-Na, respiratory dysfunction, and CLIF-ACLF score. These findings suggest that once severe organ dysfunction develops, the impact of MDROs on survival diminishes. This highlights the importance of early infection prevention and treatment to mitigate their role in triggering or worsening organ failure, particularly in ACLF patients.

Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Antibiotic resistant infections link with poor outcomes in cirrhosis. SBP prophylaxis (SBPPr) is recommended in selected cirrhosis patients, but recent US-based evidence shows that this results in resistant & recurrent SBP. Moreover, impact on subsequent infections in other regions is unclear. Aim is to determine the impact of pre-admission SBPPr on SBP as a cause of admission in a worldwide cohort of cirrhosis inpatients.

Method: CLEARED consortium enrolls non-electively admitted cirrhosis inpatients & collects inpatient clinical data & course. Comparisons between SBPPr/not vs SBP as a cause of admission was performed using univariate/multivariable analyses. Countries were divided per World Bank into high income (HIC), upper middle (UMIC) & low/low middle income (L/LMIC) countries. Separate analyses were performed for each group.
Results: 7306 patients from 115 centers in 35 countries were enrolled. Mean age was 56 yrs, 64% men, 42% alcohol etiology followed by HBV (19%) & MASH (18%). 35% from HIC, 44% UMIC & 21% from L/LMICs. History: 30%had diabetes, 28% prior HE, 19% prior infections, 29% prior variceal bleed, 18% prior AKI, and11% were listed for transplant. Admission details: 14% were on SBPPr, 10% statins, 34% β-blockers, 44% PPI, 17% HBV antivirals, 25% rifaximin, & 44% on lactulose. Median MELD-Na was 21.0, albumin 2.89 g/dl & WBC 6.21. Infections as a cause for admission: 22% had infections; most with SBP (29%), respiratory (17%), UTI (12%), & spontaneous bacteremia. Comparison SBPPr versus not: SBPPr was ↑in older men and was higher in L/LMICs (46%) vs UMIC (26%) & HIC (28%,p < 0.0001). SBPPr use was higher in alcohol & lower in HBV/Autoimmune etiologies. SBPPr use was higher in pts with prior cirrhosis complications & severity (↑MELD-Na, ↓albumin) and in those listed. PPI, HE-Rx, & β-blocker use was ↑ in SBPPr pts but statin & HBV were statistically similar. SBP as cause for admission and MV analysis: SBPPr pts had significantly higher rate of SBP (39% vs 27%, p = 0.003). MV analysis was done adjusting for SBP Prophylaxis, demographics, comorbidities, prior ascites/HE/AKI/variceal bleed, prior infections, hospitalizations within 6M and current LT listing. HICs: ↑ with SBPPr (OR1.73, p = 0.01), AKI (1.85, p = 0.001), prior infections (1.58, p = 0.02) & ↓with hypertension (0.65, p = 0.03). UMICs, SBPPr trended higher (OR 1.31, p = 0.11) & ↑ with prior infections (2.61, p < 0.0001) & ↓ with alcohol etiology (0.75, p = 0.05) & hypertension (OR 0.61, 0.39–0.97, p = 0.04) L/LMICs, Again ↓ in alcohol etiology (OR 0.75p = 0.04) & ↑ with prior infections (OR 2.31, p < 0.0001). SBPPr was not linked (1.02, p = 0.93).
Conclusion: Outpatient SBP prophylaxis is associated with a higher rate of SBP on admission, especially in high-income countries but not in lower-income countries in a global cohort of >7000 inpatients with cirrhosis.

FRI-186
Rifaximin use does not significantly affect the rate of 30-day mortality or liver transplant in patients with cirrhosis on Daptomycin in two national US-based cohorts
Scott Silvey[1], Nilang Patel[1], Alexander Khoruts[2], Jasmohan Bajaj.
[1]*Virginia Commonwealth University, Richmond, United States;*
[2]*University of Minnesota, Minneapolis, United States*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Antibiotic resistance in cirrhosis leads to poor outcomes, especially near the stage of ACLF. Rifaximin is used extensively for preventing hepatic encephalopathy (HE) recurrence. A recent study showed in vitro and using metagenomics that rifaximin use increases resistance to daptomycin without data on real-world outcomes. We aimed to define the impact of rifaximin on mortality in cirrhosis patients on daptomycin in 2 national US-based cohorts.
Method: We used the Veterans affairs Corporate Data Warehouse (CDW, national database for US Veterans) & TriNetX (large national database of privately insured patients) to extract data using validated codes for cirrhosis patients who were prescribed daptomycin between 2010–19. Rifaximin use >60 days prior was determined. Data related to demographics, cirrhosis severity/complications, concomitant medications were collected. Outcome was 30-day mortality with secondary one being liver transplant (LT). Rifaximin vs not groups were compared & logistic regression for 30-day mortality/LT were performed.
Results: VA-CDW: 2,237 patients were given Daptomycin, of which 118 (5.3%) were on Rifaximin. 511 (22.8%) died 30-days post-Daptomycin and only 59 (2.6%) received LT. Rifaximin users were younger, more likely to be on PPI, diuretics, lactulose & beta-blockers & had higher admission MELD-Na. *Regression impact of rifaximin on 30-day mortality*: After adjusting for cirrhosis severity, patient history, other medication usage, and hospital course, rifaximin use was not statistically significant (adjusted OR: 0.97 [0.52–1.55], p = 0.92). Since < 3% received LT, a separate analysis was not performed here. TriNetX: 2,291 patients were given daptomycin, of which 643 (28.1%) were on Rifaximin. 753 (32.9%) died/ received LT [422 (18.4%) died without LT and 342 (14.9%) received LT]. Again, sicker pts with more advanced cirrhosis were likely to be on rifaximin. *Regression impact of rifaximin on 30-day outcomes*: Composite LT/death: No significant impact of rifaximin(adjusted OR: 1.14 [0.83–1.57], p = 0.411) after adjusting for cirrhosis severity & hospital course. LT-free mortality: This was non-significant (adjusted OR 1.39 [0.94–2.05], p = 0.10) after adjustment. LT alone: Not-significant after adjustment (adjusted OR 1.23 [0.81–1.87], p = 0.33).
Conclusion: In two large complementary US-based experiences, rifaximin use did not significantly impact 30-day mortality and was not a systematic barrier to LT in patients with cirrhosis on daptomycin therapy. This should be reassuring to clinicians after the recent report of potential rifaximin-induced resistance to daptomycin and shows that there is no real-world translation of this findings across large and diverse population experiences.

FRI-187
Long term abdominal drains: a five-year study of safety and efficacy of long-term abdominal drains in a tertiary referral centre
Jemma Mickleburgh[1], Sarah Flatley[1], Claire Salmon[1]. [1]*Sheffield Teaching Hospitals, Sheffield, United Kingdom*
Email: jemma.mickleburgh1@nhs.net

Background and aims: Ascites is the most common cirrhosis complication with one-third of patients progressing to refractory ascites. Most patients are not candidates for liver transplantation or transjugular intrahepatic portosystemic shunt (TIPSS). Remaining options include recurrent large volume paracentesis or insertion of a palliative long-term abdominal drain (LTAD). Data on the efficacy and safety of LTADs is pending the results of the REDUCe2 trial. We aimed to review the LTAD service at Sheffield Teaching Hospitals (STH).
Method: Retrospective single-centre study of all LTAD insertions between December 2019 and October 2024. Inclusion criteria were refractory ascites secondary to cirrhosis, Child-Pugh ≥9, requiring >1 drain per month, life expectancy 3–12 months and not suitable for transplantation/TIPSS.
Results: 37 LTADs were inserted in 29 patients (52% male, age 74 (42–83) years). Underlying aetiology was MASLD (n = 14, 48%), ALD (n = 10, 35%), met-ALD (n = 4, 14%) and PSC (n = 1, 3%). There was a prior history of SBP in 55% (n = 16). 72% (n = 21) were commenced on prophylactic antibiotics post-drain insertion. Complications occurred in 68% of insertions (n = 25), including peritonitis (n = 12, 32%), colonisation (n = 7, 19%), leakage ± cellulitis (n = 7, 18%), displacement (n = 4, 15%) and drain blockage (n = 1, 3%). Peritonitis developed 15.5 (3–79) days post-insertion. Cultured bacteria included gastrointestinal (GI) bacteria in 17% (n = 2); skin commensals in 42% (n = 5); mixed GI and skin commensals in 33% (n = 4); and no growth in 8% (n = 1). 50% (n = 6) of peritonitis cases occurred within 14 days. Of these, skin commensals were cultured in 66% (n = 4). All cases of post-LTAD peritonitis were treated with intravenous antibiotics and 92% (n = 11) required LTAD removal. The time between date of insertion and date of death was 61 (24–206) days.
Conclusion: We believe this is the largest study to date of LTADs. Rates of peritonitis were higher than previously published data (32% vs 6%)[1], whilst rates of leakage, cellulitis, drain displacement and blockage were comparable. Our cohort was older (74 vs 66 years) and had a higher rate of prior SBP (55% vs 7%), which may account for the increased rate of post-LTAD peritonitis. Early infections with a skin commensal may suggest contamination at the point of insertion. This

is a palliative intervention aiming to improve quality of life. For practise, we recommend careful patient selection, to counsel regarding infective risks and to ensure a pre-procedure ascitic tap is completed. We await further data from the REDUCe2 trial.

Modification of mortality risk scores with dynamic serum creatinine definition improves survival discrimination in patients with decompensated cirrhosis

Julian Allgeier[1], Nicholas Zeuzem[1], Alina Bauschen[1], Nikola Mareljic[1], Paul Jamme[1], Johannes Sauter[1], Mona Langer[1], Christiana Graf[1], Cristina Ripoll[2], Christian M. Lange[1]. *[1]Department of Internal Medicine II, Gastroenterology and Hepatology, Ludwigs-Maximilians-Universität, Munich, Germany; [2]Internal Medicine IV, Department for Gastroenterology, Hepatology, Interdisciplinary Endoscopy and Infectious Diseases, Friedrich-Schiller-Universität, Jena, Germany*
Email: julian.allgeier@med.uni-muenchen.de

Background and aims: Acute-on-chronic liver failure (ACLF) is a severe manifestation of decompensated cirrhosis with high short-term mortality. Acute kidney injury (AKI) is a major driver of mortality in this patient group and kidney failure the most common organ failure encountered. Most scores including the Chronic Liver Failure Sequential Organ Failure Assessment (CLIF-SOFA) score assess short-term prognosis, and therefore also priority for liver transplantation, by employing static creatinine values and thus risk underestimating mortality. The aim of our study was to assess whether the addition of dynamic creatinine changes would improve mortality prediction of CLIF-SOFA ACLF grading.
Method: We prospectively included 449 patients in our biobanking system for acute and chronic liver diseases. We identified 225 patients with decompensated liver cirrhosis emergently hospitalized for an acute decompensation event. We screened for development of AKI at or during index hospitalization. We stratified according to Kidney Disease Improving Global Outcomes (KDIGO) AKI definition and assessed transplant-free short-term mortality. We created a modified score for grading of acute-on-chronic liver failure and compared it with the original CLIF-SOFA for mortality prediction.
Results: 75 (33,3%) of patients were female and 154 (68,4%) developed AKI of any stage. 36 (16,0%) of patients died within three months of baseline while 25 (11,1%) received liver transplantation (LT). Kaplan-Meier analysis showed excellent stratification capacity of KDIGO AKI definition (28 - day mortality: No AKI 0%, AKI stage I 6.1%, AKI stage II 15.5%, AKI stage III 31.0%, log-rank: $p < 0.001$) for short term mortality. A modified version of the CLIF-SOFA ACLF definition for kidney failure employing the KDIGO AKI definition reclassified ACLF grade in 30 (13,3%) patients and showed improved discriminative ability compared to the original CLIF-SOFA-ACLF score (Area under the curve (AUC) 0.841 vs. 0.751, $p = 0.0588$). This modification resulted in diagnosis of kidney failure in a subgroup of patients (24) with relevant mortality (28-day mortality: 17.4%) otherwise not classified or underclassified with CLIF-SOFA scoring.
Conclusion: Employment of static serum creatinine values in ACLF definitions underestimates mortality risk in patients with decompensated cirrhosis and renal dysfunction; modification of standard scoring systems to recognize dynamic changes in renal function improves survival prediction compared to CLIF-SOFA ACLF grading, showing excellent discriminative capacity. This is especially important in a time in which patients with ACLF are being short-tracked for liver transplantation.

FRI-192

Loss of paraspinal skeletal muscle tissue is independently associated with increased 90-, but not 28-day mortality in patients with acute-on-chronic liver failure

Matthias Reinhardt[1], Julian Pohl[1], Sina Oesinghaus[1], Teresa Villar de Rohde[1], Pablo Hartmann[1], Nick-Lasse Beetz[2], Dominik Geisel[2], Frank Tacke[1], Cornelius Engelmann[1]. *[1]Department of Hepatology and Gastroenterology, Campus Virchow Klinikum (CVK) and Campus Charité Mitte (CCM), Charité-Universitätsmedizin Berlin, Berlin, Germany; [2]Department of Radiology, Charité-Universitätsmedizin Berlin, Corporate Member of Freie Universität Berlin and Humboldt-Universität zu Berlin, Berlin, Germany*
Email: julian.pohl@charite.de

Background and aims: The loss of skeletal muscle tissue is a highly prevalent complication in patients with cirrhosis carrying significant prognostic implications, whereas Acute-on-Chronic Liver Failure (ACLF) is characterized by a sudden and life-threatening deterioration in the clinical condition of said patients. This study aimed to assess the impact of skeletal muscle tissue loss on 28- and 90-day mortality on patients with ACLF.
Method: 195 patients with ACLF were retrospectively included in this study, conducted at the Charité, Berlin. ACLF was defined according to the EASL-CLIF criteria. Skeletal muscle was estimated by measuring horizontal psoas area adjusted for patients' abdomen height in CT scans. We performed multivariable regression analyses to determine independent risk factors for transplant-free mortality.
Results: In-hospital mortality in our cohort was 49.2% for all ACLF patients. Adjusted psoas area was significantly higher in surviving patients ($p < 0.038$). Univariate Cox analysis for 90-day mortality identified psoas area as a negative predictor, INR and bilirubin as positive predictors of death. Follow-up multivariable analysis revealed psoas area (HR: 0.43, 95% CI: 0.23–0.79, $p < 0.007$), INR (HR: 1.21 95% CI: 1.05–1.39, $p < 0.011$) and bilirubin (HR: 1.04 95% CI: 1.04–1.06, $p < 0.001$) as independent risk factors. No significant impact of psoas area on 28-day survival was observed in subsequent analysis. In the subgroup analyses of patients with a minimal survival of 28-day ($n = 115$), multivariable analysis on 90-day mortality showed again psoas area (HR: 0.24, 95% CI: 0.08–0.78, $p < 0.017$), and bilirubin (HR: 1.07, 95% CI: 1.03–1.1, $p < 0.001$), but not INR as independent risk factors for mortality. Further analysis revealed no significant differences among subgroups in the impact of psoas area on 28- or 90-day mortality when stratified by patient sex or ACLF etiology.
Conclusion: Our study highlights the loss of skeletal muscle tissue as an independent predictor of increased 90-day mortality in ACLF. No significant impact on 28-day mortality was observed, which might indicate that skeletal muscle tissue loss appears to be less relevant for patients in the acute phase of ACLF, rather than in the further course of disease. These findings have to be validated in further studies and may help to identify ACLF patients who are at risk of death medium-term and also could improve in-hospital management strategies.

FRI-193

A machine-learning algorithm using real-world data identified subpopulations at risk for adverse outcomes in patients with acute-on-chronic liver failure

Email: pierbruno.ricci@genfit.com

Background and aims: Acute-on-chronic liver failure (ACLF) is associated with high morbidity and mortality, yet risk stratification in real-world settings remains challenging. This study aims to leverage real-world data (RWD) using machine learning (ML) algorithms to identify subpopulations of patients with varying risks for mortality, transplant-free survival (TFS), and time to hospital discharge (TTD).
Method: Using the U.S.-claims-based Komodo's Healthcare Map linked with Komodo Lab Results, routine and specialized laboratory tests curated by Komodo Health, from 2017 to 2024, we analyzed data from 278,593 patients with ACLF, defined according to EASL-CLIF criteria. Starting from more than 1,000 features related to ACLF, final subsets of features associated with mortality, TFS, and TTD were selected and used to build prognostic models at 90 days for each of these clinical outcomes. The cohort was randomly split into training (75%) and test (25%) sets. LightGBM modeled mortality and TFS, while Cox proportional hazards (CoxPH) estimated TTD. Feature importance rankings defined clinically relevant subpopulation. Models were validated on the test set, and mean risks for each subpopulation were computed.
Results: Models showed high performance with an Area Under the Receiver Operating Characteristic curve (AUROC) of 0.79 for mortality, 0.80 for TFS; the CoxPH model achieved a concordance index (C-index) of 0.70 for TTD. The mean risk of mortality estimated by the model in the whole study population was 0.21. Patients presenting with hepatorenal syndrome showed the highest increase in mean risk of mortality (0.42, 2-fold increase vs whole population), followed by patients with endotracheal intubation (0.40, 1.9-fold), cerebral or coagulation failure (0.39, 1.8-fold), respiratory failure (0.35, 1.7-fold) and circulatory failure (0.31, 1.5-fold). History of alcohol related liver disease was the etiology associated with the highest increase in risk of mortality (0.33, 1.6-fold increase). Patients presenting with hepatic encephalopathy or ascites (0.28, 1.3-fold), and sepsis (0.24, 1.2-fold) were also at higher risk of mortality. On the other hand, we identified subpopulations with lower risk of adverse outcomes (mortality, TFS, TTD), which included patients with history of Type 2 diabetes, insulin, statin, and metformin prescription. The decrease in mortality risk for the specified subpopulations ranged 0.7 to 0.8-fold vs the estimated mean risk in the whole ACLF population.
Conclusion: Using US RWD, this study identified subpopulations with higher and lower risks of mortality, TFS, and TTD compared with the whole ACLF population. These findings may inform clinical trial design, precision treatments, and multidisciplinary care to optimize outcomes and resource use in real-world settings.

FRI-194

Impact of home-based hepatology nurse-led care on disease knowledge in recently hospitalised patients with cirrhosis

Leya Nedumannil[1], Catherine Yu[1], Mustafa Mohamedrashed[1], Kristen Peake[1], Kendall Fitzpatrick[1], Vanessa Lowen[1], Diana Lewis[1], Siddharth Sood[1]. [1]*The Northern Hospital, Melbourne, Australia*
Email: leya.nedumannil@hotmail.com

Background and aims: Insufficient disease knowledge in patients with cirrhosis contributes to suboptimal disease management and increased healthcare utilisation. We aimed to evaluate the impact of Liver At Home (L@H), a novel 3-month home-based program designed for recently hospitalised patients with cirrhosis, on patient disease knowledge. L@H provides continued outpatient care through regular hepatology nurse home visits/telehealth reviews with a focus on the management of cirrhosis-related complications and prevention of readmissions.
Method: Patients with cirrhosis admitted under the Gastroenterology Unit of a tertiary metropolitan tertiary hospital and enrolled to L@H between 01/03/2023–01/09/2024 were assessed on knowledge regarding cirrhosis. A cirrhosis knowledge questionnaire, previously validated in patients with cirrhosis, was offered on a voluntary basis at the time of enrolment (day of hospital discharge) and culmination of L@H. The questionnaire comprised 14 questions, each scored out of 1, covering the management of ascites (out of-5), varices (out of-3), hepatic encephalopathy (HE) (out of-3), hepatocellular carcinoma (out of-1), and diet/lifestyle (out of 3). Primary outcome was total knowledge score, and secondary outcome was breakdown scores for each knowledge category. Results at the beginning and end of L@H were compared using Chi square and Mann-Whitney U tests for categorical and continuous variables, respectively.
Results: Of 89 patients enrolled to L@H in the study period, 20 completed the questionnaire at both enrolment (baseline) and discharge from the program [median age 56 years (IQR 43.5–70.5), 30% (n = 6) female, Child Pugh score 7 (IQR 7–10), MELD-Na score 17.5 (IQR 12.5–20.5)]. Of these patients, 80% (n = 16) had ascites, 10% (n = 2) had variceal bleeding, and 25% (n = 5) had ≥ Grade II HE during hospital admission. Baseline median total knowledge score was 7.5/14 (IQR 7–9), which significantly improved to 9/14 (IQR 9–12) at discharge from L@H ($p < 0.001$). Most patients (n = 17, 85%) demonstrated improved knowledge scores at the culmination of the program. Median breakdown scores revealed significantly improved knowledge regarding ascites [4/5 (IQR 3–5) vs. 3 (IQR 2–3.5), $p = 0.003$], trend towards improved knowledge regarding HE [2/3 (IQR 1–3) vs. 1 (IQR 0.5–2), $p = 0.084$], and stable knowledge regarding varices [2/3 (IQR 2–3) vs. 2 (IQR 1.5–3)] on discharge from L@H.
Conclusion: Patient education is a pivotal aspect of chronic disease management. The findings of this study highlight the potential of specialist hepatology nurse-led transitional care programs for recently hospitalised patients with cirrhosis as an intervention to help improve their disease knowledge and awareness regarding the major complications of this complex condition.

FRI-195

Single-cell multimodal analysis reveals cellular dynamics underlying divergent immune response trajectories in HBV-ACLF progression

Jun Li[1], Xi Liang[1], Jinjin Luo[1], Qian Zhou[1], Jiaojiao Xin[1], Jiaqi Li[2], Jing Jiang[1], Meiqian Hu[1], Peng Li[3], Pengcheng Chen[4], Heng Yao[1], Huafeng Zhang[1], Xingping Zhou[1], Jiaxian Chen[1], Wen Hu[1], Bingqi Li[1], Shiwen Ma[1], Xiao Wu[1], Xiao Li[1], Jing Zhang[1], Xin Chen[5], Dongyan Shi[1]. Email: lijun2009@zju.edu.cn

Background and aims: Acute-on-chronic liver failure (ACLF) is a life-threatening syndrome involving dysfunction of multiple immune cell types. This study aimed to comprehensively depict the dynamic trajectory of immune responses throughout the disease course of hepatitis B virus-related ACLF (HBV-ACLF).
Method: Single-cell RNA sequencing (scRNA-seq) and single-cell proteomics were performed on the peripheral blood mononuclear cells (PBMCs) of 45 samples from 17 hospitalized patients (progressive/stable/recovering course of HBV-ACLF, 6/5/6) and 15 control subjects (liver cirrhosis, chronic hepatitis B and healthy controls, 5/5/5). Bulk RNA-seq and flow cytometry of PBMCs were performed for external validation.
Results: Single-cell transcriptomics revealed specific alterations in the peripheral immune response in ACLF. VCAN+CD14+-monocytes with activated interferon-stimulated genes and increased inflammatory functions expanded in ACLF-1, contributing to early inflammatory storm. Low-density hyperinflammatory CXCR2+-neutrophils and M2 macrophage-like CD163+-monocytes predominated in progressive ACLF patients, serving as significant markers of disease deterioration. Elevated anti-inflammatory signalling, including ENTPD1-TMIGD3 and IL1B-IL1R2 interactions, correlated with disease severity. Highly activated cytotoxic T cells were increased in recovering patients. Natural killer cells decreased during ACLF progression, exhibiting impaired cytotoxic and metabolic functions. Six cellular modules were identified, highlighting a specific immune pattern (CM3) that could be focused as an optimal therapeutic window. The proteomic profiling showed high concordance with the transcriptomic data. External validation with bulk RNA-seq and flow cytometry confirmed the immune cell clusters involved in ACLF progression.
Conclusion: Our longitudinal multiomics study revealed the dynamic evolution of the immune response in HBV-ACLF and characterized diverse immune patterns for the precise management and therapeutic intervention.

Email: lijun2009@zju.edu.cn

Background and aims: Acute-on-chronic liver failure (ACLF) of various aetiologies is a complicated syndrome with high short-term mortality. A globally applicable diagnostic framework and accurate prognostic score for ACLF are urgently needed.
Method: Clinical data from 7388 prospectively enrolled patients with acute deterioration of chronic liver disease across various aetiologies were used to evaluate the performance of European Association for the Study of the Liver (EASL)-ACLF and Chinese Group on the Study of Severe Hepatitis B (COSSH)-ACLF criteria. Three non-Asian cohorts were performed to validate the results.
Results: Among 5288 enrolled patients, 844 patients were diagnosed with ACLF using EASL-ACLF criteria (321 with non-hepatitis B virus (HBV) aetiology, 523 with HBV aetiology), while 2038 patients were diagnosed using COSSH-ACLF criteria (602 with non-HBV aetiology, 1436 with HBV aetiology). COSSH-ACLF criteria identified 22.6% more patients compared to EASL-ACLF, including 14.2% more patients with non-HBV aetiology. COSSH-ACLF criteria also produced a more reasonable diagnostic distribution (Grade 1–3: 63.4%/27.5%/9.1%) compared to EASL-ACLF (Grade 1–3: 25.8%/56.3%/17.9%). The 28-/90-day mortality rates for patients diagnosed using COSSH-ACLF criteria were significantly lower than those under EASL-ACLF criteria (27.3%/41.0% vs. 40.7%/57.0%, both $p < 0.0001$), which may help to identify more patients with a golden window receiving early treatment. COSSH-ACLF II score showed the highest predictive values for 28-/90-day mortality in both cirrhotic and all ACLF patients (n = 844/2038) with various aetiologies, outperforming the CLIF-C ACLF and other scores. The similar outperformance of China-CLIF score was validated in three non-Asian cohorts.
Conclusion: COSSH-ACLF criteria and COSSH-ACLF II score can effectively diagnose and accurately prognose ACLF patients with all aetiologies. These findings could pave the way for improved global clinical management of ACLF.

Hospital Arnau de Vilanova, Valencia, Spain; [9]Universidad Cardenal Herrera-CEU Universities, Valencia, Spain*
Email: mapibafe@gmail.com

Background and aims: A simple, cost-effective and objective tool remains an unmet need for risk stratification of liver-related events (LRE) and death (LRD) in outpatients with cirrhosis. Recently, the AMMON-OHE model has been validated for the prediction of overt hepatic encephalopathy (OHE) occurrence, with a superior predictive performance than traditional psychometric tests and disease severity scores. This study was performed to test the ability of the AMMON-OHE model compared with other prognostic scores for risk stratification regarding development of LRE, acute-on-chronic liver failure and LRD in outpatients with cirrhosis.
Method: This observational, prospective international cohort study included 1575 outpatients with cirrhosis from 5 independent liver units. The primary endpoint was a composite of bacterial infection, variceal bleeding, new onset or worsening of ascites and OHE (defining LRE). Secondary endpoints were ACLF and LRD. Random forest methods were used and Integrated Brier Scores (IBS) were calculated to evaluate performance of each model.
Results: Overall, 597 (38%) patients developed LRE, 143 (10%) ACLF and 202 (13%) died over a median follow-up of 17 (IQR 4–46) months. The AMMON-OHE model showed an IBS of 0.180 for liver-related complications, with a lower prediction error than MELD (0.212), MELD-Na (0.210), MELD 3.0 (0.206), Child-Pugh (0.185), and other combinations of albumin, creatinine, INR, sodium and white blood cell count (0.183–0.104). Its higher predictive accuracy was reproduced for bacterial infection (IBS 0.135), variceal bleeding (IBS 0.069) and ACLF (IBS 0.085).
Conclusion: The results of the study show that the AMMON-OHE model performs better than the currently used prognostic models to identify outpatients with cirrhosis at highest risk for developing LRE.

FRI-198

Benefit-to-risk profile in the label-specific population of patients with hepatorenal syndrome-acute kidney injury treated with terlipressin

Michael Curry[1], Sanaz Cardoza[2], Richard Wu[2], Hugo Vargas[3], Chris Pappas[4]. *[1]Beth Israel Deaconess Medical Center, Boston, MA, United States; [2]Mallinckrodt Pharmaceuticals, Bridgewater, NJ, United States; [3]Mayo Clinic, Scottsdale, AZ, United States; [4]Orphan Therapeutics, LLC, Longboat Key, FL, United States*
Email: mcurry@bidmc.harvard.edu

Background and aims: Hepatorenal syndrome-acute kidney injury (HRS-AKI) is a deadly but potentially reversible form of AKI that occurs in patients with cirrhosis and ascites. Terlipressin, a vasopressin analogue, is FDA-approved to treat adult patients with HRS with a rapid worsening in kidney function, and is recommended as first-line treatment (in combination with albumin) for HRS-AKI per EASL and AASLD guidelines. A mitigation strategy to increase effectiveness and decrease the risk of respiratory failure adverse events (AEs) was developed to identify patients with a more favorable benefit-to-risk profile with terlipressin; these patients are referred to as the "label-specific population" (LSP) and include acute-on-chronic liver failure (ACLF) grade < 3, serum creatinine (SCr) < 5 mg/dL, and Model for End-Stage Liver Disease (MELD) score < 35 (if transplant listed). This study evaluated efficacy and safety outcomes in the LSP compared with those patients who do not meet any of the label-specific criteria (ie, the non-label-specific population [non-LSP]).
Method: HRS reversal—defined as a SCr level of ≤1.5 mg/dL—and the incidence of AEs and death were retrospectively assessed in the LSP and non-LSP of patients with HRS-AKI from the Phase III placebo-controlled CONFIRM study (NCT02770716).
Results: The incidence of HRS reversal in the terlipressin arm was 44.7% (59/132) in the LSP vs 19.4% (13/67) in the non-LSP; 18.3% (13/71) vs 13.3% (4/30) among patients in the placebo arm, in the LSP vs non-LSP, respectively. The incidence of AEs in the terlipressin arm was 87.9% (116/132) vs 88.2% (60/68); in the placebo arm, 88.7% (63/71) vs 89.3% (25/28), in the LSP vs non-LSP, respectively. The incidence of respiratory failure in the terlipressin arm was 6.1% (8/132) vs 19.1% (13/68); in the placebo arm, 4.2% (3/71) vs 7.1% (2/28), in the LSP vs non-LSP, respectively. The incidence of AEs leading to death up to 30 days posttreatment in the terlipressin arm was 34.1% (45/132) in the LSP vs 55.9% (38/68) in the non-LSP; in the placebo arm, 40.8% (29/71) in the LSP vs 39.3% (11/28) in the non-LSP. Respiratory failure was the cause of death in the terlipressin arm in 5.3% (7/132) of patients in the LSP vs 14.7% (10/68) in the non-LSP; in the placebo arm, in 1.4% (1/71) of patients in the LSP vs 0% (0/28) in the non-LSP.
Conclusion: Terlipressin improves the rate of HRS reversal vs placebo, especially in the LSP, as compared with the non-LSP. In the terlipressin arm, selection of the LSP vs the non-LSP resulted in approximately a 3.1-times lower incidence of respiratory failure, and a 2.8-times lower incidence of respiratory failure as a cause of death up to 30 days posttreatment. Selection of patients in the LSP leads to an improvement in the benefit-to-risk profile of patients with HRS-AKI treated with terlipressin.

FRI-199

Fibroblast growth factor 19 (FGF-19) predicts transplant free-survival in critically ill patients with acute-on-chronic liver failure

Maike Rebecca Pollmanns[1], Miclaire Soch[1], Philipp Hohlstein[1], Samira Abu Jhaisha[1], Jule Adams[1], Elena Kabak[1], Ralf Weiskirchen[2], Alexander Koch[1], Theresa Hildegard Wirtz[1]. *[1]Medical Department III, RWTH Aachen University Hospital, Aachen, Germany; [2]Institute of Molecular Pathobiochemistry, Experimental Gene Therapy and Clinical Chemistry (IFMPEGKC), RWTH Aachen University Hospital, Aachen, Germany*
Email: mpollmanns@ukaachen.de

Background and aims: Acute-on-chronic liver failure (ACLF) is a complex syndrome characterized by acute decompensation of cirrhosis (AD) and multiorgan dysfunction, leading to high short-term mortality. Fibroblast growth factor 19 (FGF-19), involved in regulation of bile acid synthesis and cellular stress response, has been linked to liver disease progression; however, its role in ACLF remains to be elucidated. This study aimed to evaluate its prognostic relevance in critically ill patients with ACLF.
Method: Data of 161 patients admitted to the medical intensive care unit (ICU) at RWTH Aachen University Hospital between 2015 and 2021 due to ACLF were retrospectively analysed. Serum samples were collected at ICU admission and after 48 hours. Serum samples from 20 healthy individuals were used as controls. All samples underwent

measurement of FGF-19 concentrations by enzyme linked immunosorbent assay (ELISA).
Results: FGF-19 serum concentrations were significantly elevated in patients compared to controls ($p = 0.004$) and correlated with ACLF severity ($p = 0.002$). Moreover, a positive correlation of FGF-19 was observed with total bilirubin, aspartate aminotransferase (AST), international normalized ratio (INR) and the model of end stage liver disease (MELD) score (all corrected $p < 0.001$). Patients who deceased or were transplanted had significantly higher FGF-19 concentrations at all investigated time points, including short-term (30, 60, and 90 days) and long-term (180 and 365 days) survival analyses (all $p < 0.001$). Cox regression analysis identified FGF-19 as an independent predictor of transplant-free survival ($p < 0.001$). An FGF-19 serum concentration of >168 pg/mL at ICU admission was associated with a reduced one-year transplant-free survival ($p < 0.001$).
Conclusion: FGF-19 serum concentrations correlate with disease severity in critically ill patients with ACLF and predict transplant-free survival. Further studies should address underlying mechanisms and evaluate the therapeutic potential of anti-FGF-19 targeted therapies in these patients.

FRI-200
Interleukin-22 is a predictor for pre-ACLF and short-term mortality in cirrhosis
Nikola Mareljic[1], Mona-May Langer[1], Lena Oeckl[1], Marc Weiß[1], Helena Stadler[1], Quan Yin[1], Christian M. Lange. *[1]LMU Klinikum, LMU University Hospital Munich, Department of Internal Medicine II, Munich, Germany*
Email: nikola.mareljic@med.uni-muenchen.de

Background and aims: Interleukin-22 (IL-22) is known to promote hepatoprotective or detrimental properties. Schwarzkopf et al. elucidated the role of IL-22 in acute-on-chronic liver failure (ACLF). In summary, serum levels of IL-22 were associated with ACLF ($p < 0.001$) and increased mortality ($p < 0.01$). In this study we analyzed associations between IL-22 plasma levels and clinical endpoints of patients with liver cirrhosis. Thereby we focused on different courses of decompensation as outlined in the PREDICT study.
Method: A retrospective analysis was conducted in clinical data of patients ($N = 204$) diagnosed with liver cirrhosis. Baseline IL-22 plasma concentrations were quantified and correlated with clinical endpoints observed over a 90-day follow-up period. IL-22 levels were assessed using enzyme-linked immunosorbent assay (ELISA) methodology.
Results: Plasma IL-22 concentrations in patients with compensated cirrhosis were comparable to those of healthy controls. In contrast, patients experiencing decompensation showed significantly higher IL-22 levels (healthy vs. decompensated, $p = 0.005$), with further increases noted in those with ACLF (healthy vs. ACLF, $p < 0.0001$). No significant variations in IL-22 levels were observed across different decompensation courses (chronic, acute stable, acute unstable); however, patients classified as pre-ACLF demonstrated significantly higher IL-22 concentrations in comparison to chronic, acute stable, and acute unstable decompensated cohorts ($p = 0.028$; $p = 0.029$; $p = 0.001$, respectively). Additional analyses indicated low IL-22 concentrations in patients without current ACLF and those who did not progress to ACLF. Patients who recovered from ACLF during the 90-day observation period showed intermediate IL-22 levels. Highest IL-22 concentrations were observed in patients with pre-ACLF and persistent ACLF. Furthermore, IL-22 plasma levels were significantly higher in patients who died within 30 days, regardless of ACLF status ($p = 0.04$). Strongest correlation was identified between IL-22 plasma levels and 7-day mortality ($p < 0.0001$).
Conclusion: IL-22 is associated with adverse outcomes in liver cirrhosis, particularly in the context of pre-ACLF and ACLF. These findings support the potential utility of IL-22 as a biomarker for predicting the dynamics of ACLF and short-term mortality in affected patients.

FRI-205
Non-acute decompensation of cirrhosis is a clinically and biologically distinct phenotype in cirrhosis
Nipun Verma[1], Parminder Kaur[1], Pratibha Garg[1], Vivek Ranjan[2], Samonee Ralmilay[1], Sahaj Rathi, Arka De, Madhumita Premkumar, Sunil Taneja[1], Akash Roy[3], Mahesh Goenka[3], Ajay Kumar Duseja[1], Rajiv Jalan[4]. *[1]Department of Hepatology, Postgraduate Institute of Medical Education and Research, Chandigarh, India, Chandigarh, India; [2]Institute of Gastrosciences and Liver Transplantation, Apollo Multispeciality Hospitals, Kolkata, India, Kolkata, India; [3]Institute of Gastrosciences and Liver Transplantation, Apollo Multispeciality Hospitals, Kolkata, India, Kolkatta, India; [4]University College London, Royal Free Campus, Institute for Liver and Digestive Health, London, United Kingdom, London, United Kingdom*
Email: r.jalan@ucl.ac.uk

Background and aims: The presentation patterns of decompensations in cirrhosis are heterogeneous, conferring varying outcomes. While acute decompensation (AD) is associated with the poorest prognosis, the clinical profile and outcomes of non-acute decompensation (NAD) remain unclear. This study aimed to characterize the clinical and pathophysiological features of NAD.
Method: A prospective, two-center study enrolled patients across the cirrhosis spectrum between 2020 and 2023: compensated cirrhosis (CC, $n = 29$), NAD ($n = 311$), and AD ($n = 201$). Clinical and laboratory parameters, cytokine levels (IL-6, TNF, IL-10, MCP-1), and cell death markers (M30, M65, Gasdermin-D, Receptor-interacting-protein-kinase; RIPK3, Mixed lineage kinase domain-like; MLKL) were assessed at baseline and patients were followed-up for 12 months. Overall survival and its determinants were evaluated in patients presenting as NAD.
Results: Patients with NAD had a poorer 12-month survival (81.7%) compared to CC (100%), but superior to AD (31.2%) ($p < 0.001$). Although the inflammatory cytokine levels were not different between CC and NAD ($p > 0.05$), cell death markers, particularly Gasdermin-D and RIPK3 (median with IQR)-in ng/ml were significantly elevated in patients with NAD [2.5 (2.2–2.9) and 2.4 (2.3–2.9)] compared to healthy [0.9 (0.8–1.0) and 0.9 (0.8–1.0)] and patients with CC [1.8 (1.6–1.9) and 1.8 (1.2–1.9)], $p < 0.001$, each. Both inflammatory and cell death markers were most pronounced in AD. Over 12 months, the cumulative incidence of progression to AD among NAD was 55.1%, significantly reducing their survival (68.2% vs. 95.3%, $p < 0.001$). Predictors of such progression to AD in competing risk survival models included severe ascites, lower IGF-1, albumin, BMI, and higher bilirubin, CTP, MELD, Gasdermin-D, and RIPK3 levels.
Conclusion: NAD represents a clinically, prognostically and pathophysiologically distinct clinical phenotype in cirrhosis. Patients with NAD had elevated cell death markers and severity scores and are at risk of progression to AD and mortality. Identifying NAD and high-risk populations within NAD should trigger enhanced protocols to prevent the progression to AD. Modulation of cell death is a novel and potentially disease-modifying target in cirrhosis.

FRI-206
Excess ICU mortality in septic patients with cirrhosis compared to a population without cirrhosis in two contemporary prospective cohorts
Natalia Jimenez-Esquivel[1], Jose Ignacio Retta[1], Juliana Zapatero[1], David Toapanta[1], Enric Reverter[1], Javier Fernández[1,2], Octavi Bassegoda[1]. *[1]Liver ICU, Liver Unit, Clinic Barcelona, Barcelona, Spain; [2]EF-CLIF Consortium, Barcelona, Spain*
Email: njimeneze@clinic.cat

Background and aims: Sepsis is common in patients with cirrhosis and may require admission to intensive care units (ICU). Previous studies suggested that short-term mortality exceeded 50%, which has

limited ICU access for these patients, due to perceived futility. Our hypothesis is that this excess in mortality is not as high and may be partly due to a higher number and severity of organ failures at ICU admission. Our aim is to analyze ICU mortality from sepsis in a cohort of patients with cirrhosis compared to a cohort without cirrhosis.
Method: This is a prospective cohort study including all consecutive patients with sepsis admitted to the Liver ICU at Clínic Barcelona from February 2022 to September 2024. ICU mortality was analyzed using logistic regression, adjusted for scales measuring the number and severity of organ failures, such as SOFA and APACHE II at admission.
Results: Of 1,475 admissions, 502 (34%) presented sepsis. Of these, 207 (41%) had cirrhosis, and 295 (58%) did not. The most common infection sources in patients with cirrhosis were abdominal (22%), respiratory (15%), and bloodstream infections without a clear focus (14%). In non-cirrhotic patients, the most common source was abdominal (38%), followed by respiratory (22%). Among cirrhotic patients, 68% required vasoactive support and 31% required respiratory support, compared to 51% and 18%, respectively, in non-cirrhotic patients. ICU mortality in cirrhotic patients was 24%, compared to 10% in non-cirrhotic patients. SOFA and APACHE scores were higher in patients with cirrhosis. The risk of mortality was higher in cirrhotic patients, with an odds ratio (OR) of 2.6 (95% CI 1.6–4.48). When adjusted for APACHE, the risk of mortality decreased to an OR of 1.96 (95% CI 1.14–3.39) and was no longer significantly higher when adjusted for SOFA, with an OR of 1.31 (95% CI 0.74–2.3).
Conclusion: Patients with cirrhosis admitted to the ICU for sepsis have higher mortality than a similar cohort without cirrhosis. However, this does not justify reduced access to intensive care. This excess mortality is partly due to the greater number and severity of organ failures at admission.

FRI-207

A retrospective study of puncture counts and diagnostic accuracy in 119 patients undergoing transjugular liver biopsy

Asako Nogami[1], Naohiro Wada[1], Michihiro Iwaki[1], Takashi Kobayashi[1], Atsushi Nakajima[1], Satoru Saito[1,2], Masato Yoneda[1]. *[1]Yokohama City University Graduate School of Medicine, Yokohama, Japan; [2]Sanno Hospital, Tokyo, Japan*
Email: nogamia@yokohama-cu.ac.jp

Background and aims: Transjugular liver biopsy (TJLB) is a vital diagnostic tool for liver disease patients, particularly those with ascites or coagulopathy. Unlike percutaneous liver biopsy, which uses a 16–18G needle and typically requires a single puncture, TJLB often involves multiple punctures with an 18G needle due to challenges like fragmented or insufficient tissue samples. This study retrospectively analyzed 119 TJLB cases over 15 years, evaluating puncture counts, tissue acquisition success rates, and diagnostic accuracy.
Method: We reviewed 119 cases of TJLB performed between December 2009 and November 2024, using an 18G needle for all procedures at our institution. Patients undergoing TJLB were those with ascites, coagulopathy, or cases where discontinuation of antithrombotic therapy was deemed challenging. Additional indications included suspected hematologic disorders, amyloidosis, or idiopathic portal hypertension requiring hepatic venous pressure gradient (HVPG) measurement. The procedure was concluded once a sufficient tissue sample was obtained, confirmed by visual inspection. We assessed the number of punctures, tissue acquisition success rates, and diagnostic outcomes.
Results: The cohort included 119 patients (50 males, 69 females) with a mean age of 54.2 years (range: 17–86). The average platelet count was 134,000/mm³ (range: 2,000–70,900/mm³), and the average PT-INR was 1.5 (range: 0.5–4.3). Key indications for TJLB were ascites (53.8%), PT-INR >1.5 (37.8%), ongoing anticoagulation (5.0%), platelet count < 50,000/mm³ (4.2%), and prior blood transfusions (27.7%). Suspected hematologic disorders were noted in 27.7% of cases, and HVPG measurement was performed in 77.3%. Tissue was successfully obtained in 104 cases (87.4%), with complications in 3 cases (2.5%, 1 bleeding, 2 renal biopsy). Among 103 cases with recorded puncture counts, the average number of punctures was 2.8 (range: 1–6), and the average number of tissue samples was 2.3 (range: 0–1). Puncture distributions were: 10 cases with 1 puncture, 39 with 2, 32 with 3, 13 with 4, 5 with 5, and 4 with 6. The success rates for obtaining tissue were 90% for 1 puncture, 97.4% for 2, 88.5% for 3, 76.9% for 4, 68% for 5, and 70.8% for 6 punctures. The percentage of cases with adequate tissue samples for diagnostics was 70% for 1 puncture, 100% for 2, 96.9% for 3, 92.3% for 4, 60% for 5, and 100% for 6.
Conclusion: This study highlights that TJLB is a safe procedure enabling the reliable collection of tissue samples. Additionally, it analysed tissue acquisition rates in relation to the number of punctures performed during TJLB cases. Despite an average of 2.8 punctures, a higher number of punctures did not correlate with better tissue acquisition. It was found that cases requiring multiple punctures often had underlying challenges that made tissue collection difficult in a single attempt. Further studies are needed to identify which case characteristics predict successful tissue acquisition.

FRI-208

Pre-existing sarcopenia as the 7th organ failure and one of the leading predictors of 90-day mortality in acute decompensated cirrhosis

Yan Ling Ong[1], Sakktivel Elangovan[1], Jeanette Ng[1], Pooi Ling Loi[1], Nazia Chowdhury[1], Hiang Keat Tan[2], Marianne DeRoza[3], Chanda Ho[2], Jason Pik Eu Chang[2], Rahul Kumar[1,4]. *[1]Department of Gastroenterology and Hepatology, Changi General Hospital, Singapore, Singapore; [2]Department of Gastroenterology and Hepatology, Singapore General Hospital, Singapore, Singapore; [3]Department of Gastroenterology and Hepatology, Sengkang General Hospital, Singapore, Singapore; [4]Duke-NUS Medical School, Singapore, Singapore*
Email: ongyanlings@gmail.com

Background and aims: The short-term mortality of acute decompensation (AD) of cirrhosis is dependent on the development of organ failures. Sarcopenia is common in decompensated cirrhosis but its prognostic implications are poorly understood. Intense systemic inflammation has also been reported as a predictor of mortality. This study aims to determine the transplant-free short-term mortality (90-day) of AD and investigate the role of sarcopenia and inflammatory mediators in AD.
Method: In this multicentre prospective study, 249 patient visits were analysed. AD and acute-on-chronic liver failure (ACLF) were defined according to EASL-CLIF consortium definitions. Sarcopenia was assessed using psoas muscle index (PMI) calculated at the third lumbar vertebra level on computed tomography scan done within the last one year. PMI cut-offs for sarcopenia were 6.36 cm^2/m^2 for men and 3.92 cm^2/m^2 for women. Systemic inflammation was assessed using white cell count (WCC) and neutrophil to lymphocyte ratio (NLR). Standard statistical tests were used for group comparisons. Predictors of mortality were analyzed using Cox-proportional hazards regression. Multivariable logistic regression analysis was done to determine the independent predictors of 90-day mortality.
Results: Majority were male (66.7%). Alcohol was the predominant etiology (44.2%) followed by MASLD (27.7%). 57 patients (22.9%) had ACLF; 32 (12.9%) had grade-1, 16 (6.4%) had grade-2, and 9 (3.6%) had grade-3 ACLF. 61 patients (24.5%) had sarcopenia, of which 14 had ACLF as well. The 28- and 90-day mortality of the overall cohort were 11.6% and 28.1% respectively. Mortality in AD were 6.3% and 22.4% while in ACLF, were 29.8% and 47.4% at 28- and 90-day respectively. In the univariate analysis, predictors of 90-day mortality were presence of sarcopenia ($p < 0.001$), MELD score ($p < 0.001$), NLR ($p < 0.001$), WCC ($p = 0.008$), high serum bilirubin ($p = 0.002$), high creatinine ($p = 0.003$), circulatory failure ($p < 0.001$), liver failure ($p = 0.001$), renal failure ($p = 0.005$), cerebral failure ($p = 0.008$), coagulation failure ($p = 0.019$) and respiratory failure ($p = 0.043$). A multivariate logistic regression analysis with MELD, sarcopenia, WCC, respiratory, cerebral

and circulatory failure showed that MELD, sarcopenia and circulatory failure were the independent predictors of mortality (p < 0.05 for all). In another multivariable model involving EASL-CLIF defined organ failures, sarcopenia (aHR: 2.79 (95%CI: 1.70–4.58); p < 0.001), circulatory failure (aHR: 3.76 (95%CI: 1.77–7.98); p < 0.001), liver failure (aHR: 2.64 (95%CI: 1.31–5.32); p = 0.007), renal failure (aHR: 1.89 (95%CI: 1.03–3.48); p = 0.040) and cerebral failure (aHR: 2.23 (95%CI: 1.01–4.92); p = 0.048) were independent predictors of 90-day mortality.

Conclusion: The result of this study shows that in addition to CLIF-C OF score, presence of sarcopenia should be treated as the 7th organ failure as it is one of the independent predictors of 28- and 90-day mortality in acutely decompensated cirrhosis.

FRI-209

Prevalence of advanced liver fibrosis and accuracy of non-invasive tests in primary, secondary and tertiary care in Austria

Email: paul.thoene@meduniwien.ac.at

Background and aims: Background and aims: Identifying individuals with steatotic liver disease (SLD) and advanced fibrosis is crucial, as these are at increased risk for liver and non-liver-related morbidity and mortality, and subject to intensified medical management and potential new therapies. Therefore, we studied patient characteristics, fibrosis prevalence and accuracy of emerging blood-based non-invasive tests (NITs) throughout elastography-based screening initiatives in primary, secondary and tertiary care.

Method: Five cohorts spanning primary-tertiary care including unselected individuals (colonoscopy screening, n = 1197, Cohort I), those at risk of SLD (metabolic risk factors/prediabetes, n = 1333/n = 996, Cohort II/III), and after referral to hepatology outpatient clinics (n = 2397/n = 2598, Cohort IV/V) between 2016 and 2024 were retrospectively included. All subjects underwent liver stiffness measurement (LSM) with controlled attenuation parameter (CAP), clinical and laboratory examination on the same day (Cohort I-IV) or within 90 days (Cohort V). NITs included LiverPRO, LiverRisk score, and CORE.

Results: Mean age was 49.1–58.3 years (range across cohorts), 51%-61% were male, mean BMI was 26.8–31.3 kg/m², 21–59% were obese (BMI ≥30 kg/m²), 25–100% had prediabetes. Mean CAP was 262–294 dB/m and 57–82% showed hepatic steatosis (defined by CAP ≥248 dB/m). Suspected advanced fibrosis (LSM ≥8 kPa) was found in 6.4% of Cohort I, 7.3/6.8% of Cohort II/III, and 21/30% of Cohort IV/V. This prevalence was especially high in obese subjects (15, 10/14, 38/38%) and individuals with diabetes (11. 17/NA, 52/49%). However, the prevalence in individuals with overweight, prediabetes or elevated ALT/GGT was not increased. Applying possible referral strategies, sensitivity of LiverPRO ≥25% (71, 51/51, 87/88%) was higher for LSM ≥8 kPa across primary, secondary and tertiary care as compared to FIB-4 >1.3 (44, 33/37, 69/62%) and LiverRisk score ≥6 (52, 31/39, 86/78%) at lower specificity and comparable PPV. However, screening based on lab-based tests did only marginally increase net-benefit for true- and false-positives (using LSM ≥8 kPa as a reference) in primary/secondary care. Overall diagnostic accuracy for LSM ≥8 kPa was numerically higher for LiverPRO (area under the curve: 0.755, 0.595/0.632), LiverRisk (0.746, 0.607/0.621) and CORE score (0.726, 0.583/0.636) in primary/secondary care as compared to FIB-4 (0.612, 0.576/0.571).

Conclusion: Prevalence of suspected advanced fibrosis/cirrhosis was 6–7% in primary/secondary care populations undergoing liver fibrosis screening in Austria, and 20–30% in tertiary care, being pronounced in individuals with diabetes or obesity, but neither overweight, prediabetes nor elevated ALT/GGT. In low-prevalence settings, LiverPRO had higher sensitivity to detect individuals with LSM ≥8 kPa as compared to FIB-4 and LiverRisk score.

FRI-210

Impact of blood cell count derived inflammatory markers on the outcome of critically ill cirrhotic patients

Maria Eduarda Soares[1], Anna Clara Rios Rocha[2], Bianca Sampaio de Carvalho[2], Lucas Celes Dominguez[1], Jade de Oliveira Santana[2], Fabiola Santos Sousa[2], Myriam Sofia Angeli Guimarães de Oliveira[2], Mariana Rebouças de Calasans[2], Liana Codes[3], Paulo Bittencourt[3].

Email: mechavessoares@gmail.com

Background and aims: Neutrophil-to-lymphocyte (NLR) and monocyte-to-lymphocyte-(MLR) ratios and systemic immune-inflammation index (SII) have been associated with adverse outcomes in critically ill cirrhotic patients with acute decompensation (AD) or acute on chronic liver failure (ACLF). The aim of this present study is to investigate the performance of leukocyte markers, including NLR, MLR and SII in predicting mortality of cirrhotic patients admitted to the ICU with AD and ACLF.

Method: All patients admitted to the ICU with decompensated cirrhosis with and without ACLF were retrospectively evaluated. All leukocyte markers were calculated in the first three hours of ICU admission. Their ability to predict mortality was measured using the analysis of the area under the receiver operating characteristic curve (AUC). Primary outcome was in-hospital mortality.

Results: Six hundred and two patients (444 males, mean age 67 ± 12 years) with either AD (n = 360) or ACLF (n = 242) were investigated. Baseline NLR, MLR and SII of those patients were, respectively, 12.7 ± 7, 0.96 ± 0.67 and 1.547 ± 717. Mortality was observed in 102 (17%) patients. NLR (21.5 [16.4–21.5] *vs.* 10.9 [9.7–12.3] in survivors, (p < 0,001), MLR (1.20 [0.96–1.49] *vs.* 0.95 [0.81–1.00] in survivors, p < 0,001) and SII (2617.6 [1966.1–3.269.1] *vs.* 1.328.4 [1088.4–1568.5] in survivors, p < 0,001) were associated with in-hospital mortality. After exclusion of patients with ACLF, even higher AUCs were observed for SII (0.754) and NLR (0.746).

Conclusion: Leukocyte ratios, particularly SII and NLR are readily available and low-cost biomarkers capable of predicting mortality in patients with decompensated cirrhosis irrespective of the presence of concurrent ACLF.

FRI-211

Vasopressin is safe and effective as a second vasopressor in patients with cirrhosis and septic shock: results of the VITEL-C trial. NCT05315557

Rakhi Maiwall[1], Vishnu Girish[1], Harshvardhan Tevethia[1], Mohit Prajapati[1], Fagun Sharma[1], Dr. Prashant Mohan Agarwal[1], Satender Pal Singh[1], Vijayraghavan Rajan[1], Sumegh Talwalkar[1],

Ayush Jain[1], Bindiya Arora[1], Priyanka Sharma[1], Charvi Nayyar[1], Sherin Thomas[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: rakhi_2011@yahoo.co.in

Background and aims: Septic shock in critically ill patients with cirrhosis (CIC) is associated with high mortality and requires targeted management. Terlipressin (TERLI) and vasopressin (VASO) are used as second-line vasopressors after norepinephrine (NE), but their comparative efficacy and safety have not been established. Additionally, vasopressin has not been studied in CIC. We hypothesized that VASO would be non-inferior to TERLI as an add-on agent for reversing septic shock in CIC.
Method: Open-label randomized controlled trial; CIC patients in septic shock unresponsive to NE at 0.05 μg/kg/min were randomly assigned to either VASO (0.03 U/min) or TERLI (1 mg/24 hours). NE doses were titrated to maintain a target mean arterial pressure (MAP) of ≥65 mmHg. The primary outcome was shock reversal at 6 hours(h), defined as cessation of NE.
Results: Patients with septic shock with mean age 46.7 ± 10.4 years, 97% males, 41% alcohol-related, with 67% pneumonia, mean SOFA score 12.5 ± 1.9 were randomized to receive VASO (n = 50) or TERLI (n = 50). Baseline characteristics were similar: MAP [(63.36 ± 12.59) vs. (62.18 ± 10.4) mmHg; p = 0.61], arterial lactate [(3.76 ± 1.65 mmol/L) vs. (3.40 ± 1.35 mmol/L); p = 0.240], KDIGO stage of acute kidney injury [0 (34% vs. 38%), 1 (34% vs. 22%), 2 (16% vs. 20%), 3 (16% vs. 20%); p = 0.61], MELD scores [(28.38 ± 8.62) vs. (30.13 ± 8.62); p = 0.313]. The reversal of shock at 6 h [(58% vs. 48%); p = 0.32] including dose of vasopressors in norepinephrine equivalents (0.15 ± 0.19 vs. 0.17 ± 0.12 ug/kg/min) was similar in TERLI vs. VASO. The reversal of shock at 72 h was also comparable [(34% vs. 50%); p = 0.11], however, rapid reversal of shock at 3 h (22% vs. 6%; p = 0.02) and significantly improved urine output at 6 h [(55.1 ± 21.9) vs. (41.6 ± 22.93); p = 0.003], and at 12 h [(49.0 ± 25.1) vs. (39.8 ± 20.7); p = 0.048] were observed in TERLI vs. VASO, respectively. KDIGO stage at 72 h [0(14% vs. 28%), 1(40% vs. 30%), 2(8% vs. 6%), 3(38% vs. 6%); p = 0.36], need for dialysis (42% vs. 42%; p = 0.10), 28-day mortality (84% vs. 80%; p = 0.60), days of mechanical ventilation [(5.28 ± 3.59) vs. (4.48 ± 2.86); p = 0.22] were similar in TERLI vs. VASO. A significant improvement in systemic vascular resistance (SVR) at 12 h and 24 h (p < 0.05) and lactate clearance at 6 h [(−2.69 ± 16.48) vs. (−10.65 ± 18.23); p = 0.02] and 24 h [(−0.067 ± 17.42) vs. (−14.76 ± 21.90); p < 0.001] was seen with VASO compared to TERLI. Adverse events (34% vs. 8%; p = 0.001) and rebound hypotension (44.1% vs. 21.2%; p = 0.046) were significantly higher with TERLI. The majority of adverse events were ischemic and occurred after 12 h.
Conclusion: In CIC with septic shock, vasopressin is comparable to terlipressin as an adjunct to NE in reversing shock. While terlipressin led to a faster reversal of shock, it was associated with a higher incidence of adverse events and rebound hypotension. Vasopressin is a safer and effective second-line vasopressor for CIC with septic shock.
[Trial Registration: NCT05315557].

Background and aims: Critically ill patients with cirrhosis and ascites are at high risk of developing intra-abdominal hypertension (IAH), which is associated with increased mortality. Clinical guidelines recommend maintaining intra-abdominal pressure (IAP) below 16 mmHg. However, over 75% of these patients develop IAH within the first week of ICU admission. Large-volume paracentesis (LVP) is the standard treatment to relieve abdominal wall tension in these patients, resulting in intermittent reduction of IAP associated with transient improvements in renal and pulmonary function. Continuous passive paracentesis (CPP) offers a strategy to treat and prevent IAH, potentially improving clinical outcomes. However, no studies have compared paracentesis strategies for IAH management. This study aims to compare clinical outcomes of patients with cirrhosis and ascites treated with CPP versus LVP in intensive care.
Method: A randomized clinical trial in a tertiary hospital center, open to collaboration with other centers, with an estimated duration of 36 months. A total of 72 patients with liver cirrhosis and grade 2 ascites will be enrolled and randomly allocated (1:1) to either the LVP (control) or CPP (intervention) groups. Randomization within the initial 24 hours of admission will be stratified based on maximum values of serum creatinine concentration (sCr) and IAP. LVP will be performed intermittently according to clinical guidelines, while CPP will drain ascitic fluid for up to 7 days. The primary outcome is sCr measured up to day 7, with secondary outcomes including 28-day mortality.
Results: Between September 2022 and November 2024, 89 patients were screened, and 26 (29%) were included in the study and in this preliminary analysis (LVP n = 10 vs. CPP n = 16, henceforth). The most frequent exclusion criterium was minimal ascites (n = 21). The median patient age was 58 (50–62) years-old and male gender represented 73%. Clinical severity at admission showed SAPS II 44 (30–76), MELD-Na 31 (25–38), ACLF 3 (1–3) and CLIF-SOFA 13 (9–17) and CLIF-C 56 (37–63) median score values. The baseline sCr was similar between groups (2.0 vs 1.9 mg/dL, p = 0.9). The results for sCr from days 1 to 4 post-randomization are presented. No significant differences between groups were observed (general linear model repeated measures, p = 0.06). The overall 28-day mortality rate was 42%, with no significant group difference (50% vs. 38%, p = 0.7), as depicted by Kaplan-Meier analysis.
Conclusion: This preliminary analysis of the COPPTRIAHL clinical trial revealed a slow patient recruitment rate. There was no significant difference in sCr or 28-day mortality between critically ill patients with cirrhosis and ascites submitted to LVP or CPP.
The study remains open for collaboration with other centers. ClinicalTrials.gov registration NCT04322201. Protocol published in Trials, 24, 534 (2023).

FRI-213-YI
The presence of chronic kidney disease does not worsen 28- or 90-day survival in cirrhotic patients with acute on chronic liver failure

Sakktivel Elangovan[1], Yan Ling Ong[1], Jeanette Ng[1], Pooi Ling Loi[1], Nazia Chowdhury[1], Hiang Keat Tan[2], Marianne DeRoza[3], Chanda Ho[2], Jason Pik Eu Chang[2], Rahul Kumar[1,4]. Email: sakktivel.elangovan@mohh.com.sg

Background and aims: With the rise in metabolic associated steatotic liver disease (MASLD), patients presenting with acute decompensation (AD) of cirrhosis with pre-existing chronic kidney disease (CKD) is increasing. AD with organ failures is known as acute on chronic liver failure (ACLF) and exhibits high mortality. The CANONIC study showed that kidney failure (KF) was the strongest prognostic factor for worse outcomes in ACLF. Currently however, there is no clarity on the prognostic implication of CKD in either AD or ACLF as published literature [1, 2] excluded these patients. The aim of

this study thus is to evaluate the impact of underlying CKD on 28- and 90-day mortality in patients with AD and ACLF.
Method: In this multicenter prospective study of "predictors of decompensation, ACLF and mortality in cirrhosis (SoLiDaRity-DAM), 396 AD patients visits were analyzed. AD and ACLF was defined as per e-CLIFF consortium definitions [1]. CKD was defined as glomerular filtration rate (eGFR) < 60 for minimum 3 months and loss of corticomedullary differentiation on renal ultrasonography. The study was approved by the institutional review board and was in accordance of declaration of Helsinki. Standard statistical tests were used for group comparison. Predictors of mortality was analyzed using Cox-proportional hazards regression. Patients were characterized in 4 groups, No ACLF with and without CKD and ACLF with or without CKD for Kaplan-Meier survival function.
Results: Out of 396, majority were male (67.2%) with mean age of 64.4 ± 11.5 years. Alcoholic was the predominant etiology (43%) followed by MASLD (30%). CKD was adjudicated for 75 (18.9%), whereas 62% of the cohort has at least 1 metabolic dysfunction. A total of 89 (22.5%) had ACLF of which 53 (60%) had grade-1, 22 (25%) grade-2, and 12 (13%) had grade-III ACLF. The 28 and 90- day mortality was (44/396) 11% and (99/396) 25% respectively. The important predictors of 90-days mortality were serum creatinine (p = 0.005), CRP (p = 0.036), procalcitonin (p = 0.022), Bilirubin (p < 0.001) and MELD score (p < 0.001). Of the organ failures, liver, renal, circulatory and brain (p < 0.001 for all) were, whereas coagulation and respiratory failure were not 90-days mortality predictors. The prevalence of CKD was 19%. CKD was adjudicated in 43% patients with ACLF and 12% without ACLF and most importantly presence of CKD was not a predictor of 90-days mortality. The highest probability of 90-day survival corresponded to patients with CKD but no ACLF (81%) which mirrors the survival of patients without CKD or ACLF (p = NS between the groups). The worst survival was seen in patients with ACLF but no CKD (57%) which mirrors the survival of patients with CKD who developed ACLF (p = NS).
Conclusion: The result of our study shows that the presence of CKD does not impact the survival in patients admitted with AD or ACLF. Further large-scale prospective, multicenter studies with biomarkers of CKD are suggested.

FRI-214
Predicting the risk of clinically relevant bleeding in patients with acute-on-chronic liver failure and acute decompensated liver cirrhosis
Sanna Norén[1], Charlotte Gran[2], Staffan Wahlin[1], Gabriel Dumitrescu[3], Per Stal[1], Maria Magnusson[4]. Email: sanna.noren@ki.se

Background and aims: Hemostasis in acute decompensated liver cirrhosis (AD) and acute-on-chronic liver failure (ACLF) is complex and a challenge in the clinical setting. This study aims to predict clinically relevant bleeding in patients with AD or ACLF using two new point-of-care laboratory methods: the Quantra hemostasis system (Quantra) and the Total Thrombus formation Analysis System (T-TAS).
Method: In this interim analysis, individuals with decompensated liver cirrhosis were prospectively included at a tertiary hepatology center. Hemostasis was assessed with T-TAS and Quantra at inclusion and patients were followed up for 28 days for clinically relevant non-variceal bleeding. Non-variceal bleeding was defined as major bleeding, relevant minor bleeding and non-relevant minor bleeding according to the International Society on Thrombosis and Haemostasis. Quantra is a viscoelastic test that uses sonic assessment to evaluate the elasticity and formation of a clot, measuring clotting time. T-TAS measures the elevation of flow pressure during platelet plug formation (PL-chip) and fibrin clot formation (HD-chip) and is presented as the area under the curve (AUC). Individuals with clinically relevant bleeding (major bleeding or relevant minor bleeding) were compared to a combined group of non-relevant bleeding and no bleeding using the Mann-Whitney U-test.
Results: 47 consecutive patients, 17 with ACLF and 30 with AD, were included. The ACLF group had significantly (p = 0.02) lower AUC using the PL-chip suggesting smaller and/or less stable platelet plugs in the ACLF group. In contrast, no difference in fibrin clot formation and/or stability was observed between ACLF and AD using the HD-chip (p = 0.33). Quantra clotting time was significantly longer in the ACLF group than the AD group (p = 0.01). We documented 19 bleedings in the first 28 days: 8 major bleedings, 5 relevant minor bleedings and 6 non-relevant minor bleedings. The T-TAS showed a significantly reduced AUC of the PL-chip in patients with clinically relevant bleeding (major or relevant minor bleeding) compared to patients with non-relevant or no bleeding (p = 0.029) indicating a diminished capacity for platelet aggregation in patients with clinically relevant bleeding. HD-chip did not show a difference between the groups (p = 0.087). Quantra clotting time showed a significantly increased clotting time (p = 0.02) in the group with clinically relevant bleeding compared to the others, suggesting a risk for clinically relevant bleeding in patients with a clotting time over 150 seconds.
Conclusion: T-TAS and Quantra both show promising potential to predict the risk of clinically relevant bleeding in patients with ACLF and AD. The result of the T-TAS PL-chip indicate a compromised primary hemostasis in patients with subsequent clinically relevant non-variceal bleeding. This will be further evaluated in our ongoing study.

FRI-215
An argument for risk-based case-finding in chronic liver disease
Sava Handjiev[1,2], Ruairi Lynch[1,2], John F. Dillon[1,2]. [1]*University of Dundee, Dundee, United Kingdom;* [2]*NHS Tayside, Dundee, United Kingdom*
Email: sava.handjiev@nhs.scot

Background and aims: Most Liver disease is preventable, if diagnosed early, yet 75% of cirrhotic patients are diagnosed at presentation with liver failure. 25% die within 60 days. There is no strategy for optimium identification of patients. This study aims to identify what proportion of patients admitted were known to have prior alcohol excess, type 2 diabetes mellitus (T2DM), or abnormal liver function tests (LFTs), to provide evidence for targeted case finding to reduce presentations with decompensated cirrhosis.
Method: Records of patients aged 18 and over admitted to NHS Tayside with an ICD-10 code for liver disease between August 2018 and July 2023 were interrogated to quantify the proportion who presented because of decompensated liver disease, and if these were known to have T2DM, consume excess alcohol, or had an LFT in the 3–12 months prior to admission.
Results: Of the 7387 admissions, 634 individuals were primarily admitted for liver disease (541 in liver failure) of which 408 (64%) presented due to alcohol-related liver disease (ALD), 82 (13%) due to metabolic dysfunction-associated liver disease (MASLD), 52 (8%) due to hepatocellular carcinoma (HCC), 31 (5%) due to MASLD and increased alcohol intake (MetALD), 22 (3%) with other/unspecified aetiology (including cryptogenic cirrhosis), 19 (3%) due to

autoimmune hepatitis, 10 and 3 (2%) due to primary biliary cirrhosis and primary sclerosing cholangitis, respectively, 6 and 2 (1%) due to hepatitis C and B viruses, respectively, and 1 due to Wilson's disease. Overall, 355 (53%) had a history of excess alcohol use prior to admission and 173 (27%) had T2DM. For the ALD + MetALD subgroup, 333/439 (76%) had a history of excess alcohol use. For the MASLD + MetALD subgroup, 79/113 (70%) had T2DM. 316 (50%) of patients had LFTs checked by primary care 3–12 months prior to admission; this increased to 65% if LFTs taken in secondary care were counted. Of these 316, median alanine aminotransferase (ALT) was 43 U/L, interquartile range (IQR) 26–61. For ALD and MASLD it was 46 U/L (31–65) and 29 U/L (22–44), respectively. 67% had ALTs ≤55 U/L (lab's upper limit of normal (ULN)), 34% had ALTs ≤30 U/L (the true ULN), and 17% had both an ALT ≤30 U/L and alkaline phosphatase (ALP) ≤130 U/L. For the combined ALD + MASLD + MetALD subgroup, 448/521 (86%) patients could be identified before presentation if they had a known history of excess alcohol use, T2DM, or LFTs demonstrating an ALT >30 U/L or ALP >130 U/L.

Conclusion: Of patients admitted to hospital for liver disease, 50% had LFTs checked in primary care (65% in total), 3–12 months before admission. For those, depending on ULN used, 34% and 67% of ALTs were within reference intervals Knowing whether patients have T2DM, alcohol excess or abnormal LFTs could mean up to 86% of patients with ALD, MASLD or MetALD are identified, and it remains to be seen whether non-invasive fibrosis scores could pick up the remainder, provided these patients are tested.

Interprofessional therapeutic drug monitoring of Piperacillin/Tazobactam enhances care for patients with acute-on-chronic liver failure in the ICU

Stephan Schmid[1], Chiara Koch[1], Jonas Buttenschoen[1], Petra Stöckert[1], Vlad Pavel[1], Katharina Zimmermann[1], Georgios Athanasoulas[1], Sophie Schlosser-Hupf[1], Martina Müller-Schilling[1], Alexander Kratzer[2]. [1]*Department of Internal Medicine I, University Hospital Regensburg, Regensburg, Germany;* [2]*Hospital Pharmacy, University Hospital Regensburg, Regensburg, Germany*
Email: stephan.schmid@ukr.de

Background and aims: Acute-on-chronic liver failure (ACLF) is a rapidly progressive and severe condition in patients with underlying liver cirrhosis, frequently precipitated by bacterial infections. Effective and timely management of these infections, particularly with targeted antibiotic therapy, is critical. Piperacillin/Tazobactam is a key agent for treating severe infections in critically ill patients. However, optimizing its dosing is challenging due to altered pharmacokinetics in ACLF patients. Therapeutic drug monitoring (TDM) offers a precise, evidence-based approach to achieving optimal drug concentrations, especially for time-dependent antibiotics like Piperacillin/Tazobactam. This study aimed to evaluate the impact of an interprofessional TDM strategy on optimizing Piperacillin/Tazobactam dosing in ACLF patients in the intensive care unit (ICU).

Method: This analysis was conducted in a medical ICU with a strong interprofessional framework, including physicians, clinical pharmacists, and nursing staff. Twenty-seven ACLF patients underwent initial TDM, and eight received follow-up TDM. Serum concentrations of Piperacillin/Tazobactam were measured weekly using high-performance liquid chromatography (HPLC). Patient severity was characterized using Child-Pugh, SOFA, MELD, and CLIF-C-ACLF scoring systems. TDM results guided individualized dosing adjustments, and the outcomes were compared to a seasonally adjusted control cohort without TDM intervention. The adherence to interprofessional recommendations for dose adjustments or antibiotic switches was assessed.

Results: Initial TDM revealed that 63% of patients achieved Piperacillin/Tazobactam serum concentrations within the target range, while 22% exceeded and 15% fell below the target. Follow-up TDM demonstrated improved outcomes, with 75% of patients achieving target concentrations, 25% exceeding the range, and none falling below. In five cases, antibiotic switches were recommended due to resistance or clinical necessity, and all recommendations for dose adjustments or therapy changes were fully implemented. The interprofessional approach ensured consistent adherence to evidence-based dosing strategies, reflecting robust team collaboration.

Conclusion: The integration of an interprofessional TDM strategy significantly optimized Piperacillin/Tazobactam dosing in critically ill ACLF patients. This approach led to higher rates of target achievement and facilitated individualized antibiotic management. Beyond improving clinical outcomes, this strategy underscores the importance of rational antibiotic use in critically ill patients and contributes to global efforts to combat antimicrobial resistance. The findings highlight the value of TDM in achieving precision medicine in complex patient populations, such as those with ACLF.

FRI-221

APASL ACLF research consortium (AARC) liver failure score and first week(transplant window) defines the limits of medical management and time frame for liver transplant in acute on chronic liver failure patients

Background and aims: Acute-on-Chronic Liver Failure (ACLF) is associated with a high risk of short-term mortality in the absence of liver transplantation (LT). This study aimed to evaluate the AARC score's effectiveness in predicting 90-day survival and determining the appropriate timing for LT in ACLF patients.
Method: We analysed data from the AARC registry data of 7721 patients enrolled between Dec 2012 to Nov 2023. Patients aged 18 to 70 years with a diagnosis ACLF according to the APASL criteria were enrolled in the study and prospectively followed for up to 90 days or liver transplantation. Predictors of 90-day mortality were identified through multivariate Cox regression analysis. To evaluate the predictive accuracy, a propensity matching analysis was performed for ACLF patients who underwent liver transplantation (n = 265) with 3 times matched non-transplant cohort (n = 795). The AARC score was dynamically evaluated at time points (days 4, 7, 15, and 28 post-hospitalization) to predict 90-day outcomes by repeated measures analysis with a General Estimating Equations (GEE) model.
Results: Of the 7,721 ACLF patients, mean age of 44.4+12.4 years and 85% being male. The cohort is relatively sick with MELD (29.5 ± 7.3), SOFA (9.2 ± 3.2), CLIF SOFA (11.6 ± 2.7) and AARC Score (10.2 ± 1.4) with only 421 cases (5.45%) had undergone LT. The survival among the non-transplanted cohort is 45.6% at 90 days. In multivariate analysis, age >55 years (HR = 1.013, 95% CI 1.005–1.022, p = 0.002), new-onset sepsis within the first week (HR = 3.02, 95% CI 2.15–4.02, p < 0.001), and baseline AARC score (HR = 1.435, 95% CI 1.37–1.50, p < 0.001) as independent predictors of mortality. The mortality rate was 29% for patients with an AARC score of 5–8, rose sharply to 62% for those with a score of 10, and exceeded 92% for patients with a score of 13 or higher. For patients with a baseline AARC score of 10 or greater, the 90-day mortality rate was 76.5%, which increased to 92.8% if the score remained unchanged at day 7. Conversely, patients with an AARC score below 10 had a 90-day mortality rate of 30.2%, which further decreased to 12% if the score remained stable after 7 days. Median survival was significantly higher in the LT group (76.8%, 95% CI 73.2–80.5 days) compared to the non-LT group (50.9%, 95% CI 48.7–53.8days) (p < 0.001). Among non-survivors, cumulative mortality was 31% by the end of the first week, escalating sharply to 55% by the second week and 78% by the fourth week, highlighting the importance of first week.
Conclusion: The AARC score is a reliable tool for stratifying ACLF patients, guiding the timing and necessity of liver transplantation. Patients with an AARC score of 10 or more during the first week of hospitalization i.e. the "transplant window" should be considered for early LT to improve clinical outcomes. This model will assist clinicians in making timely decisions regarding whether to escalate to LT or manage conservatively.

FRI-222

One-week criteria of potential care inappropriateness for patients with acute-on-chronic liver failure not eligible for liver transplantation

Thierry Gustot[1], Javier Fernández[2], Eva Uson[3], Cristina Sanchez[3], Paolo Angeli[4], Rajiv Jalan[5], Jonel Trebicka[6], Vicente Arroyo[3], Flair Jose Carrilho[7], Richard Moreau[3]. *[1]HUB Hôpital Erasme, Université Libre de Bruxelles, Brussels, Belgium; [2]Hospital Clinic, Barcelona, Spain; [3]EF-Clif, Barcelona, Spain; [4]University Hospital of Padova, Padova, Italy; [5]Royal Free Hospital and University College of London, London, United Kingdom; [6]University Clinic Münster, Münster, Germany; [7]Universidade de Sao Paulo, Sao Paulo, Brazil*
Email: thierry.gustot@erasme.ulb.ac.be

Background and aims: Patients with Acute-on-Chronic Liver Failure (ACLF) had very poor short-term prognosis and required frequently intensive care with organ supports. The definition of inappropriate care where the recovery is highly improbable is an urgent medical need to limit unnecessary and expensive management and to stimulate palliative care.
Method: This analysis investigated 791 patients with EASL-CLIF-defined ACLF enrolled in two independent prospective multicenter cohorts (PREDICT and ACLARA) according to baseline and 1-week number of organ failures (OF), organ supports and CLIF-C ACLF scores. A threshold of 100% of 90-day transplant-free mortality rate was used to define inappropriate care.
Results: Overall, there were 55%, 26% and 19% patients with initial ACLF-1, 2 and 3, respectively. 34% of the patients were admitted to ICU and the overall 90-day transplant-free mortality rate was 60%. Neither number of OF, organ supports or value of CLIF-C ACLFs at baseline, were associated with inappropriate care, as defined above. The accuracy of 1-week CLIF-C ACLF score in distinguishing patients who died from those who survived by 90 days was significantly higher than that of the baseline CLIF-C ACLF score (AUROC 0.83 (95% CI 0.79–0.87) vs. 0.73 (0.67–0.78); p < 0.001). A 90-day mortality rate of 100% was found in patients with baseline ACLF-1 or 2 who had at 1 week 5 or more OFs and/or CLIF-C ACLF score ≥70 and in those with initial ACLF-3 who had at 1 week 4 or more OFs and/or CLIF-C ACLF score ≥60. Importantly, the definition of inappropriate care was not reached with any number of organ supports at 1 week.
Conclusion: The number of OF and CLIF-C ACLF scores one week after ACLF onset should be used to define future inappropriate care and to

suggest palliative care when curative treatments, as liver transplantation, are not available. On behalf of the PREDICT and ACLARA study groups.

FRI-223

Intermediate-term survival in patients with hepatorenal syndrome-acute kidney injury treated with terlipressin

R. Todd Frederick[1], Michael Curry[2], Sanaz Cardoza[3], Richard Wu[3], Ethan Weinberg[4]. [1]*California Pacific Medical Center, San Francisco, CA, United States;* [2]*Beth Israel Deaconess Medical Center, Boston, MA, United States;* [3]*Mallinckrodt Pharmaceuticals, Bridgewater, NJ, United States;* [4]*University of Pennsylvania, Philadelphia, PA, United States*
Email: todd.frederick@sutterhealth.org

Background and aims: Hepatorenal syndrome-acute kidney injury (HRS-AKI) is a deadly but potentially reversible complication of decompensated cirrhosis resulting in rapid (days to weeks) mortality if left untreated. Terlipressin is FDA-approved to treat adult patients (pts) with HRS with a rapid worsening in kidney function and is recommended as the first-line treatment (in combination with albumin) for HRS-AKI per EASL and AASLD guidelines. While for most pts liver transplantation (LT) may be the only definitive treatment for the underlying disease, some pts with HRS-AKI survive for >90 days without LT. Identification of factors associated with the intermediate-term survival of pts with HRS-AKI could facilitate their treatment optimization.
Method: Data from pts treated with terlipressin in 3 Phase III placebo-controlled clinical studies, OT-0401(NCT00089570), REVERSE (NCT01143246), and CONFIRM (NCT02770716), were pooled for the retrospective analysis of factors associated with intermediate-term survival, defined as >90 days without LT, using univariable and multivariable logistic regression.
Results: In the terlipressin group (N = 352), 87 (24.7%) pts survived >90 days without LT, and 265 (75.3%) pts survived ≤90 days or received LT. The rate of HRS reversal—defined as a serum creatinine level of ≤1.5 mg/dL—was 63.2% (55/87) among pts who survived >90 days without LT vs 23.4% (62/265) who survived ≤90 days or had LT ($p < 0.001$). In the univariable analysis, survival >90 days without LT was significantly associated with the following parameters: HRS reversal (odds ratio [OR] = 5.63, $p < 0.001$); acute-on-chronic liver failure (ACLF) score (OR = 0.51, $p < 0.001$); baseline Model for End-Stage Liver Disease (MELD) and MELD-sodium (Na) scores (OR = 0.89 and OR = 0.88, respectively, both $p < 0.001$); MELD ≥35 (OR = 0.45, $p = 0.004$); alcohol-related etiology of cirrhosis (OR = 1.90, $p = 0.016$); and systemic inflammatory response syndrome (SIRS; OR = 1.85, $p = 0.022$). In the multivariable analysis, HRS reversal (OR = 3.99, $p < 0.001$); MELD ≥35 (OR = 0.38, $p = 0.006$); SIRS (OR = 2.80, $p = 0.002$), and alcohol-related etiology (OR = 2.57, $p = 0.011$) were independent predictors of survival > 90 days without LT.
Conclusion: Significantly more pts with HRS reversal experienced intermediate-term survival >90 days without LT, compared with pts without HRS reversal. Lower ACLF score correlated with >90-day survival without LT in the univariable but not in the multivariate analysis. In the multivariable analysis, HRS reversal was the strongest independent predictor of survival >90 days without LT, followed by the presence of SIRS, lower MELD score, and alcohol-related etiology of disease.

Time-varying effect of acute-on-chronic liver failure on post-liver transplant survival accounting for selection bias

Tomohiro Tanaka[1], Emily Roberts[2], Jonathan Platt[2]. [1]*University of Iowa, Carver College of Medicine, Iowa City, United States;* [2]*University of Iowa, Iowa City, United States*
Email: tomohiro-tanaka@uiowa.edu

Background and aims: Prior studies show severe acute-on-chronic liver failure (ACLF) at liver transplantation (LT) negatively impacts short-term, but not long-term, post-LT outcomes. However, not accounting for ACLF's time-varying effect on the waitlist may underappreciate its dynamic nature. Moreover, excluding those who died or dropped off the waitlist raises concerns about selection bias.
Method: This US nationwide retrospective cohort study estimated the effect of severe ACLF (grade 3) on post-LT outcomes, including adult, first-time deceased donor LT candidates listed from June 2013 to May 2023. A counterfactual pseudopopulation was constructed using a marginal structural model (MSM) to address selection bias and time-varying exposure (ACLF grade-3). Cox proportional hazard (PH) models and an extended Cox model with a Heaviside step function assessed the hazard of death post-LT.
Results: Among 31,267 eligible LT candidates (baseline cohort), 11.2% (n = 3,518) had ACLF-3 at listing; 13.6% (n = 4,243) died or dropped out while on the LT waitlist. Of the 27,024 patients who received LT (transplanted cohort), 12.3% (n = 3,333) had ACLF-3 at LT. In the inverse probability weighted, extended Cox model, ACLF-3 at LT (but not at waitlisting) was associated with a higher hazard of death (HR1.87, 95%CI; 1.15–3.05) within one-year post-LT but not thereafter. This MSM effect size was 12% higher than conventional multivariable Cox PH models. Sensitivity analyses corroborated these findings.
Conclusion: Compared to previous studies, ACLF-3 at LT in our MSM was associated with a discernible increase in short-term mortality post-transplant, presumably due to our addressing of selection bias, while long-term survival was similar to those without severe ACLF at LT. However, potential vulnerability to post-transplant complications warrants further investigation.

FRI-225

Predictors of shock reversal and outcomes in acute-on-chronic liver failure with septic shock

Vishnu Girish[1], Rakhi Maiwall[1], Shiv Kumar Sarin[1], Ashok Choudhury[1], Dr. Babu Lal Meena[1], Akhil Deshmukh[1], Rahul Khajuria[1], Tushar Madke[1], Mohit Prajapati[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: rakhi_2011@yahoo.co.in

Background and aims: Acute-on-chronic liver failure (ACLF) patients with septic shock have high mortality. Identifying predictors of shock reversal and survival can modify our therapeutic strategies.
Method: In this prospective cohort study, two hundred and three ACLF patients diagnosed per the Asia-Pacific Association for the Study of the Liver (APASL) criteria and presenting with septic shock were enrolled. Septic shock was defined according to Sepsis-3 criteria. Shock reversal was defined as sustained MAP ≥65 mmHg without vasopressors for at least 12 hours within 3 days of onset or admission.
Results: The cohort had a mean age of 45.0 ± 9.3 years; 94.2% were male, 52% had alcohol-related liver disease, the mean baseline MELD score was 34.0 ± 6.0, and the mean SOFA score was 12.5 ± 2.5. The mean baseline Asia Pacific ACLF Research Consortium (AARC) score was 11.5 ± 1.5. Pneumonia was the predominant infection focus (75%, n = 152). The mean norepinephrine equivalent dose was 0.12 ± 0.06 μg/kg/min. CRRT was initiated in 84 patients (41.4%). The mean length of ICU stay was 7.9 ± 3.2 days. At 7 days, 72% of patients were alive. Shock reversal within 3 days occurred in 81 patients (39.9%). Univariate analysis showed that patients who achieved shock reversal had significantly lower baseline lactate levels (3.5 ± 1.6 mmol/L vs. 4.8 ± 1.7 mmol/L; $p = 0.01$), higher lactate reduction at 6 hours (−35% ± 15% vs. −10% ± 18%; $p < 0.001$), lower baseline AARC scores (10.8 ± 1.2 vs. 12.5 ± 1.4; $p < 0.001$), lower MELD scores (32.5 ± 5.5 vs. 35.8 ± 6.2; $p = 0.02$), and lower SOFA scores (11.8 ± 2.3 vs. 13.5 ± 2.6; $p = 0.01$). They also received higher volumes of fluid resuscitation (35 ± 8 mL/kg vs. 22 ± 9 mL/kg; $p < 0.001$), required fewer vasopressors (1.5 ± 0.5 vs. 2.1 ± 0.7; $p < 0.04$), and had shorter ICU stays (6.5 ± 2.8 days vs. 9.2 ± 4.5 days; $p < 0.03$). Rebound hypotension was less frequent in patients who achieved shock reversal (20% vs. 45%; $p < 0.001$). Multivariable analysis showed lactate reduction ≥15% at 6 hours [odds ratio (OR) = 5.8; 95% confidence interval (CI): 3.0–11.2; p <

0.001], lower AARC score [OR = 1.5; 95% CI: 1.3–1.8; p < 0.001] absence of mechanical ventilation requirement [OR = 2.5; 95% CI: 1.3–4.7; p = 0.006]. Patients who achieved shock reversal had a higher 28-day survival rate compared to those who did not (60% vs. 15%; log-rank p < 0.001).
Conclusion: In ACLF patients with septic shock, early lactate reduction of more than 15%, lower baseline AARC scores, and absence of need for mechanical ventilation are significant predictors of shock reversal. Achieving shock reversal is associated with improved survival outcomes.

Email: wenyi.gu@ukmuenster.de

Background and aims: The impact of acute-on-chronic liver failure (ACLF, the most severe form of decompensated cirrhosis characterized by the presence of extra-hepatic organ failures [EHOF]) on the European health care systems has not been well characterized, in part due to the lack of a code for ACLF in the International Classification of Diseases (ICD). We used ICD-codes for extrahepatic organ failure to assess the burden of cirrhosis with EHOFs from routinely collected data of a number of European health care systems.
Method: We searched national health care system databases from Germany, France, Italy and Denmark for admissions between 2017 and 2020 with an ICD diagnosis of cirrhosis and analyzed in those renal, cerebral, respiratory or circulatory failures. Healthcare claims refer to reimbursement requests for medical expenses submitted by healthcare providers to insurers. In this study, we also analyzed the healthcare claims incurred during admissions for EHOFs and calculated their proportion relative to all cirrhosis-related admissions.
Results: During the 4-year period, 1,599,680 hospital admissions for cirrhosis, which included 329,093 (20.6%) admissions with at least one EHOF, were recorded across the 4 countries. The most frequent failing organ systems were kidneys (52.9%) and respiratory (41.2%). The annual number of admissions for cirrhosis decreased over time (from 414,093 in 2017 to 375,112 in 2020), whereas the percentage of admissions with EHOF rose from 19.9% to 21.5%. Overall, in-hospital mortality rate of admissions with diagnosis of EHOF was high (29.2%), markedly exceeding mortality of admissions with diagnosis of cirrhosis alone (7.9%). The estimated median hospital stay was 12 days of each admission due to EHOF, and proportion of estimated healthcare claims of all hospital admissions between 2017 and 2020 due to EHOF accounting for almost half (44.9%) of the admissions for liver cirrhosis.
Conclusion: This study reveals that the burden of cirrhosis with EHOF was high and rising over time in 4 European countries studied, and associated with high mortality.

Email: jgracia@recerca.clinic.cat

Background and aims: Chronic liver disease (CLD) arises from progressive liver injury, fibrosis and tissue remodeling, leading to cirrhosis and liver failure. Increased tissue stiffness is a powerful biomechanical stimulus driving extracellular matrix (ECM) deposition and causes liver sinusoidal endothelial cell (LSEC) dedifferentiation. Mechanical forces transmitted to the nucleus influence chromatin, shifting euchromatin to heterochromatin to prevent DNA damage. MeCP2, an epigenetic regulator, modulates chromatin and nuclear structure, influencing gene expression. While MeCP2 knockout reduces liver fibrosis, its role in high stiffness-induced LSECs dysfunction remains unclear. This study aimed at investigating this aspect.
Method: MeCP2 expression was measured in healthy and cirrhotic human liver tissue slides via immunofluorescence. Liver cirrhosis was induced by thioacetamide (TAA) administered at 200 mg/kg twice a week for 12 weeks in male and female Sprague-Dawley rats. Freshly isolated LSECs were cultured on polyacrylamide (PAA) gels with stiffness of 0.5 kPa (healthy) and 30 kPa (cirrhosis) with and without cytoskeleton disruptors. Transcriptomic analysis and nuclear-proteomic analyses were employed to provide insights on the LSECs phenotype. Enrichr tool was used to identify genes co-expressed with MeCP2 and predict related pathways.
Results: Immunofluorescence analysis of human liver tissue revealed significant MeCP2 upregulation in patients with cirrhosis, as also observed in cirrhotic rat livers by nuclear deformation and reduced circularity. Gene set expansion via Enrichr linked MeCP2 to bZIP domain transcription factors, including CREB-binding protein (CBP), suggesting that stiffness-induced MeCP2 upregulation impacts transcription factors. MeCP2 protein levels increased under high stiffness. Its distribution near lamina-associated domains confirmed a mechanosensory role. Intracellular tension regulated MeCP2 in vitro of healthy and cirrhotic LSECs. Cytoskeletal inhibition reversed its upregulation in cirrhotic LSECs under high stiffness. Transcriptomic analysis on healthy LSECs cultured at 0.5 and 30 kPa, revealed 586 dysregulated genes with a repressive epigenetic profile, showing negative enrichment for euchromatin and transcription. Pathway analysis indicated dysregulation of bZIP transcription factors like CBP and AP-1 components (e.g., JUN). Proteomic analysis of LSEC nuclei identified 491 dysregulated proteins in response to

high stiffness, linked to cell cycle arrest and transcriptional repression.
Conclusion: MeCP2 is upregulated in cirrhotic LSECs in response to high stiffness in CLD. Moreover, MeCP2 provided for mechanical support as well as repressed transcription factors related to endothelial dysfunction. These findings highlight MeCP2 as a key transcription factor regulator in CLD.

Matrix remodeling and versican upregulation in mesenteric lymph nodes modulate bacterial phagocytosis and migration of activated CD4+ T cells, fueling systemic bacterial infections in cirrhosis
Pinky Juneja[1], Aarti Sharma[1], Deepika Jakhar[1], Dinesh Mani Tripathi[1], Shiv Kumar Sarin[1], Savneet Kaur[1]. [1]*Institute of Liver and Biliary Sciences, Vasant Kunj, India*
Email: savykaur@gmail.com

Background and aims: Mesenteric lymph nodes (MLN) act as a critical barrier against bacterial dissemination. In cirrhosis, enhanced gut bacterial translocation (BT) through MLN promotes systemic inflammation. Here, we investigated mechanisms underlying the failure of MLN to effectively contain bacteria in cirrhosis through a series of proteomic, in vitro, in vivo, and human studies.
Method: Cirrhosis was induced in rats using 12 weeks of CCl_4 treatment. Endogenous bacterial load and exogenous BT using GFP bacteria were assessed in MLN, lymph, blood, and other organs. MLN proteome profile and immune response to infection were analyzed. The role of one of the extracellular matrix proteins (ECM), versican (Vcan), was deciphered using $CD45^-$ $CD31^-$ $Pdpn^+$ fibroblastic reticular cell (FRC). Effects of FRC on bacterial phagocytosis, T cell migration, and function were studied *in vitro*. Effect of in vivo siRNA-mediated Vcan inhibition in CCl_4 models was delineated. Plasma Vcan levels and T cells were quantified in cirrhotic patients with and without bacterial sepsis.
Results: High endogenous bacterial load was present in cirrhotic rats' MLN, efferent lymph, portal blood, and all organs vs none in control. In control, GFP bacteria were retained in MLN; in cirrhotic rats, bacteria were translocated from MLN (3-fold high vs control) to lungs, liver, spleen, lymph, and blood. In cirrhotic MLN, CD134+ CD4+ activated Th cells and antigen-presenting CD80+ DC were significantly higher than control. Conversely, in systemic circulation, activated Th cells and DC were reduced in cirrhosis vs control. Proteome analysis of MLN from healthy and cirrhotic rats revealed 73 differentially expressed proteins (DEP), of which many ECM proteins were upregulated in cirrhotic MLN. From the top 10 upregulated DEP, we selected the ECM protein, Vcan, which was found to be highly expressed in FRC of cirrhotic MLN compared to control FRC. *In vitro*, cirrhotic FRC had reduced bacterial phagocytosis activity than control FRC and Vcan-siRNA treated cirrhotic FRC. Coculture of T cells with cirrhotic FRC resulted in increased T cell clumping and attachment, reduced T cell migration, and Th cell activation compared to when cultured with control FRC. *In vivo* inhibition by Vcan siRNA in CCl_4 rats led to increased Th cell migration in systemic blood with reduced BT compared to that in control siRNA treated CCl_4. Plasma Vcan levels were higher (by 35%) in cirrhotic patients with bacterial sepsis than in non-septic cirrhotics. Patients with high Vcan levels had reduced activated Th cells than those with low Vcan levels.
Conclusion: In cirrhosis, ECM remodeling and elevated Vcan expression in MLN cause impaired bacterial clearance, reduced activation, and migration of Th cells from MLN to systemic circulation, fostering systemic bacterial dissemination. Targeting Vcan in MLN presents a potential therapeutic target to treat systemic bacterial infections. Also, plasma Vcan may serve as a biomarker for MLN dysfunction and bacterial sepsis in cirrhosis.

Email: r.jalan@ucl.ac.uk

Background and aims: Acute-on-chronic liver failure (ACLF) is associated with high short-term mortality and its treatment is an unmet need. Hepatocyte senescence and lack of regeneration are important mechanisms underlying poor recovery. Insulin-like growth factor system (IGFs), IGF-1, its receptor (IGF-1R) and binding proteins (IGFBPs), are involved in the regulation of hepatocyte proliferation. This study was conducted to explore whether IGF-1 could reduce liver injury whilst enhancing liver regeneration.
Method: *Patients:* Serum samples from patients with hepatitis, stable cirrhosis, acute decompensation cirrhosis (AD), pre-ACLF or ACLF from European DASIMAR cohort (n = 103) and Chinese cohort (n = 304) were used to explore the association between IGFs and liver diseases. *Animal models*: Hepatic IGFs was measured in cirrhosis and ACLF animals treated with TAK-242 (Toll-like receptor-4 antagonist); Nec-1 (Receptor interacting serine/threonine kinase-1 inhibitor); combination of granulocyte colony stimulating factor and TAK-242 (G-TAK). Each of the interventions protected from liver injury and ACLF. *Recombinant IGF-1 (rhIGF-I) therapy*: rhIGF-1 (1 mg/kg/day, i.p.) was administered for 2-weeks prior to sacrifice. The clinical effect of rhIGF-I administration in models of cirrhosis (4 wk, bile duct ligation, BDL) and ACLF (BDL + lipopolysaccharide) were observed.
Results: *Patients*: Serum level of IGF-1 and IGFBP-3 were significantly lower in patients with AD, pre-ACLF and ACLF, than in the healthy subjects in both the European and Chinese cohorts while IGFBP-1 was increased significantly ($p < 0.001$, $p = 0.004$, $p < 0.001$, for both cohorts). *Animal models*: mRNA level of IGF-1 in liver was decreased in both BDL (3.4-fold) and CCl4 cirrhosis models (2.4-fold) compared with Sham, while IGF-IR and IGFBP1 were increased, which was confirmed with immunohistochemistry. The decrease of IGF-1 and IGFBP3 were reversed with TAK-242, Nec-1 or G-TAK. Conversely, IGFBP1 decreased significantly after TAK-242 (11-fold), Nec-1 (8.7-fold) and G-TAK (13.5-fold). *rhIGF-1 therapy*: Administration of rhIGF-1 resulted in a significant reduction in sarcopenia in cirrhosis and ACLF animals, significant reduction in bilirubin, ammonia and creatinine in ACLF animals and reduced hepatic fibrosis. Liver gene profiling showed that rhIGF-1 modulated senescence pathways, inhibited p53/pRb signalling and reduced IFN signalling in the liver of rhIGF-1 treated mice.
Conclusion: IGFs were reduced in cirrhosis and partially corrected with interventions targeting inflammation. Treatment with rhIGF-1 improved organ function and sarcopenia in cirrhosis and ACLF animals and should be further as a novel therapeutic.

Email: aenne@harberts.de

Background and aims: Cirrhosis-associated immune dysfunction (CAID) is characterized by systemic hyperinflammation and impaired immune responses in patients with advanced liver disease that favors infections and organ dysfunction to precipitate acute-on-chronic liver failure (ACLF). Molecular CAID networks remain poorly defined but may involve interleukin (IL)-18 and its antagonist IL-18BP as targetable agents. IL-18 is a potent inflammatory cytokine involved in liver inflammation, fibrosis, and cell death. However, the contribution of intrahepatic and systemic IL-18/IL-18BP balance to CAID is unknown. The study aimed to delineate IL-18 and IL-18BP expression patterns in decompensated cirrhosis (DC) and ACLF and evaluate their associations with established inflammatory markers and disease severity.
Method: Hepatic mRNA expression was quantified via RNAseq from 36 patients (compensated cirrhosis [CC] n = 13, DC n = 13, ACLF n = 10). Plasma IL-18, IL-18BP, sCD14, LPS-binding protein (LBP), and intestinal fatty acid binding protein (iFABP) levels were measured via ELISA in a prospective cohort of 111 cirrhosis patients (CC n = 12, DC n = 24, ACLF n = 75) and correlated with CRP, IL-6, white blood cell count (WBC), neutrophil-to-lymphocyte ratio (NLR), organ dysfunction, and clinical outcomes.
Results: Expression levels of IL-18 and IL-18BP were progressively upregulated in DC and ACLF livers. Circulating IL-18 levels increased with progressing hepatic decompensation, independent of cirrhosis etiology, with a particularly high IL-18/IL-18BP ratio in ACLF (median ratio DC vs. ACLF 0.4 vs 0.8, p = 0.009). IL-18 was more robustly correlated with ACLF grade, MELD, MELD-Na, and Child-Pugh scores compared to CRP, IL-6, WBC, and NLR. Notably, IL-18, IL-6, WBC, and NLR were significantly lower in ACLF survivors compared to non-survivors and patients requiring liver transplantation, whereas CRP and IL-18BP were not. The correlation between IL-18 and IL-18BP with IL-6 was only moderate (<0.5), and remarkably low with markers of intestinal barrier dysfunction.
Conclusion: This study demonstrates that intrahepatic and systemic IL-18 induction characterizes hepatic decompensation and is especially pronounced in ACLF. The expression pattern of IL-18 is distinct from IL-6, WBC, CRP, and NLR. In ACLF, the disproportionate IL-18/IL-18BP ratio, driven by a relative IL-18BP deficiency, may contribute to organ dysfunction and adverse outcomes. These findings highlight the need for further research to elucidate the specific contributions of IL-18 to CAID.

THU-132
Hepatocyte derived extracellular vesicles promote endothelial dedifferentiation in chronic liver disease through the miR-153-3p – pyroptosis axis

Laia Abad-Jorda[1], Maria Andres-Rozas[1], Ana Martínez-Alcocer[1], Emilio Tonina[2], Yilliam Fundora[2], Sergi Guixe-Muntet[1], Anabel Fernández-Iglesias[1], Jordi Gracia-Sancho[1]. [1]*Liver Vascular Biology Lab - IDIBAPS - Hospital Clínic Barcelona - CIBEREHD, Barcelona, Spain;* [2]*Liver Transplant Unit - Hospital Clínic Barcelona - CIBEREHD, Barcelona, Spain*
Email: jgracia@recerca.clinic.cat

Background and aims: Liver cells paracrinally affect neighbouring cells through the release of extracellular vesicles (EVs). The aim of this study was to investigate the role of microRNAs (miRNAs) enclosed in hepatocyte-derived EVs (hepEVs) in sinusoidal endothelial dedifferentiation in chronic liver disease (CLD).
Method: Healthy (CT) or cirrhotic (CH) hepEVs were obtained from human and rat livers. Healthy rats received fluorescently labelled hepEVs-CT or hepEVs-CH (200 µg/day, 3 days, i.v.) or vehicle (n = 10/group) to evaluate their biodistribution and their effects on the phenotype of liver sinusoidal endothelial cells (LSECs) using RNAseq, IF, and WB. The profile of deregulated miRNAs in human and rat hepEVs-CH was analysed, and common miRNAs were exogenously overexpressed in LSEC-CT for transcriptomic and pathway analysis. The most deregulated pathway was studied in LSEC-CH, in human and rat cirrhotic livers, and in LSEC-CT treated with hepEVs overexpressing a specific miRNA. Cirrhotic rats were treated with the caspase-1 (casp1) inhibitor VX-765 (15 mg/kg, 10 doses, 2 weeks) or vehicle (n = 11/group) to evaluate hepatic hemodynamic, liver function, and endothelial phenotype.
Results: LSEC-CT *in vitro* treated with hepEVs-CH exhibited increased expression of pro-inflammatory, fibrogenic, angiogenesis, and cell death-related genes. *In vivo* administration of hepEVs-CH mainly accumulated in the hepatic endothelium, resulting in marked dysregulation of genes associated with fibrogenic and inflammatory pathways, together with increased vWF expression and alterations in nitric oxide synthase, suggesting a direct effect on endothelial dysfunction. Characterization of hepEVs-CH from patients revealed significant dysregulation of 37 miRNAs, with upregulation of miR-200a-3p and miR-153-3p validated in rat hepEVs-CH. Transfection of LSEC-CT with miR-153-3p dysregulated 771 genes implicated in inflammation and cell death pathways, particularly pyroptosis, with 51% homology to the transcriptome of LSEC-CH. Additional analyses in liver tissue showed increased expression of active casp1 and GSDMD-N, indicating activation of the pyroptosis pathway during CLD progression. Furthermore, activation of pyroptosis was observed in LSEC-CT upon treatment with miR-153-3p-enriched hepEVs. Finally, cirrhotic rats treated with VX-765 exhibited reduced hepatic pyroptosis (−60% active casp1), leading to significant amelioration in portal hypertension (−16.5%), fibrosis (−11.4%), and endothelial phenotype (−42% vWF). All results p < 0.05.
Conclusion: miRNAs contained in hepEVs actively contribute to hepatic endothelial dedifferentiation in CLD through the activation of the miR-153-3p-pyroptosis pathway, suggesting caspase 1 inhibition as a novel therapeutic strategy for endothelial dysfunction in CLD.

THU-133-YI
Risk of hypoglycemia in people with cirrhosis without diabetes

Alan Hutchison[1], Celeste Thomas[1], Mary E. Rinella[1]. [1]*University of Chicago Medicine, Chicago, IL, United States*
Email: alan.hutchison@uchicagomedicine.org

Background and aims: People with cirrhosis have disrupted glycemic metabolism which puts them at risk of dangerous hyper- and hypoglycemia. People with cirrhosis are encouraged to have high protein snacks before bedtime due to impaired endogenous glucose production while they sleep. While studies of hypoglycemia focus on people with cirrhosis with diabetes, little is known about the risks of hypoglycemia in people with cirrhosis who do not have diabetes. The low blood glucose index is a calculated score based on continuous glucose monitor measures that assesses risk for severe hypoglycemia.
Method: We enrolled people with cirrhosis without a diagnosis of diabetes presenting for liver transplant evaluation. Thirteen subjects (10 male, 3 female, mean age 50.3 years) were given a blinded Abbott Libre Pro continuous glucose monitor (CGM) for 14 days and a Fitbit Inspire 3 wristwatch. After an overnight fast blood was sampled for insulin, glucagon, and A1c. Using the Fitbit-designated wake and sleep events, we classified our CGM glucose measurements as occurring during wake or sleep.
Results: Seven out of thirteen subjects had greater than 4% of the time in hypoglycemic ranges of glucose less than 70 mg/dL (3.9 mmol/L), which is above the American Diabetes Association's goal for patients with diabetes. Eight out of nine subjects had CGM-estimated A1c greater than laboratory hemoglobin A1c (mean ±

standard deviation 5.7 ± 0.2 vs 5.1 ± 0.6, respectively). Fasting glucagon was strongly correlated with the overall CGM coefficient of variation (Pearson r = 0.815, p < 0.02), strongly correlated with the sleeping low blood glucose index (LBGI, an indicator of hypoglycemic risk) (r = 0.95, p < 0.02) and inversely correlated with the number of Wakes after Sleep Onset (WASO) (r = –0.72, p < 0.03). Fasting insulin was not correlated with the fasting glucagon (r = 0.34, p < 0.24), but was also strongly correlated with the sleeping LBGI (r = 0.977, p < 0.005), and negatively correlated with the WASO (r = –0.67, p < 0.05).
Conclusion: Even people with cirrhosis who do not have diabetes are at risk of dangerous hypoglycemia. We found that two straightforward and readily available blood tests, the fasting insulin and fasting glucagon, were strongly associated with hypoglycemia. These tests were also associated with disrupted sleep, as measured by wakes after sleep onset. This suggests that obtaining fasting insulin and glucagon could help risk stratify people with cirrhosis without diabetes into further evaluation of hypoglycemia and sleep. Further work will need to validate these findings in larger cohorts.

THU-134-YI
Bone morphogenic protein 9 (BMP9): a novel therapeutic agent for the prevention of circulatory and renal failure in animal models of acute-on-chronic liver failure (ACLF)

Alexandra Phillips[1], Rudmer Postma[2], Susan Fischer[3], Abeba Habtesion[1], Fausto Andreola[1], Nathan Davies[1], Paul Upton[4], Nick Morrell[4], Anton Jan van Zonneveld[2], Minneke Coenraad[5], Rajiv Jalan[1]. *[1]Liver Failure Group, UCL Institute for Liver and Digestive Health, Division of Medicine, London, United Kingdom; [2]Department of Internal Medicine, Leiden University Medical Center, Leiden, Netherlands; [3]Department of Gastroenterology and Hepatology, Leiden University Medical Center, Leiden, Netherlands; [4]Victor Phillip Daldaleh Heart and Lung Research Institute, Department of Medicine, University of Cambridge, Cambridge, United Kingdom; [5]Department of Gastroenterology and Hepatology, Leiden University Medical Center, Leiden, United Kingdom*
Email: alexandra.phillips5@nhs.net

Background and aims: Endothelial dysfunction in ACLF is associated with extrahepatic organ failure, reduced organ perfusion and lactatemia. Bone morphogenic protein 9 (BMP9) regulates endothelial cell (EC) function, is produced by the liver and is reduced in decompensated cirrhosis. We hypothesise that administration of BMP9, by virtue of its known positive effect on the endothelial function may prevent extrahepatic organ dysfunction, organ injury and improve survival in models of ACLF.
Method: *Animal Models*: Two animal models of ACLF: (1) Rat model induced by 4-week bile duct ligation (BDL) ± 0.025 mg/kg ip Lipopolysaccharide (LPS) (2) Mouse model induced by 12-week oral gavage of 0.5 mL/kg carbon tetrachloride (CCL4) ± 2 mg/kg LPS (ACLF). Both models received BMP9 ip or placebo (±90 µg/kg/day) daily for two weeks prior to LPS. Survival, mean arterial pressure (MAP), biochemistry, liver histology and kidney qPCR and RT^2 PCR profiler for EC dysfunction related genes were evaluated. *Experiments in endothelial cells (EC)*: human ECs were exposed to plasma from ACLF patients (n = 7), decompensated patients (n = 4), or healthy control (n = 5), supplemented with BMP9 (0, 0.37, 3.7 ng/ml). EC morphological responses to exposure were quantified by image-based high-content morphological profiling. Shifts in EC morphology for BMP9 titration and disease status were scored and compared by linear discriminant analysis model.
Results: *Animal models*: BMP9 administration significantly increased survival of ACLF rats [75% vs 22%, p = 0.03], which was associated with significantly higher MAP in ACLF animals [82.1 to 108.5 mmHg, p = 0.01], reduction of renal injury [plasma creatinine: 82.3 to 65.4 µmol/L, p = 0.056] and significantly improved tissue perfusion [plasma lactate: 10.4 to 6.6 mmol/L, p = 0.019]. The effects seen in BDL animals were validated in the CCL4 mouse model. qPCR analysis of kidney tissue showed BMP9 treatment reduced gene expression of markers of endothelial dysfunction in ACLF with a reduction in KDR [p = 0.079], and significant reduction in eNOS [p < 0.05] and AQP1 [p < 0.05]. RT^2 PCR profiler showed a significant reduction in genes including CAV1, IL-1β, IL-6, PLAT and PAI-1 following BMP9 treatment. *EC experiments:* Plasma from decompensated cirrhosis and ACLF patients induced a highly activated EC morphology compared to healthy plasma. No effect of BMP9 was observed in healthy plasma. EC activation and disturbances of the EC border morphology induced by decompensated and ACLF plasma was prevented in a dose dependent manner by BMP9 (p < 0.001), indicating BMP9 modulates the inflammatory response in ECs.
Conclusion: This data suggests that BMP9 may be a novel treatment to prevent the progression of circulatory and renal failure in ACLF by modulating endothelial function and organ perfusion, which results in reduced mortality. The data provide the rationale to initiate clinical studies.

Associations between cardiorespiratory fitness and physical frailty in patients with cirrhosis

Alexis Couret[1,2], Camille Marcantei[1], Fabrice Rannou[3], James King[4,5], Bruno Pereira[6], Sylvie Massoulier[2], Sarah Arbogast[2], Leon Muti[2], Benjamin Buchard[2], Delphine Weil-Verhoeven[7], Gael Ennequin[1], Armand Abergel[2]. *[1]Clermont auvergne university, laboratory of metabolic adaptations to exercise under physiological and pathological conditions (AME2P), Clermont-Ferrand, France; [2]University hospital of Clermont-Ferrand, department of digestive and hepatobiliary medicine, Clermont-Ferrand, France; [3]University hospital of Clermont-Ferrand, Department of sport medicine and functional exploration, Clermont-Ferrand, France; [4]Loughborough university, national centre of sport and exercise medicine, school of sport & exercise sciences, Loughborough, United Kingdom; [5]University of Leicester, NIHR Leicester Biomedical Research Centre, University Hospitals of Leicester NHS Trust, Leicester, United Kingdom; [6]Hospital university of Clermont-Ferrand, biostatistics unit, Clermont-Ferrand, France; [7]University hospital of Besançon, department of hepatology, Besançon, France*
Email: Alexis.couret@uca.fr

Background and aims: Cirrhosis leads to severe impairment in cardiorespiratory fitness and frailty, both of which are strong predictors of poor prognosis. Our objectives were twofold: first, to validate the Liver Frailty Index (LFI) as a practical tool for assessing the physical fitness of patients with cirrhosis by studying its correlation with cardiorespiratory fitness (CRF); and second, to evaluate the impact of liver function on maximal oxygen consumption (VO_2).
Method: Each participant with confirmed compensated cirrhosis (by hepatic elastography) or decompensated cirrhosis underwent the Liver Frailty Index (LFI) assessment. Patients also performed an incremental test on a cycle ergometer to determine maximal oxygen consumption (VO_{2Peak}).
Results: 10 females and 28 males, aged of 60.6 ± 7.9 years (females are older (p = 0.042)) completed the study. The mean VO_{2Peak} value was 16.1 ± 6.1 $ml.min^{-1}.kg^{-1}$ corresponding to 68.2 ± 28.5% of predicted VO_{2Peak}. According to the LFI, 28.9% are frail, 57.9% are pre-frail and 13.2% are robust with a mean LFI of 3.99. Concerning the Child-Pugh (CP) groups, 52.6% are in CPA, 21.1% are in CPB and 26.3% in CPC. The LFI was negatively correlated with CRF variables: absolute VO_{2Peak} ($l.min^{-1}$) (r = –0.538, p < 0.001), relative VO_{2Peak} ($ml.min^{-1}.kg^{-1}$) (r = –0.537, p < 0.001), and percentage of predicted VO_{2Peak} (r = –0.682, p < 0.001). The LFI was positively correlated with liver failure, as reflected by the Child-Pugh (CP) score (r = 0.476, p = 0.016) and MELD score (r = 0.384, p = 0.011). CPA and CPB patients were less frail than CPC patients (p < 0.001 and p = 0.007, respectively), but no significant difference was found between CPA and CPB (p = 0.792). Similar differences were observed for absoluteVO_{2Peak} ($l.min^{-1}$): CPA and CPB patients had higher values compared to CPC patients (p < 0.001 and p = 0.006, respectively), with no difference between CPA and CPB (p = 1.000). For relative VO_{2Peak} ($ml.min^{-1}.kg^{-1}$), values were

higher for CPA and CPB patients versus CPC ($p < 0.001$ and $p = 0.029$, respectively), with no significant difference between CPA and CPB ($p = 0.959$). A difference was also noted for the percentage of predicted VO_{2Peak} achieved by CPA and CPB, CPB and CPC, and CPA and CPC patients ($p = 0.031$, $p = 0.008$, and $p < 0.001$, respectively).
Conclusion: The LFI is associated with both cardiorespiratory fitness and liver failure severity. As a simple tool, it could be included in pre-transplant evaluations, provided its independent prognostic value is confirmed in diverse populations, including European and Asian cohorts. Our findings also demonstrate that cardiorespiratory fitness is reduced in CPC patients but remains relatively preserved in CPA and CPB patients.

THU-136
Clinical relevance of the evaluation of cardiorespiratory fitness in patients with cirrhosis: a systematic review with meta-analysis

Email: Alexis.couret@uca.fr

Background and aims: Cirrhosis is a major public health issue, with a high prevalence of associated morbidity and mortality. It also leads to severe impairment in cardiorespiratory fitness (CRF). Some studies have suggested that reduced CRF is linked to an increased risk of early mortality. The primary objective of this systematic review is to determine whether cardiopulmonary exercise testing (CPET) can predict the mortality and morbidity of patients with cirrhosis.
Method: The literature was reviewed across electronic databases (PubMed, Scopus, Embase, Google Scholar) from their inception to April 2024. Two independent researchers applied inclusion criteria to assess the eligibility of articles. Studies were eligible if they involved maximal exercise testing and reported oxygen consumption at anaerobic threshold (AT) and at maximum (VO_{2Peak}).
Results: This review includes sixty-one articles' data from 2,991 patients with cirrhosis. The mean values were: 11.80 $ml.min^{-1}.kg^{-1}$ [95% CI 11.16; 12.45] for AT, 19.51 $ml.min^{-1}.kg^{-1}$ [95% CI 18.75; 20.26] for VO_{2Peak}, and 61.1% [95% CI 60.7; 67.6] of predicted VO_{2Peak}. Concerning analysis between Child-Pugh (CP) groups, we found for AT, CPA and CP B have higher values than CP C with 12.75 $ml.min^{-1}.kg^{-1}$ (95%CI, 11.65; 13.85), 11.43 $ml.min^{-1}.kg^{-1}$ [95%CI, 10.22; 12.65] and 9.15 [95%CI 7.55; 10.75], respectively. Relating to VO_{2Peak} values, CP A have B superior results than CP C with 20.68 $ml.min^{-1}.kg^{-1}$ [95% CI, 17.92; 23.43], 17.95 [95%CI and 14.95 $ml.min^{-1}.kg^{-1}$ [95%CI 13.51; 16.38], respectively. CRF was identified as a predictor of mortality in eight of nine studies (n = 1,193 patients). Additionally, eight studies found CRF to be predictive of morbidity, including two studies with 160 patients for sepsis, four studies with 538 patients for hospitalization duration, and four studies with 551 patients for intensive care unit (ICU) stay duration. One study (n = 98) reported no significant effect on ICU stay duration.
Conclusion: Evaluating CRF should be recommended to improve the ability to predict prognosis by providing a better understanding of patients' physical function. This meta-analysis of CRF levels across studies establishes reference values that can serve as practical and efficient tools for clinical decision-making.

Email: anindro.b@outlook.com

Background and aims: Although ammonia is a known toxin associated with overt hepatic encephalopathy (OHE), the metabolic basis remains unknown. OHE is part of the acute-on-chronic liver failure (ACLF) definition and often occurs with other organ failures making it difficult to understand whether OHE has a particular metabolic basis. The aims of this study were to define the metabolome of OHE patients and whether they are distinct from ACLF and other organ failures. Other aims were to identify metabolites associated with clinical course.
Method: This study was performed on a subset of 252-unselected patients with cirrhosis hospitalized with acute decompensation [PREDICT study] in whom the metabolomic profile (using high-resolution mass spectroscopy) were available. Differences in mean metabolite expression levels were quantified by using pairwise t-tests. Univariable Cox regression models were fitted on each metabolite to identify those that were associated with survival. All p-values were controlled for false discovery rate.
Results: 15-metabolites were significantly different between OHE(−) [n = 211] and OHE(+) [n = 41] from which 13-overlapped with ACLF. Two metabolites in OHE(+) patients were independent of ACLF, namely alanine/sarcosine and lactic acid, which represent altered amino acid metabolism and gut permeability. There were no significant different in metabolites between OHE(+) ACLF(−) and single liver failure. There were 3-significant metabolites between OHE(+) ACLF(−) [n = 14] and single kidney failure, namely N-acetyl-L-alanine, reduced hexoses and 2,2′-thiodiacetic acid. Among OHE(+) ACLF(+) patients, [n = 27], 64-metabolites were significantly associated with 90-day mortality. Of these metabolites, those with the highest coefficients included cis/trans aconitic acid, lactic acid, carnitine and N-acetyl-L-alanine. Among OHE(-) ACLF(+) patients [n = 81], 3-[(R)-butyryl-carnitine, carnitine, hexanoylcarnitine)] were significantly associated with 90-day mortality. No metabolites were significantly associated with 90-day mortality among OHE(+) ACLF(−) and OHE(−) ACLF(−) [n = 128] patients. No metabolites were associated with progression or regression of OHE.
Conclusion: The data show for the first time that OHE patients exhibit a distinct metabolic profile that provides novel pathophysiological insights. Metabolites significantly associated with mortality were only found in the ACLF(+) groups suggesting that mortality attributed to OHE are due to non-metabolome factors.

Albumin infusion improves albumin binding capacity in patients with cirrhosis and MHE on gut-specific therapy

Anna Mestre[1], Raquel Horrillo[1], Andrew Fagan[2], Ruben Sabido[1], Jordi Vidal[1], Ricardo Gonzalo[1], Maria Isabel Bravo[1], Montserrat Costa[1], Jasmohan Bajaj[2]. [1]*Scientific Innovation Office, Grifols, Barcelona, Spain;* [2]*Virginia Commonwealth University and Richmond VAMC, Richmond, United States*
Email: anna.mestre@grifols.com

Background and aims: Minimal hepatic encephalopathy (MHE), or cognitive impairment that affects patient's quality of life (QoL), can persist despite adequate HE gut-directed therapy such as lactulose/rifaximin. Albumin has been investigated in HE for its potential therapeutic benefits related to non-oncotic functions, particularly on its capacity to bind, transport and modulate biologically active molecules such as fatty acids, proinflammatory mediators and reactive oxygen species. In the HEAL study (NCT03585257), albumin infusions in patients with cirrhosis and MHE were associated with improved cognitive function and psychosocial QoL. The aim of the present study was to characterize the albumin binding capacity of patients from the HEAL study and its correlation with cognitive parameters.
Method: Serum samples from 47 patients included in the HEAL study were analyzed. This was a double-blind, placebo-controlled randomized clinical trial in outpatients with cirrhosis and MHE on HE therapy, who received either weekly intravenous infusions of albumin 1.5 g/kg or saline over 5 weeks. The impairment in the drug albumin binding capacity to Sudlow Binding Site II (ABiC) was determined using a specific fluorescent marker. Results were compared with age-matched healthy controls (HC) (n = 13). Cognitive response was evaluated with psychometric hepatic encephalopathy score (PHES). Wilcoxon test was used to assess the differences in ABiC of patients versus HC at baseline. Lasting effects were analyzed with a mixed model for repeated measures. Relationship between cognitive impairment and ABiC was assessed through Spearman correlations. All analyses were performed with R (v4.3.0).
Results: At baseline, albumin from patients with cirrhosis and MHE tended to present lower binding capacity compared to HC (80.1% [72.4–92.6] vs 93.2% [82.2–96.3]; median [IQR]; p = 0.086), which led to a statistically significant decrease in effective albumin for transport (30.2 mg/mL [25.9–32.8] vs 35.1 mg/mL [33.1–36.6]; p < 0.001). Albumin infusions increased progressively the content of albumin binding capacity, reaching 36.1 mg/mL at the end of the study (p = 0.022, compared to placebo). Moreover, the increased functionally active albumin for transport correlated with a higher PHES at the end of treatment (binding capacity: p = 0.04, r = 0.33; total binding: p = 0.06, r = 0.29).
Conclusion: Albumin binding capacity was impaired in patients with cirrhosis and MHE on lactulose and rifaximin, which was restored to normal levels in parallel with improvement in cognitive function after albumin administration. Our data suggested that albumin treatment could exert its beneficial effects through the restoration of albumin transport functionality, over and above traditional HE therapies.

THU-139

Glycated albumin is increased in patients with cirrhosis and hepatic encephalopathy already on gut-directed therapy and links with cognitive and quality of life impairment

Anna Mestre[1], Raquel Horrillo[1], Andrew Fagan[2], Ruben Sabido[1], Jordi Vidal[1], Ricardo Gonzalo[1], Maria Isabel Bravo[1], Montserrat Costa[1], Jasmohan Bajaj[2]. [1]*Scientific Innovation Office, Grifols, Barcelona, Spain;* [2]*Virginia Commonwealth University and Richmond VAMC, Richmond, United States*
Email: anna.mestre@grifols.com

Background and aims: Cognitive impairment in cirrhosis can persist despite adequate treatment of HE with gut-directed therapies such as lactulose and rifaximin. This impairment, or minimal hepatic encephalopathy (MHE), negatively impacts outcomes. Albumin has shown benefit in HE patients with improved cognitive function and psychosocial quality of life (QoL) (HEAL study, NCT03585257). The aim of the present study was to describe albumin post-translational modifications (PTMs) of patients with cirrhosis and MHE compared to healthy controls (HC) and its correlation with clinical parameters, since structural modifications of albumin could alter albumin's non-oncotic functions.
Method: Serum samples from 24 cirrhosis patients in the HEAL study without diabetes and 10 age-matched HC were evaluated. Albumin PTMs were assessed on the intact mass protein (top-down) by using ultra HPLC coupled to electrospray ionization mass spectrometer (LC_ESI_qTOF-MS) and expressed as percentage of relative intensity. Principal Component Analysis (PCA), limma Bioconductor package and Wilcoxon test were used to assess the differences in PTMs of patients versus HC. Relationship between cognitive impairment, QoL and PTMs was assessed through Spearman correlations. All analyses were performed with R (v4.3.0).
Results: PCA showed good separation between samples from HC and non-diabetic patients with cirrhosis and MHE. Fourteen out of 25 PTMs presented statistically significant differences between both groups. In comparison to HC, albumin from patients showed less native albumin (50.1% [44.6–55.9] vs 56.1% [54.5–57.3]; median [IQR]; p = 0.05) and less truncated forms (5 PTMs) (6.3% [5.4–7.0] vs 7.0% [6.5–8.7]; p = 0.025), as well as more overall glycated forms (13 PTMs) (14.8% [12.4–16.1] vs 10.5% [9.5–10.9]; p < 0.001) being the forms HSA+Glyc and HSA+Cys+Glyc the most relevant. Decreased native albumin correlated with worse cognitive testing (psychometric hepatic encephalopathy score) (p = 0.05, r = 0.41), and the increase of HSA+Glyc, HSA+2Glyc and HSA+3Glyc forms correlated with poor QoL (p < 0.01, r = 0.58; p = 0.01, r = 0.56; p = 0.02, r = 0.46, respectively).
Conclusion: Albumin from patients with cirrhosis and MHE even without diabetes shows higher glycation versus HC. These structural alterations contributed to decrease native albumin levels that could impair non-oncotic albumin functions in these patients.

The in vitro immune response of mononuclear cells to Escherichia coli is not dependent on antibiotic multidrug resistance

Berta Cuyàs[1,2], Elisabet Cantó[3], Elisabet Sanchez[1,2], Elisenda Miró[4], Edilmar Alvarado-Tapias[1,2], Eva Roman[1,2], Maria Poca[1,2], Ferran Navarro[4], Àngels Escorsell[1,2], Silvia Vidal[3], German Soriano[1,2]. [1]*Department of Gastroenterology, Hospital de la Santa Creu i Sant Pau, Universitat Autònoma de Barcelona, Barcelona, Spain;* [2]*CIBERehd, Instituto de Salud Carlos III, Madrid, Spain;* [3]*Department of Inflammatory Diseases, Institut de Recerca Sant Pau (IR Sant Pau), Barcelona, Spain;* [4]*Department of Microbiology, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain*
Email: bcuyas@santpau.cat

Background and aims: Multidrug-resistant organisms (MDRO) pose a serious global health threat. Infections caused by MDRO are increasing and are associated with poor outcomes, especially in patients with cirrhosis, although the underlying mechanisms are not fully understood and may involve variations in the elicited immune response. The aim was to evaluate whether the immune response to multidrug-resistant *Escherichia coli* isolates from cirrhotic patients differs from the response to antibiotic-susceptible *E. coli* strains.
Method: Surface and nuclear protein extracts were obtained from multidrug-resistant *E. coli* (n = 6) and antibiotic-susceptible *E. coli* (n = 6) strains isolated from bacteremia and spontaneous bacterial peritonitis in patients with cirrhosis. These extracts were used to

stimulate *in vitro* peripheral blood mononuclear cells from healthy donors (n = 8). After 48 hours of culture, we quantified several mediators of immune response (IFN-gamma, IL-1beta, IL-10, IL-12p70, MCP-1, IL-8, IL-6, MIP-1alpha, and MIP-1beta) in the supernatant using Luminex or ELISA. The results were normalized using a ratio to mediator production by a reference *E. coli* strain (ATCC® 25922) and analyzed with the Mann-Whitney test and multivariable linear regression models.

Results: The mediators with the highest production were IL-1beta in surface extracts (ratio of 2.15 ± 2.87 for multidrug-resistant vs. 2.47 ± 2.56 for sensitive strains, p = 0.54) and IL-10 and MCP-1 in nuclear extracts (ratios of 1.24 ± 2.38 vs. 2.46 ± 4.07, p = 0.19, and 1.71 ± 1.84 vs. 1.29 ± 1.56, p = 0.33, respectively). No statistically significant differences were observed in the production of any mediators between multidrug-resistant and susceptible strains. However, differences in mediators production were noted among the various healthy donors, except for IFN-gamma and IL-6 in surface extract and MCP-1 in nuclear extract, in which production was similar across donors.

Conclusion: Multidrug-resistant *E. coli* strains produced an *in vitro* immune mediator profile similar to that of antibiotic-susceptible strains. However, differences in mediator production were significantly associated with donor variability. The poor prognosis linked to infections caused by multidrug-resistant *E. coli* does not appear to be related to a different immune response compared to susceptible strains.

Early detection of hepatic encephalopathy using wearable sensors: preliminary data

Clelia Asero[1], Maria Stella Franzè[2], Giorgio Lo Giudice[3], Dario Milone[4], Cristiano De Marchis[4], Roberto Filomia[5], Gaia Caccamo[5], Concetta Pitrone[5], Carlo Saitta[1], Irene Cacciola[6]. *[1]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Messina, Italy; [2]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Messina, Italy; [3]Departiment of medicine and surgery, University of Enna "Kore," Enna (Italy), Department of Biochemical and dental sciences and morphofunctional imaging, University of Messina, Messina (Italy), Messina, Italy; [4]Laboratory of Bioengineering BioME, Department of Engineering, University of Messina, Messina (Italy), Messina, Italy; [5]Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Messina, Italy; [6]Department of clinical and experimental medicine, University Hospital of Messina, Messina (Italy), Internal medicine and hepatology Unit, University Hospital of Messina, Messina (Italy), Messina, Italy*
Email: clelia.asero@gmail.com

Background and aims: Hepatic encephalopathy (HE) is a common complication of liver cirrhosis, with clinical manifestations ranging from mild neuropsychiatric symptoms to coma. Covert HE (cHE) diagnosis is difficult because specific symptoms and validated tests are lacking. This study evaluates its presence by using wearable sensors.

Method: Thirty-four cirrhotic patients and five control cases (without liver disease) were enrolled at the Medicine and Hepatology Unit of the University Hospital of Messina between August 2024 and October 2024. Study cohort was evaluated by positioning 6 sensors on the dorsum of both hands and the flexors/extensor muscles of forearms: 2 configured as Inertial Measurement Units (IMUs) (continuously measuring linear acceleration and angular velocity on 3 axes) and 4 configured as IMUs with additional electromyography channels. Data were recorded during arm extension with palms facing up/down (repeated twice) and arm extension with palms extended for at least 10 seconds. The frequency domain analyzed all the documented signals, extracting features from each signal power spectrum. ANOVA, Kruskal-Wallis, and Eta Squared tests were applied for feature sampling, and the Birch method was used for unsupervised clustering.

Results: Twenty-two subjects were males (mean age 63 ± 14 years). Available clinical data identified 22 of 34 (64.7%) cirrhotic patients without overt HE (oHE), with a possible cHE, and 12 (35.3%) with an overt HE (oHE). Diseased subjects exhibited frequency peaks between 3 and 8 Hz, with significantly higher energy content than the control group. Five features were found to be relevant in the selection process: Left-hand Mean Frequency (LHMF) Gyroscope X, LHMF Gyroscope Y, LH Difference between Power inside boundaries and outside Accelerometer Y, LH Amplitude spectrum outside ratio Gyroscope Z, and Right-Hand MF (RHMF) Gyroscope Y. A comparison of features showed significant differences between the 3 groups (controls vs. non-HE vs. oHE): LHMF Gyroscope X (5.5 ± 0.5 vs. 5.9 ± 1.3 vs. 7.2 ± 1.6 Hz, p = 0.04), LHMF Gyroscope Y (11.0 ± 2.5 vs. 7.9 ± 2.5 vs. 9.9 ± 2.3 Hz, p = 0.04), LH Difference between Power inside boundaries and outside (−1.1 ± 1.3 vs. −4.5 ± 11.2 vs. −0.2 ± 1.9 m/s^2, p = 0.01), LH Amplitude spectrum outside ratio (356.6 ± 272.6 vs. 266.7 ± 140.8 vs. 374.2 ± 143.2, p = 0.01), and RHMF (11.1 ± 1.4 vs. 7.7 ± 2.7 vs. 7.9 ± 2.9 Hz, p = 0.04). The unsupervised clustering identified 3 groups of patients: 4 in cluster 1, 15 in cluster 2, and 11 in cluster 3. Nine patients did not cluster with others. The unsupervised analysis clustered 68.2% of cases as potential cHE, 13.6% as healthy, and 18.2% as oHE. Clustering identified original diagnosis in 77% of patients, but 4 cases clinically evaluated as non-HE showed typical features for oHE.

Conclusion: Wearable IMUs present a promising, noninvasive, objective method for early diagnosis of cHE and oHE. However, increasing the sample size would be crucial for broader use.

THU-143-YI

TLR7-mediated immunomodulation in experimental liver fibrosis

Dimitrios Patseas[1], Eoin Mitchell[1], Zuobin Liu[1], Sarah M. G. Morel[2], Lauren Roberts[1], Cathrin Gudd[1], Lucia A. Possamai[1], Prakash Ramachandran[2], Mark R. Thursz[1], Mark J. W. McPhail[3], Evangelos Triantafyllou[1]. *[1]Section of Hepatology and Gastroenterology, Department of Metabolism, Digestion and Reproduction, Imperial College London, London, United Kingdom; [2]Centre for Inflammation Research, Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, United Kingdom; [3]Department of Inflammation Biology, King's College London, London, United Kingdom*
Email: d.patseas@imperial.ac.uk

Background and aims: Cirrhosis, a global healthcare burden, is characterized by liver fibrosis, immune dysregulation, and impaired pathogen clearance that contribute to an increased infection risk and mortality. Here, we assessed the administration of a Toll Like Receptor (TLR) 7 agonist (R848) in toxin- and diet-induced mouse models of liver fibrosis with or without infectious challenge, as a novel immune-modulatory strategy to restore antimicrobial responses.

Method: Fibrosis was induced in C57BL/6J male and female mice by a) Choline-Deficient, L-Amino-Acid defined High-Fat-Diet (CDA-HFD) for 8 weeks compared to normal diet (ND), or b) intraperitoneal (i.p.) injections of CCl_4 (0.4 μl/g) twice-weekly for 6 weeks compared to control (oil). During the last week of treatments, mice received three i.p. injections of saline (PBS) or TLR7 agonist (R848; 1 mg/kg). Liver immune cells were assessed by flow cytometry; tissue fibrosis and hepatic damage were quantified in Picro Sirius Red (PSR) stained liver sections and serum, respectively. In separate experiments (6-week control vs CCl_4), *Escherichia coli (E. coli)* was intravenously administered. After 24 hours, mice were culled; liver and spleen were harvested, and tissue lysates were plated on agar to quantify bacterial load.

Results: Compared to PBS, R848-treated CDA-HFD and CCl_4-fibrotic mice displayed increased numbers of conventional dendritic cells (cDC1, cDC2), NK, $CD8^+$ and $CD4^+CD25^-FoxP3^+$ T_{reg} cells. Moreover, monocyte, neutrophil, Kupffer cell and liver-recruited monocyte-derived macrophage numbers did not differ between groups.

Interestingly, liver fibrosis (percentage of PSR^+ area) and tissue damage (serum ALT and AST) were not impacted by R848 treatment. Compared to control, CCl_4-fibrotic mice showed increased liver and spleen bacterial load (*E. coli* CFU per tissue gram); notably, R848 treatment of CCl_4-fibrotic mice led to significantly reduced tissue bacterial burden.

Conclusion: Our findings demonstrate that, in the mouse fibrotic liver, R848 treatment reshapes the hepatic immune compartment resulting into improved *E. coli* clearance following systemic infection. Future studies will elucidate the underlying mechanisms of TLR7-mediated immunomodulation in fibrosis, and potentially translate TLR-targeted therapies in a clinical setting.

THU-144

Epigenetic regulation of LSECtin in hepatic antigen presenting cells during experimental cirrhosis

Enrique Ángel-Gomis[1,2,3], Sebastián Martínez-López[1,2,3], Isabel Gómez-Hurtado[1,2,4], Paula Boix[1,2], Oriol Juanola[1,2,3], Maite G. Fernandez-Barrena[4,5], Manel Hadid[1], Matías A. Avila[4,5], Esther Caparrós[1,2,3], Rubén Francés[1,2,3,4]. *[1]Liver and gut immunobiology group, Clinical medicine dpt, Universidad Miguel Hernández, Alicante, Spain, Alicante, Spain; [2]IIS ISABIAL, Hospital General Universitario Dr. Balmis, Alicante, Spain, Alicante, Spain; [3]Instituto IDIBE, Universidad Miguel Hernández, Elche, Spain, Elche, Spain; [4]CIBERehd, Instituto de Salud Carlos III, Madrid, Spain, Madrid, Spain; [5]Hepatology research program, CIMA, Universidad de Navarra, Pamplona, Spain, Pamplona, Spain*
Email: eangel@umh.es

Background and aims: LSECtin/*Clec4 g* is a pattern recognition receptor and T cell ligand expressed in Kupffer Cells (KCs) and Liver Sinusoidal Endothelial Cells (LSECs). Its expression is reduced during advanced chronic liver disease (CLD). The main aim of this work is to characterize the epigenetic regulation of LSECtin.

Method: DNA methylation levels and histone post-translational modification (HPTMs) profile where studied by methylation array and ChIP-Seq experiments carried out on KCs and LSECs isolated by FACS from untreated and cirrhotic (12 weeks of CCl_4 gavage) mice. Immortalized KCs and LSECs were treated with epigenetic effector inhibitory drugs (OTS186935-Suv39h2i, UNC0642-G9a/Glpi, UNC1999-EZH2/1i, 5-Aza-2′-deoxycitidine-DNMTi), alone and in combination with IL-4, an LSECtin expression inductor. Drugs with relevant regulatory potential were intraperitoneally injected to untreated and CCl_4 mice.

Results: Statistically significant changes were observed in specific loci methylation levels in both KCs and LSECs, being macrophages especially susceptible to methylome modification by CCl_4 treatment. Significant changes were also observed in gene body and promoter region of *Clec4 g*, primarily in KCs. ChIP-Seq experiment allowed the study of HPTMs profile of chromatin associated to H3K3me3/H3K27me3. KCs and LSECs showed a specific peak profile at the genomic level; however, no significant differences were identified in proximal promoter region of *Clec4 g*. Immortalized cell lines treatment with epigenetic effectors inhibitory drugs caused a slight reduction in LSECtin expression, which was further retrieved by IL-4 +drug treatment. Additionally, LSECtin expression was increased by 5-Aza-2′-deoxycitidine, a passive DNA demethylating agent; causing a higher increment of expression by the combined treatment of Aza +IL-4. Cirrhotic mice treated with OTS186935 and UNC1999 showed an increment of LSECtin expression studied by WB, qPCR and flow cytometry, as well as an improvement in hepatic transferases and other liver damage markers. These animals also had a reduction in activation and proinflammatory profile of T CD4+/CD8+ cells, which in combination with a reduction of IL-17+ T cells population, mechanistically correlates with LSECtin expression recovery.

Conclusion: The increment of LSECtin expression by passive demethylation of DNA and methylation array results point out methylation of *Clec4 g* promoter is a key mechanism in expression regulation. Modulation of LSECtin expression both *in vitro* and *in vivo* by epigenetic effector inhibitory drugs strongly suggest that HPTMs profile alteration contributes to protein regulation during CLD, thus positioning periodical administration of epigenetic inhibitors as a candidate for LSECtin expression recovery in the pathological scenario.

THU-145-YI

Propranolol reverses splanchnic β-adrenergic induced small intestinal barrier disruption stabilizing gut-liver axis in experimental cirrhosis

Email: elisa.castillo@uah.es

Background and aims: Propranolol (PROP) exerts beneficial effects in cirrhosis by reducing portal pressure and decreasing pathological bacterial translocation (PBT). The mechanisms underlying its effect on the intestinal barriers (IB) however, are largely unknown. This study investigates (1) the effect of splanchnic β-adrenergic hyperstimulation on the IB, and (2) whether PROP reverses the potential harmful effects of β-adrenergic hyperstimulation in experimental models with and without cirrhosis.

Method: *Models*: A) Wistar rats and C57BL/6 mice with cirrhosis induced by CCl_4 or bile duct ligation (BDL), treated with PROP or placebo for 2 weeks. B) β-adrenergic hyperstimulation model: C57BL/6 mice treated with peritoneal osmotic pumps delivering isoproterenol (ISO), ISO plus PROP or vehicle for 7 days. C) β-Catenin gain-of-function (GOF) mice: generated from β-catenin-lox(ex3)/lox(ex3) and Cdh5(PAC)-CreERT2 strains presenting with VE-cadherin-dependent stabilized gut-vascular barrier (GVB). *Methods:* i) Muco-epithelial barrier: ileal tight junctions (TJ: ZO-1, claudin 1 and 5) by immunofluorescence (IF) and RT-qPCR, and mucus thickness (PAS). ii) Vascular barrier: PV1, VE-cadherin expression (IF), fecal albumin (ELISA), in-vitro transwell-permeability for FITC-albumin in murine endothelial cells, in-vivo extravasation of FITC-albumin (by laser endomicroscopy) iii) hepatic 4KDa-FITC-dextran recovery after ileal loop injection (=translocation to liver).

Results: ISO increased endothelial FITC-albumin permeation and down-regulated VE-cadherin (0.20 vs 0.09, $p < 0.05$) and claudin-5 (0.07 vs 0.03, $p < 0.05$) in the duodenal vasculature. ISO induced pathological albumin extravasation in small intestinal microcirculation (15 vs 10 AUC, $p < 0.05$), being mitigated by PROP and not observed in GOF mice, indicating VE-cadherin as key driver of GVB-disruption induced by β-adrenergic hyperstimulation. In CCl_4-cirrhotic rats, PROP restored the ileal mucosal-epithelial barrier by

increasing mucus thickness and TJ expression (each, $p < 0.01$, respectively). PROP reduced PV1 expression in ileal vessels (PROP vs. placebo; 0.81 ± 0.11 vs 0.42 ± 0.09U, $p < 0.01$), dextran translocation to the liver (0.81 ± 1 vs 0.42 ± 4 part., $p < 0.05$), and fecal albumin loss (from 24,579 ± 1,040 to 1,187 ± 373 ng/mg feces, $p < 0.01$). Similar results were seen in BDL-cirrhotic rats, with PROP attenuating also duodenal albumin extravasation. PROP improved intestinal dysbiosis in CCl_4-induced cirrhosis but not in BDL, and reduced PBT in both models (CCl_4: 86 vs 34%, $p < 0.01$. BDL: 64 vs. 42%).
Conclusion: β-adrenergic hyperstimulation impacts on the IB by increasing endothelial and epithelial permeability through direct cellular mechanisms. PROP restores both the structure and function of the IB in cirrhosis, thereby limiting PBT. The beneficial effects of PROP in cirrhosis are largely associated with the stabilization of the gut-liver axis, an effect at least partially being independent of hemodynamic mechanisms.

THU-146
Global trends in antimicrobial resistance in chronic liver disease patients with bacteremia: a systematic review and meta-analysis of observational studies
Ellis Paintsil[1], Cynthia Adu-Asiamah[2], Yevedzo Ntuli[1], Victoria Kronsten[1], Debbie L. Shawcross[1]. [1]*King's College London, London, United Kingdom;* [2]*Kumasi Centre for Collaborative Research, Kumasi, Ghana*
Email: ellis.paintsil@kcl.ac.uk

Background and aims: In cirrhotic patients, bacteremia can rapidly progress to sepsis and multi-organ failure, contributing to significant morbidity and mortality. This systematic review and meta-analysis assess global trends in antimicrobial resistance (AMR) among bacterial pathogens responsible for bacteremia in patients with cirrhosis.
Method: We conducted a systematic review and meta-analysis following PRISMA guidelines, registered on PROSPERO (CRD42024539347). Searches across PubMed, Embase, Web of Science, and Scopus were completed up to September 30, 2024. Pooled proportions (PPs) and 95% confidence intervals (CIs) were calculated using random-effects models. Heterogeneity was assessed with the I^2 statistic, and subgroup analyses were conducted by geographic region, bacterial species, and AMR type.
Results: A total of 26 studies comprising 5,488 bacteremia cases in patients with cirrhosis were included in the analysis. The pooled bacteremia infection proportion was 21.53% (95% CI: 13.07–31.37), with 76.56% (95% CI: 63.66–87.49) identified as nosocomial. *Escherichia coli* was the predominant pathogen (27.07%; 95% CI: 16.66–38.84), followed by *Staphylococcus aureus* (15.25%; 95% CI: 11.36–19.58). The overall pooled proportion of multidrug-resistant (MDR) bacteria was 30.77% (95% CI: 19.03–43.88), with higher rates in Asia (35.10%, 95% CI: 22.41–48.93) and Europe (35.05%, 95% CI: 25.80–44.87). Methicillin-resistant *Staphylococcus aureus* (MRSA) infections were observed at 11.46% (95% CI: 0.00–57.88) in Asia and 9.96% (95% CI: 2.97–19.79) in Europe. Extended-spectrum beta-lactamase (ESBL) *E. coli* had a pooled proportion of 13.81% (95% CI: 7.04–22.24), with rates in Asia reaching 20.91% (95% CI: 12.26–31.10). The global pooled proportion of carbapenem-resistant *Enterobacteriaceae* (CRE) was 4.86% (95% CI: 0.69–11.49).
Conclusion: Bacteremia represents a significant global burden among chronic liver disease patients, marked by geographic variability in resistance patterns. This necessitates targeted regional strategies and collaborative efforts to effectively combat the increasing incidence of infections in this vulnerable population.

THU-149-YI
Sex-specific estradiol signaling in liver cirrhosis and portal hypertension
Fabian Schachteli[1], Sabine Klein[1], Robert Schierwagen[1], Maximilian Joseph Brol[1], Jonel Trebicka[1], Frank Erhard Uschner[1]. [1]*Department of Internal Medicine B, University Hospital Münster, Münster, Germany*
Email: frankerhard.uschner@ukmuenster.de

Background and aims: Recently, it has been shown that estradiol (E2) may have long-term anti-fibrotic and metabolic effects in liver disease mediated through the nuclear estradiol receptor alpha (ERalpha). Additionally, E2 was shown to cause rapid, non-genomic effects in human heart disease via the G-protein-coupled ER (GPER) receptor - cyclic guanosine monophosphate (cGMP) - nitric oxide (NO) pathway, but its role in liver cirrhosis remains unclear. Therefore, this study investigated the sex-specific effects of estradiol on GPER and cGMP-NO pathway in liver cirrhosis and portal hypertension.
Method: Liver cirrhosis was induced using bile duct ligation (BDL) in male, female and female ovariectomized rats. Animals received either (i) a single high dose of E2 one day before sacrifice, (ii) an acute dose of phosphodiesterase-5-inhibitor (PDE-5-I) for cGMP augmentation directly before sacrifice, or (iii) a combination of both. Male and female BDL rats without E2 and PDE-5-I served as controls. Subsequently, portal and systemic hemodynamics were assessed using colored microspheres and vascular contractility using *ex vivo* aortic ring contraction. Furthermore, expression of E2 receptors and NO signal pathway in aorta and liver tissue was analyzed using Western blot and qPCR.
Results: In male BDL rats, E2 did not affect portal and systemic hemodynamics, ERalpha and GPER expression, or response to PDE-5-I. In female BDL rats, ovariectomy led to an increased hepatic portal vascular resistance (HpVR), a decreased hepatic GPER expression, and a reduced hepatic NO pathway activity compared to non-ovariectomized female BDL rats. In addition, ovariectomized female BDL rats exhibited a decreased systemic vascular resistance, but higher contractility of aortic rings *in situ* compared to female BDL control rats. Additionally, GPER and ERalpha expression was increased in aorta of ovariectomized rats compared to female rats without ovariectomy. PDE-5-I significantly reduced portal pressure (PP) in male and female control BDL rats but had no hemodynamic effect on ovariectomized female BDL rats. The substitution of E2 in ovariectomized female BDL rats caused a significant decrease in HpVR and PP and restored susceptibility to PDE-5-I.
Conclusion: Estradiol deficiency after ovariectomy deteriorates portal hypertension in female cirrhotic rats, which can be reversed by estradiol substitution. These effects might be mediated by the cGMP-NO pathway. Thus, targeting the GPER – NO pathway could be a therapeutic approach in postmenopausal women with liver cirrhosis and portal hypertension.

THU-150
Comparative analysis of surrogate markers of intestinal permeability, bacterial translocation, and gut vascular barrier damage across different stages of cirrhosis
Haedge Frederic[1], Philipp Reuken[2], Johanna Reißing[1], Karsten Große[1], Mick Frissen[1], Majda El Hassani[1], Andreas Stallmach[2], Tony Bruns[1]. [1]*Department of Internal Medicine III, Aachen, Germany;* [2]*Department of Internal Medicine IV, Jena, Germany*
Email: tbruns@ukaachen.de

Background and aims: Portal hypertension, impaired gut barrier function and pathological bacterial translocation are hallmarks of advanced liver disease driving complications of cirrhosis. As measuring gut barrier function is demanding, surrogate markers have been proposed but their intercorrelation and applicability across different stages of advanced liver disease, particularly in acute-on-chronic liver failure (ACLF) is largely unknown.

Method: Proposed markers of gut barrier dysfunction and bacterial translocation were quantified in sera from 160 patients with cirrhosis across different disease stages of compensated and decompensated cirrhosis as well as in hepatic and portal vein serum before and after the insertion of transjugular intrahepatic portosystemic stent (TIPS) using ELISA.
Results: Across all stages of liver disease, the gut vascular barrier marker plasmalemma vesicle protein-1 (PV-1) correlated with the bacterial translocation markers endogenous endotoxin-core IgA antibodies (EndoCAb) and LPS-binding protein (LBP) but not with intestinal damage markers intestinal fatty acid binding protein (I-FABP) and Zonulin-family peptides (ZFP). PV-1 and EndoCAb were higher in decompensated cirrhosis without further increase in ACLF. Among investigated markers, only I-FABP correlated with the portosystemic pressure gradient and TIPS insertion significantly reduced portal concentrations within 24 h hours. Higher PV-1 levels indicated poor transplant-free survival in univariate and multivariable analysis.
Conclusion: The investigated surrogate markers of bacterial gut barrier dysfunction and bacterial translocation appear of limited use in advanced stages cirrhosis and are differently confounded by the hepatic synthesis capacity, portal congestion, and acute phase responses. The prognostic implications of circulating PV-1 in decompensated cirrhosis levels demands further investigation.

THU-151-YI

Aberrant monocyte function promotes systemic inflammation in decompensated advanced chronic liver disease and can be therapeutically targeted

Malgorzata Grzelka[1], Roseanne Khawaja[1], Alejandro Brenes[1], Daniel Dugger[2], Guiquan Jia[2], Dario Nicetto[2], Nandhini Ramamoorthi[2], Andrew Thorley[2], Jonathan Fallowfield[1], Prakash Ramachandran[1]. *[1]Centre for Inflammation Research, The University of Edinburgh, Edinburgh, United Kingdom; [2]Genentech, South San Francisco, United States*
Email: grzelka.malgorzata@gmail.com

Background and aims: Systemic inflammation has been proposed as a key driver of disease progression in advanced chronic liver disease (ACLD), with monocyte dysfunction suggested to play a pivotal role. However, the exact causes and mechanisms are not fully understood, limiting therapeutic opportunities. We aimed to study differences in monocyte phenotype, function and molecular mechanisms that drive the development of systemic inflammation in cirrhosis and identify novel anti-inflammatory therapeutic targets for ACLD.
Method: Four study groups were defined as: healthy controls, non-cirrhotic CLD (fibroscan < 10 kPa in the absence of other signs of cirrhosis), compensated ACLD (cACLD, fibroscan ≥10 kPa without clinical signs of decompensation) and stable decompensated ACLD (dACLD, stable clinical signs of decompensation regardless of fibroscan). 28-colour spectral flow cytometry panels were designed for the immunophenotyping of whole blood to determine cell counts, inflammatory cytokine expression and phagocytic capacity using pHrodo green E. Coli bioparticles. Proteomics (mass spectrometry) was performed on monocytes from dACLD and cACLD (n = 9, 6 respectively) subjects.
Results: Samples from 13 healthy, 17 non-cirrhotic CLD (9 PBC, 8 MASLD), 59 cACLD (31 MASLD, 16 ALD, 7 other, 5 PBC) and 20 dACLD (7 MASLD, 6 ALD, 6 PBC, 1 PSC) patients were analysed. Quantitation of cell numbers demonstrated significant reductions in $CD8^+$ (cytotoxic), $CD4^+CD45RA^+$ (naïve), NKT and gamma delta T cells in patients with dACLD. No difference was observed in monocyte numbers, but there was a significant phenotypic shift in monocytes between cACLD and stable dACLD. dACLD monocytes were more activated (upregulated CD9 and CD64), showed higher phagocytic capacity ($p < 0.05$) and increased inflammatory cytokine production (IL-1β, $p < 0.005$, TNF-α, $p < 0.05$, IL-6 $p = 0.08$) compared to cACLD. Quantitative proteomics analysis of monocytes identified a significant increase in proteins related to interferon signalling (including STAT1, TBK1, IRF3) and pattern recognition receptors (PRRs) in dACLD, which could drive excessive inflammatory mediator production.
Conclusion: Our analyses show a step-change in monocyte phenotype between cACLD and dACLD, with aberrant monocyte function contributing to the systemic inflammation observed in dACLD. Our proteomic data identified candidate mechanisms and PRRs driving this monocyte activation. Ongoing work is focused on modulating candidate dACLD-associated PRRs to attenuate inflammatory activity.

THU-152

CLM-022, a dual inhibitor of priming and activation steps of NLRP3 inflammasome, as a potential treatment for acute and chronic inflammatory late-stage liver diseases

Hana Elkhatib[1], Alexandra Caron[1], Elodie Delecroix[1], Victor Launay[1], Maryse Malysiak[1], Claire Devos[1], Guillaume Vidal[1], Dean Hum[1], Bart Staels[2], Sakina Sayah Jeanne[1]. *[1]Genfit SA, Loos, France; [2]Univ. Lille, Inserm, CHU Lille, Institut Pasteur Lille, U1011, Lille, France*
Email: guillaume.vidal@genfit.com

Background and aims: Inflammasomes are intracellular multi-protein complexes involved in liver diseases that, in response to cellular danger signals, activate caspase-1 and release pro-inflammatory cytokines IL-1beta and IL-18 (Ribeiro et Szabo 2022). NLRP3 activation requires two signals: the first signal inducing cell priming is the first step of NLRP3 inflammasome activation leading to up regulation of NLRP3 expression, and the second signal includes a broad variety of activators leading to the NLRP3 inflammasome complex activation. The ability of investigational drug CLM-022 to inhibit the NLRP3 inflammasome has been shown through the inhibition of 1) inflammasome complex formation, 2) IL-1β production, and 3) pyroptosis. The aim of this work was to characterize the activity of CLM-022 on the priming and activation of NLRP3 activity both in vitro and in vivo.
Method: PBMC were stimulated with LPS, and priming of NLRP3 activity was assessed by measuring gene expression by RT-qPCR. To assess the specificity of CLM-022 inhibition on NLRP3 inflammasome and pyroptosis, WT THP-1 and NLRP3 KO THP-1 macrophages were primed with LPS and stimulated with nigericin; IL-1beta release and pyroptotic cell death were measured by HTRF and LDH release, respectively. For in vivo efficacy studies, CLM-022 was administrated to different acute liver failure and inflammation rodent models. Systemic inflammation, liver functions and inflammation were assessed by measuring circulating levels of IL-1beta, ASAT, ALAT, and hepatic inflammasome gene expression, respectively.
Results: The addition of CLM-022 inhibits IL-1beta & NLRP3 gene expression induced by LPS stimulation of human PBMC. CLM-022 treatment strongly inhibits the NLRP3 inflammasome dependent pyroptotic cell death in THP1 human macrophages (inhibition of IL-1β production, LDH release) but not in the Thp1- NLRP3 KO THP1 cells. In vivo, CLM-022 inhibits circulating IL-1β in the GalN/LPS model and decreases inflammasome pathway priming in the liver, by inhibiting the NF-kB dependent gene expression. CLM-022 administration improves hepatic functions monitored with ASAT and ALAT.
Conclusion: Investigational drug CLM-022 is a dual inhibitor of inflammasome expression and activity with nanomolar activity. It enables disruption of both the priming and activation steps of NLRP3 activity and thus, as a dual inhibitor, demonstrates therapeutic potential for the treatment of acute and chronic inflammatory late-stage liver diseases, including ACLF.

THU-153

Immunometabolism of mononuclear cells from blood and ascites in patients with decompensated cirrhosis: compartment-specific features of metabolic dysfunction

Hasan Tarik Cosgun[1,2], Pavitra Kumar[1], Linda Hammerich[1], Ingrid Wei Zhang[1], Virein Sudheer[1], Charalampos Pavlidis[1],

Hannah Schwarz[1], Juan Wang[1], Frank Tacke[1], Ali Canbay[2], Cornelius Engelmann[1]. [1]*Charité - Universiätsmedizin Berlin, Berlin, Germany;* [2]*Universitätsklinikum Knappschaftskrankenhaus Bochum, Bochum, Germany*
Email: hasan.cosgun@rub.de

Background and aims: The development of ascites is a common decompensation event in patients with cirrhosis and is linked to complications such as spontaneous bacterial peritonitis (SBP) and acute-on-chronic liver failure (ACLF). While systemic inflammatory processes in liver disease have been well-studied, the immune and metabolic dynamics within the peritoneal compartment remain less explored. Therefore, this study aims to investigate metabolic characteristics of peritoneal immune cells in advanced liver disease.
Method: Matched blood and ascites samples from patients with acute decompensation (AD) without SBP (n = 20) were analyzed. Mononuclear cells (MNCs) were isolated using density gradient centrifugation and magnetic cell separation. Mitochondrial stress test was performed using the Seahorse Xfe96 Analyzer to assess oxidative phosphorylation (OXPHOS) and glycolysis rates. Immune cell phenotyping in ascites and blood was performed using spectral flow cytometry.
Results: Among all enrolled patients, alcohol-associated liver disease (48%) represented the main cause of liver cirrhosis. The median age of patients was 58 years (range: 29–84), patients were predominantly male (62%) and the median MELD score was 15.5 (range: 6–28). Flow cytometry revealed comparable T-lymphocyte prevalence in blood and ascites (50.6% vs. 56.6%; $p > 0.05$). Monocytes were more abundant in blood (32.6% vs. 5.8%; $p < 0.001$), while NK (6.7% vs. 20.5%; $p < 0.001$) and NKT cells (1.3% vs. 7.3%; $p < 0.001$) were more prevalent in ascites. Furthermore, peritoneal monocytes were predominantly identified as CD14+CD16+ intermediate monocytes with 59.6% compared to 50.6% in blood. Classical monocytes were more frequent in ascites (24.5% vs. < 1%) and nonclassical monocytes were predominantly found in blood (47.5% vs. 15.9%). Peritoneal MNCs demonstrated a metabolically activated phenotype compared to blood MNCs, characterized by significantly higher basal and maximal oxidative respiration ($p < 0.01$) and markedly lower glycolytic activity ($p < 0.001$). Proton leak, a possible indicator of mitochondrial damage, was elevated in peritoneal MNCs ($p < 0.001$). These metabolic changes were accompanied with the presence of activated immune cell subsets. PD1 expression was increased in ascites CD4 T cells (36.7% vs. 11.5%; $p < 0.001$). Moreover, there was a shift in differentiation, with fewer naïve CD45RA+ cells (14.1% vs. 32%; $p < 0.001$) and a higher number of effector/memory CD45RO+ cells in ascites (85.9% vs. 67.8%; $p < 0.001$). Additionally, CD206 expression, a marker for activated macrophages and monocytes, was significantly increased in peritoneal intermediate monocytes (ascites 65.4% vs. blood 21.4%; $p < 0.001$), while expression of CD86 and CD163 showed no significant differences.
Conclusion: Peritoneal immune cells exhibit, in comparison to their blood counterparts, a metabolically active phenotype and show features of immune exhaustion, indicating a distinct role in immune regulation within the peritoneal environment.

THU-154

Downregulation of interleukine-6 receptors on ascitic T cells may shape the immune compartment in the peritoneal cavity

Helena Stadler[1], Mona-May Langer[1], Quan Yin[1], Lena Oeckl[1], Marc Weiß[1], Alina Bauschen[1], Nikola Mareljic[1], Severin Jacobi[2], Christian M. Lange[1]. [1]*Department of Medicine II, University Hospital LMU, Munich, Germany;* [2]*Department of General- Visceral- and Transplant-Surgery, University Hospital LMU, Munich, Germany*
Email: helena.stadler@med.uni-muenchen.de

Background and aims: In patients with advanced liver cirrhosis, high cytokine levels in ascites indicate a dysregulated and excessive immune response within the abdominal cavity. Although it is already known that impaired intestinal permeability and bacterial translocation serve as triggers for this hyperinflammation, the resulting cellular mechanisms remain insufficiently understood. This study aims to analyze the effect of dysregulated interleukin-6 (IL-6) signaling on the T cell compartment in ascites.
Method: Ascitic fluid and peripheral blood samples were collected from patients with liver cirrhosis, and immune cells were isolated. Cytokine and soluble receptor concentrations were measured by ELISA. T cell phenotype and surface receptor expression was analyzed by flow cytometry.
Results: In ascites, the natural IL-6 trans-signaling inhibitor soluble gp130 was found to be 14.4-fold higher than the soluble IL-6 receptor (IL-6R), suggesting a blockade of IL-6 trans-signaling. Further, the surface expression of IL-6R and gp130 was significantly lower among T cells within ascites compared to those circulating in blood ($p = 0.009$ and $p = 0.036$, respectively). gp130+IL-6R+ T cells, that are reactive to IL-6 classical-signaling, were predominantly CD8+ with naïve or effector-phenotype. Overall, gp130+IL-6R+ T cells were significantly decreased in ascites compared to blood ($p = 0.019$). However, CD4+ Th17 cells, whose differentiation is dependent on IL-6, were significantly more enriched in ascites than in blood ($p = 0.0025$).
Conclusion: We suggest that the blockade of trans-signaling and downregulation of IL-6 surface receptors on T cells may represent compensatory mechanisms to mitigate excessive IL-6 signaling driven by high IL-6 levels in ascites. However, IL-6 signaling seems to shape the immune compartment in the peritoneal cavity and may thus contribute to systemic hyperinflammation.

Cyclooxygenase-2 promote hepatic microvascular thrombosis and portal hypertension via AKT/mTOR-Thbs1 pathway in partial inferior vena cava ligation mice

Jisen Xu[1,2], Shuaijie Qian[1,2], Xu Guo[1,2], Ying Li[1,2], Xin Quan[1,2], Jinhang Gao[1,2], Huan Tong[1,2], Yang Tai[1,2], Bo Wei[1,2], Chengwei Tang[1,2], Hao Wu[1,2]. Email: hxxhwh@163.com

Background and aims: Dysfunction of Liver sinusoidal endothelial cells (LSECs) plays a key role in the formation of hepatic microvascular thrombosis and portal hypertension. Many studies have proven that Cyclooxygenase-2 (COX-2) could regulate chronic liver diseases. However, the role of COX-2 in hepatic microvascular thrombosis and portal hypertension remains unknown and is the focus of this study.
Method: Hepatic microvascular thrombosis and portal hypertension were induced by partial inferior vena cava ligation (pIVCL). We investigated the hepatic differentially expressed genes by RNA sequencing in the sham and pIVCL groups. The role of COX-2 in hepatic microvascular thrombosis and portal hypertension induced by pIVCL was explored in wild-type mice treated with celecoxib and mice with LSEC-specific *Ptgs2* deletion (*Ptgs2*$^{LSEC\Delta/\Delta}$). Human hepatic sinusoidal endothelial cells (HSECs) were used to probe the prothrombotic role of COX-2.
Results: The increase in hepatic microvascular thrombosis was observed in murine liver induced by pIVCL. RNA sequence of liver tissue showed upregulation of *Ptgs2* gene, and pro-inflammatory genes in pIVCL mice compared to sham mice. Hepatic microvascular thrombosis, portal hypertension, and liver inflammation were relieved in *Ptgs2*$^{LSEC\Delta/\Delta}$mice and treated with celecoxib compared to control mice. As revealed by RNA sequence of liver tissue, compared to the pIVCL mice, celecoxib can downregulate the *Thbs1* gene, which plays a vital role in thrombogenesis, and AKT/mTOR pathway. In vitro, upregulation of *PTGS2*, *THBS1*, and AKT/mTOR pathway in HSECs was induced by TNF-α. Treated with celecoxib or the inhibitors of AKT/mTOR pathway reduced the expression of *THBS1* and AKT/mTOR pathway. These results suggested that COX-2

might regulate hepatic microvascular thrombosis by AKT/mTOR-Thbs1 signaling pathway.
Conclusion: In hepatic microvascular thrombosis and portal hypertension mice, the up-regulated COX-2 promotes the expression of the pro-thrombogenesis gene, *Thbs1*, via the AKT/mTOR pathway to contribute to hepatic microvascular thrombosis.

An antimicrobial peptide, melittin attenuates gut urease activity and ammonia production in experimental model of cirrhosis
Deepika Jakhar[1], Pinky Juneja[1], Aarti Sharma[2], Bhaskar Sharma[1], Dinesh Mani Tripathi[2], Shiv Kumar Sarin[1], Savneet Kaur[2]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India, New Delhi, India;* [2]*Institute of Liver and Biliary Sciences, New Delhi, India, New Delhi, India*
Email: savykaur@gmail.com

Background and aims: Antimicrobial peptides (AMPs) are a vital part of innate immune response that play a key role in regulating gut bacteria and protect against infection. Urease expressing bacteria, predominantly gram negative, are increased in cirrhotic gut and contribute significantly to endogenous ammonia production. Here we investigated a novel hypothesis of using AMPs as a therapeutic to target gut urease bacteria and studied the potential of one of the identified AMPs to reduce gut urease activity and ammonia production.
Method: Urease expressing bacteria were screened using BactPepDB database. AMPs were computationally identified and validated through databases (DBAASP.v3, DRAMP, APD) and CAMPR3 predictive models, employing support vector machines, random forests, discriminant analysis to ensure selection of potential AMPs. This led to the selection of a natural AMP derived from bee venom, melittin. Next, in vitro studies with varying concentrations of melittin were performed with a urease expressing bacteria, *Klebsiella pneumoniae* (*kp* 1.5×10^9) for reducing bacterial urease activity and ammonia release. For in vivo studies, ethyl cellulose nanoparticles loaded with melittin using double emulsion method were prepared. Nano-formulated melittin (NM) was administered orally at 10 μg/kg twice weekly in a 10-week thioacetamide induced cirrhosis rat model and compared with a vehicle group with empty ethyl cellulose nanoparticles. Impact of melittin on gut microbiome, bacterial urease activity, ammonia metabolism in organs, plasma ammonia levels and liver disease progression was assessed.
Results: In vitro studies demonstrated that melittin at 390 μg/ml significantly reduced *Kp* urease activity (2fold) and ammonia levels (4.9fold). NM exhibited a spherical morphology, 303 nm size, 76.3% encapsulation efficiency, demonstrating potential for controlled oral delivery with good stability. In animal study, in comparison to controls, NM led to a decrease in portal ammonia by 1.4fold ($p = 0.007$), peripheral ammonia levels by 2.6fold ($p = 0.02$), stool ammonia by 1.3fold ($p = 0.1$), stool and colonic urease activity by 3fold ($p = 0.05$) and 1.4fold ($p = 0.05$) respectively. No significant changes were observed in glutaminase (PAG) gene expression in kidney, colon, duodenum, or glutamine synthetase (GS) expression in muscles and liver. 16S rRNA sequencing revealed reduced species diversity (Shannon index, $p = 0.44$) and significant alterations in gut microbiome composition (87% variance, $p = 0.33$), notable decrease in urease expressing taxa (*Escherichia coli, Streptococcus*) and increased abundance of commensal *Prevotella copri* in NM treated rats vs vehicle. NM treated rats also showed a significant reduction in hepatic fibrosis and immune infiltration as compared to vehicle rats.
Conclusion: Nano-formulated melittin demonstrates a promising therapeutic approach to modulate gut microbiota, ammonia production and also disease progression by targeting urease expressing bacteria in cirrhosis.

Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Even after recovery from overt hepatic encephalopathy (HE), minimal HE (MHE), which impairs quality of life (QoL), can persist. A double-blind, placebo-controlled randomized clinical trial (HEAL) showed improvement in cognition with albumin infusion versus placebo (normal saline) in patients with prior HE on standard of care (Fagan A., J. Hepatol., 2022). However, the mechanisms of improvement are unclear. Aim: determine differences in serum metabolomics in albumin versus saline in HEAL study.
Method: HEAL included cirrhosis outpatients with prior HE, MHE and hypoalbuminemia already on treatment for HE given 25% IV albumin 1.5 g/kg or saline weekly over 5 weeks. Blood was drawn pre and 1-hour post-infusion at baseline, week 3 (mid) & 5 (study end). Untargeted metabolomics of serum samples was performed using liquid chromatography coupled to high resolution mass spectrometry. Changes in serum metabolites pre vs post-infusion were compared within/between albumin & saline groups for these 3 visits.
Results: Forty-eight (24/group) pts were randomized and balanced (including by HE medication use) at baseline. Adverse events were similar, with MELD and ammonia remaining stable between/within groups. Albumin levels increased and ischemia-modified albumin decreased only in the albumin group at study end vs. baseline. Cognition improved as well as psychosocial QOL. Within group metabolomics: Pre vs post-albumin infusion: There was a significant increase in 2 broad groups tryptophan metabolites & acylcarnitines post-albumin vs pre-albumin, which was only significant at baseline. Tryptophan metabolites were higher (N-acetyl tyrosine, 2.3 fold, $p = 0.003$, Xanthurenic acid 2.7 fold, $p = 0.013$, Kynurenic acid 1.9 fold, $p = 0.02$) as well as acylcarnitines (Decanoylcarnitine 1.8 fold $p = 0.003$, Octanoylcarnitine 1.8 fold, Hexanoylcarnitine 1.5 fold, $p = 0.01$) after albumin compared to pre-albumin. Pre vs post-saline infusion: No change in metabolites vs baseline were found. Between groups: *Visit 1*: post-albumin pts vs placebo had again higher concentrations of tryptophan derivatives and aromatic pathways (N-acetyl tyrosine, 2.6 fold, $p = 0.005$, xanthurenic acid 3.1 fold, $p = 0.013$, kynurenic acid 2.2 fold, $p = 0.005$,L-kyunerine 2.3 fold, $p = 0.007$, hydroxy-kyunerine 2.3 fold, $p = 0.02$ N-acetyl ornithine 2.4 fold $p = 0.007$, o-hydroxyhippuric acid, 5.4 fold, $p = 0.02$), decanoylcarnitine 1.6 fold $p = 0.03$), and lower concentrations of spermidine (0.44, $p = 0.03$). *Subsequent visits*: N-acetyl ornithine remained significantly higher in albumin vs saline (mid 2.5 fold $p = 0.04$, end fold 1.7, $p = 0.006$).
Conclusion: Novel metabolomic pathways related to higher tryptophan metabolites that favorably affect the gut-brain axis & gut barrier, and long-chain acylcarnitines that modulate bio-energetics increase with albumin infusion compared to placebo in an RCT. These changes are maximal after the first albumin infusion and saturate subsequently.

Email: k.gananandan1@nhs.net

Background and aims: Cirrhosis patients hospitalized with acute decompensation (AD) have a high 90-day mortality. Asymmetric dimethylarginine (ADMA) and its stereoisomer symmetric dimethylarginine (SDMA) reduce nitric oxide generation, cause endothelial cell dysfunction and play a role in driving portal hypertension and liver-related mortality. This study aimed to develop and validate a new scoring system termed DAS, combining these 2 biomarkers, in predicting liver-related events following AD.
Method: The derivation cohort encompassed patients from the DASIMAR study (n = 247), a prospective, observational, UK study recruiting patients admitted non-electively with AD cirrhosis. The validation cohort was from the PREDICT study (n = 409) which was a multicentre European trial with a similar design. ADMA and SDMA analysis were performed by liquid chromatography- tandem mass spectrometry at baseline (T0) and a second time point within 7 days (T1).
Results: Both cohorts exhibited similar baseline characteristics. With regards to inpatient transplant-free mortality in the DASIMAR cohort, T0 DAS was significantly higher in those who died (13%) compared to survivors (6.7 vs 4.1 umol/L, $p < 0.001$). Indeed, T0 DAS remained a predictor of inpatient mortality in multivariate analysis (OR 1.3 [95% CI 1.1–1.5], $p = 0.002$) and was superior to the baseline CLIF-C AD score (OR 1.1 [95% CI 1.0–1.2], $p = 0.003$). When assessing 90-day mortality, T0 DAS was also significantly higher in those who died (n = 56) compared to survivors (5.7 vs 4.1 umol/L, $p < 0.001$). Whilst both T0 and T1 DAS were significant predictors in univariate analysis, only T1 DAS remained significant in multivariate analysis (OR 1.48 [95% CI 1.18–1.86], $p = 0.001$). When assessing 90-day mortality in the PREDICT cohort a similar signal was demonstrated with significantly higher T0 DAS scores in those who died (5.5 vs 4.2 umol/L, $p = 0.033$). Significantly higher T0 DAS scores were noted in the DASIMAR cohort in the pre-ACLF patients (5.3 vs 3.6 umol/L, $p < 0.001$). This was confirmed in the PREDICT cohort where T0 DAS was an independent predictor of ACLF development in multivariate analysis (OR 1.13 [95% CI 1.01–1.25], $p = 0.027$). With respect to renal dysfunction in the DASIMAR population, T0 DAS scores were significantly higher in those who developed an acute kidney injury (AKI) during admission compared to those who did not (5.2 vs 3.5 umol/L, $p < 0.001$). This was shown in multivariate analysis (OR 1.3 (1.1–1.5, $p < 0.001$) and replicated in the PREDICT cohort where T0 DAS also predicted renal failure in multivariate analysis (OR 1.2 [95% CI 1.0–1.3, $p = 0.025$).
Conclusion: This study demonstrates that the novel DAS score can predict liver-related events including mortality, ACLF development and renal dysfunction. With further validation, DAS could be translated for clinical use in identifying patients with pre-ACLF and those at high risk of mortality.

Characterization of the muscle-liver axis in a murine model of liver injury
Karen Rischmüller[1], Emma Schröder[1], Jana Weiß-Müller[1], Luise Ehlers[1], Robert Jaster[1], Georg Lamprecht[1]. *[1]Rostock University Medical Center, Department of Internal Medicine II, Division of Gastroenterology and Endocrinology, Rostock, Germany*
Email: karen.rischmueller@med.uni-rostock.de

Background and aims: Loss of muscle mass and function is a common complication of liver cirrhosis associated with poor outcome. Beyond direct effects of liver damage on muscle wasting, skeletal muscle interacts with the liver via myokines, potentially affecting disease progression. Mechanisms underlying the muscle-liver axis remain poorly understood. Therefore, this study aimed to explore skeletal muscle and myokine changes during disease progression in a murine model of liver injury.
Method: Male BALB/c mice (n = 54, aged ≥12 weeks, 25–30 g) received intraperitoneal injections of corn oil (placebo, n = 16) or 25% carbon tetrachloride (CCl_4) in corn oil (0.6 µl/g body weight (bw), n = 33) twice weekly for 4 weeks to induce liver injury, followed by weekly injections for 8 weeks. Untreated mice served as controls (n = 5). Bw was recorded daily, and grip strength (BIO-GS3, Bioseb) was measured weekly. Tissue samples from muscle (M. quadriceps, M. gastrocnemius) and liver, and plasma were collected at 4, 8, and 12 weeks. Fibrosis was assessed by Sirius Red staining. Myokine levels (MILLIPLEX Magnetic Bead Panels), and gene/protein expression in muscle and liver were quantified. Data were analyzed using two-way ANOVA with Tukey's multiple comparison test.
Results: Liver injury ranged from early acute liver failure to mild/moderate fibrosis as shown by Sirius Red staining and increased collagen 1 alpha 1 expression at 4–12 weeks. The liver/bw ratio increased in CCl_4 mice over the study course vs. controls and placebo ($p < 0.05$) reflecting liver injury. Plasma albumin, pseudocholinesterase, cholesterol, triglycerides, and bilirubin levels increased, while alkaline phosphatase decreased during disease progression and vs. placebo ($p < 0.05$). Muscle/bw ratios (at 4, 8, and 12 weeks) and grip strength (at 10–12 weeks) decreased vs. placebo ($p < 0.05$). Follistatin gene expression in M. quadriceps decreased ($p < 0.05$), while myostatin tended to increase ($p = 0.077$). Activin A protein levels marginally increased ($p = 0.0571$) at 12 weeks. Among plasma myokines, only fibroblast growth factor (Fgf) 21, oncostatin M, and osteonectin levels were detectable, but without significant differences between CCl_4 and placebo groups. Acute liver failure was associated with increased muscle myostatin and Fgf21 expression.
Conclusion: CCl_4-induced liver injury was associated with notable reductions in muscle mass and strength, reflecting sarcopenia. While changes in plasma myokines were not detectable, altered myostatin signaling and Fgf21 expression, particularly during acute liver failure, suggest impaired muscle-liver crosstalk. The heterogeneity of liver injury in CCl_4 intoxication is challenging for conducting controlled studies of the muscle-liver axis in chronic liver disease.

Proximity extension assay-based proteomics: a reliable tool for prediction of major adverse liver outcomes
Sriram Balasubramani[1], Anna Karl[1], Christina Schrader[1], Malin Fromme[1], Can Kayatekin[2], Bailin Zhang[2], Mikhail Levit[2],

Pavithra Krishnaswami[2], Katharina Remih[1], Pavel Strnad[1]. [1]*University Hospital RWTH Aachen, Aachen, Germany;* [2]*Sanofi Pharmaceuticals, Cambridge, Massachusetts, United States*
Email: sbalasubrama@ukaachen.de

Background and aims: Since liver disease is often clinically unapparent, plasma biomarkers predicting the future development of major adverse liver outcomes (MALO) are urgently needed. Therefore, we assessed the usefulness of a novel, proximity extension assay (PEA)-based high-throughput proteomics to predict MALOs.
Method: Proximity extension assay (PEA)-based plasma proteomic data (>2900 proteins) and clinical information were accessed via the population-based UK biobank (UKB) cohort including >53000 individuals with a median follow-up of >10 years and the subcohorts of obese (>12900) and diabetic (>1600) participants. A validation cohort comprised 287 subjects with severe alpha1-antitrypsin deficiency (Pi*ZZ genotype) with a median follow-up of 3.8 years and fibrosis assessment with transient elastography (21 MALOs). Selected PEA parameters were compared to measurements with routine techniques. Linear models with empirical Bayes moderation (with age and sex as covariates) assessed the differential abundance. Multivariable logistic regression was used to explore the predictive power of identified markers.
Results: Routine measurements of gamma-glutamyl transferase (GGT) and aspartate aminotransferase (AST)) strongly correlated with PEA values (r = 0.91 and r = 0.68, respectively). In the entire UKB PEA cohort with 490 MALOs, >1700 plasma proteins remained significantly different between the groups after adjustment for multiple testing. Most altered proteins were predominantly of liver, intestine, or lymphoid tissue origin and remained significant in the diabetic/obese sub-cohort. Five proteomic biomarkers, ADAMTS-like protein 2, polymeric immunoglobulin receptor, integrin beta like protein 1, thrombospondin 2 (THBS2), and insulin-like growth factor binding protein 7 robustly predicted future MALO at least as good GGT as the best routinely available predictor in all three UKB (sub-) cohorts (AUROCs between 0.80 and 0.86). In the AATD cohort, they all showed gradual increase along fibrosis stages. In AATD cohort, all five markers numerically outperformed routinely measured GGT in the prediction of MALO (AUROCs of 0.88–0.94 vs. 0.78). PEA-based THBS2 strongly correlated with ELISA-based values (r = 0.85).
Conclusion: Our analyses reveal the reproducibility of several PEA-based proteomic biomarkers and demonstrate that they can serve as a promising source of non-invasive MALO predictors.

Profiling of intestinal blood vessel-associated macrophages in cirrhosis

Lena Smets[1], Maria Viola[2], Markus Boesch[3,4], Frederik Nevens[5], Hannelie Korf[1], Guy Boeckxstaens[2], Schalk van der Merwe[1]. [1]*KU Leuven, Laboratory of Hepatology, Leuven, Belgium;* [2]*KU Leuven, Laboratory for Intestinal Neuro-Immune Interaction, Leuven, Belgium;* [3]*KU Leuven, Laboratory of Reproductive Genomics, Leuven, Belgium;* [4]*KU Leuven, KU Leuven Institute for Single Cell Omics, Leuven, Belgium;* [5]*University Hospitals Leuven, Department of Gastroenterology and Hepatology, Leuven, Belgium*
Email: lena.smets@kuleuven.be

Background and aims: To prevent dissemination of luminal bacteria, the gastro-intestinal tract is equipped with several barriers, including the epithelial layer, pathogen-clearing intestinal macrophages, and the gut-vascular barrier. Failure of these barriers results in bacterial translocation, a major driver of morbidity and mortality in cirrhosis. In this study, we investigated the role played by specialised intestinal macrophages in preserving vascular barrier integrity in an animal model of cirrhosis.
Method: Cirrhosis was induced in animals by subcutaneous injection of CCl_4 for 20 weeks. We performed single-cell transcriptomics of the small intestinal lamina propria macrophage population from cirrhotic and control animals, and from (de-)compensated cirrhosis patients.
Results: In a murine cirrhosis model, intestinal submucosal macrophages from animals at advanced disease stages appeared disorganised and dispersed in the tissue, neither connecting with each other nor the blood vessels, and displaying an ameboid morphology. The disorganised network of these macrophages coincided with increased bacterial translocation in our model. By performing transcriptional profiling of intestinal macrophages, one identified mature macrophage subset showed a reduction of the expression of key chemokines and their receptors (e.g. *Pf4*, *Cxcr4*) and a TGF-beta-related receptor (*Tgfbr1*) in cirrhosis. Moreover, decreased levels of genes involved in heme degradation were observed. Interestingly, transcriptional profiling of duodenal macrophages of cirrhosis patients revealed a similar dysregulation of pathways supporting blood vessels and increased chemokine expression. In our experimental model of cirrhosis, an enrichment in pathways associated to apoptotic cell clearance and scavenging by class B receptors was observed. Functional validation of the latter by performing intravital microscopy experiments, confirmed reduced bacterial clearance by macrophages closely associated to submucosal blood vessels during cirrhosis.
Conclusion: Our findings provide a transcriptional analysis of specialised intestinal lamina propria macrophages, revealing functional impairments in these cells during cirrhosis. These alterations coincide with increased bacterial translocation in our experimental model, underscoring their critical role in maintaining intestinal barrier integrity.

Attenuation of inflammatory bystander CD8+ T cell activation in decompensated cirrhosis via non-selective beta-blockers

Ayesha Lietzau[1], Anke R. M. Kraft[1], Benjamin Maasoumy[2], Heiner Wedemeyer[3], Markus Cornberg[1], Christian Niehaus[1]. [1]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School (MHH), Hannover, Germany; Centre for Individualised Infection Medicine (CiiM), a joint venture between Helmholtz-Centre for Infection Research and Hannover Medical School, Hannover, Germany, TWINCORE, Centre of Experimental and Clinical Infection Research, a joint venture between Helmholtz-Centre for Infection Research and Hannover Medical School, Hannover, Germany, Hannover, Germany;* [2]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School (MHH), Hannover, Germany, Hannover, Germany;* [3]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School (MHH), Hannover, Germany, German Center for Infection Research (DZIF), partner site Hannover-Braunschweig Germany, Cluster of Excellence RESIST (EXC 2155), Hannover Medical School, Hannover, Germany, Hannover, Germany*
Email: lietzau.ayesha@mh-hannover.de

Background and aims: Patients with advanced liver cirrhosis display a dysfunctional immune system, leading to immune deficiency on the one hand and systemic inflammation on the other hand. Recently, bystander-activated $CD8^+$ T cells were identified as a key contributor to the inflammatory milieu. Non-selective beta blockers (NSBB) are often used in cirrhosis to reduce portal pressure and subsequently decompensation risk. Moreover, evidence suggests that NSBBs also mediate anti-inflammatory effects, however, the underlying mechanism remains elusive.
Method: In this study, we investigated the impact of NSBBs on $CD8^+$ T cells in patients with decompensated liver cirrhosis (n = 31). Therefore, we performed ex vivo phenotype and in vitro functional analyses of matched blood and ascites $CD8^+$ T cells in patients on NSBB therapy (n = 18) compared to those without (n = 13).
Results: $CD8^+$ T cells from blood and ascites expressed comparable levels of adrenergic beta receptors (ADRB1 and ADRB2). In vitro, propranolol not only reduced the frequency of bystander-activated

($CD69^+CXCR6^+$) $CD8^+$ T cells upon IL12/15/18 stimulation, but also the IFN-gamma production was diminished. In contrast, propranolol did not inhibit antigen-specific $CD8^+$ T cell responses upon CMV pp65 stimulation. *Ex vivo* phenotypic analysis confirmed the *in vitro* data, revealing decreased expression of innate activation markers and lower frequencies of bystander-activated $CD8^+$ T cells in patients on NSBB therapy compared to those without. Of note, plasma and ascites NSBB levels from selected patients negatively correlated with bystander $CD8^+$ T cell frequencies.
Conclusion: These results indicate that propranolol effectively inhibits bystander-activated $CD8^+$ T cells in decompensated cirrhosis while preserving antigen-specific functions. This opens up NSBBs as a promising therapeutic strategy for the targeted inhibition of hyperinflammation and subsequent mitigation of CAID and its associated complications.

Mitochondrial transfer from mesenchymal stem cells to hematopoietic stem cells mitigates bone marrow failure and promotes liver regeneration in pre-clinical model of cirrhosis
Manisha Bhardwaj[1], Deepanshu Maheshwari[2], Nidhi Nautiyal[2], Sandeep Kumar[2], Sunidhi Diwakar[2], Nikita Sharma[2], Anupam Kumar[2], Shiv Kumar Sarin[2], Anupama Kumari[2]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India;* [2]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: dr.anupamkumar.ilbs@gmail.com

Background and aims: Progressive loss of hematopoietic stem cells reserves accounts for regeneration failures in cirrhosis. Metabolic adaptation in HSC plays a critical role in balancing self-renewal and differentiation. Mesenchymal stem cells play a central role in maintaining HSC and functional exhaustion of same has been shown to be associated with poor hematopoietic reserve and osteodystrophy in cirrhosis. In the current study we aim to restoring bone marrow niche in augmenting HSC and their impact on liver repair and regeneration.
Method: Cirrhosis was induced in C57BL/6J mice through intraperitoneal dose of carbon tetrachloride. BM-MSC was infused through either intra-femoral or intravenous route. Animals were randomly divided into 2 groups, one received DiR tagged BM-MSC infusion at the end of 10^{th} week, while the other group received saline. Aged matched healthy controls were used as healthy controls. BM-HSCs was studied using flow cytometry. Mitochondrial biomass and potential were studied using Mito Tracker dyes. Bioenergetics of HSCs was analyzed using Seahorse Extracellular Flux Assay. Mitochondrial transfer from MSCs to HSCs was studied in-vivo and in-vitro co-culture assay.
Results: Intra-femoral MSC infusion showed better recruitment of BM-MSC than Intravenous, enabling a comprehensive evaluation of all parameters through intra-femoral route. Chronic liver injury showed a significant loss of LT-HSCs along with a decrease in maximal respiration, indicating impaired oxidative phosphorylation. Intra-femoral infusion of MSC increase LT-HSC population at 24 h, 72 h and day11 along with increase in the maximal respiration indicating improved oxidative phosphorylation capacity. MSC infused group showed significant increase in mitochondrial biomass (MTG), mitochondrial potential (MTR) in LT-HSCs. The relative expression of TFAM showed no increase at 24 h and 72 h but rises significantly by Day 11, suggesting mitochondrial biogenesis in LT-HSCs initiates later post-therapy. Further In vitro and In vivo study confirmed transfer of mitochondria from MSC to LT-HSC in early time point and HSC account for increase in mitochondrial mass and potential at early time point. Restoring LT-HSC reserve increase F4/80, CD86, CD206, so it augments resolving macrophage number and function, increase regression of fibrosis and regeneration in cirrhotic animal.
Conclusion: MSC-mediated mitochondrial transfer to LT-HSCs restores BM HSC reserve in cirrhosis. Restoring BM HSC reserve augments monocytes number and function, increase regression of fibrosis and regeneration in cirrhosis.

Spleen Area affects the predictive performance of the platelet count-based non-invasive tools in MASLD
Marcello Dallio[1], Mario Romeo[1], Fiammetta Di Nardo[1], Carmine Napolitano[1], Paolo Vaia[1], Annachiara Coppola[1], Simone Olivieri[1], Luigi Vitale[1], Marco Niosi[1], Alessandro Federico[1]. [1]*Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples, Italy, Naples, Italy*
Email: mario.romeo@unicampania.it

Background and aims: Most of the currently available non-invasive tools (NITs) predicting hepatic decompensation (HD) in advanced chronic liver disease (ACLD) include the platelet (PLT) count. However, a non-negligible proportion of Metabolic dysfunction-associated Steatotic Liver Disease (MASLD)-related compensated ACLD patients with clinically significant portal hypertension (CSPH) do not show splenomegaly and hypersplenism-related thrombocytopenia. The present research explored the performance of NITs in predicting a 3-year first HD according to spleen size.
Method: 148 splenic and 27 asplenic (ASP: 25-splenectomized; 2-agenesis) MASLD-cACLD patients receiving an endoscopy evidencing CSPH were enrolled. Ultrasound artificial intelligence (AI)-based tools distinguished splenomegaly-affected (SAP: 91) and normal spleen patients (NSP: 57). Albumin-bilirubin (ALBI) score and PLT count-based NITs (PLNs) [Fibrosis-4 (FIB-4), ALBI-FIB-4 score, red-cell-distribution-width/PLT-ratio (RPR), Liver Stiffness Measurement (LSM)/PLT-ratio (LSM/PLTr), and ANTICIPATE±NASH] were determined. During a 3-year semiannual follow-up, NITs and spleen size were reassessed, as well as the HD occurrence was recorded.
Results: Limitedly to SAP, Spleen Area inversely correlated with PLT count (R: −0.981; $p < 0.0001$), confirming the predominant role of splenomegaly-related hypersplenism in conditioning thrombocytopenia. HD occurred similarly in SAP (20.48%), NSP (21.15%), and ASP (25%) (chi-square, p:0.198). In NSP, PLNs showed a reduced influence on HD [FIB-4 (p: 0.03), ALBI-FIB-4 (p:0.001), RPR (p:0.002), LSM/PLT ratio (p:0.01), and ANTICIPATE ± NASH (p:0.001)] compared to SAP. In NSP, the Spleen Area was inversely associated (aSHR: 0.870) and more significantly ($p < 0.0001$) impacted HD. Consistently, unlike SAP, in NSP and ASP, PLNs showed poor performance, and exclusively ALBI maintained a good accuracy (NSP: AUC 0.651, p: 0.04; ASP: AUC: 0.625, p: 0.03) in predicting 3-year HD.
Conclusion: Spleen size dramatically affects the predictive performance of the PLNs in CSPH-affected MASLD-cACLD patients.

THU-166
NTZ alleviates stress-induced hepatocyte cell death through modulation of oxidative stress and DNA damage signaling pathways in ACLF models
Marie Bobowski-Gerard[1], Nicolas Stankovic Valentin[1], Sylvie Deledicque[1], Simon Debaecker[1], Nina Tserstevens[1], Philippe Delataille[1], Sakina Sayah Jeanne[1], Dean Hum[1], Vanessa Legry[1], Jerôme Eeckhoute[2], Joan Clària[3], Bart Staels[2]. [1]*GENFIT S.A., Loos, France;* [2]*Université de Lille - CHU Lille, INSERM U1011, Institut Pasteur de Lille, Lille, France;* [3]*Hospital Clinic-IDIBAPS, Universitat de Barcelona, European Foundation for the Study, Barcelona, Spain*
Email: marie.gerard@genfit.com

Background and aims: Acute-on-chronic liver failure (ACLF) is a severe syndrome affecting patients with acutely decompensated cirrhosis, associated with multiple organ failures and high short-term mortality rates. We previously showed that the anti-parasitic drug nitazoxanide (NTZ) directly protects from systemic inflammation and organ damage in preclinical models of ACLF, with a direct effect demonstrated on stress-induced cell death and liver damage (*J Hepatol.* 2022, 2023, 2024). To further characterise the mechanism of

action of NTZ, transcriptomic analyses were performed in stress-induced hepatocytes and liver from a rat model of ACLF.
Method: Immortalized human hepatocytes were stressed with 0.5 mM H_2O_2, a method commonly used to trigger cellular oxidative damage. Tizoxanide (TZ), NTZ active metabolite, was added concomitantly to H_2O_2 for 3 h or 6 h. *In vivo*, ACLF was precipitated through lipopolysaccharide (LPS) injection in rats displaying advanced liver fibrosis induced by carbon tetrachloride (CCl_4). A single dose of NTZ (100 mg/kg) or vehicle was orally administered 1 h before LPS injection. Liver and blood samples were collected 6 h or 24 h post-LPS. Transcriptional changes in hepatocytes and livers were assessed using oligonucleotide microarrays and pairwise comparisons were performed to identify differentially expressed genes.
Results: H_2O_2 treatment of human hepatocytes for 3 h induced a significant transcriptome remodeling, associated with apoptotic cell death. Enrichment analysis revealed that differentially expressed gene sets were mainly related to oxidative stress, DNA damage and cell death pathways. After 6 h, a modulation of genes involved in cell cycle response was also observed. TZ blunted the H_2O_2-induced gene signature at both timepoints by modulating pathways such as NRF2-mediated oxidative stress response, apoptosis, p53 signaling and cell cycle. As an example, expression level of the NRF2-targeted gene HMOX1, was reduced in TZ-treated cells, suggesting that modulation of NRF2 signaling by TZ could explain its protective role on hepatocyte cell death.
In ACLF rats, NTZ treatment reduced LPS-induced serum levels of total bilirubin (−103%, $p < 0.0001$) and bile acids (−130%, $p = 0.02$) and alleviated hepatocellular injury by blunting LPS-induced rise of AST (−100%, $p = 0.003$) and GGT (−99%, $p = 0.014$), in comparison with fibrotic rats. Interestingly, gene expression analysis of ACLF livers revealed that NRF2 response was also modulated by NTZ.
Conclusion: These results suggest that a direct effect of NTZ on oxidative stress response could explain its protective role against hepatocyte cell death and liver damage. Combined with its antibacterial and anti-inflammatory activities, these findings further support the investigation of NTZ treatment as a promising approach to prevent systemic inflammation and organ damage in ACLF patients.

Recombinant ADAMTS13 attenuates LPS-induced acute kidney injury and renal microangiopathy in mice with liver cirrhosis by cleaving vWF

Hiroyuki Masuda[1], Kosuke Kaji[1], Masayoshi Takami[1], Norihisa Nishimura[1], Shinya Sato[1], Tadashi Namisaki[1], Hitoshi Yoshiji[1].
[1]*Department of Gastroenterology, Nara Medical University, Kashihara, Japan*
Email: masudah@naramed-u.ac.jp

Background and aims: Hepatorenal syndrome (HRS) has a poor prognosis among the complication of liver cirrhosis, yet treatment options are limited. Thrombotic microangiopathy with reduced ADAMTS13 activity and von Willebrand factor (vWF) accumulation has been reported to play a key role in the pathogenesis of acute kidney injury (AKI) in liver cirrhosis. In this study, we aimed to investigate the effect of recombinant ADAMTS13 (rADAMTS13) on acute kidney injury using a mouse model of HRS.
Method: HRS was induced in C57BL/6J mice by intraperitoneal administration of carbon tetrachloride and lipopolysaccharide (AKI-C group). Additionally, a group of mice was treated with rADAMTS13 (10 μg/body) (rAD group). Serological, histological and molecular analyses were performed to assess the effect of rADAMTS13 on liver and kidney injuries in AKI-C group. Tissue blood flow was also measured using a laser Doppler tissue blood flow meter to evaluate differences between the groups.
Results: AKI-C group showed a marked liver dysfunction as well as renal dysfunction with elevated serum level of AKI including KIM-1, osteopontin and NGAL. Plasma ADAMTS13 activity was reduced, and vWF antigen levels were increased. A decrease in blood flow in the liver and kidney tissues was also observed. In the rAD group, compared to the AKI-C group, plasma ADAMTS13 activity was increased, vWF antigen levels were decreased, and liver and kidney blood flow were improved. As a result, liver and kidney injuries were significantly alleviated. Furthermore, in the rAD group, macrophage (F4/80-positive) infiltration and the increased expression of inflammatory cytokines observed in the AKI-C group were suppressed. Accumulation of oxidative stress (4-HNE-positive) was also reduced. In addition, the deposition of CD41a-positive microthrombi in kidney tissues seen in the AKI-C group was significantly suppressed in the rAD group. This group also showed an increased expression of angiogenesis markers (Vegf) and a decreased expression of vascular inflammation markers (Vcam1, Icam1, Sele, Selp).
Conclusion: Administration of rADAMTS13 may improve inflammation, oxidative stress, and reduced blood flow in liver and kidney, thereby mitigating HRS.

HBV-specific metabolic footprints and impact on mortality in patients with HBV reactivation and acute-on-chronic liver failure

Mirco Glitscher[1], Keerthihan Thiyagarajah[2], Lining Guo[3], Wenyi Gu[4], Jonel Trebicka[5], Eberhard Hildt[6], Hai Li[4], Kai-Henrik Peiffer[7]. [1]*Paul Ehrlich-Institute, Department of Virology, Langen, Germany;* [2]*Paul Ehrlich-Institute, Langen, Germany;* [3]*Precion Inc., Morrisville, United States;* [4]*Ren Ji Hospital, Shanghai, China;* [5]*University Hospital, Medical Clinic B, Münster, Germany;* [6]*Paul Ehrlich-Insitute, Langen, Germany;* [7]*University Clinic, Medical Clinic B, Münster, Germany*
Email: kai-henrik.peiffer@ukmuenster.de

Background and aims: Acute-on-chronic liver failure (ACLF) is one of the deadliest complications of chronic liver disease and no therapeutic options are available except liver transplantation. HBV is the most common trigger for ACLF in Asia. In a recent study ACLF in HBV patients was associated with distinct changes in the metabolome. Based on this cohort, both pre-ACLF and ACLF patients, triggered by the HBV reactivation were analyzed in more depths for HBV-specific changes.
Method: Clinical data and metabolic profiles of 1024 Chinese patients from the CATCH-LIFE studies with chronic HBV mono-infection who were hospitalized due to an acute hepatic exacerbation were analyzed. ACLF was diagnosed according to the COSSH ACLF criteria. Metabolites of serum samples were quantified using LC-MS and significantly altered footprints were correlated to differing metabolic pathways using the database SMPD via MetaboAnalyst v6. These were then compared between different ACLF and HBV-reactivation statuses in meta-analyses and pathway maps were deduced.
Results: Of the 1024 patients, 357 patients were diagnosed with ACLF at time of admission, 135 with a pre-ACLF and 532 without ACLF. In 30.9% of the ACLF patients and in 10.8% of the pre-ACLF patients, HBV reactivation was observed. HBV reactivation was associated with higher transaminases and CRP in the pre-ACLF patients. 28-day, as well as 90-day and 365-day mortality was increased in pre-ACLF with HBV reactivation in comparison with patients with another ACLF precipitating event (2.1% vs. 25%, 12.5% vs 29.2% and 18.8% vs. 33.3%, respectively). This strong increase in pre-ACLF-linked mortality correlated with a pronounced augmentation of metabolic pathways contributing to the formation of reactive oxygen species (ROS), which prevailed in HBV reactivated ACLF patients. Notably, this was not accompanied by an increase in respective metabolic pathways detoxifying oxidative products. Additionally, metabolites revolving around the urea cycle, thus nitric monoxide (NO) formation, and the polyamine metabolism were highly increased in pre-ACLF and ACLF patients with HBV reactivation. Along these routes, specific metabolites could be identified as putative markers for the differing clinical situations, among which are distinct endogenous amino acid, nucleotide and fatty acid derivatives.

Conclusion: HBV reactivation is accompanied by a high degree of hepatic inflammation, and an early onset and is associated with an increase of mortality in pre-ACLF patients. Importantly, pre-ACLF as well as ACLF are linked to disruptions in distinct metabolic pathways, including the NO, ROS and polyamine pathways in dependency of HBV reactivation. The underlying regulatory mechanisms may present as extremely interesting targets for studies to treat HBV-related development of ACLF as well as decrease its persistence and associated mortality.

Statins as an alternative therapy to improve the cardiac chronotropic dysfunction in cirrhotic cardiomyopathy in cirrhotic rats

Muhammad Shafique[1], Qamar Niaz[2], Muhammad Adil Rasheed[1], Khalid Abdul Majeed[3], Ghulam Mustafa[4], Muhammad Ovais Omer[1], Adeel Sattar[1], Sania Mehreen[5], Muhammad Bilal Khan[6]. *[1]Department of Pharmacology and Toxicology, Faculty of Bio-Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan; [2]Department of Pharmacology and Toxicology, Faculty of Bio-Sciences, University of Veterinary And Animal Sciences, Lahore, Pakistan; [3]Department of Physiology, Faculty of Bio-Sciences, University of Veterinary and Animal Sciences, Lahore, Pakistan; [4]Department of Pathology, Faculty of Veterinary Sciences, University of Veterinary And Animal Sciences, Lahore, Pakistan; [5]Department of Zoology, Faculty of Fisheries and Wildlife, University of Veterinary and Animal Sciences, Lahore, Pakistan; [6]Department of Zoology, Faculty of Biological Sciences, Quaid-I-Azam University, Islamabad, Pakistan*
Email: qamar.niazuvas@gmail.com

Background and aims: Cirrhotic cardiomyopathy (CCM) is a cardiac complication of liver cirrhosis with chronotropic hypo-responsiveness. Statins act as anti-inflammatory, anti-fibrotic, and anti-oxidant agents and decrease the portal pressure in liver cirrhosis. No proper treatment for targeting CCM exists and needs to be developed. Therefore, we evaluated the effect of simvastatin on CCM in cirrhotic rats.
Method: Total of 80 Albino Westar male rats were divided as Sham (control) and bile duct ligation (BDL) (cirrhotic) groups i.e., Sham/Normal saline, BDL/Normal saline, Sham/Simvastatin-15 (15 mg/kg/day), BDL/Simvastatin-15, Sham/Simvastatin-20 (20 mg/kg/day), BDL/Simvastatin-20, Sham/Simvastatin-25 (25 mg/kg/day), BDL/Simvastatin-25, Sham/Lactulose-1.5 (g/kg/day), and BDL/Lactulose-1.5 groups. BDL surgery was conducted to induce cirrhosis while, for control groups, the Sham surgery was performed. After induction of cirrhosis, the animals were gavaged orally the respective drug in normal saline for two weeks. Finally, in-Vivo chronotropic study through electrocardiography, liver function tests i.e., alanine aminotransferase (ALT), aspartate aminotransferase (AST), and bilirubin through enzyme-linked immunosorbent assay (ELISA), liver histopathology through hematoxylin and eosin staining, and heart malondialdehyde (MDA), brain natriuretic peptide (BNP), and tumor necrosis factor-alpha (TNF-alpha) levels through ELISA were evaluated post-treatment.
Results: Our results indicated that the chronotropic responses decreased in the BDL/Normal saline group and improved in the BDL/Simvastatin-25 group, BDL/Simvastatin-20 group, and BDL/Simvastatin-15 group, dose-dependently, both before and after stimulation with adrenaline (0.5, 1, and 2 mg/kg). The QTc interval was raised in the BDL/Normal saline and declined more in BDL/Simvastatin-25 group than BDL/Simvastatin-20 and BDL/Simvastatin-15 groups. The hepatic fibrosis and inflammation were elevated and graded severe in the BDL/Normal saline group and attenuated and graded minimal in BDL/Simvastatin-25, mild in BDL/Simvastatin-20, and moderate in BDL/Simvastatin-15 group. The spleen weight was increased in BDL/Normal saline group and reduced in BDL/Simvastatin-25 group, BDL/Simvastatin-20 group, and BDL/Simvastatin-15 group in a dose-dependent manner. The heart MDA, BNP, and TNF-alpha and serum ALT, AST, and bilirubin levels were elevated in BDL/Normal saline group and reduced more in BDL/Simvastatin-25 group as compared to BDL/Simvastatin-20 and BDL/Simvastatin-15 groups.
Conclusion: Simvastatin at 25 mg/kg has maximum effect to improve the chronotropic hypo-responsiveness and reduce the QTc interval in cirrhosis-induced CCM in rats. It reduces liver inflammation and fibrosis, serum ALT, AST, and bilirubin levels, and heart inflammation (TNF-alpha), stress marker (BNP), and oxidative stress (MDA) in CCM.

THU-172

A disintegrin and metalloproteinase with a thrombospondin type 1 motif 13 and von Willebrand factor axis regulates acute kidney injury in mice with liver cirrhosis

Norihisa Nishimura[1], Kosuke Kaji[1], Hiroyuki Masuda[1], Shinya Sato[1], Tadashi Namisaki[1], Hitoshi Yoshiji[1]. *[1]Nara Medical University, Kashihara, Japan*
Email: nishimuran@naramed-u.ac.jp

Background and aims: Although hepatorenal syndrome-acute kidney injury (HRS-AKI) is one of prognostic risk factors among cirrhosis-related complications in patients with liver cirrhosis, there are still limited established therapeutic options. We have reported that the decreased level of a disintegrin-like and metalloproteinase with thrombospondin type 1 motifs 13 (ADAMTS13) activity and the increase of von Willebrand factor (vWF) involved in hemostatic coagulation were observed along with the development of liver cirrhosis and closely correlates with the level of portal hypertension, suggesting their influences on the circulatory dynamics in chronic liver diseases. In the current study, we investigated the effects of ADAMTS13/vWF axis for the pathogenesis of AKI in a cirrhotic mouse model.
Method: Wild type (WT) and ADAMTS13-deficient (ADKO) mice were used to create an AKI mouse model with liver cirrhosis by combining chronic injury injected by chronic carbon tetrachloride (CCl4) and acute hepatic insult by injection with a double dose of CCl4 followed by administration with lipopolysaccharides to elucidate the effect of ADAMTS13 in AKI in mice with liver cirrhosis. Similarly, WT and vWF-deficient (vWFKO) mice were used to investigate the role of vWF in AKI in cirrhotic mice, as described above. We collected serum, liver, and kidney tissue and compared differences in liver and kidney injury due to ADAMTS13 deficiency.
Results: AKI groups in both WT and ADKO mice increased serum AST/ALT and BUN/Cre levels. These changes in ADKO mice were significantly higher than those in WT mice. Tissue blood flow in liver and kidney were significantly decreased in ADKO group compared to WT group with the increase in vWF level. ADKO mice with AKI showed the elevation of inflammatory markers such as Tnf-α and Il-1β, and the increased number of F4/80-positive cells in kidney tissue. Likewise, the expressions of kidney injury markers including Kim-1, Vim, Hif1α were significantly elevated in ADKO group compared to WT group. In addition, higher elevation of oxidative stress markers such as NOX2/4, HO-1 and eNOS were observed in ADKO mice with AKI compared to WT mice with AKI. On the other hand, vWFKO mice showed the decrease in AST/ALT, BUN/Cre level compared to WT mice. The knockdown of vWF also improve the lowering of tissue blood flow in liver and kidney with the reduction of inflammatory changes and oxidant factors.
Conclusion: ADAMTS13/vWF axis contributes to regulating the induction of inflammation and tissue damage, as well as lowering tissue blood flow in the AKI mouse model. These results suggest that the imbalance of ADAMTS13/vWF axis plays an important role on the progression of AKI in patients with liver cirrhosis, and may be a novel therapeutic target for HRS-AKI.

THU-173

A biliary organoid model to investigate the malignant transformation of primary sclerosing cholangitis to cholangiocarcinoma

Lea Allescher[1], Noah Sendtner[1], Noah Brandl[1], Manuela Gunckel[1], Kunst Claudia[1], Karsten Guelow[1], Martina Müller-Schilling[1], Arne Kandulski[1]. [1]*University Hospital Regensburg, Internal Medicine I, Regensburg, Germany*
Email: lea.allescher@stud.uni-regensburg.de

Background and aims: The underlying molecular mechanisms of the progression of primary sclerosing cholangitis (PSC) to cholangiocarcinoma (CCC) are not fully understood. RNA sequencing has revealed that primary human cholangiocytes lose their transcriptional diversity in organoid cultures; however, these organoids retain key cellular properties. Based on this potential, we are developing a robust system to isolate cholangiocyte organoids directly from bile fluid obtained from healthy controls as well as patients with PSC and CCC. This approach aims to enable detailed investigations into the molecular and cellular mechanisms driving the transition from chronic inflammation to tumorigenesis.
Method: Organoids were generated from bile fluid and bile duct biopsies obtained from healthy individuals as well as patients with PSC and CCC. The molecular characterization of the organoids included gene expression analysis, protein expression profiling, morphological assessment, and the evaluation of surface marker protein expression using immunofluorescence. Cholangiocyte-specific markers and hepatocyte-specific markers were analyzed to confirm the cholangiocyte origin of the organoids and to exclude contamination with hepatocytes.
Results: We established organoids from bile fluid and bile duct biopsies, creating a patient-specific repository for PSC, CCC, and control groups. Organoids derived from bile fluid exhibited strong expression of cholangiocyte-specific markers, such as Epcam, Cytokeratin-19, and Sox9, which matched those observed in biopsy/tissue-derived organoids, confirming their cholangiocyte origin. Hepatocyte-specific markers, including Alpha-1-Antitrypsin and Serum Albumin, were not detected, excluding contamination by hepatocytes or other cell populations. This method enables reliable disease modeling. The established organoid model provides an optimal platform for studying molecular changes associated with the progression from PSC to CCC and conducting functional studies.
Conclusion: Our findings confirm that bile-derived organoids represent a reliable and minimally invasive model for investigating PSC and CCC. The cholangiocyte origin of the organoids was validated through specific markers, with no evidence of contamination. This model offers a reliable platform to study molecular changes driving the progression from PSC to CCC and to evaluate potential therapeutic strategies.

Activated intestinal fibroblasts induce inflammatory Th17 differentiation in experimental cirrhosis

Oriol Juanola[1,2,3], Isabel Gómez-Hurtado[1,2,3], Sebastian Martinez[1,2,4], Enrique Ángel-Gomis[1,2,4], Paula Boix[1,2], Manel Hadid[1,4], Esther Caparrós[1,2,3], Rubén Francés[1,2,3,4]. [1]*Hepatic and Intestinal Immunobiology Group, Department of Clinical Medicine, Miguel Hernández University, San Juan, Alicante, Spain, San Juan de Alicante, Spain;* [2]*IIS ISABIAL, Dr. Balmis General University Hospital, Alicante, Spain, Alicante, Spain;* [3]*CIBERehd, Instituto de Salud Carlos III, Madrid, Spain, Madrid, Spain;* [4]*IDIBE Institute, Miguel Hernández University, Elche, Spain, Elche, Spain*
Email: ojuanola@gmail.com

Background and aims: Increased intestinal permeability is a central factor in the disruption of the gut-liver axis during cirrhosis. Innovative strategies focused on limiting intestinal inflammation are needed to restore the integrity of the mucosal, endothelial, and epithelial barriers in cirrhosis. Modulating the interaction between intestinal fibroblasts (Fib_{INT}) and cellular immunity in the lamina propria may help to restore intestinal homeostasis in cirrhosis.
Method: A prospective experimental study was conducted using mice with advanced liver injury induced by oral administration of CCl_4 for 12 weeks (n = 5). Control mice received olive oil as vehicle (n = 5). Fib_{INT} activation, chemokine production, and immune recruitment were assesed in ileum samples through gene (RT-qPCR) and protein expression (immunofluorescence). Activation states of primary Fib_{INT} (CD45-CD326-CD90+) isolated from the small intestine and colon of control and cirrhotic mice were evaluated, as well as the expression of molecules involved in T-cell activation (MHC-II, CD40, CD80, CD86, OX-40L, PD-L1) by flow cytometry. Co-cultures of Fib_{INT} (cirrhosis) and T lymphocytes (control), and vice versa, were conducted to determine the modulatory effects of cell-to-cell interactions.
Results: An increase in gene (*COL1A1, FAP, PDPN*) and protein (α-SMA, Pdpn, Vim) expression of stromal cell activation markers was observed in the ileum during experimental cirrhosis. Augmented expression of chemokines (*CCL2, CXCL10*) in the ileum of cirrhotic mice correlated with increased leukocyte (CD45+) infiltration into the villi. Local increases in intestinal lymphocyte (CD3+) and macrophage (F4/80+) populations were detected. In cirrhosis, the percentages of primary Fib_{INT} from the small intestine expressing stromal cell activation markers (Vim and Pdpn) and T-cell stimulation molecules (CD40, CD80, CD86) were elevated compared to control mice. Isolated Fib_{INT} from cirrhotic mice interacted with more CD4+ T lymphocytes *in vitro* and were more effective at inducing their activation (CD25+) and differentiation towards a Th17 profile (IL-17+). Similarly, CD4+ intestinal T lymphocytes from cirrhotic mice could activate Fib_{INT} isolated from control animals (Vim+, CD86+, OX40L).
Conclusion: Fib_{INT} are activated in experimental cirrhosis and acquire the ability to induce an inflammatory Th17 response. These findings suggest that modulating the interaction between intestinal fibroblasts and T lymphocytes may recover intestinal homeostasis in cirrhosis.

THU-175

Characterising renal dysfunction in chronic liver disease rodent models

Olivia Greenham[1], Abeba Habtesion[1], Andrew Hall[2], Cornelius Engelmann[3], Rajiv Jalan[1], Rajeshwar Prosad Mookerjee[4]. [1]*Liver Failure Group, University College London, London, United Kingdom;* [2]*Royal Free Hospital, London, United Kingdom;* [3]*Charite University Hospital, Berlin, Germany;* [4]*Liver Failure Group, London, United Kingdom*
Email: olivia.greenham@nhs.net

Background and aims: Acute kidney injury (AKI) in patients with cirrhosis carries significant morbidity and mortality and accounts for 20% of acute decompensation admissions. However, currently we lack well characterized models to study renal dysfunction in chronic liver disease, necessary to explore targets for new interventions. This study characterises renal dysfunction in known rodent models of chronic liver disease.
Method: 5 rodent models were selected which included 3 models of acute on chronic liver failure (ACLF): bile duct ligation (BDL) rat with addition of lipopolysaccharide (BDL+LPS); carbon tetrachloride (CCL4) mouse model with addition of lipopolysaccharide (CCL4 +LPS); combined western and alcohol diet (WD+ETOH) with alcohol binge (WD+ETOH+Binge). In addition, 2 chronic fatty liver disease models: high fat high cholesterol rat (HFHC) and amylin liver NASH (ALNM) mouse model. All models had a control group. A minimum of 4 animals were assessed in each group. 6 parameters were assessed including Periodic Acid Schiff (PAS) for macrostructural analysis, neutrophil gelatinase-associated lipocalin (NGAL) for tubular damage, macrophage marker CD68, apoptosis marker cleaved caspase 3 (CC3), proliferation marker Ki-67 and Picro Sirius Red (PSR) for collagen deposition. 4 micrometre kidney slices were cut

from paraffin blocks. PAS and PSR stains were performed according to protocol. IHC was performed with CD68, Ki-67, CC3, and NGAL primary antibodies. Tissue was reviewed at x20 microscopic field and analysis performed using Image J, with the analyser blinded to group. Statistical analysis was performed using STATA and GraphPad.
Results: There was a statistically significant increase in NGAL between control and BDL+LPS models (Control vs BDL+LPS p = 0.013,). This was also demonstrated in the WD+ETOH model but was not statistically significant (Control vs WD+ETOH+Binge p = 0.18, WD +ETOH vs WD+ETOH+Binge p = 0.26). The BDL model also demonstrated an increase in CD68 positive cells with increasing severity of model (Control vs BDL+LPS p = 0.043). The majority of models also demonstrated an upward trend between number of glomerular nuclei and increasing model severity suggesting an influx of inflammatory cell types. Ki-67, CC3 and PSR staining did not yield any significant findings across the models.
Conclusion: The results suggest that there are heterogenous structural changes in the kidneys of chronic liver disease models to varying degrees. The BDL model appears to show the most quantifiable changes of severe kidney injury, followed by the ETOH +WD model using the parameters studied. Further work is needed to best exemplify a translational model of renal dysfunction in chronic liver disease, to enable assessment of drug targets and response to intervention, in order to improve clinical outcomes and treatment options in cirrhosis induced kidney injury.

THU-176
Sex-specific differences in preclinical models of advanced chronic liver disease and portal hypertension

Peio Aristu[1,2], Maria Andres-Rozas[1], Zoe Boyer-Diaz[1], David Al-Adra[3], Douglas Maya-Miles[4], Sergi Guixe-Muntet[5], Anabel Fernández-Iglesias[5], Jordi Gracia-Sancho[5,6]. Email: jgracia@recerca.clinic.cat

Background and aims: Cirrhosis is a major health concern, but sex-specific differences in its pathophysiology remain unclear. Preclinical studies mainly focused on male animals, limiting translational applicability. This project aimed to comprehensively characterize cirrhotic portal hypertension in male and female rats to understand sex complexities and potential implications. Human relevance was assessed by analyzing two well-defined patient cohorts.
Method: Advanced chronic liver disease (ACLD) was induced in male and female Sprague-Dawley rats by thioacetamide administration (TAA, 250 mg/kg; 12 weeks) or common bile duct ligation (BDL, 28 days). Healthy rats served as controls (n = 15/group). *In vivo* hepatic and systemic hemodynamic (mean arterial pressure; portal pressure, PP; portal flow, intrahepatic vascular resistance), hepatic microvascular function, and general parameters were assessed. Hepatic tissue underwent transcriptomic analysis, including an assessment of sex-specific differences in pathways and cellular composition using gene deconvolution (n = 5/group). Bioinformatic analyses were performed in transcriptomic data from patients' cohorts (GSE: 84044 & 162694).
Results: As expected, animals with ACLD exhibited portal hypertension. TAA males had similar PP to females, whereas BDL males had higher PP than BDL females. There were no differences in other hemodynamic parameters. In the BDL model, females exhibited more fenestrae and porosity, and less fibrosis. Transcriptomic analysis in TAA revealed males had dysregulated pathways in metabolism, while females showed deregulated genes in hormone signaling. In the BDL model, males had higher deregulation in platelet activation, protein degradation regulation, vesicular transport, and disease-related pathways. Gene deconvolution revealed that male rats had a more specialized endothelial phenotype at baseline than females, with greater changes in endothelial and macrophage phenotypes after injury. In MASLD patients, men had dysregulated pathways involved in metabolism, while women showed dysregulated genes in fibrosis, extracellular matrix, and endocrine regulation. In HBV patients, men exhibited more dysregulation in fibrosis, extracellular matrix, inflammation, immune response, cellular alterations, and disease-related pathways. No sex differences in cellular populations were observed in HBV cirrhotic patients. However, female MASLD patients had more activated HSCs and greater loss of healthy endothelial cells compared to men, suggesting these changes could stem from inherent metabolic pathway differences described above.
Conclusion: This study defines the molecular sex differences in the pathophysiology of cirrhosis. Further research in preclinical and human liver disease is essential to accelerate the development of safe and effective treatments for ACLD in both sexes.

THU-177
Albumin as a therapeutic target for endothelial dysfunction in patients with decompensated cirrhosis

Susan Fischer[1], Rudmer Postma[2], Annarein Kerbert[1], Roel Bijkerk[2], Anton Jan van Zonneveld[2], Minneke Coenraad[1]. [1]*Leiden University Medical Center, Department of Gastroenterology and Hepatology, Leiden, Netherlands;* [2]*Leiden University Medical Center, Department of Internal Medicine, Leiden University Medical Center, the Einthoven Laboratory for Vascular and Regenerative Medicine, Leiden, Netherlands*
Email: s.e.fischer@lumc.nl

Background and aims: Endothelial cell (EC) dysfunction is a critical driver of disease progression in patients with liver cirrhosis, contributing to acute decompensation (AD) and acute-on-chronic liver failure (ACLF). The administration of human albumin in cirrhotic patients with hypoalbuminemia has been shown to improve EC function. However, the direct effects of albumin on ECs in cirrhosis are unknown. Furthermore, it is unknown which patient category might benefit from albumin treatment. This study investigates *ex vivo* the impact of human albumin administration on ECs exposed to plasma derived from patients with different stages of cirrhosis, in order to explore the mechanisms underlying its protective effects and therapeutic response.
Method: A high-throughput *in vitro* EC model was used to observe EC responses to patient-derived plasma with or without albumin administration. Cultured human umbilical vein ECs were exposed to plasma from patients with decompensated cirrhosis and hypoalbuminemia (serum albumin < 30 g/L, n = 20), patients with compensated cirrhosis (serum albumin >30 g/L, n = 20), or healthy controls (n = 20). Albumin was administered to the plasma samples of patients with decompensated cirrhosis and healthy controls, aiming at physiological levels (~40 g/L) in patients with decompensated cirrhosis and similar doses to samples of healthy controls resulting in supraphysiological levels. The modulatory effects of albumin on EC activation were tested for well-described circulating factors involved in EC dysfunction (lipopolysaccharide (LPS), TNFα and bilirubin). Multiple cellular components were investigated using high-content imaging and multivariate analysis.
Results: Factor analysis identified mitochondrial morphology as a key feature responsible for the discrimination between patients with decompensated cirrhosis from those with compensated cirrhosis and healthy controls. Multivariate analysis revealed that albumin administration shifted EC morphology in plasma of decompensated cirrhosis toward a healthier phenotype, resembling the plasma of patients with compensated cirrhosis and healthy controls. No significant shifts in morphology were observed upon titration of albumin to ECs stimulated by LPS, TNFα or bilirubin.

Conclusion: Plasma from patients with decompensated cirrhosis and hypoalbuminemia induces important morphological changes to ECs, of which changes in mitochondrial morphology are most discriminative. Albumin administration reduces EC activation and dysfunction induced by plasma from patients with decompensated cirrhosis and hypoalbuminemia. These data underline the crucial role of albumin in EC function and point towards a potential therapeutic role of albumin in reducing vascular dysregulation and liver disease progression. Further research is required to explore the potential of this assay in predicting therapeutic responses to albumin.

Email: sachiyo@hosp.ncgm.go.jp

Background and aims: Patients with liver cirrhosis suffer from immune dysfunction. However, the mechanisms by which cirrhosis-associated immune dysfunction contributes to the difficulty in controlling infections and the progression of liver cancer remain unclear. Sialic acid-binding immunoglobulin-like lectin-5 (Siglec-5), an immunosuppressive molecule expressed on immune cells, has both a membrane-bound form and a soluble form (sSiglec-5) present in the blood. High levels of sSiglec-5 have been reported in sepsis, colorectal cancer, and lung cancer patients, where it is associated with poor prognosis. We aimed to clarify the significance of Siglec-5 as a biomarker and functional molecule in patients with liver cirrhosis.
Method: The expression of membrane-bound Siglec-5 on peripheral blood mononuclear cells (PBMCs) was analyzed using mass cytometry in patients with chronic liver disease and healthy volunteers (HV). Siglec-5 expression on various immune cell subsets was evaluated. The factors inducing Siglec-5 and the functional significance of sSiglec-5 were investigated in vitro. Additionally, the relationship between sSiglec-5 and prognosis was analyzed in 103 patients with cirrhosis and HCC undergoing transarterial chemoembolization (TACE) and 124 patients undergoing living donor liver transplantation (LDLT).
Results: Membrane-bound Siglec-5 on monocytes was significantly elevated in patients with live cirrhosis (F4) as compared with those with chronic hepatitis (F0-3) and HV. Serum sSiglec-5 levels were comparable between F0-3 patients and HV but were markedly elevated in F4 patients. The expression of membrane-bound Siglec-5 on monocytes strongly correlated with serum sSiglec-5 levels. In vitro, monocytes and macrophages stimulated with LPS or TNF-α/IL-1β showed increased expression of Siglec-5, accompanied by elevated sSiglec-5 levels in the culture supernatant. These findings suggest a mechanism underlying the elevated membrane-bound Siglec-5 on monocytes and serum sSiglec-5 observed in cirrhotic patients, potentially driven by gut barrier dysfunction. The addition of sSiglec-5 to PBMC cultures induced upregulation of the immunosuppressive molecule TIM-3 on CD8+ T cells, reduced their proliferation capacity, and impaired their cytotoxic activity. Patients with high serum sSiglec-5 levels demonstrated worse survival rates after TACE for cirrhosis with HCC. Similarly, in LDLT recipients, high sSiglec-5 levels were associated with increased sepsis incidence and reduced survival rates. These results suggest that sSiglec-5 negatively regulates CD8+ T cell activity as a functional molecule.
Conclusion: Siglec-5 derived from monocytes/macrophages impairs T cell function and is associated with poor prognosis in patients with liver cirrhosis.

Comparison of hepatocellular carcinoma risk scores in people with cirrhosis: concordance analysis of four prediction tools

Sude Yarar[1], Michael Pavlides[2], Christina Levick[3], Eleanor Barnes[4].
[1]Istanbul University, Faculty of Medicine, Istanbul, Türkiye; [2]Translational Gastroenterology and Liver Unit, University of Oxford, Oxford NIHR Biomedical Research Centre, University of Oxford, Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom; [3]Royal Devon University Healthcare NHS Foundation Trust, Department of Hepatology, Exeter, United Kingdom; [4]Translational Gastroenterology and Liver Unit, University of Oxford, Oxford, United Kingdom
Email: michael.pavlides@cardiov.ox.ac.uk

Background and aims: People with liver cirrhosis are at high risk of hepatocellular carcinoma (HCC). Several HCC risk stratification models have been developed, but no single one has yet been sufficiently validated for adoption in clinical practice. The aim of this study was to conduct an analysis of the concordance of HCC scores.
Method: Four HCC risk scores were identified from the literature (aMAP, ADRESS-HCC, THRI, and FASTRAK) and calculated using baseline data from 151 people with cirrhosis participating in local studies. Participants were categorized into low risk (LR), intermediate risk (IR), and high risk (HR) groups according to the HCC risk scores. Available data included age, sex, race, body mass index (BMI; kg/m²), diabetes status, liver disease etiology, platelet count (10^3/L), gamma-glutamyl transferase (GGT; IU/L), alpha-fetoprotein (AFP;ng/mL), and ALBI (Albumin-Bilirubin) score. Visual methods were used to evaluate the distribution of the scores in each risk category, and kappa values were calculated using GraphPad software to assess the agreement between scores.
Results: The cohort had a median age of 60 years (IQR 21–79.9), with 60% male and 99% Caucasian. The median BMI was 29.4 kg/m² (IQR 17.1–43.4), and 36% had diabetes. Metabolic-associated steatotic liver disease (MASLD) was the most common liver disease etiology (31%). Risk categorization according to the HCC scores was as follows: aMAP classified patients into HR (53.6%), IR (29.8%), and LR (16.6%); ADRESS-HCC categorized 24% of patients as HR, 49.7% as IR, and 26.3% as LR; THRI identified 41.7% of patients as HR, 46.4% as IR, and 11.9% as LR; and FASTRAK classified patients as HR (36.4%), IR (27%), and LR (36.6%). Kappa statistics were calculated to assess agreement among aMAP, ADRESS-HCC, THRI, and FASTRAK models. The values were as follows: aMAP vs. ADRESS-HCC: 0.286 (fair agreement), aMAP vs. THRI: 0.497 (moderate agreement), aMAP vs. FASTRAK: 0.327 (fair agreement), ADRESS-HCC vs. THRI: 0.392 (moderate agreement), ADRESS-HCC vs. FASTRAK: 0.201 (fair agreement), and THRI vs. FASTRAK: 0.247 (fair agreement). Among these comparisons, the highest kappa value was between aMAP and THRI (0.497; moderate agreement), indicating the strongest concordance in risk stratification. The lowest kappa value was between ADRESS-HCC and FASTRAK (0.201; fair agreement), reflecting significant differences in their classifications.
Conclusion: Our results indicate considerable variability in risk stratification across models. This highlights a clinical need for prospective studies that follow up people with cirrhosis for HCC development and include validation of existing HCC risk prediction models. Such validation would serve as external corroboration and facilitate clinical adoption of these models.

THU-180-YI

Toll-like receptor 4 inhibition restores cytochrome C oxidase mitigating hyperammonemia-induced hepatocyte mitochondrial dysfunction

Supachaya Sriphoosanaphan[1,2,3], Annarein Kerbert[1], Francesco De Chiara[4], Abeba Habtesion[1], Fausto Andreola[1], Gautam Mehta[1], Jan-Willem Taanman[5], Rajiv Jalan[1]. Email: r.jalan@ucl.ac.uk

Background and aims: Hyperammonemia has been demonstrated to induce mitochondrial dysfunction in hepatocytes, with a particular impact on oxidative phosphorylation (OXPHOS). While inhibition of Toll-like receptor 4 (TLR4) has shown potential in preserving mitochondrial stability, supporting urea cycle enzyme (UCE) function, and reducing oxidative stress, the underlying mechanisms remain unclear. This study investigates how TLR4 inhibition can restore mitochondrial function under hyperammonemic conditions.
Method: Hyperammonemia was induced in wild-type (WT) and TLR4 knock-out (TLR4KO) mice via a 14-day amino acid (AA) diet. WT-AA mice were treated with either the TLR4 antagonist, TAK-242 (10 mg/kg i.p.) or the ammonia scavenger Ornithine Phenylacetate (OP, 300 mg/kg i.p.) from days 10 to 14. Liver transcriptomic analysis was performed using whole RNA sequencing, with specific focus on OXPHOS genes. Data were analysed with KEGG and Gene Ontology databases. Liver qPCR and western blot were used to confirm related genes and proteins. Quantitative activity of cytochrome C oxidase in isolated hepatocyte mitochondria was assessed using spectrophotometric enzyme assay.
Results: WT-AA mice exhibited significantly elevated ammonia levels compared to controls (333.4 ± 54.5 vs. 47.0 ± 11.9 micromol/L, $p < 0.0001$), which were markedly reduced by both TAK-242 and OP treatment (121.1 ± 51.5 and 131.6 ± 79.8 micromol/L, respectively, $p < 0.0001$). Transcriptomic analysis revealed that, among all five OXPHOS complexes, only complex IV (cytochrome C oxidase) was significantly affected by hyperammonemia, with marked upregulation of cytochrome C oxidase subunit genes (Cox6a2, Cox6b2, Cox7a1, Cox4i2, Cox8b), which normalised following TAK-242 treatment (all $p < 0.001$). These changes were aligned with increased protein expression of cytochrome C oxidase subunits (all $p < 0.05$). Mitochondrial cytochrome C oxidase activity assays further confirmed significantly elevated enzyme activity in WT-AA mice compared to controls (52.6 k/min/mg vs. 33.8 k/min/mg, $p = 0.012$), which was significantly reversed by TAK-242 (39.1 k/min/mg, $p = 0.028$) but remained unchanged with OP treatment (58.5 k/mg/min, $p = 0.906$). Notably, TLR4KO mice showed no changes in cytochrome C oxidase gene or protein expression, nor in enzyme activity, regardless of the AA diet.
Conclusion: Our findings demonstrate for the first time that hyperammonemia drives mitochondrial dysfunction by selectively upregulating cytochrome C oxidase subunits, which are critical for mitochondrial OXPHOS function. TLR4 inhibition effectively mitigates this dysregulation, stabilising mitochondrial bioenergetics and preserving UCE activity. These results suggest that TLR4 antagonist may offer a promising therapeutic approach for hyperammonemia by restoring cytochrome C oxidase regulation.

Email: r.jalan@ucl.ac.uk

Background and aims: Bacterial infection is an important cause of acute decompensation (AD) in cirrhotic patients and further complicates their clinical course and increases mortality. Previous studies have demonstrated significant neutrophil defects in patients with AD and their potential role in identifying the risk of new infection. This study aimed to validate plasma-induced dysfunction of healthy neutrophils (PIND) as a predictor of subsequent infection risk and 90-day mortality.
Method: A total of 160 patients with AD [117 without ACLF (AD-NoACLF) and 43 with ACLF (AD-ACLF)] were prospectively recruited from two tertiary liver units. Plasma samples from 21 healthy controls (HC) and 74 patients with stable compensated cirrhosis were used as controls. Neutrophils isolated from HC were co-incubated with patient plasma and assessed for oxidative burst, reactive oxygen species (ROS) production, and phagocytic capacity. Neutrophils were stimulated with phosphate-buffered saline (constitutive), N-formyl-Met-Leu-Phe (fMLP), opsonised bacteria (*E. coli*), or phorbol 12-myristate 13-acetate (PMA) for 20 minutes prior to flow cytometry analysis. Cell surface expression of CD62L in neutrophils was measured by fluorescence-activated cell sorting (FACS) and reported as geometric mean fluorescent intensities (GMFI).
Results: Neutrophils exposed to plasma from patients in both the AD-NoACLF and AD-ACLF groups showed significantly increased constitutive ROS production (119.4 ± 17.2% in AD-NoACLF and 115.1 ± 23.1% in AD-ACLF, $p < 0.0001$) and fMLP-induced ROS production (128 ± 14.5% in AD-NoACLF and 142.7 ± 35.9% in AD-ACLF, $p < 0.01$) compared to controls, indicating a primed state. However, there was a significant reduction in PMA-induced ROS production (−8.2 ± 4.9% in AD-NoACLF and −25.9 ± 6.9% in AD-ACLF, $p < 0.05$), phagocytic activity (−48.1 ± 4.0% in AD-NoACLF and −54.2 ± 5.4% in AD-ACLF, $p < 0.001$), and CD62L expression [GMFI 449 (95% CI 225–857) in AD-NoACLF and GMFI 423 (95% CI 229–713) in AD-ACLF, $p < 0.0001$). Among AD-NoACLF patients, *E. coli*-induced ROS production was predictive of subsequent infection [AUROC 0.75 (95% CI 0.62–0.87), $p < 0.001$], while PMA-induced ROS production was associated with 90-day mortality ($p = 0.035$). In contrast, none of the other neutrophil function assays were predictive of clinical outcomes in patients with AD-ACLF.
Conclusion: Multiple aspects of normal neutrophil function are impaired by plasma from AD-NoACLF patients, which are associated with an increased risk of subsequent infection and 90-day mortality. The observed phenotype is priming of neutrophil response with a

paradoxically reduced capacity to respond to stimuli and perform phagocytosis. PIND could be further developed as a biomarker to allow identification of patients at risk of new infection and complement existing prognostic scores to enhance identification of those at risk of death.

THU-182

Transcriptomic and metabolic insights into hyperammonemia: the complementary therapeutic roles of toll-like receptor 4 inhibitor and ornithine phenylacetate

Supachaya Sriphoosanaphan[1,2,3], Francesco De Chiara[4], Annarein Kerbert[1], Abeba Habtesion[1], Fausto Andreola[1], Gautam Mehta[1], Rajiv Jalan[1]. *[1]Institute for Liver and Digestive Health, University College London, London, United Kingdom; [2]Division of Gastroenterology, Department of Medicine, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand; [3]Centre of Excellence in Liver Diseases, King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [4]Institute for Bioengineering of Catalonia, Barcelona, Spain*
Email: r.jalan@ucl.ac.uk

Background and aims: Hyperammonemia is a critical issue in patients with liver disease, where elevated ammonia levels predict mortality and a reduction in ammonia levels is linked to improved survival. Despite this, no effective therapies are available, highlighting an unmet clinical need. Previous studies have identified toll-like receptor 4 (TLR4) as a potential therapeutic target for hyperammonemia by modulating mitochondrial function. This study aims to explore the therapeutic potential of TLR4 inhibition and the ammonia scavenger Ornithine Phenylacetate (OP) through transcriptomic analysis to identify pathways for targeted treatment strategies.
Method: A wild-type (WT) mouse model was studied using a two-week amino acid-enriched diet (AA) to induce hyperammonemia. During the last four days, mice were treated with either the TLR4 antagonist TAK-242 (10 mg/kg, i.p.) or the ammonia scavenger OP (300 mg/kg, i.p.). TLR4 knock-out (TLR4KO) mice, fed the same diet, were included for comparison. Liver transcriptomic analysis was performed using RNA sequencing to investigate key metabolic pathways, including the urea cycle, tricarboxylic acid cycle, oxidative phosphorylation (OXPHOS) complexes, and oxidative stress pathways. Gene expression changes were reported as log2 fold change (FC).
Results: Ammonia levels were significantly elevated in WT-AA mice compared to controls (333.4 ± 54.5 vs. 47.0 ± 11.9 micromol/L, $p < 0.0001$). Both TAK-242 and OP treatments effectively reduced ammonia levels to 121.1 ± 51.5 micromol/L and 131.6 ± 79.8 micromol/L, respectively (both $p < 0.0001$). In contrast, ammonia levels in TLR4KO mice remained low despite the AA diet. Among all metabolic pathways, hyperammonemia in WT-AA mice significantly impacted the OXPHOS complex IV [Cox7a1 (FC 2.19, $p < 0.001$) and Cox6b2 (FC 2.15, $p = 0.006$)] and the urea cycle pathways [Ass1 (FC 1.15, $p = 0.018$), Asl (FC 0.72, $p < 0.001$), and Glul (FC −1.45, $p < 0.001$)]. Both TAK-242 and OP treatment reverted Cox6b2 and Glul expression [*TAK-242*: Cox6b2 (FC −1.64, $p = 0.031$), Glul (FC 1.49, $p < 0.001$); *OP*: Cox6b2 (FC −2.44, $p = 0.001$), Glul (FC 1.51, $p < 0.001$)]. Additionally, Cox7a1 was downregulated in the TAK-242 group (FC −0.76, $p = 0.029$), while Oscp1 was downregulated in the OP group (FC −1.91, $p = 0.021$) indicating distinct mechanisms of action for each treatment. Notably, TLR4KO mice exhibited gene expression changes consistent with a combined effect of TAK-242 and OP treatment.
Conclusion: Transcriptomic analysis revealed that TLR4 plays an important role in mediating metabolic and mitochondrial dysfunction induced by hyperammonemia. The shared and distinct gene expression changes observed with TAK-242 and OP treatments highlight complementary mechanisms, which could be leveraged for more effective therapeutic strategies.

THU-183-YI

Mesenchymal stem cells restore gut-liver axis integrity by targeting intestinal barrier dysfunction and MLN inflammation in cirrhotic mice

Sandeep Kumar[1], Manisha Bhardwaj[1], Nikita Sharma[1], Anupama Kumari[1], Shvetank Sharma[1], Sukriti Baweja[1], Shiv Kumar Sarin[1], Anupam Kumar[1]. *[1]Institute of Liver and Biliary Sciences, New Delhi, India*
Email: dr.anupamkumar.ilbs@gmail.com

Background and aims: Intestinal and mesenteric lymph nodes (MLNs) inflammation along with loss of intestinal epithelial integrity and gut dysbiosis, accounts for increased enteric bacterial translocation (BT) to liver (a hallmark of cirrhosis that drive liver injury) and systemic inflammation in cirrhosis. Till date there is no available treatment to augment intestinal and MLN inflammation in cirrhosis. This study aims to evaluate the therapeutic potential of mesenchymal stem cells (MSCs) in mitigating intestinal and MLN inflammation, their impact on liver injury/repair in murine model of CCl4 induced cirrhosis.
Method: Cirrhosis was induced in C57BL/6 mice through intraperitoneal (i.p.) injections of carbon tetrachloride (CCl4, 0.1–0.5 ml/kg) 10 weeks. Histological and molecular analyses were used to evaluate intestinal injury, tight junction protein (TJP) expression. Immune cell populations in MLNs were quantified. Gut permeability and BT were assessed via serum endotoxin and IgG+ gut bacteria. Biodistribution of i.p. and intravenously (i.v.) administered MSCs was analyzed in vivo and ex vivo. Therapeutic effects of MSCs on intestinal injury, MLN inflammation and liver function markers were evaluated 7 and 11 days post treatment.
Results: Animals with chronic liver injury exhibited significant increases in intestinal injury [villus blunting, immune infiltration, and reduced TJPs: OCLN (2.8 fold, $p < 0.01$) and Zo-1 (2.6 fold, $p < 0.001$)], MLN inflammation [elevated CD3+ (1.3 fold, $p < 0.01$), CD4+ (1.2 fold, $p < 0.05$), CD8+ (1.2 fold, $p < 0.01$), B cells (1.3 fold, $p < 0.01$)], and reduced enteric BT (IgG^+ gut bacteria, $p < 0.01$), particularly during transition from fibrosis to cirrhosis. Initial assessment of MSC administration routes revealed that i.v. infused MSCs primarily localized to the lungs, liver, and spleen, while i.p. infused MSCs preferentially localized to the MLNs, intestine and liver, persisting for up to 21 days. MSC therapy via the i.p. route significantly alleviated intestinal injury (reduced villus blunting, immune infiltration, and increased TJPs [OCLN (4.2 fold, $p < 0.01$) and Zo-1 (6 fold, $p < 0.01$)], MLN inflammation [reduced CD3+ (0.77 fold, $p < 0.001$), CD8+ (0.86 fold, $p < 0.001$), B cells (0.6 fold, $p < 0.01$)], and reduced enteric bacterial translocation ($p < 0.01$). It also significantly reduced liver fibrosis ($p < 0.001$), liver enzymes AST ($p < 0.001$) and ALT ($p < 0.01$), and restored TJP expression. While i.v.-MSC therapy significantly reduced liver fibrosis and liver enzyme levels compared to i.p.-MSC therapy, it failed to alleviate intestinal injury, MLN inflammation, or enteric bacterial translocation.
Conclusion: Intra peritoneal MSC therapy ameliorates both intestinal and hepatic injury in cirrhotic mice by reducing MLN inflammation, improving intestinal barrier integrity, mitigating bacterial translocation, and restoring liver repair. These findings highlight the potential of MSCs as a therapeutic strategy for management of gut liver axis complications in cirrhosis.

THU-184

Synergy between ornithine phenylacetate and strategies targeting endotoxemia with either a toll-like receptor 4 antagonist (TAK-242) or Yaq-001 for the treatment of hyperammonemia in cirrhosis and ACLF

Tingting Qi[1], Annarein Kerbert[2], Fausto Andreola[3], Rajiv Jalan[3]. *[1]Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom; Department of Hepatology Unit and Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China, London, United Kingdom; [2]Liver*

Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom, Department of Gastroenterology & Hepatology, Leiden University Medical Center; Leiden, the Netherlands, London, United Kingdom; [3]Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom, London, United Kingdom
Email: r.jalan@ucl.ac.uk

Background and aims: Ammonia, accumulates in the blood of patients with cirrhosis, playing a critical role in the development of hepatic encephalopathy (HE). Elevated plasma ammonia levels correlate strongly with disease severity and poor prognosis. Endotoxemia is a feature of decompensated cirrhosis, which worsens hyperammonemia and acts synergistically with it to produce HE. Bacterial infection worsens hyperammonemia and is a common precipitant of HE, Therefore, this study investigated whether targeting ammonia and endotoxin or its signalling would act synergistically to reduce ammonia and prevent HE in rodent models of cirrhosis and acute-on-chronic liver failure (ACLF).
Method: Animal model: Sham or 4-week bile duct ligation (BDL) rat model with or without lipopolysaccharide (LPS) to mimic cirrhosis or ACLF (Total, n = 82; 10-groups). Treatments: 1. Ornithine phenylacetate (oral OP, ammonia scavenger, administered for 5-days prior to sacrifice) or Placebo; 2. OP + Toll-like 4 antagonist (intraperitoneal TAK-242, administered prior to LPS) or Placebo; 3. OP + Yaq-001 (oral, a gut-restricted carbon bead adsorbent, administered for 2 weeks prior to sacrifice) or Placebo. Consciousness was monitored for 6-hours in the ACLF model. Animals were sacrificed after observation, and plasma samples were collected for biochemical analysis.
Results: Ammonia levels were significantly elevated in the BDL group (82.5 ± 14.7 µmol/L) compared to Sham (26.7 ± 3.0 µmol/L, $p < 0.001$) and were markedly higher after LPS injection (280.5 ± 38.7 µmol/L, $p < 0.001$ vs. Sham). OP or TAK-242 monotherapy reduced ammonia levels in BDL (53.1 ± 10.3 and 59.6 ± 7.6 µmol/L, $p = 0.002$ and $p = 0.019$) and BDL+LPS models (145.9 ± 28.4 and 130.5 ± 32.2 µmol/L, $p < 0.001$ for both). Combined OP and TAK-242 therapy further lowered ammonia levels (73.4 ± 11.5 µmol/L, $p < 0.001$) in BDL+LPS model. Clinically, 100% of BDL+LPS rats developed coma within 6 hours. Monotherapy with OP and TAK-242 improved coma-free survival to 62.5% ($p = 0.026$) and 75.0% ($p = 0.007$), while combined therapy achieved 100% coma-free survival ($p < 0.001$ vs. untreated). Yaq-001, reduced ammonia levels in BDL rats (82.5 ± 14.7 µmol/L to 60.8 ± 9.0, $p = 0.004$), which was normalised when combined with OP (35.9 ± 4.9 µmol/L, $p = 0.001$). Blood urea levels increased in BDL+LPS rats treated with TAK-242 alone (8.7 ± 1.5 mmol/L) or combined with OP (8.4 ± 1.9 mmol/L), compared to untreated animals (6.9 ± 1.1 mmol/L, $p = 0.006$ and $p = 0.017$). Besides, compared with untreated models, all the therapies reduced the alanine-aminotransferase (ALT) levels ($p < 0.05$ for all).
Conclusion: Dual targeting of ammonia and endotoxins are synergistic in reducing ammonia levels, enhancing ureagenesis, ameliorating liver injury and preventing coma in ACLF animals. This combined approach should be explored in clinical trials for managing hyperammonemia and HE in ACLF.

THU-185

Neuropathological basis of brain failure in acute-on-chronic liver failure (ACLF): insights into the roles of hyperammonaemia and neuroinflammation

Tingting Qi[1], Annarein Kerbert[2], Andrew Hall[3], Abeba Habtesion[4], Fausto Andreola[4], Rajiv Jalan[4]. *[1]Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom; Department of Hepatology Unit and Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China, London, United Kingdom; [2]Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom, Department of Gastroenterology & Hepatology, Leiden University Medical Center; Leiden, the Netherlands, London, United Kingdom; [3]The Sheila Sherlock Liver Centre, Royal Free Hospital, London, United Kingdom, Department of Cellular Pathology, Royal Free Hospital, London, United Kingdom, London, United Kingdom; [4]Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom, London, United Kingdom*
Email: r.jalan@ucl.ac.uk

Background and aims: Brain failure is a component of acute-on-chronic liver failure (ACLF). No treatments are available. Both hyperammonemia and systemic inflammation are pathogenically important and role of 'immunopathology' unknown. Given the heterogeneity of ACLF, clinical manifestations and underlying mechanisms of HE in ACLF are likely to be different. This study aimed to characterize the clinical symptoms and neuropathological features in ACLF rodent models and the role of hyperammonemia.
Method: *Animal models*: ACLF – 4 wk bile duct ligation (BDL) rat model+lipopolysaccharide (LPS); 6-wk carbon tetrachloride (CCl4) mouse+LPS. Hyperammonemia: Administering an amino acid (AA) mixture (1:2 ratio); 14-days. Consciousness was monitored in ACLF models. Three behavioral tests were performed in the hyperammonemic animals. Brains were obtained at sacrifice and neuronal loss and neuroinflammation were evaluated with immunohistochemistry using neuronal nuclei (NeuN), Ionized Calcium-Binding Adapter Molecule 1 (IBA-1, specific for microglia) and Glial Fibrillary Acidic Protein (GFAP, specific for astrocytes).
Results: BDL ACLF animals developed severe coma. Ammonia levels were significantly elevated (Sham: 46.5 [44.1–49.2], BDL: 100.6 [36.9–164.2], BDL+LPS: 340.4 [244.5–532.4] µmol/L, $p = 0.033$). Systemic inflammation markers, including TNF-α, IL-1β, IL-6, IL-10, and IFN-γ increased remarkedly. Histologically, hippocampal microglial loss was noted (percentage of IBA positive areas in hippocampus (%), Sham: 21.15 (18.55–30.84), BDL 14.09 (10.40–22.79), BDL+LPS 12.98 (10.04, 15.68), $p = 0.033$), while astrocyte and neuronal numbers in the hippocampus, cortex, and cerebellum remained unchanged. In the CCl4 ACLF, animals exhibited reduced activity post-LPS injection but did not develop coma, with all surviving to sacrifice at 24-hours. Unlike BDL+LPS animals, microglial activation and increased microglia numbers were observed in the hippocampus (percentage of IBA positive areas in hippocampus (%), vehicle: 8.66 ± 1.92, CCL4+LPS: 15.54 ± 2.44, $p = 0.019$). The expressions of NeuN and GFAP remained similar between vehicle and CCL4+LPS groups. In the pure hyperammonemia models, the ammonia level was significantly increased with AA diet (NP:46 ± 6.33, AA: 86.0 ± 26.7, $p = 0.004$). However, mice on the AA diet showed no behavioral differences, nor any neuroinflammatory or neuronal markers in any brain regions.
Conclusion: The results provide novel insights into the brain immunopathology in ACLF demonstrating distinct clinical manifestations and neuroinflammatory responses attributable partially to hyperammonemia and to neuroinflammation. Hyperammonemia alone was insufficient to induce neurobehavioral or neuroinflammatory changes. Therapeutic approach to brain failure in ACLF will require combinatorial approaches targeting ammonia and inflammation.

THU-186-YI

Endotoxin induced Liver sinusoidal endothelial cell metabolic reprogramming promotes vascular dysfunction and contribute to portal hypertension in experimental cirrhosis

Vaibhav Tiwari[1], Rajni Yadav[1,1], Tahseen Khan[1], Aishwarya Bhatnagar[1], Himanshi Himanshi[1], Praveen Kumar[2], Savneet Kaur[1], Shiv Kumar Sarin[1], Dinesh Mani Tripathi[1]. *[1]Institute of Liver and Biliary Sciences, New Delhi, India; [2]Jawaharlal Nehru University, New Delhi, India*
Email: dineshmanitripathi@gmail.com

Background and aims: Liver sinusoidal endothelial cells (LSECs) act hepatic gatekeeper and first to encounter pathogens and xenobiotic due to gut barrier dysfunction in cirrhosis. Sepsis in cirrhosis

aggravates vascular dysfunction and portal hypertension (PHT). Knowledge on LSECs metabolic dysfunction and its contribution to vascular complication in cirrhosis is limited. This study investigated the role of 6-phosphofructo-2-kinase (PFKFB3) via pharmacological modulation of PFKB3 in hepatic microvascular dysfunction during sepsis in cirrhosis and its contribution to PHT.

Method: Experimentally, sepsis was induced by caecum ligation and puncture (CLP) in non-cirrhotic and by exogenous administration of LPS in CCl4 and TAA cirrhotic animals. PFKFB3 targeted inhibition was achieved by 3PO. Controls (Ct1), Ct+ CLP(Ct2), Ct+CLP+3PO(Ct3) were compared with CCl4 cirrhotic rats (Gr1), CCl4+LPS(Gr2), CCl4+LPS +3PO(Gr3) and TAA cirrhotic rats (Tm1), TAA+LPS(Tm2), TAA+LPS +3PO(Tm3). Hepatic hemodynamic were monitored, followed by ex vivo hepatic microvascular function. Cellular, molecular, biochemical, and histological and hematological analysis were performed. Lactate, arterial blood gas, malondialdehyde and nitric oxide (NO), ROS levels were measured. In vitro monocyte adhesion on LSEC was investigated.

Results: Increased Portal pressure (PP) Ct2(+32%), Supra-mesenteric artery blood flow Ct2(+38%), and Portal Blood Flow (PBF) Ct2(+30%) ($p < 0.05$) in vs Ct1 and a marked reduction in Ct3 vs Ct2($p = 0.01$) in non-cirrhotic was observed. Raised PP Gr2(+15%) and Tm2(+18%) vs Gr1 and Tm1($p < 0.05$) and reduction in Gr3(−13%) and Tm3(−15%) ($p = 0.01$) was observed in treated group. Endothelial dysfunction was improved in Ct3, Gr3, Tm3 vs Ct2, Gr2, Tm2 respectively ($p < 0.05$). ROS and lactate levels were increased (+170%) in Gr2, (+140%) Tm2 and was further decreased (−100%Gr3), (−120%Tm3) ($p < 0.01$) upon treatment. Interestingly, increased protein expression of PFKFB3, HK1, LDH1, ICAM1, Claudin5 levels ($p < 0.01$) Gr2, Tm2 & Ct2 vs respective controls confirms metabolic reprograming, further reversal was archived upon treatment. In-vitro increased monocyte adhesion on LSEC was improved upon inhibition of PFKFB3. Periportal inflammation and immune cells infiltration was improved post treatment. Gene expression of IL1-beta, IL-6, HMGB1, DPEP1, ICAM1, TLR4, PFKFB3, HK1, Sem3A and LDH1 were upregulated in Gr2, Tm2 and Ct2 ($p < 0.05$) vs Gr3, Tm3 and Ct3.Serum levels of ALT, AST, ALP and LDH were reduced ($p < 0.05$) in Gr3, Tm3 & Ct3 vs Gr2, Tm2 & Ct2.

Conclusion: The study findings suggest endotoxemia induced metabolic reprograming in LSEC primarily mediated through PFKFB3, a key enzyme participates in energy metabolism. Pharmacological modulation of PFKFB3 restores LSECs function, alleviates vascular dysfunction and PHT, highlighting its therapeutic potential for improving hemodynamic stability and associated vascular complication precisely due sepsis in non-cirrhotic and cirrhotic liver.

Efficacy of the apoptosis-signal-regulating kinase 1 (ASK1) inhibitor SRT-015 in in vivo and in vitro pathogen-associated molecular patterns (PAMPs)-induced disease models

Vanessa Legry[1], Manon Clarisse[1], Simon Debaecker[1], Nicolas Stankovic Valentin[1], Philippe Poulain[1], Dean Hum[1], Bart Staels[2], Joan Clària[3], Sakina Sayah Jeanne[1]. *[1]GENFIT SA, Loos, France; [2]Univ. Lille, INSERM, CHU Lille, Institut Pasteur de Lille, U1011, Lille, France; [3]Hospital Clinic-IDIBAPS, Universitat de Barcelona, European Foundation for the Study of Chronic Liver Failure (EF CLIF), Barcelona, Spain*

Email: vanessa.legry@genfit.com

Background and aims: Patients with liver cirrhosis have an increased risk of infections and are at high risk of death from sepsis due to severe immune dysfunction, impaired liver function and altered gut microbiota and permeability. In these patients, immune dysfunction also results into a hyperinflammatory condition in the systemic circulation, as attested by elevation of circulating pro-inflammatory cytokines such as TNFalpha, IL-6 and IL-1beta, which plays a major role in the progression to acute decompensation and acute-on-chronic liver failure (ACLF). Apoptosis-signal-regulating kinase 1 (ASK1) is a key mediator of the inflammatory response, activated by reactive oxygen species produced after recognition of pathogen-associated molecular patterns (PAMPs) by toll-like receptor (TLR) family. Its phosphorylation results in activation of c-Jun N-terminal kinase (JNK) and p38 that regulate cell death and cytokine production. The aim of this study was to investigate the effects of SRT-015, a new investigational drug inhibiting ASK1, on overt activation of human blood immune cells by a variety of PAMPs, and evaluate its efficacy to counteract polymicrobial sepsis in a rodent model.

Method: Fresh whole blood from healthy volunteers was treated 4 h with TLR2 (Pam3CSK4), TLR4 (LPS *E.coli*) and TLR5 (FLA-ST) agonists in presence or not of SRT-015 (2–15 µM). In mice, sepsis was induced through Cecal Ligation and Puncture (CLP) surgery. SRT-015 (10 mg/kg BID) or vehicle was orally administered 30 min before and 5.5 h after CLP, then BID for 6 days.

Results: While cytokines levels were almost not detectable in blood from healthy volunteers, TLR activation greatly induced their secretion reaching 598 pg/ml TNFalpha, 1800 pg/ml IL-6 and 33 pg/ml IL-1beta with TLR2 agonist, 4367 pg/ml TNFalpha, 9667 pg/ml IL-6 and 3300 pg/ml IL-1beta with TLR4 agonist, 3049 pg/ml TNFalpha, 4992 pg/ml and 1148 pg/ml IL-1beta with TLR5 agonist, respectively. SRT-015 (added concomitantly or after TLRs agonists) dose-dependently reduced TNFalpha by 62%***, 30%** and 60%***, IL-6 by 31%**, 33% and 12%, and IL-1beta by 79%***, 59%*** and 91%*** after TLR2, TLR4 and TLR5 activation, respectively (***$p < 0.001$, **$p < 0.01$). In CLP mice, SRT-015 administration significantly improved the survival curves, with 65% surviving mice in SRT-treated mice vs 15% of mice in the control group, 7 days post-CLP ($p = 0.004$).

Conclusion: Although further experiments are needed to fully understand how SRT-015 improved survival in septic mice, it seems to be at least mediated by regulation of the innate immune response. These results further support the development of SRT-015 in advanced liver disease and ACLF.

Immunocompetence in outpatients and hospitalized chronic liver disease patients: gene expression profiles and cell-type estimation from stimulated whole blood

Xiaomian Tan[1], Alexander Maini[2], J. Bernadette Moore[1], Alastair O'Brien[2]. *[1]Institute of Systems, Molecular and Integrative Biology, University of Liverpool, Liverpool, United Kingdom; [2]Institute for Liver and Digestive Health, University College London, London, United Kingdom*

Email: xiaomian.tan@liverpool.ac.uk

Background and aims: Acute decompensation (AD) of chronic liver disease markedly increases patients' risk of organ failure and mortality. While systemic inflammation and immune cell dysfunction are implicated in adverse outcomes, the underlying mechanisms are incompletely understood. Utilising a combination of ex vivo whole blood lipopolysaccharide (LPS) stimulation, bulk RNA sequencing (RNA-seq), and in silico cell-type deconvolution methods, this study aimed to characterise the immunocompetence of patients hospitalised with AD in comparison to stable outpatients and healthy volunteers (HV).

Method: With NHS ethical approval (IRAS: 170839, REC: 15/LO/0800), venous whole blood samples were taken from healthy non-smoking volunteers aged 18–50 (HV, n = 5), outpatients with refractory ascites attending for day-case paracentesis (ORA, n = 5), and hospitalised AD patients (n = 10). The blood samples were treated with or without 1 ng/mL LPS for 4 hours (Enzo Life Sciences, United States). Next generation sequencing and data pre-processing were done by the Wellcome Sanger Institute. Differential expression and enrichment analyses were conducted utilising DESeq2 (v1.42.0) and clusterProfiler (v4.10.0) in the R environment (v4.3.0). Cell fractions were predicted by CIBERSORTx and differences between groups were

assessed using two-way analysis of variance (ANOVA) followed by Tukey's test.
Results: While HV responded robustly to LPS stimulation, ORA and AD patients showed markedly altered responses. Specifically, 5,404, 2,500 and 3,376 genes were identified significantly altered by LPS in HV, ORA and AD groups, respectively (padj < 0.05, with Benjamini-Hochberg correction). T cell receptor signalling and Th1 and Th2 cell differentiation pathways were enriched in the HV response but not in ORA and AD patients. Notably, only one KEGG pathway was found uniquely dysregulated by LPS in AD patients, namely glycerolipid metabolism (padj = 0.03). In silico deconvolution predictions suggested higher monocytes and far fewer CD4 and CD8 T cells and NK cells in unstimulated samples from ORA and AD patients, who also displayed markedly fewer activated dendritic cells (50.7% decreased, p = 0.001 in AD compared to HV) and far fewer eosinophils (83.0% decreased, p = 0.003 in AD compared to HV) in response to LPS stimulation.
Conclusion: Immunocompetency was impaired in both ORA and AD patients with markedly fewer activated dendritic cells and far fewer eosinophils found in response to LPS stimulation. Unique changes in glycerolipid metabolism were observed in AD patients. Ongoing work includes the validation of cell type deconvolution utilising complete blood count data and determination of cell type-specific gene expression.

Ultrasound localization microscopy for diagnosis of clinically significant portal hypertension: a prospective multicenter study
Wei Zhang[1], Chuan Liu[2], Yanping Ma[1], Xiaolong Qi[2], Jie Ren[1]. *[1]The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China; [2]Liver Disease Center of Integrated Traditional Chinese and Western Medicine, Department of Radiology, Zhongda Hospital, Medical School, Southeast University, Basic Medicine Research and Innovation Center of Ministry of Education, Zhongda Hospital, Southeast University, State Key Laboratory of Digital Medical Engineering, Nanjing, China*
Email: renjieguangzhou@126.com

Background and aims: Currently, hepatic venous pressure gradient (HVPG) remains the gold standard for diagnosing clinically significant portal hypertension (CSPH), but its use is restricted by invasiveness and accessibility. This multicenter study aims to apply ultrasound localization microscopy (ULM) to visualize and quantify hepatic microvasculature in cirrhotic patients, evaluating its potential in non-invasive CSPH diagnosis.
Method: This study enrolled patients aged 17 to 80 with clinical diagnosis of cirrhosis who underwent HVPG measurement between April 2024 and November 2024 based on clinical needs. Exclusion criteria included prior hepatosplenic surgery, TIPS, SonoVue allergy, hypovolemia, and HVPG contraindications. After informed consent, patients underwent ULM, with data acquisition in the portal phase. Real-time imaging was performed, followed by offline quantitative analysis of microvessel functional and morphological parameters. HVPG ≥10 mmHg was considered the gold standard for diagnosing CSPH. The Mann-Whitney U test was used to compare microvessel parameters between the CSPH and non-CSPH groups. Spearman correlation analysis assessed the correlation between microvessel parameters and HVPG values. Simple and multiple linear regression models evaluated independent predictors of HVPG. receiver operating characteristic curve was used to assess the diagnostic performance of microvessel parameters in identifying CSPH.
Results: A total of 11 patients were enrolled, including 8 males, with an average age of 52 (range: 42–54) years. Among them, 7 had alcoholic cirrhosis (including 2 co-infected with hepatitis B), 2 had hepatitis B cirrhosis, 1 had non-alcoholic steatohepatitis, and 1 had primary biliary cirrhosis. Eight patients were diagnosed with CSPH, and 3 were non-CSPH. Compared to the non-CSPH group, the CSPH group exhibited lower vessel density (VD) (62.0 ± 11.2 vs. 43.9 ± 3.3, p = 0.002). There was a strong correlation between VD and HVPG (r = −0.93, p < 0.001), and a moderate correlation between the minimum velocity (r = −0.69, p = 0.02) and HVPG. VD was an independent predictor of HVPG (r^2 = 0.78). The diagnostic performance of VD for CSPH (AUC = 1.0, p = 0.014) was higher than that of the CSPH risk score (AUC = 0.69, p = 0.43).
Conclusion: ULM-based microvessel parameters were proposed with good diagnostic consistency for HVPG measurement.

Effect of exercise based regimen on frailty in children with liver disease-a randomized controlled trial
Deepika Yadav[1], Vikrant Sood[1], Seema Alam[1], Rajeev Khanna[1], Bikrant Bihari Lal[1], Jaya Benjamin[2], Rakesh Kumar[3], Sukriti Baweja[4]. *[1]Department of Pediatric Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India; [2]Department of Clinical Nutrition, Institute of Liver and Biliary Sciences, New Delhi, India; [3]Department of Physiotherapy, Institute of Liver and Biliary Sciences, New Delhi, India; [4]Department of Molecular and Cellular Medicine, Institute of Liver and Biliary Sciences, New Delhi, India*
Email: deepikayadav2012mamc@gmail.com

Background and aims: Cirrhosis leads to reduced muscle mass and strength, limiting daily activities and impacting quality of life. Resistance training and physical exercise may improve muscle mass and functional capacity in cirrhosis. There is limited available pediatric literature on interventions to improve frailty. We performed a randomized controlled trial to study the effect of exercise-based regimen on frailty in children with cirrhotic liver disease.
Method: Children (9–18 years of age) with cirrhotic liver disease (CLD) with five fried's frailty score more than five were randomly assigned to groups that received exercise training (n = 23) or standard medical treatment (SMT) alone (n = 23). Exercise regimen included aerobic and resistance exercises for a total of at least 50 minutes per day for 3 to 5 days per week for 24 weeks. Frailty assessment was done at baseline, 12 weeks and 24 weeks while myokines, hepatokines levels and body composition analysis was evaluated at baseline and after 12 weeks.
Results: At 12 and 24 weeks, the delta change in frailty scores was significantly greater in the exercise group compared to the SMT group (mean difference (MD) −1.38, 95% CI −2.07, −0.69, p < 0.001) and (MD-2.36, 95% CI −3.3, −1.44, p < 0.001) respectively. By 12 weeks, 60% of patients in the exercise group became non-frail (frailty score less than 5), increasing to 85% by 24 weeks. In the SMT group, 32% and 37% of patients achieved non-frail status at 12 and 24 weeks, respectively. At 12 weeks, the exercise group showed a significant delta reduction in myostatin levels compared to the SMT group (p = 0.02), while no significant differences were noted for follistatin, decorin, or irisin levels. Significant improvements were observed in skeletal muscle mass and phase angle in the exercise group at 12 weeks.
Conclusion: In this pilot trial, exercise regimen significantly improved frailty scores and skeletal muscle mass compared to the SMT. Larger trials are warranted to further evaluate the long-term benefits of exercise in pediatric cirrhotic population.

Prevalence and clinical impact of rectal colonization by multidrug-resistant (MDR) bacteria in patients with acute decompensation of cirrhosis
Nicola Zeni[1], Juan Bañares[2], Marzia La Franca[1], Simone Incicco[1], Roberta Gagliardi[1], Anna Barone[1], Antonio Accetta[1], Valeria Calvino[1],

Giulia Antonacci[1], Antonietta Romano[1], Carmine Gambino[1], Marta Tonon[1], Paolo Angeli[1], Salvatore Piano[1]. [1]*Unit of Internal Medicine and Hepatology, Department of Medicine, University and Hospital of Padua, Padua, Italy;* [2]*Liver Unit, Digestive Diseases Division, Hospital Universitari Vall d'Hebron, Vall d'Hebron Institut de Recerca (VHIR), Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain*
Email: salvatore.piano@unipd.it

Background and aims: Infections by multi-drug resistant organisms (MDRO) are frequent and difficult to treat in patients with cirrhosis. In addition to standard risk factors (epidemiology, antibiotics/health-care exposure), colonization by MDRO may increase the risk of MDRO infections. The screening for rectal colonization by MDRO could be a valuable tool to identify patients with cirrhosis at risk for MDRO infection. This study aimed to assess the prevalence and clinical impact of rectal colonization by difficult-to-treat MDRO (carbapenem resistant [CR] *enterobacteriaceae*, CR *A. baumannii*, CR *P. aeruginosa*, vancomycin-resistant *enterocci*) in hospitalized patients with acute decompensation (AD) of cirrhosis.
Method: Patients admitted for AD underwent rectal swab screening for MDRO colonization at admission and were followed up until death, liver transplant or 90-days. The following clinical endpoints were assessed: development of MDRO infections during hospitalization; transfer to intensive care unit (ICU); development of acute-on-chronic liver failure (ACLF); in-hospital mortality; 28-day mortality; 90-day mortality.
Results: During study period 204 patients underwent rectal swab (mean age 62 ± 12 years old; 64% male, median MELD score 18) and 37 (18%) tested positive for colonization by MDRO (CR *enterobacteriaceae* accounted for 60% of cases). Patients colonized by MDRO had higher incidence of MDRO infections (29 vs 6%; p = 0.006). Almost two third of MDRO infections were sustained by the same pathogen identified in rectal swab. In multivariable analysis (adjusted by age, sex and MELD score), MDRO colonization was associated with higher risk of developing MDRO infections [HR = 5.22; p = 0.003]. Patients colonized by MDRO had higher incidence of ACLF (43 vs 21%; p = 0.009), transfer to ICU (16 vs 8%; p = 0.018) and 90-day mortality (51 vs 14%; p < 0.001). In multivariable analysis, MDRO colonization was associated with an increased risk of developing ACLF (OR = 3.50, p = 0.005), being transferred to the ICU (OR = 3.03; p = 0.016), and mortality during hospitalization (OR = 9.38; p < 0.001), as well as mortality at 28-days (sHR = 5.11; p < 0.001) and 90-days (sHR = 4.89; p < 0.001).
Conclusion: Colonization by MDRO is associated with an increased risk of developing MDRO infections, organ failures and mortality in patients with AD of cirrhosis. Rectal swab could be a valuable screening tool for the clinical management of these patients.

Sustained improvement in minimal hepatic encephalopathy and quality of life in patients with cirrhosis through two-session fresh fecal microbiota transplantation: An open-label pilot randomized controlled trial (The FLAME trial)

Ankit Agarwal[1], Sagnik Biswas[1], Shekhar Swaroop[1], Rithvik Golla[1], Arnav Aggarwal[1], Ayush Agarwal[1], Mridul Mahajan[1], Umang Arora[1], Baibaswata Nayak[1], Amit Goel[2], Samagra Agarwal[1], Shalimar[1]. [1]*All India Institute of Medical Sciences, New Delhi, India;* [2]*SGPGI, Lucknow, India*
Email: drshalimar@yahoo.com

Background and aims: Fecal microbiota transplantation (FMT) is emerging as an effective treatment for hepatic encephalopathy (OHE) in patients with cirrhosis but its role in minimal hepatic encephalopathy (MHE) is unclear. We aimed to assess the efficacy of FMT in comparison to lactulose for improvement in MHE and quality of life.
Method: In this open-label pilot randomized controlled trial patients with cirrhosis and MHE were randomized to receive 2 sessions of freshly prepared FMT 4 weeks apart or daily oral lactulose. The primary outcome was MHE resolution at 12 weeks, defined by Psychometric hepatic Encephalopathy Score (PHES) ≥5. Secondary outcomes included the development of overt HE, changes in the CTP, MELD score, SF-36 score at 12 weeks and PHES scores at 4, 8, and 12 weeks. Between-group and within-group comparisons were performed.
Results: We randomized 130 patients of whom 122 were eligible for analysis (FMT:60; lactulose:62; age:44.3 ± 8.9 years; 118(96.7%) males; Child A/B/C: 54.9%/18.0%/20.5%; median MELDNa: 13 (IQR:10–17)). At 12 weeks, MHE resolution was similar in both groups (FMT:41/60(68.3%) vs lactulose:41/62(66.1%); absolute risk-difference:2.2% (95% CI: −14.4%–18.9%); p = 0.80). Both groups showed significant improvement in all components of PHES and SF-36 scores over 12 weeks. There were no differences in OHE, follow-up CTP and MELD scores. Adverse events [32(53.3%) vs 26(41.9%); p = 0.21], serious adverse events [6(10%) vs 3(4.8%); p = 0.28] and mortality [2(3.3%) vs 1(1.6%); p = 0.62] were similar.
Conclusion: Two sessions of FMT administered four weeks apart were well tolerated and resulted in MHE resolution, improved neuropsychological performance, and quality of life similar to daily oral lactulose.

Email: fjunliang@163.com

Background and aims: The psychometric hepatic encephalopathy score (PHES) and Stroop are widely used for diagnosing minimal hepatic encephalopathy (MHE). However, PHES requires normalization based on the healthy population, and consumes 20–30 minutes to complete. Additionally, the Stroop has limited diagnostic accuracy. Our study aims to establish an efficient diagnostic strategy that integrates the normalized PHES and adjusted Stroop method (the Stroop-CN) to accurately assess the prevalence of MHE in patients with cirrhosis.
Method: This prospective, multicenter study enrolled 1,428 healthy controls and 1,442 patients with cirrhosis from 40 hospitals. The PHES norms and Stroop-CN model were established based on healthy controls and then applied to diagnose MHE in patients with cirrhosis. The diagnostic efficacy of the combination diagnostic strategies was calculated by constructing the crosstabulation.
Results: Using the PHES norms derived from healthy controls, 24.2% (349/1442) of patients with cirrhosis were diagnosed with MHE (PHES score ≤4). In further analysis, 757 patients with available Stroop test results were divided into the test and validation cohorts. The 2-step diagnostic strategy, which integrated the Stroop-CN with a subtest from the PHES, demonstrated high discriminatory efficiency, achieving an accuracy of 0.825, sensitivity of 0.830, specificity of 0.824, positive predictive value (PPV) of 0.512, and negative predictive value (NPV) of 0.952. These results were consistent across both test and validation groups. According to this 2-step strategy, 59.6% of patients were able to avoid the full PHES assessment, resulting in a significant reduction in testing time by approximately 20–70%.
Conclusion: Our study revealed a notably significant prevalence of MHE among patients with cirrhosis based on the PHES norms

established using a large sample of healthy people. Furthermore, the optimized two-step diagnostic strategy significantly enhances diagnostic efficiency and substantially reduces testing time.

Impact of growth hormone therapy on complications, disease severity, and frailty in decompensated cirrhosis: a randomized controlled trial

Parminder Kaur[1], Nipun Verma[1], Pratibha Garg[1], Pinaki Dutta[2], Sunil Taneja[1], Ajay Kumar Duseja[1], Virendra Singh[3]. [1]*Post Graduate Institute of Medical Education and Research, Chandigarh, India;* [2]*Post Graduate Institute of Medical Education and Reseach, Chandigarh, India;* [3]*Punjab Institute of Liver and Biliary Sciences, Mohali, India*
Email: nipun29j@gmail.com

Background and aims: Disruptions in the growth hormone (GH) and insulin-like growth factor 1 (IGF-1) axis are associated with complications and mortality in decompensated cirrhosis. This trial evaluates the effects of long-term GH therapy on IGF-1 levels, complications, and survival in patients with decompensated cirrhosis.
Method: In a single-center, parallel-group, randomized open-label randomized trial, 96 patients with decompensated cirrhosis (excluding those with HCC, PVT, AD, or ACLF) were randomized to standard medical therapy (SMT) alone (control, n = 48) or SMT plus GH (GH group, n = 48). GH was administered subcutaneously at 2 IU/day for 12 months, with dosing adjusted based on IGF-1 levels. Patients were followed monthly for one year to monitor complications (new/worsening/refractory ascites, gastrointestinal bleeding, grade ≥2 hepatic encephalopathy [HE], bacterial infections, acute kidney injury [AKI] stage ≥1B, ACLF), liver transplantation, and mortality. The primary endpoint was 12-month complication-free survival, with secondary endpoints including individual complication rates, changes in MELD and CTP scores, liver frailty index (LFI), GH, and IGF-1 levels.
Results: Median age was 47 years (IQR: 42–46.3), with 96.9% male participants. The median MELD score was 14.8 (SD: 3.76), and baseline characteristics were similar across groups. Complication-free survival was significantly higher in the GH group (59.5%) compared to controls (34.9%, p = 0.034). The GH group showed lower cumulative incidences of ascites (27.6% vs. 50.2%, p = 0.028), ACLF (2.5% vs. 22.3%, p = 0.004), and hospitalization (17.3% vs. 47.0%, p = 0.005). No significant differences were observed for HE, gastrointestinal bleeding, bacterial infections, or AKI. A trend toward better survival was noted in the GH group (86.1% vs. 70.9%, p = 0.068). No patients underwent liver transplantation.
Significant improvements in MELD and CTP scores were observed in the GH group (delta-MELD: −10.9% [−25.2 to 7.97], p = 0.007; delta-CTP: −14.3% [-28.6 to 12.5], p = 0.003), whereas no meaningful changes occurred in the control group (delta-MELD: −3.32% [-21 to 27.8], p = 0.729; delta-CTP: 0% [−16.7 to 12.5], p = 0.356). Liver frailty (LFI) improved significantly in the GH group (delta-LFI: −2.24% [−6.72 to 2.46], p < 0.001), as did IGF-1 levels (delta-IGF-1: 78.8% [12.6 to 160], p < 0.001). These improvements were significantly different from the control group for both LFI (p = 0.004) and IGF-1 (p < 0.001). GH levels showed a trend toward reduction in the GH group (p = 0.059), with no change in controls.
Conclusion: GH therapy significantly improved complication-free survival, liver frailty, disease severity, and IGF-1 levels in patients with decompensated cirrhosis. These findings highlight the potential of GH as a therapeutic strategy, warranting further exploration into its molecular mechanisms and implications for transplant outcomes.

Neurofilament light chains and glial fibrillary acidic protein in serum for predicting post-TIPS hepatic encephalopathy

Simon Johannes Gairing[1], Eva Maria Schleicher, Myriam Meineck[1], Martin Kabelitz[2], Alena Friederike Ehrenbauer[2], Anja Tiede[2], Jim Benjamin Mauz[2], Sven Danneberg[3], Michael Bernhard Pitton[1], Julia Weinmann-Menke[1], Peter R. Galle[1], Stefan Bittner[1], Felix Luessi[1], Jens U. Marquardt[3], Benjamin Maasoumy[2], Christian Labenz[1].
[1]*University Medical Center of the Johannes Gutenberg-University, Mainz, Germany;* [2]*Hannover Medical School, Hannover, Germany;* [3]*University Hospital Schleswig-Holstein, Lübeck, Germany*
Email: sgairing@uni-mainz.de

Background and aims: Predicting the development of hepatic encephalopathy (HE) after transjugular intrahepatic portosystemic shunt (TIPS)-insertion is challenging in routine clinical practice, and biomarkers would be desirable to identify patients at risk. This study evaluated the value of neurofilament light chains (NfL) and glial fibrillary acidic protein (GFAP) measured in serum prior to TIPS insertion for predicting post-TIPS HE.
Method: A total of 144 patients with cirrhosis from three tertiary care centers in Germany (Mainz, Hannover, Lübeck) were prospectively recruited. Patients were followed for post-TIPS HE, death and liver transplantation. NfL and GFAP levels were measured using the single molecule array technology. In a subgroup of patients from Mainz, NfL and GFAP levels were also measured longitudinally on day 30 and 180 after TIPS.
Results: Median age was 61 years (interquartile range (IQR) 53, 67), median MELD was 12 (IQR 9, 14) and Child-Pugh stages were A: 21 (15%), B: 108 (75%), C: 15 (10%). The main indications for TIPS-insertion were ascites (72%) and secondary prophylaxis after bleeding (24%). In total, 55 (38%) patients developed post-TIPS HE during follow-up, and 43 (30%) died or underwent liver transplantation. Cumulative incidence of post-TIPS HE 3 months after TIPS-insertion was 42% in patients with NfL levels above the median vs 23% in patients with NfL levels below the median (p = 0.018). In contrast, cumulative incidence of patients dichotomized by median GFAP did not differ significantly (30% vs 35%, p = 0.7). In Fine and Gray competing risk regression analyses, higher NfL levels (sHR 1.01, 95% CI 1.00–1.01, p = 0.028) were independently associated with post-TIPS HE after adjusting for relative portosystemic gradient reduction, MELD, history of HE, platelets, and age. In contrast, GFAP levels were not (sHR 1.00, 95% CI 1.00–1.00, p = 0.2). In addition, higher NfL levels were associated with a higher risk of death/ transplantation in multivariable Cox regression analyses after adjusting for MELD and age (HR 1.01, 95% CI 1.00–1.01, p = 0.027), while GFAP levels were not. In a subgroup of patients with sera available 30 and 180 days after TIPS-insertion, NfL levels were stable at day 30 and decreased at day 180, while GFAP levels did not change significantly.
Conclusion: NfL serum levels measured prior to TIPS-insertion are associated with both post-TIPS HE and prognosis. Thus, NfL may be a valuable biomarker to identify patients at high risk for poorer outcome.

Email: schuette.sarah@mh-hannover.de

Background and aims: Patients with decompensated liver cirrhosis exhibit alterations in the gut and oral microbiome, leading to mucosal barrier dysfunction resulting in an increased risk of infections. Dysbiosis is closely linked to an overall lower number of bacteria compared to healthy controls. This shift creates an environment where fungal organisms, particularly those of the *Candida* genus, become more abundant and are more likely to be detected, especially when highly sensitive diagnostic methods are employed. To date, the clinical relevance of the detection of fungal species in body fluids is poorly investigated. This study aims to compare the clinical outcome of cirrhotic patients with positive *Candida* detection versus those without.
Method: A number of 155 patients were enrolled in this prospective study that is part of the INFEKTA trial. Urine and ascites samples were collected from all patients when available. *Candida* detection was performed using shotgun metagenomics sequencing utilizing rapid, long-read technology for DNA analysis. Clinical data were analyzed utilizing binary logistic regression and competing risk regression analysis, considering death and liver transplantation (LTx) as competing events. All parameters demonstrating a significant association with the outcome of interest were included in the multivariable models. The study endpoints were mortality, acute kidney injury (AKI), acute-on-chronic liver failure (ACLF) and infections within 365 days after urine and ascites sample collection.
Results: Out of the 155 patients, 60 (39%) had positive *Candida* detection (Cand +) in either ascites or urine, while 95 (61%) had no *Candida* detection (Cand -) in both specimens. The overall frequency of positive *Candida* results was similar in urine (31%) and ascites (31%) samples. At timepoint of sampling, patients had comparable MELD scores (Cand +: 16 [12–21] vs. Cand -: 15 [11–21], p = 0.71) and CRP levels (Cand +: 18 [9–34] vs. 15 [7–28] mg/dL, p = 0.41). Binary logistic regression identified alkaline phosphatase as the sole variable significantly associated with *Candida* detection (OR 1.004, 95% CI 1.001–1.007, p = 0.01). However, Cand + patients demonstrated a significantly higher risk of mortality (HR 2.28, 95% CI 1.11–4.68, p = 0.03) and ACLF (HR 1.97, 95% CI 1.02–3.80, p = 0.04) compared to Cand – patients. Detection of *Candida* was not associated with the risk of AKI (HR 1.82, 95% CI 0.99–3.32, p = 0.053) or infections (HR 1.59, 95% CI 0.88–2.88, p = 0.13).
Conclusion: *Candida* species are frequently detected in the urine and ascites of patients with decompensated cirrhosis when modern, highly sensitive techniques are employed. Although its presence is not associated with the risk of infections or AKI, it is linked to an impaired survival and higher incidence of ACLF. Thus, it may serve as an indicator of inferior clinical outcome.

SAT-120
DOACs offer superior safety and survival over traditional agents in anticoagulant therapy for cirrhosis

Eun Young Cho[1], Jeong-Ju Yoo[2], Minae Park[3]. *[1]Wonkwang University School of Medicine, Wonkwang University Hospital, Iksan, Korea, Rep. of South; [2]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South; [3]Department of Data Science, Hanmi Pharm. Co., Ltd, Seoul, Korea, Rep. of South*
Email: 69-70@hanmail.net

Background and aims: Liver cirrhosis presents a complex hemostatic balance, increasing risks of both thrombosis and bleeding. Anticoagulants like warfarin, LMWH and DOACs have been used to manage these risks, but their safety and efficacy in cirrhotic patients remain unclear. This study aims to compare the clinical outcomes of these anticoagulants in cirrhotic patients using a large-scale, real-world dataset.
Method: This retrospective cohort study utilized claim data from the Korean National Health Insurance System, encompassing 38,770 patients newly diagnosed with liver cirrhosis between 2015 and 2022. Patients were categorized based on the anticoagulant therapy they received: warfarin (n = 2,644), DOAC (n = 15,297) or LMWH (n = 20,829). Inverse Probability of Treatment Weighting (IPTW) was utilized to adjust for confounders, and survival outcomes were analyzed using Kaplan-Meier methods.
Results: Major bleeding events were more frequent in warfarin (34.93%) than in DOAC (26.33%) and LMWH (25.15%) (P < 0.001). Variceal bleeding occurred in 9.82% of warfarin users, significantly higher than in DOAC (4.75%) and LMWH (4.08%) users. Other gastrointestinal bleeding was also the most prevalent in the warfarin group (32.29%), followed by DOAC (23.67%) and LMWH (25.91%) groups. The DOAC group also had the lowest rates of liver-related complications, with hepatic encephalopathy at 2.76% and refractory ascites at 12.71%, compared to respective rates of 4.98% and 20.09% in the warfarin group. DOAC showed better 3-year (75.49% vs 67.15% or 66.37%) and 5-year survival rates (65.56% vs 57.59% or 56.64%) than LMWH or warfarin.
Conclusion: DOACs offer lower bleeding risks and better survival than warfarin, suggesting DOAC may be a safer alternative for cirrhotic patients.

SAT-121-YI
Hybrid care models in liver disease management: lessons from telemedicine during the COVID-19 pandemic

Nada Abedin[1], Christian Kilbinger[1], Ulrike Mihm[1], Anita Pathil-Warth[1], Alexander Queck[1], Michael von Wagner[1], Stefan Zeuzem[1]. *[1]Medical Clinic 1, University Hospital, Goethe University Frankfurt, Frankfurt am Main, Germany*
Email: abedin@med.uni-frankfurt.de

Background and aims: COVID-19 necessitated rapid adoption of telemedicine, highlighting its role in hybrid care models for liver disease management. Patients with cirrhosis, viral hepatitis, and post-liver transplantation (LTX) care require frequent monitoring, making continuity of care essential. This study evaluated telemedicine's effectiveness and safety during the pandemic at a German tertiary center and explored its integration into future hybrid care models.
Method: In a retrospective study, we analyzed 2,557 appointments (1,963 Hepatology, 594 LTX) between March–June 2020 at University Hospital Frankfurt. Outcomes included appointment modality, adherence rates, and safety parameters. Patient characteristics and predictors of successful telemedicine implementation were assessed using multivariate analysis.
Results: Overall, 35.3% of appointments were conducted via telemedicine (40.4% Hepatology, 32.8% LTX). LTX patients were older (median 58 vs 51 years) and had more comorbidities. Among hepatology patients, chronic HBV (29.9%), MASLD (18.6%), and cirrhosis (19.3%) were most common. Routine check-ups and stable patients were managed remotely, while complex cases requiring diagnostics were scheduled in person. MASLD patients were predominantly managed remotely (46.7%), while HBV/HDV co-infected patients required in-person visits (81.8%). Telemedical adherence rates were higher than in-person visits (91.8% vs 89.4%). In LTX patients, telemedical adherence was significantly higher than in-person visits (97.9% vs 89.5%, p < 0.001). In multivariate analysis, older age (OR 1.018, p < 0.01) predicted better adherence. Hospitalization rates were low and comparable across modalities, confirming telemedicine's safety. Importantly, appointment modalities were determined by physicians based on clinical urgency, ensuring patient-centered and safe care delivery.
Conclusion: Telemedicine proved effective and safe for managing selected hepatology and LTX patients during the pandemic. Higher

adherence rates and stable clinical outcomes support its integration into routine care. A hybrid model combining remote monitoring for stable patients with in-person visits for complex cases or procedures optimizes resource utilization while maintaining quality of care.

Acute kidney disease in acutely decompensated cirrhosis: impact on clinical outcomes

Alberto Calleri[1], Maria Laura Robone[1], Marco Tizzani[1], Chiara Lisi[1], matteo botta[1], Giulia Pecorella, Mimma Bonomo, Francesco Frigo[1], Daniela Campion[1], Antonio Ottobrelli[1], Alfredo Marzano[1], Elisabetta Bugianesi[1], Giorgio Maria Saracco[1], Carlo Alessandria[1].
[1]Division of Gastroenterology and Hepatology, A.O.U. Città della Salute e della Scienza di Torino, University of Turin, Turin, Italy
Email: alberto.calleri.md@gmail.com

Background and aims: Patients with cirrhosis are prone to developing kidney dysfunction, with acute kidney injury (AKI) being common and significantly affecting prognosis. In this context, the impact of acute kidney disease (AKD), whether occurring after an AKI episode (AKI-AKD) or independently (NAKI-AKD), remains poorly understood.
Method: Patients hospitalized for acute decompensation (AD) between July 2022 and November 2024 were prospectively enrolled. AKI and AKD were defined as per 2024 International Club of Ascites criteria. Follow-up ended at liver transplantation (LT) or death.
Results: A total of 307 patients were prospectively enrolled. Median age was 60 years (IQR 53–68); 71% were male. Alcohol was the most common etiology (45%) and the primary reason for hospitalization was ascites (60%). Patients were categorized as follows: no kidney disease (NKD) 111 (36%), AKI 53 (17%), AKD 81 (26%), with AKI-AKD 31 (10%) and NAKI-AKD 50 (16%), chronic kidney disease (CKD) 37 (12%), and acute-on-chronic kidney disease 25 (8%). NKD patients were significantly younger compared to all the other groups ($p < 0.05$), while median age was similar between NAKI-AKD, AKI-AKD and AKI ($p > 0.6$ for all comparisons). The proportion of patients in Child class C was higher in AKI compared to NKD and NAKI-AKD (62% *vs* 41% *vs* 38%, $p = 0.015$ and $p = 0.024$), while it was not significantly different compared to AKI-AKD (48%, $p = 0.31$). After a median follow-up of 5.8 (IQR 1.7–13.4) months, 87 (28%) patients received LT and 79 (26%) died. Following discharge from index hospitalization (282 patients), the 3-month probability of rehospitalization was 23% for NKD and NAKI-AKD, 24% for AKI-AKD and 34% for AKI (overall log-rank $p = 0.51$). The risk of new-onset CKD at 3-month after inclusion was 2/65 (3%) for NKD, 3/15 (20%) for AKI, 6/21 (29%) for NAKI-AKD and 8/15 (53%) for AKI-AKD (all groups *vs* NKD, $p < 0.05$; AKI *vs* AKI-AKD $p = 0.13$, AKI *vs* NAKI-AKD, $p = 0.71$; AKI-AKD *vs* NAKI-AKD, $p = 0.18$). The 1- and 6-month LT-free survival were: 98% and 96% in NKD, 96% and 82% in NAKI-AKD, 86% and 66% in AKI-AKD, 74% and 59% in AKI. The 6-month LT-free survival was significantly higher for NKD (log-rank $p < 0.01$ for all comparisons), not significantly different between NAKI-AKD and AKI-AKD ($p = 0.12$), significantly worse in AKI compared to NAKI-AKD (log-rank $p = 0.007$), while no significant difference was observed between AKI and AKI-AKD (log-rank $p = 0.35$).
Conclusion: AKD is common among patients hospitalized for decompensated cirrhosis, particularly the NAKI-AKD form. While AKD seems not to influence the risk of short-term rehospitalization, our data show: 1) a clear trend towards an increased risk of new-onset CKD, in particular for AKI-AKD; 2) significantly worse LT-free survival with respect to NKD; 3) similar LT-free survival rates between AKI-AKD and AKI. Overall, our preliminary findings suggest that AKD, and specifically AKI-AKD, is clinically relevant in these patients as it entails a negative impact on prognosis.

SAT-123-YI

5-year outcomes of a dedicated, multidisciplinary clinic for decompensated cirrhosis

Alexander Mitropoulos[1], Natalie Ngu[2], Poh Loh[1], Chania Lobo[1], Patricia Anderson[3], Thomas Worland[1], Jo Hunter[4], Erin Russell[5], William Sievert[3], Suong Le[3], Sally Bell[3]. *[1]Monash Health - Department of Gastroenterology, Melbourne, Australia; [2]Monash Health - Department of Gastroenterology, Monash University - Faculty of Medicine, Nursing, and Health Sciences, Melbourne, Australia; [3]Monash Health - Department of Gastroenterology, Monash University - Sub-faculty of Clinical and Molecular Medicine, Melbourne, Australia; [4]Monash Health - Department of Pharmacy, Melbourne, Australia; [5]Monash Health - Department of Nutrition and Dietetics, Melbourne, Australia*
Email: alexander.mitropoulos@monashhealth.org

Background and aims: Decompensated cirrhosis is a complex multi-system condition associated with high rates of healthcare utilisation, morbidity and mortality. Multidisciplinary chronic disease collaboration is standard of care in conditions such as heart failure where it has been proven to reduce hospitalisation and mortality. There is limited evidence regarding the potential efficacy of extending such models of care to patients with decompensated cirrhosis outside of liver transplant settings. This study aims to conduct a prospective, non-randomised, single arm feasibility study to assess the impact of a multidisciplinary and multifaceted liver clinic on admission rates, liver disease severity, and survival.
Method: The Complex Liver Care Clinic (CLCC) is a multidisciplinary ambulatory care service co-designed with clinicians, researchers and patients based at a tertiary hospital in Melbourne, Australia servicing a population of 1.5 million people. The CLCC integrates clinicians (Pharmacists, Nurses, Hepatologists, Dietitians and Addiction Medicine) and day procedures (large volume abdominal paracentesis and albumin infusion). Between January 2019 and June 2024, 282 adult patients with decompensated cirrhosis were recruited following their index hospital admission to receive care through CLCC. Patients were excluded if they did not attend at least one appointment. Outcomes assessed included 12-month liver-related readmission, time to readmission, transplant free survival, and liver disease severity.
Results: A total of 282 CLCC patients were analysed: mean age 57 (±13.32 SD) years and predominantly male (61%). The median baseline Model for End-Stage Liver Disease (MELD) was 14.6 (Interquartile range (IQR): 11–18.9) and median Child-Pugh 8 (IQR: 6–9). By 3 months, there was a statistically significant reduction in median MELD to 12.8 (IQR: 9.8–16.5, $p = 0.003$) and median Child-Pugh score to 7 (IQR: 6–8, $p = 0.01$). A total of 93 patients (33%) had at least one liver related readmission within 12 months, of which 21% were due to ascites, at a median time of 88 days (IQR: 31–189) from index appointment. Child-Pugh score was identified as a statistically significant marker of 12-month re-admission (HR 1.203, $p < 0.001$). A total of 27 referrals were made for liver transplant assessment, with 9 patients progressing to transplantation at a median of 313 days (IQR: 234–733). There were 101 (36%) deaths over the follow up period at a median 388 days (IQR: 125–668). The median transplant-free survival time was 641 days (IQR: 304–1061).
Conclusion: Our 5-year study demonstrated improved clinical outcomes for patients who participated in a novel model of care for decompensated cirrhosis. There was significant reduction in liver prognostic scores by 3 months and no liver-related admission in two-thirds of patients by 12 months. We plan to conduct a larger controlled study to evaluate overall cost effectiveness of this novel model, which integrates care and the infrastructure to deliver whole of person care.

SAT-131

Physical frailty is associated with myosteatosis and physical frailty assessment tools may predict the presence of myosteatosis in liver cirrhosis

Eleni Geladari[1], Theodoros Alexopoulos[2], Larisa Vasilieva[3], Iliana Mani[4], Andreas Theophilou[5], Vasileios Sevastianos[1], Alexandra Alexopoulou[4]. *[1]3rd Department of Internal Medicine & Liver Outpatient Clinic, Evangelismos General Hospital, Athens, Greece; [2]Gastroenterology Department, Medical School, National & Kapodistrian University of Athens, Laiko General Hospital, Athens, Greece; [3]Gastroenterology Department, Alexandra Hospital, Athens, Greece; [4]2nd Department of Internal Medicine & Research Laboratory, Medical School, National & Kapodistrian University of Athens, Hippokration General Hospital, Athens, Greece; [5]Medical School, National & Kapodistrian University of Athens, Athens, Greece*
Email: elgeladari@gmail.com

Background and aims: Myosteatosis (MyoS) is considered a prodromal phase of sarcopenia, signaling the onset of muscle loss. Nutritional and lifestyle interventions during the MyoS stage may help prevent the progression to sarcopenia. Physical frailty (PF) is a syndrome characterized by diminished physical function and reserves, making it difficult for patients to manage stressors. This study aimed to investigate the association between PF and MyoS and evaluate whether PF assessment tools can serve as cost-effective and simple alternatives to imaging for MyoS evaluation.
Method: Skeletal muscle index (SMI) and MyoS were assessed via computed tomography (CT) at third lumbar vertebra (L3). MyoS was defined by muscle radiodensity values of < 41 Hounsfield Units (HU) for body mass index (BMI) < 24.9 kg/m² and < 33 HU for BMI ≥25 kg/m². The Liver Frailty Index (LFI) and the Short Physical Performance Battery (SPPB) were used as PF assessment tools in patients with liver cirrhosis (LC).
Results: The study included 199 consecutive patients with LC (67.3% male; median age: 61 years, IQR 52–68; MELD score: 10.5, IQR 8–16; 38.7% with compensated LC). MyoS was identified in 144 (72.4%) patients. Among those with MyoS, 52 patients (36.1%) were classified as frail using LFI (≥4.5), and 53 (36.8%) were frail according to SPPB (≤8), compared to 4 (7.3%) and 5 (9.1%), respectively, in the non-MyoS group ($p < 0.001$). LFI scores were significantly higher in patients with MyoS than in those without [median 4.195 (IQR 3.82–4.86) vs. 3.86 (IQR 3.45–4.20), $p < 0.001$]. Similar differences were observed with SPPB scores ($p < 0.001$). In multivariate analyses adjusted for age, gender, and MELD scores, LFI [HR 1.933 (95% CI 1.091–3.426), $p = 0.024$] or SPPB [HR 0.771 (95% CI 0.635–0.937), $p = 0.009$] were significantly associated with MyoS. SPPB values demonstrated the strongest correlation with HU values (correlation coefficient $r = 0.453$, $p < 0.001$), followed by LFI ($r = 0.388$, $p < 0.001$). When patients were categorized into three groups (no muscle changes, MyoS alone, and MyoS with muscle loss), PF scores worsened progressively as muscle quality and quantity declined ($p < 0.001$ for both LFI and SPPB). In receiver operating characteristic (ROC) curve analysis, SPPB exhibited adequate diagnostic accuracy for detecting MyoS (AUROC 0.701). An SPPB cut-off value of 9 yielded a sensitivity of 80.1%, specificity of 45.1%, positive predictive value (PPV) of 79.3%, and negative predictive value (NPV) of 46.3%.
Conclusion: Physical frailty was more prevalent in patients with MyoS compared to those without. PF assessed using SPPB or LFI independently predicted the presence of MyoS after adjusting for multiple covariates. PF scores worsened proportionally with declines in muscle quality and quantity. The SPPB test may serve as a surrogate marker for evaluating muscle quality.

SAT-132

Loculated ascites in the setting of spontaneous bacterial peritonitis is associated with increased morbidity and mortality

Angela Lee[1], Anita Mahadevan[1], James Crismale[1], Sara Lewis[1], Thomas Schiano[1]. *[1]The Mount Sinai Hospital, New York, United States*
Email: alee47@bidmc.harvard.edu

Background and aims: Loculated ascites generally refers to ascitic fluid that is compartmentalized within the peritoneal cavity, often due to adhesions or inflammatory processes, such as infections. The presence of loculated ascites can complicate the management of cirrhotic patients by limiting paracentesis. This study sought to analyze the clinical outcomes of patients with spontaneous bacterial peritonitis (SBP) and loculated ascites at a large metropolitan area hepatology transplant center.
Method: The International Classification of Disease-10 codes for cirrhosis, SBP, and ascites were used to identify patients hospitalized from 1/1/2010–9/10/2024. Chart review via the electronic medical record was then performed using the following inclusion criteria: 1) clinical and radiographic evidence of cirrhosis with or without histology, 2) SBP confirmed with ascitic fluid polymorphonuclear cell count >250/mm³, and 3) evidence of complex loculated ascites on CT or MRI imaging. Patients with secondary bacterial peritonitis, prior liver transplant, and/or non-hepatobiliary malignancy were excluded. Descriptive statistics were used to analyze the primary endpoints of survival and major adverse liver outcome (MALO) events, along with the following secondary endpoints: length of stay (LOS), ICU admission, and escalation of antibiotic therapy.
Results: Initial database screening identified 1447 patients, of whom 28 met inclusion criteria. Average MELD score on admission and at time of SBP diagnosis was 27.5 and 30, respectively. The etiology of liver disease was highly variable, with the most common being alcohol (29%) followed by metabolic-dysfunction associated steatohepatitis (21%). The overall mortality rate for these 28 patients was 75% (21/28), with 80.9% (17/21) dying during or within 6 months of hospitalization. 50% (14/28) developed hepatic encephalopathy (HE) during admission while 64% (18/28) developed renal impairment, of whom 33% (6/18) required renal replacement therapy. Response to antibiotic therapy was limited; 93% (26/28) did not show any improvement in ascitic fluid PMN count upon follow up paracentesis. 70% (21/28) had persistent neutrocytic ascites despite antibiotic escalation in all but one patient, of which 62% (13/21) received empiric anti-fungal treatment. 46% (13/28) underwent intraperitoneal drain placement or surgical washout. The median LOS was 30 days, with 43% (12/28) requiring ICU stay.
Conclusion: Patients with decompensated cirrhosis who develop loculated ascites in the setting of SBP have a high risk of developing adverse outcomes, including renal impairment and HE. Such patients also have high mortality, which may be driven in part by infection that is refractory to antibiotic therapy. Prevention of loculation formation via earlier diagnosis of SBP followed by prompt guideline-directed antimicrobial therapy may improve outcomes.

SAT-133

Adherence to a remote monitoring platform for the liver cirrhosis population, a multicenter feasibility study

Email: britt.vanruijven@maastrichtuniversity.nl

Background and aims: Remote monitoring (RM) for liver cirrhosis patients may improve clinical outcomes through patient education, tight control and efficient communication. We designed a multicenter cohort study aimed to develop an RM platform with and for patients with (de)compensated liver cirrhosis to assess its feasibility regarding satisfaction and adherence.
Method: A stakeholder committee iteratively defined the project's goals, scope, design and content. We adapted generic content from myIBDcoach for Dutch Inflammatory Bowel Disease patients. We created an RM platform for smartphone, tablet and computer with a liver-specific monitoring module incorporating LDSI 2.0, CLDQ, QuickStroop and weight tracking together with e-learnings. Monitoring frequency was tailored to disease stage: (recent) decompensation vs. compensated state. Healthcare providers responded to alerts of exceeded thresholds within 48 hours. We conducted a prospective feasibility study in a secondary and tertiary Dutch center. Adult liver cirrhosis patients were eligible. We excluded patients with hepatocellular carcinoma, post liver transplantation or insufficient Dutch proficiency. Participants were followed for 6 months, with post-follow-up evaluations including disease outcomes, adherence, a questionnaire and interviews until data saturation. We performed subgroup analyses using Pearson Chi-Square or Fisher's Exact Tests.
Results: Of 139 screened patients, 89 were excluded due to: no consent (28%), no interest (24%), digital illiteracy (17%), language barriers (11%) or other reasons (20%). We included fifty patients, with a median age 64.0 years (IQR 57.75–67.0), the majority was male and treated in the tertiary center (both n = 32; 64%). Predominant etiologies were steatotic liver diseases (SLD, n = 27, 54%) and autoimmune diseases (n = 10; 20%). At baseline, 50% (n = 25) was decompensated, and 40 patients completed follow-up (80%). Liver-related complications occurred in 17 patients (34%), with 5 admissions, 2 liver-related deaths and 3 liver transplants. Thirty-six patients had one or more unfinished modules during follow-up (72%). Of 24 evaluation respondents, 18 patients thought the idea of RM was valuable, 5 were neutral, 1 disagreed (75%, 20.8% and 4.2%). More SLD patients had unfinished modules compared to patients with other etiologies ($p < 0.05$), although the two groups did not significantly differ in their perceived RM value ($p = 0.142$).
Conclusion: This multicenter feasibility study demonstrates moderate adherence and satisfaction to an integrative RM platform in a representative liver cirrhosis population. Patients with SLD were more likely to have one or more incomplete modules. Future research should elaborate on the patients' barriers and adherence markers through larger prospective studies to improve RM effectiveness and complication prevention.

SAT-134
Impact of parenteral nutrition on the risk of infections and the disease course of malnourished patients with decompensated liver cirrhosis

Laura Buttler[1], Katharina Luise Hupa-Breier[1], Claudia Seipt[1], Andrea Markowski[1], Marie Griemsmann[1], Tammo Lambert Tergast[1], Birgit Kaufmann[1], Hannah Schneider[1], Heiner Wedemeyer[1,2,3], Benjamin Maasoumy[1,2], Andrea Schneider[1]. [1]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany, Hannover, Germany; [2]German Centre for Infection Research (DZIF), partner-site Hannover-Braunschweig, Hannover, Germany, Hannover, Germany; [3]Hannover Medical School, Excellence Cluster RESIST, Hannover, Germany, Hannover, Germany
Email: Buttler.Laura@mh-hannover.de

Background and aims: Malnutrition is a common problem in patients with advanced liver disease and associated with an increase of mortality and complications of cirrhosis. Guidelines consequently recommend the early and intensive implementation of nutritional interventions, for example the initiation of (home) parenteral nutrition (HPN). However, there is a lack of evidence regarding the safety and prognostic impact of HPN on disease progression in patients with decompensated liver cirrhosis (dLC). Therefore, we aimed to investigate the impact of HPN on relevant cirrhosis-specific complications and its safety among patients with end-stage liver disease.
Method: We analyzed a number of 96 prospectively collected, consecutive patients with dLC and malnutrition who were treated at our center between 2013 and 2018. Of these, 32 patients received HPN and were compared with those patients who remained without intervention using 1: 2 propensity score matching. The primary endpoint was mortality, secondary endpoints were the incidence of infections, bloodstream infections, overt hepatic encephalopathy (oHE) and non-elective rehospitalization within 90-days of follow-up.
Results: The investigated patients had a median MELD score of 16 points at baseline. The median age was 54 years in the intervention group and 58 years in the control group. The predominant etiology of liver cirrhosis was alcohol-associated in both groups (43.7% and 57.8%).
In the competing risk analysis, no differences in mortality (HR = 1.44; $p = 0.48$) or rehospitalization rate (HR = 1.28; $p = 0.47$) were found between the groups. Patients with HPN had a significantly higher incidence (28.1%; n = 9 vs. 1.6%; n = 1) and a significantly higher risk (HR = 21.3; $p = 0.004$) of bloodstream infections compared to the control group. However, the incidence of total bacterial infections was high in both the intervention and control group (59.4%; n = 19 vs. 65.6%; n = 42), with no significant differences (HR = 0.82; $p = 0.45$) in the competing risk model. Of note, a significantly ameliorated risk for oHE was detected in the HPN group compared to the controls (HR = 0.28; $p = 0.03$) after adjusting for rifaximin treatment in the multivariable competing risk model.
Conclusion: The implementation of HPN in patients with advanced liver cirrhosis is not associated with an increased risk for overall infectious complications, although a linkage with a higher risk for bloodstream infections was detected. Furthermore, HPN may reduce the likelihood for oHE in malnourished patients with decompensated cirrhosis.

SAT-135-YI
SHiNE-UK: a national evaluation of hepatocellular carcinoma surveillance and treatment pathways

Christopher Mysko[1], Christopher Mysko[2,3], Yazan Haddadin[4], Giovanna McGinty[5], Maja Kopczynska[3], Stephanie Landi[2,3], Jade King, Darren Griffiths[2], Azita Rajai[2], Sarah Guthrie[6], Syed Mujtaba Hasnain Nadir[2], Ayodele Sasegbon[3], Pedram Modarres[7], Huw Purssell[3], Kimberley Butler[8], Oliver Street[3], Deepankar Gahloth[3], Oliver Tavabie[9,10], Ian Rowe[9,10], Karen Piper Hanley[3], Neil Hanley[11,12], Varinder Athwal[2,3]. Email: christopher.mysko@postgrad.manchester.ac.uk

Background and aims: Hepatocellular carcinoma (HCC) is a rapidly growing cause of cancer mortality despite advancing treatment strategies, with the mounting burden of chronic liver disease a major concern. Earlier diagnosis and improved access to curative treatments are key, with concerted efforts to achieve 'precision surveillance' via risk-prediction modelling and better diagnostics. However, low adherence to surveillance standards is widely reported, though measurement fraught with heterogeneity and limitations, fuelling the debate over its effectiveness. This study aims to evaluate the performance of current UK HCC pathways.
Method: A pan-UK multi-centre retrospective cohort study was conducted. Eligible cases were identified and local audit performed with follow up 1/1/22–30/1/24. REDCap facilitated data collection and query resolution. Analysis was performed in RStudio. Surveillance adherence was measured using a modified proportion of time covered (mPTC) method, assuming 6-months cover per test. Regression analysis was performed to identify factors associated with adherence and Barcelona Clinic Liver Cancer (BCLC) stage.
Results: A total of 68 UK hospitals participated including specialist and non-specialist liver centres. Surveillance pathways included a dedicated imaging procedure code (26%), pathway navigators (21%), interventional programmes (15%) and automated recall (9%). LI-RADS was used for ultrasound (11%) and CT/MRI (64%). Patients in surveillance (n = 1,674) had median mPTC rates of 27.5% for alpha-fetoprotein testing, 68.4% for surveillance scans, and 72.9% for all abdominal imaging. Over two years, HCC incidence in surveillance was 2.5%, with 41% at early stage (BCLC 0-A). Cumulative incidence by aMAP risk—low (0%), medium (1.1%), high (5.2%)—was significant ($p < 0.001$), with no events in the low-risk group. Among patients with incident HCC (n = 723), the rates of early-stage diagnosis (BCLC 0-A) were 44% and curative first-line treatment 27%. Only 48% had known cirrhosis and 42% were enrolled in surveillance prior to diagnosis. Presentation occurred through incidental findings (38%), surveillance (37%), and symptomatic channels (24%). The rate of first-line treatment utilisation was 79%, with frailty and HCC progression the most common reasons for non-utilisation. Absence of surveillance was significantly associated with late-stage diagnosis (BCLC B-D; $p = 0.025$).
Conclusion: This national evaluation assessed the current performance of HCC surveillance and treatment pathways in the UK. Underperformance appears to stem from a combination of failures in identifying cirrhosis and ineffective surveillance, compromising early-stage diagnosis and access to curative treatment. Future efforts should harness both service improvement and emerging innovations to improve equitable access to curative treatment.

SAT-136-YI
Identification of prognosis determining risk factors in outpatients with cirrhosis

Moritz Passenberg[1], Clara Guntlisbergen [1], Georgios Konstantis[1], Nargiz Nuruzade[1], Katharina Willuweit[1], Hartmut Schmidt[1], Jassin Rashidi-Alavijeh[1]. *[1]Medical Faculty University Duisburg-Essen, Department of Gastroenterology, Hepatology and Transplantation Medicine, University Hospital Essen, Essen, Germany*
Email: moritz.passenberg@uk-essen.de

Background and aims: Cirrhosis is one of the leading causes of liver transplantation (LT) and mortality worldwide, so it is essential to improve prognostic assessment for better disease management and patient outcomes. Ascites, a common complication, is a sign of disease progression and poorer outcome. However, the impact of ascites volume changes over time on long-term outcomes remains underexplored. This study investigates the influence of ascites development and volume changes on transplant-free survival, with the aim of providing refined and specific thresholds.
Method: This prospective observational cohort study includes adult outpatients with cirrhosis at the LT outpatient clinic at the University Hospital Essen. Patients underwent blood analysis and detailed sonographic ascites measurements. Follow-ups at three and 12 months tracked disease progression and endpoints (death or LT). Baseline measurements and disease progression were analyzed using univariable logistic regression, repeated with delta values representing changes from baseline to follow-up. Multivariable logistic regression incorporated delta scores as independent variables, with baseline measurements, age, sex, and MELD scores as covariates. Predictive performance was assessed using AUROC, sensitivity, specificity, PPV, and NPV. Thresholds for score changes were based on ≥90% sensitivity or specificity. Nonlinear associations were visualized with spline plots using restricted cubic splines.
Results: The study includes 342 patients, 58% male patients with an overall mean MELD-Score of 12. ROC analysis showed a high predictive accuracy (AUC: 94%) for measurements in the lower abdomen. A 21 mm increase in ascites, measured in the lower abdomen, was linked to high risk (90% specificity) and increases up to 10 mm were not associated with adverse outcomes (91% sensitivity). Baseline measurements were statistically significant in predicting outcomes ($p < 0.01$). Correlations with the ICA classification suggest the following thresholds: grade 1 (≤10 mm), grade 2 (11–43 mm), and grade 3 (>43 mm), improving precision and reducing observer bias.
Conclusion: These findings highlight the prognostic significance of lower abdominal ascites measurements, underscoring the need for an objective classification of ascites volume and measurement, emphasizing the importance of documenting longitudinal changes in ascitic volumes systematically and more detailed.

SAT-137
Community-acquired infections requiring hospitalization in patients with alcohol-related cirrhosis

Clara Stenderup[1,2], Peter Jepsen[1,2,3]. *[1]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark; [2]Department of Clinical Medicine, Aarhus University, Aarhus, Denmark; [3]Department of Clinical Epidemiology, Aarhus University Hospital, Aarhus, Denmark*
Email: clarsn@rm.dk

Background and aims: Liver cirrhosis is associated with increased risk of bacterial infections, which also worsen the prognosis of their disease. However, there is a lack of reliable population-based data to quantify the incidence and mortality of these infections, which is crucial to contemplate future preventative measures. Therefore, we examined the incidence of community-acquired bacterial infections leading to hospitalization.
Method: In this population-based observational study, we identified all patients in the Central Denmark Region who were diagnosed with alcohol-related cirrhosis (ALD cirrhosis) between 2013–2022. We followed them from diagnosis of ALD cirrhosis until death or the end of follow-up on 31 August 2023. We computed the cumulative incidence of culture-positive bacteremia considering death a competing risk event. Further, we used the Kaplan-Meier method to compute survival from the date of positive blood culture.
Results: We included 2,525 patients with median age 61 (IQR: 54–68), 69% male. During 7,225 person-years of follow-up, 282 patients were hospitalized with a culture-positive bacteremia. 34 of these patients had more than one type bacteria in their blood, according to the positive cultures, with a maximum of 7 different bacterial agents in one patient. Of the bacteria identified, 74 (26%) were infections with Staphylococcus Aureus, 58 (21%) were Escherichia coli, 31 (11%)

were Enterococcus species, 25 (9%) were Klebsiella species, whilst 6 (2%) of the infections were with Streptococcus Pneumoniae. The risk of bacteremia was 6% after 1 year (95% CI: 5–7), 10% after 3 years (95% CI: 9–11), and 12% after 5 years (95% CI: 10–13). Following a positive culture for bacteremia the 7-day mortality in the cohort was 21% (95% CI: 17–27), whilst the 30-day mortality was 35% (95% CI: 30–41).
Conclusion: Patients with ALD cirrhosis have a 10% risk of being hospitalized with bacteriemia within 3 years after being diagnosed with cirrhosis. Patients with a bacteremia have a very high short-term mortality. By mapping out this risk more precisely, our hope is that future interventions to prevent bacteremia, such as vaccination programs or prophylactic antibiotics, could reduce mortality among patients with ALD cirrhosis.

SAT-138

Functional and structural evaluation of patients with cirrhosis to consider recompensation

Jose Luis Perez Hernandez[1], Carlos Andres Campoverde Espinoza[2], Fatima Higuera-de-la-Tijera[2], Ángel Daniel Santana Vargas[1]. [1]*Hospital General de México, Ciudad de México, Mexico;* [2]*Hospital General de Mexico, Ciudad de México, Mexico*
Email: carlosandr14@hotmail.com

Background and aims: Decompensated cirrhosis is defined as the appearance of events such as ascites, variceal hemorrhage and/or overt hepatic encephalopathy. Nowadays, there is evidence that, eliminating or controlling the etiological factor, not only slows down its progression but can induce recompensation. The Baveno VII consensus proposes the concept of rewarding the partial structural and functional regression of cirrhosis, implying the disappearance of decompensations. Objectives: To evaluate the recompensation stage in patients whose etiological factor of liver disease was eliminated.
Method: Longitudinal, observational and analytical study, patients with liver disease related to alcohol consumption (OH) and hepatitis C virus (HCV) were included, patients who were confirmed by the patient and the primary caregiver abstinent from alcohol for more than 12 months were evaluated, and determination of decreasing gamma-glutamyl transferase (GGT). And those who were cured of hepatitis C (using DAAs) with sustained viral response for 12 months were evaluated by viral load. Transitional elastography was performed at baseline and 12 months (Fibroscan touch 502 equipment), evaluation of laboratory studies and absence of any decompensation with the withdrawal of diuretics, anti-ammonium measures and non-selective beta-blockers to consider compensation. The protocol was approved by the ethics and research committees; it was ensured that the personal data of the patients were not published. Statistical analysis: Qualitative variables were expressed in frequencies and percentages, and numerical variables in means and standard deviation. We used X2, Fisher's exact, Student's t, and Mann-Whitney U to compare groups. A logistic regression model was built to analyze favorable factors. The value of $p < 0.05$ was considered statistically significant.
Results: In a period of 6 years and evaluation of 1187 patients seen in the liver clinic consultation, 300 patients with decompensated cirrhosis were included, 208 due to OH consumption who completed abstinence and 92 HCV treated with DAAs who achieved SVR, only 41 (13.66%) had recompensation criteria, 32 patients (78%) men with age 54.84 ± 10.58 years old, who previously presented ascites, hepatic encephalopathy and variceal hemorrhage. As a follow-up, it was documented that they ascended one stage on the Child Pugh scale (from C to B and from B to A), and a decrease in the MELD score from 16.3 to 8.42 ± 1.47 points, with withdrawal of medications (diuretic, measures antiammonia and beta blocker), liver stiffness decreased from a baseline average of 35.04 ± 16.93 kpas versus 21.13 ± 10.89 kpas in the recompensation stage, a decrease of 13.91 kpas, which represents 39.69%. Male gender ($p = 0.025$) and the absence of previous ascites ($p = 0.014$) favored the recompensation.
Conclusion: The concept of recompensation is real, with >20% reduction in liver stiffness and functional improvement; Male sex and the absence of previous ascites favor the recompensation.

SAT-139

Prevalence and determinants of reduced muscle status among adults with cirrhosis attending liver clinics

Damian Harding[1,2], Edmund Tse[3], Alan Wigg[4,5], Olga Sukocheva[3], Gary Wittert[3,6]. [1]*University of Adelaide, Lyell McEwin Hospital, Adelaide, Australia;* [2]*Lyell McEwin Hospital, Adelaide, Australia;* [3]*Royal Adelaide Hospital, Adelaide, Australia;* [4]*Flinders Medical Centre, Adelaide, Australia;* [5]*Flinders University, Adelaide, Australia;* [6]*University of Adelaide, Adelaide, Australia*
Email: damian.harding@adelaide.edu.au

Background and aims: Cirrhosis, particularly decompensated disease, is characterised by reduced skeletal muscle mass and function that is associated with increased mortality, morbidity, and healthcare utilisation. Mechanisms implicated in impaired muscle status: alterations in sex steroids, altered ammonia and glycogen metabolism, and malnutrition. The Sarcopenia in Cirrhosis study is an ongoing prospective observational study of adults with cirrhosis who attend out-patient hepatology services in Adelaide, Australia. Study aims are to (i) investigate the prevalence and determinants of impaired skeletal muscle quality in an outpatient population of adults with cirrhosis. (ii) determine the trajectory of change in muscle quality over time, and (iii) assess relationships of muscle quality and its trajectory of change to clinical outcomes. Baseline cohort data are presented here.
Method: Adults aged 18–70 years who attend liver outpatient services in Adelaide, Australia. Cirrhosis diagnosed based on liver transient elastography >20 kPa, or >15 kPa with supporting histology, radiology, or clinical findings. Patients were excluded if unable to provide informed consent, diagnosis of hepatocellular carcinoma or other malignancy, pregnant or breastfeeding, or where the treating clinician believes the patient's prognosis is terminal. Consenting eligible subjects undergo study assessments at baseline and at 12 months. Assessments include upper arm circumference, DXA height-adjusted appendicular lean mass, handgrip strength and liver frailty index. End of study data to be collected include incident clinical events, hospital admissions and mortality.
Results: 97 eligible, consenting participants. Females 36 (37.1%). Age range 32–71 years, median age 57 years (IQR 52.1–63.8). Median MELD 11 (IQR 7–13). Median liver stiffness 38 kPa (IQR 23.3–65.9). 59.2% of subjects have had previous decompensation. Aetiologies of liver disease: alcohol-related cirrhosis 36 (37.1%), MASH 21 (21.6%), Met ALD 19 (19.6%), hepatitis C (± alcohol/ MASH) 7 (7.2%), cholestatic liver disease 8 (8.2%), others 6 (6.2%). Mean dominant handgrip strength 29.3 kg (sd 12.7). Prevalence reduced muscle strength (defined as handgrip strength < 15 kg female, < 30 kg male): 19 of 86 subjects assessed (22.1%). Prevalence frailty (defined as Liver Frailty Index score >4,5): 12 of 82 subjects assessed (14.6%).
On univariate analysis, reduced muscle strength is associated with low zinc status (OR 0.61, p 0.009). On univariate analysis, frailty is associated with reduced mid arm circumference (OR 0.86, p 0.014).
Conclusion: In a cohort of adults with cirrhosis who attend out-patient liver services the prevalence of reduced muscle strength is 22.1%. Prevalence of frailty is 14.6%. Factors associated with impaired muscle status include zinc status.

SAT-140

Predictive value of systemic inflammation biomarkers towards recompensation versus progression to further decompensation in patients with decompensated cirrhosis

Dalila Costa[1], Benedikt Hofer[1], Georg Kramer[1], Ana Frias[2], Ricardo Silvestre[2], Joana Camões Neves[3], João Belmiro[3], Kerstin Zinober[1], Vlad Taru[1], Georg Semmler[1], Benedikt Simbrunner[4], Carla Rolanda[3], Mattias Mandorfer[1], Thomas Reiberger[1]. [1]*Vienna*

Email: dc.dalilacosta@gmail.com

Background and aims: The clinical course of patients with decompensated cirrhosis is heterogenous, since while many progress to further decompensation and experience liver-related death, some may recover and achieve recompensation with cure/control of the primary etiologic factor. Given the gradual increase of systemic inflammation (SI) with clinical cirrhosis stages, we investigate a broad panel of SI biomarkers and their dynamics across the course of decompensated cirrhosis patients.
Method: A two-center, prospective cohort of cirrhosis outpatients evaluated between 01/2017 and 12/2023 were stratified at baseline (BL) as compensated (CC), decompensated (DC) and recompensated (ReC) cirrhosis. At baseline and follow-up (FU: after a minimum of ≤ 6-months), surrogates of portal hypertension (PH) and multiple markers of SI were evaluated by a bead-based immunoassay using a flow cytometer. The cirrhosis stage at FU and further clinical outcomes were recorded. Patients were censored upon occlusive portal vein thrombosis, liver transplantation, hepatocellular carcinoma or death.
Results: A total of 152 cirrhosis patients were included with a median follow-up of 19.2 months (median age: 59.8 years; 68.4% men; n = 92 ALD as the main etiology). At BL, 39 (25.7%) showed CC, 23 (15.1%) ReC, and 90 (59.2%) DC. MELD was significantly higher in DC (10 v 9.5 v 12, p < 0.001) as well as SI markers such as IL6 (11.6 v 11.1 v 22.5, p < 0.001), IL8 (33 v 43.9 v 89.3, p = 0.005) and IL10 (6.9 v 3.5 v 10.5; p = 0.001), and PH surrogates such as VWF (264 v 203 v 306, p < 0.001). HVPG was significantly lower in recompensated patients (18 v 13 v 19 mmHg, 0.030) in comparison to CC and DC. There were no significant differences within other SI markers. DC showing progression to further decompensation (n = 23, 25,6% of DC) revealed significantly higher levels of multiple cytokines (IL10, Il1b, IL12p70, IL17A, IL8, IP10) vs. BL (all p < 0.05). In turn, DC patients achieving recompensation (n = 25, 27,8% of DC) showed significantly decreasing MELD (13 v 10, p = 0.05) and PH (HVPG (18 v 13mmHg, p = 0.001) and VWF (285 v 210, p = 0.001), but also of SI biomarkers (IL6, IL8, IL10, IL23, IP10, all p < 0.05) vs. BL.
Conclusion: Patients with DC show not only impaired liver function and PH but also a pro-inflammatory state. Importantly, with progression to further decompensation or regression to recompensation, we found significant dynamics in SI biomarkers paralleling liver disease surrogates (MELD, HVPG).

SAT-141
Chronic Liver Disease and Autoimmune Haemolytic Anaemia: A Case Series

Dorien Pint[1,2], Abid Suddle[2], Ceesay Mansour[3]. *[1]University Hospital Antwerp, Edegem, Belgium; [2]Institute of Liver Studies, King's College Hospital, London, United Kingdom; [3]King's College Hospital London, London, United Kingdom*
Email: dorien.pint@uza.be

Background and aims: Chronic anaemia is common in patients with chronic liver disease (CLD), often due to multifactorial causes and causes increased morbidity and mortality rates. Autoimmune haemolytic anaemia (AIHA) is a rare autoimmune disorder that can complicate CLD. AIHA is characterised by autoantibody-mediated red blood cell destruction, and its coexistence with CLD, presents diagnostic and management challenges. This study aims to explore the clinical characteristics, management, and outcomes of patients with AIHA and CLD at King's College Hospital over a 21-year period.
Method: This retrospective case series involved adult patients (≥18 years) with a diagnosis of both CLD and AIHA at King's College Hospital from 2002 to 2022. Data on demographics, liver disease aetiology, AIHA treatment, and outcomes were collected from electronic health records. The patients were identified using search criteria for various CLD combined with AIHA diagnosis. AIHA diagnosis was based on laboratory parameters, including a positive direct anti-globulin.
Results: Ten patients (70% female) with concurrent AIHA and CLD were identified. The median age at time of diagnosis for CLD and AIHA was 34 years and 43 years, respectively. The most common liver disease was autoimmune hepatitis (40%), followed by alcohol-related liver disease (30%). 80% of the patients presented with chronic liver disease before the onset of AIHA. Seven patients (70%) had cirrhosis, and five (50%) received liver transplantation. In three cases, AIHA occurred post-liver transplantation. Treatments included corticosteroids (90%), IVIG (40%), and rituximab (40%). Rituximab was particularly used in treatment-refractory cases or post-liver transplant patients. Treatment-refractory AIHA occurred in four patients (40%), 2 of which developed treatment-refractory AIHA after their liver transplantation. Possible cofactors that were identified that might influence the development of AIHA in patients with CLD were COVID-19 infection in 3 patients (30%), cytomegalovirus (CMV) infection in 1 patient (10%), and Crohn's disease in 1 patient (10%).
Conclusion: This study highlights the complex pathophysiology and treatment landscape for AIHA in patients with chronic liver disease, particularly those who have undergone liver transplantation. Our findings underscore the necessity for further research to better understand the role of chronic liver disease as an immunological trigger for AIHA. Investigating the pathways linking liver inflammation and immune dysregulation could provide valuable insights into the pathogenesis of AIHA in patients with CLD as well as patients developing AIHA post-liver transplantation.

SAT-142-YI
Liver frailty index: a prognostic tool for predicting mortality in cirrhotic patients

Burcu Gurbuz[1], Yasemin Polat[2], Arzu Okyar Bas[2], Cafer Balci[2], Burcu Balam Dogu[2], Meltem Gulhan Halil[2], Mustafa Cankurtaran[2], Bengi Ozturk[1], Taylan Kav[1], Onur Keskin[1]. *[1]Hacettepe University Faculty of Medicine, Department of Gastroenterology, Ankara, Türkiye; [2]Hacettepe University Faculty of Medicine, Department of Geriatrics, Ankara, Türkiye*
Email: drburcuusta@gmail.com

Background and aims: Liver frailty represents a critical prognostic indicator in cirrhosis, reflecting the intricate relationship between chronic liver disease and systemic physiological deterioration. The Liver Frailty Index (LFI) quantifies functional decline through objective physical performance measures, including handgrip strength, standing balance, and repeated chair rise tests. Emerging research suggests LFI provides a measurable score correlating with adverse clinical outcomes. This study aims to evaluate the LFI's utility in assessing functional status and predicting mortality among patients with cirrhosis.
Methods: This prospective cohort study included 75 patients diagnosed with cirrhosis during their outpatient control visits between April 2023 and September 2024. Patients with physical disabilities precluding performance of LFI assessment were systematically excluded. Standardized evaluations of handgrip strength, standing balance, and repeated chair rises were systematically applied to all participants. Patients with an LFI score ≥4.5 are categorized as frail. Clinical evaluations included MELD 3.0 scores, Charlson comorbidity scale and mortality were documented during the study period. Cirrhosis etiology was primarily MASH (32%). Viral hepatitis represented the second common cause of cirrhosis (22%).
Results: Of the 75 cirrhosis patients studied, 11 patients died during the median follow-up period of 18 months. Comparative analysis

revealed statistically significant differences between deceased and surviving patients. Specifically, the initial LFI and MELD 3.0 scores were significantly higher in the mortality group, while albumin levels were lower (4.6 ± 0.5 vs. 4.1 ± 0.5; p:0.003, 14 ± 4 vs. 10.6 ± 3.3; p:0.02 and 3.15 ± 0.4 vs. 3.67 ± 0.6; p:0.01) Notably, age, gender, bilirubin, creatinine, and Charlson Comorbidity Index (CCI) scores showed no significant difference. Stratification by the predefined LFI cut-off value (≥4.5) demonstrated mortality patterns: 6 of 17 frail patients and 5 of 58 non-frail patients died during the study period. Multivariate analysis identified frailty [hazard ratio: 6.41 (95% CI: 1.42–28.5); p = 0.016] and MELD 3.0 score [hazard ratio: 1.29 (95% CI: 1.07–1.55); p = 0.007] as independent mortality predictors. Kaplan-Meier survival analysis revealed cumulative mortality rates at 6, 12, and 18 months were 26.1%, 33%, and 40.2% in the frail group, compared to 2%, 3.4%, and 10% in the non-frail group (p = 0.002), underscoring the prognostic significance of the LFI.

Conclusion: Frailty, measured by LFI during outpatient examinations, serves as an independent predictor of mortality in cirrhotic patients. The index represents a convenient non-invasive method for comprehensively assessing patient fragility and predicting survival in clinical hepatological practice.

SAT-143

Cirrhotic cardiomyopathy: diagnostic challenges and debating role in mortality prediction in cirrhosis

Burcu Gurbuz[1], Ugur Karakulak[2], Aytekin Idikut[3], Ebru Damadoglu[3], Baris Kaya[2], Bengi Ozturk[1], Taylan Kav[1], Onur Keskin[1]. *[1]Hacettepe University Faculty of Medicine, Department of Gastroenterology, Ankara, Türkiye; [2]Hacettepe University Faculty of Medicine, Department of Cardiology, Ankara, Türkiye; [3]Hacettepe University Faculty of Medicine, Department of Pulmonology, Ankara, Türkiye*
Email: drburcuusta@gmail.com

Background and aims: Cirrhotic cardiomyopathy (CCM) is a complex and underrecognized condition in chronic liver cirrhosis, characterized by impaired systolic and diastolic function, electrophysiological abnormalities, and/or chronotropic incompetence. Initially defined by the 2005 World Gastroenterology Congress Montreal Criteria, CCM was subsequently refined by the 2020 Cirrhotic Cardiomyopathy Consortium (CCC) Criteria. This study aimed to evaluate CCM in cirrhosis patients according to these two diagnostic criteria and to assess its prognostic significance.

Method: Between September 2022 and June 2023, a total of 75 patients with liver cirrhosis were prospectively enrolled in the study. Patients younger than 18 years and those with a history of cardiac revascularization, coronary artery disease, congenital heart disease, valvular heart disease, or severe pulmonary disease were excluded. Individuals presenting for routine gastroenterological evaluation were referred to the cardiology department, where cardiac assessments, including electrocardiography (ECG) and transthoracic echocardiography (TTE), were performed. Data on hospitalizations, episodes of decompensation, and mortality were documented during and after the study period. The median patient follow-up was 18 months (1–29 months).

Results: Of 75 patients, CCM was identified in 29 patients (38.7%) according to the 2005 Criteria, with 2 patients meeting systolic dysfunction and 27 meeting diastolic dysfunction criteria. The median Child-Pugh score for these patients was 6 (5–12), the median MELD-Na score was 10 (7–26), and the median MELD 3.0 score was 12 (7–26). Among these patients, 14 (48.3%) were in the decompensated group, while 15 (51.7%) were in the compensated. When the 2020 (CCC) Criteria were applied, 3 patients (4%) were diagnosed with CCM, 1 had systolic and 2 had diastolic dysfunction. Of these, 2 patients (%66.7) were decompensated and 1 patient (% 33.7) was compensated. When the 2005 Criteria were applied, the cumulative mortality rate in patients diagnosed with CCM was 14% at 12-month follow-up and 20% at 24-month follow-up. When the 2020 criteria were applied, mortality occured only 1 in 3 patients diagnosed with CCM during the 24-month follow-up. The mortality rate did not differ significantly in patients with and without CCM detected for both 2005 and 2020 criteria (p:0.94; p:0.90).

Conclusion: Although CCM has traditionally been associated with poor outcomes in cirrhosis, emerging evidence indicates that its direct role in predicting mortality is limited. Further research is required to elucidate the pathogenesis, refine diagnostic criteria, and better understand the clinical relevance of CCM in cirrhosis, ultimately informing potential therapeutic strategies. This study presents a thorough review of the current understanding of CCM, highlighting its diagnostic challenges, clinical implications, and the ongoing debate regarding its influence on the progression of cirrhosis and patient survival.

SAT-144-YI

FastPHES offers a rapid but valid alternative for the detection of cognitive impairment in patients with liver cirrhosis

Julius Egge[1,2], Alena Friederike Ehrenbauer[1,2], Maria Magdalena Gabriel[1], Jana Al-Ayoubi[1], Jennifer Witt[2], Jim Benjamin Mauz[2], Martin Kabelitz[2], Anja Tiede[2,3], Lea Wagner[2], Heiner Wedemeyer[2,3], Hartmut Hecker[4], Benjamin Maasoumy[2,3], Karin Weissenborn[1]. *[1]Hannover Medical School, Department of Neurology, Hannover, Germany; [2]Hannover Medical School, Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover, Germany; [3]German Center for Infection Research (DZIF), Hannover/Braunschweig, Germany; [4]Hannover Medical School, Institute of Biostatistics, Hannover, Germany*
Email: Egge.Julius@mh-hannover.de

Background and aims: Guidelines recommend screening for cognitive impairment (CI) in patients with liver cirrhosis. The PSE-Syndrome test yielding the Psychometric Hepatic Encephalopathy Score (PHES) is considered "gold standard," but is often criticized as time consuming. Recently, the Animal Naming Test (ANT) and the QuickStroop have been proposed as time-saving alternatives. However, the lack of age- and education-adjusted norms for these tests impede a valid diagnosis. Considering the fact that the PHES in patients with cirrhosis results predominantly from the digit symbol (DS) and serial dotting (SD) test scores, we aimed to establish German norm values for a significantly shortened PHES (fastPHES) test consisting only of DS and SD. We aimed to compare the easier fastPHES with the PHES, ANT and QuickStroop in patients with cirrhosis. In addition, the predictive value of the fastPHES for the development of overt hepatic encephalopathy (oHE) episodes within a year after assessment was evaluated.

Method: The test results of the German cohort of healthy subjects (n = 217) assessed for the re-evaluation of PHES norms in 2020, was used for the calculation of fastPHES norms. Then the new fastPHES was compared to PHES and ANT in a prospectively recruited cohort of patients with cirrhosis (n = 271). In a part of these patients (n = 155), a comparison with QuickStroop was also possible. For each test, sensitivity and specificity analyses were performed in relation to abnormal PHES or the presence of HE grade 1–2. Additionally, receiver operating characteristics (ROC) analyses with abnormal PHES as reference value were performed. Finally, the predictive value of the different tests in forecasting oHE during one year follow-up was estimated using Fine and Gray's competing risk analyses. Here, death and liver transplantation were competing events.

Results: The analysis of the norm cohort's test results revealed an appropriate cut-off of ≤2 for an abnormal fastPHES. In 92.5% of the patients with HE grade 1–2 the fastPHES was abnormal. Compared to an abnormal PHES as reference, the fastPHES showed a sensitivity of 82.1% and a specificity of 90.9%. In comparison, the ANT and Quickstroop showed a sensitivity of 66.7% and 83.3% and a specificity of 59.6% and 59% respectively. Area under ROC was 0.92, 0.67 and 0.79 for fastPHES, ANT and QuickStroop, accordingly. Regarding the predictive value for the development of oHE in one year of follow-up, the abnormal PHES revealed a subdistribution hazard ratio (sHR)

of 3.24 (p < 0.001) while the fastPHES showed a sHR of 2.1 (p = 0.006). ANT and QuickStroop showed an sHR of 1.8 (p = 0.035) and 1.05 (p = 0.89) in this respect.
Conclusion: The here proposed fastPHES offers a rapid but still valid diagnosis of CI in patients with cirrhosis when there is a lack of time to determine the PHES and is, in this respect, superior to other time-saving test procedures.

SAT-145-YI
Clinical trajectories of patients with cirrhosis and ascites receiving long-term albumin. A proposal for a personalized management based on real-world experience
Enrico Pompili[1,2], Giulia Iannone[1,2], Salvatore Piano, Pierluigi Toniutto[3], Antonino Lombardo[4], Stefania Gioia[5], Giacomo Zaccherini[1,2], Marta Tonon[6], Roberta Gagliardi[6], Maurizio Baldassarre[2], Greta Tedesco[1], Lorenzo Lani[1,2], Valeria Guarneri[1], Vito Di Marco[4], Silvia Nardelli[5], Vincenza Calvaruso[4], Davide Bitetto[3], Paolo Angeli[6], Paolo Caraceni.
[1]Department of Medical and Surgical Sciences, Alma Mater Studiorum - University of Bologna, Bologna, Italy; [2]Unit of Semeiotics, Liver and Alcohol-related diseases, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy; [3]Hepatology and Liver Transplantation Unit, University Academic Hospital, Udine, Italy; [4]UOC di Gastroenterologia, Dipartimento di Promozione della Salute, Materno Infantile, Medicina Interna e Specialistica (PROMISE), University of Palermo, Palermo, Italy; [5]Department of Translational and Precision Medicine, Sapienza University of Rome, Rome, Italy; [6]Unit of Internal Medicine and Hepatology, Department of Medicine - DIMED, University and Hospital of Padova, Padova, Italy
Email: enrico.pompili2@studio.unibo.it

Background and aims: Long-term albumin (LTA) is widely used in Italy in patients with cirrhosis and ascites. This study aims to analyse the clinical course and outcomes of patients receiving LTA to provide tools for personalizing their management.
Method: Patients with cirrhosis and ascites included in an Italian multicentre, retrospective, real-world study (Real-ANSWER) were followed during LTA treatment until death, liver transplantation, or end of follow-up. Based on the response at 3 months of LTA, patients were classified as 'responders' (resolution of ascites to grade 0–1), 'partial responders' (persistent ascites but no need for further paracentesis) and 'non-responders' (still receiving paracentesis).
Results: Of the 312 patients enrolled (median Child-Pugh 8, MELD 15, MELD-Na 18), 34% were responders, 33% partial responders and 33% non-responders. At baseline, non-responders had more severe ascites, higher White Blood Cells (WBC) count (6.0 vs 4.80 vs 4.90 10^9/L, p = 0.001) and creatinine (1.1 vs 0.9 vs 0.9 mg/dl, p = 0.003) compared to other groups, while no differences were found in aetiology of cirrhosis, serum albumin, MELD and Child-Pugh scores. Effective etiological treatment was higher (but not statistically significant) in responders than partial and non-responders (44% vs 35% vs 30%, p = 0.09). Among responders, 40% discontinued LTA due to improvement (median: 7 months; IQR 4–12), 26% received a transplant, 15% died. Among non-responders, 18% received TIPS (median: 5 months; IQR 3–12), 33% died, 11% received a transplant. Interestingly, among non-responders, 15% discontinued LTA due to subsequent improvement (median: 14 months; IQR 10–22), half of whom received etiological treatments. Among partial responders, 16% discontinued LTA due to improvement (median: 10 months; IQR 5–22), 21% underwent transplantation and 42% died. The cumulative incidence of 18-month mortality was lower in responders, while no differences were seen between partial responders and non-responders (18% vs 46% vs 42%, p < 0.001).
Conclusion: Based on the ascites response after 3 months of LTA, three categories with different clinical courses can be identified, thus helping the decision-making process. Non-responders should be assessed for TIPS placement, except those undergoing effective aetiological treatment who can be re-evaluated later. Responders should continue with LTA as they have the highest chance of survival, resolution of ascites and possibly recompensation. A case-by-case decision should be instead performed in partial responders.

SAT-146
A novel non-invasive diagnostic model for high-risk varices in cirrhosis: a multicenter retrospective and prospective study
Yanhu Wang[1], Junliang Fu. *[1]the Fifth Medical Center, Chinese PLA General Hospital, Beijing, China*
Email: fjunliang@163.com.

Background and aims: The non-invasive diagnostic method recommended by the Baveno VI and Baveno VII consensus for the diagnosis of high-risk varicose veins (HRV) have limited endoscopy sparing rates or require additional diagnostic equipment. This study aims to develop a novel diagnostic model to improve the diagnostic efficiency of HRV without requiring extra equipment.
Method: A multicenter retrospective cohort and a prospective cohort were established. Data including endoscopy findings, abdominal ultrasound results, liver stiffness measurements (LSM) using iLivTouch, and laboratory test parameters were collected from cirrhotic patients aged 18–65 years. Univariate and multivariate logistic regression analyses were conducted to identify influential variables. The area under the receiver operating characteristic curve (AUC) was calculated. A new diagnostic model was developed in the retrospective cohort and validated in the prospective cohort.
Results: As of June 19, 2024, the study included 3,405 patients from 22 centers, comprising 2,862 patients in the retrospective cohort and 543 patients in the prospective cohort. In the retrospective cohort, the Baveno VI (BV6) and Expanded Baveno VI (E-BV6) criteria spared 17.68% and 29.00% of endoscopies, respectively. The HRV missing rates were 2.53% for BV6 and 7.59% for E-BV6. After adjusting the cutoff values for LSM and platelet count (PLT), we established a Modified Baveno VI (M-BV6) criteria with an endoscopy sparing rate of 22.68%, higher than BV6, with an equivalent HRV missing rates of 2.53%. In the prospective cohort, the endoscopy sparing rates for BV6 and M-BV6 were 26.34% and 32.04%, respectively, with HRV missing rates of 1.83% for both. Univariate and multivariate logistic regression analyses revealed that spleen area (SA) was an independent predictor for HRV diagnosis. The AUCs for PLT, LSM, and SA for diagnosing HRV were 0.833, 0.715, and 0.794, respectively. Then BV6-SA diagnostic model was developed by incorporating SA into the BV6 criteria. Using this model, the endoscopy sparing rates were 64.35% in the retrospective cohort and 74.68% in the prospective cohort, with HRV missing rates of 4.26% and 4.81%, respectively. The MBV6-SA model, which integrated SA into the M-BV6 criteria, demonstrated endoscopy-sparing rates of 65.33% and 74.94%, and HRV missing rates of 4.26% and 4.81% in the retrospective and prospective cohorts, respectively.
Conclusion: This study is the first to validate the applicability of LSM measured by iLivTouch in diagnosing HRV with the BV6 criteria, and M-BV6 further improved the endoscopy sparing rates compared to BV-6. Most importantly, the BV6-SA model and MBV6-SA model we established substantially increased the endoscopy sparing rates with acceptable HRV missing rates.

SAT-149-YI
Hospital acquired infection is associated with higher mortality in patients hospitalised with acute decompensation of liver cirrhosis and infection
Gemma Wells[1,2], Louise China[1,2], Alastair O'Brien[2]. *[1]Royal Free Hospital, London, United Kingdom; [2]University College London, London, United Kingdom*
Email: gemma.wells3@nhs.net

Background and aims: Infection is a common decompensating event in patients hospitalised with complications of liver cirrhosis. The impact and significance of recurrent and nosocomial infections in these patients is not as well described.

Method: We performed a post-hoc analysis of antibiotic usage and outcomes for patients diagnosed with hospital acquired infection (HAI) during the Albumin to Prevent Infection in Chronic Liver Failure (ATTIRE) trial. A total of 777 patients were randomized to daily 20% human albumin infusions or standard of care during hospitalisation due to an acute decompensation of cirrhosis across 35 different UK hospitals between 2016–2019. Data on type of infection for those who developed HAI after being treated empirically for infection on trial entry was available from 15/17 patients that survived to 90 days and 16/19 patients that died by 90 days.
Results: HAI was diagnosed in a higher proportion of patients who did not survive to 90 days (27.5% vs 12.4%, p = 0.007). Median time to HAI in those that went on to die (n = 16) within 90 days was 6 days compared to 8 days in those that went on to survive 90 days (n = 15 (p = 0.029, HR log rank ratio 0.53, 95% CI 0.25–1.11). Overall, 90-day mortality in infected patients at hospitalisation that developed subsequent HAI was 53%. The most frequently diagnosed site of HAI in survivors and non-survivors was the lower respiratory tract (5/17 and 5/19), then spontaneous bacterial peritonitis (2/17 and 3/19). Most patients in both groups did not have a causative pathogen identified (n = 5 in survivors, n = 2 in non-survivors) and there was no antimicrobial resistance reported.
Conclusion: 90-day mortality was high in patients admitted with decompensated liver cirrhosis who developed additional HAI after being treated for infection at presentation and did not appear influenced by site of infection, specific pathogens or antimicrobial resistance in this cohort. Non-survivors developed HAI earlier in their admission and may reflect that intrinsic patient factors are likely to be more important to survival than choice of empirical antibiotics. The high mortality in the HAI group may also be related to clinicians being less vigilant for infection in patients already empirically treated with antibiotics, resulting in delayed diagnosis.

SAT-150
Highly variable antibiotic prescribing practices in a real world cohort of patients in the United Kingdom with decompensated cirrhosis

Gemma Wells[1,2], Louise China[1,2], Alastair O'Brien[2]. [1]*Royal Free Hospital, London, United Kingdom;* [2]*University College London, London, United Kingdom*
Email: gemma.wells3@nhs.net

Background and aims: Increasing antimicrobial resistance is described in hospitalised patients with liver cirrhosis, encouraging rationalising empirical antibiotic prescribing where infection is suspected. Yet liver care bundles promote early broad spectrum use because of the harm associated with infection. In view of these potentially contrasting messages, we examined real world antibiotic usage and outcomes in hospitals in the United Kingdom (UK).
Method: This was a post-hoc analysis of antibiotic prescribing in the first 48 hours in patients diagnosed with infection at entry to the Albumin to Prevent Infection in Chronic Liver Failure (ATTIRE) trial, from a total of 777 patients randomized to daily 20% human albumin infusions or standard of care during hospitalisation due to an acute decompensation of cirrhosis across 35 UK hospitals (2016–2019). We performed a descriptive analysis of empirical antibiotic choices, and assessed baseline characteristics and outcome data for patients treated empirically with single versus multiple agents to detect any significant differences between the groups using Mann-Whitney U test.
Results: 211 patients were diagnosed with infection and prescribed antibiotics at trial entry, with antibiotic prescribing data available for 205. The total number of empirical antibiotics prescribed was 279 for 205 patients, of which the most frequently occurring were piperacillin-tazobactam (74) and co-amoxiclav (46). 149 patients received a single agent and 56 received multiple agents, with 38 different combinations of antibiotics identified. Overall, 91/205 (44%) patients had their antibiotics changed from 1st line empirical choice during their hospitalisation, with 72/91 (79%) switched to agents of equal or broader spectrum antimicrobial activity. Baseline characteristics were similar between the multiple and single agent groups, with the only significant difference being the median admission CRP, which was higher in the multiple agent group (61 versus 39.5, p = 0.03). There was no significant difference in 28-day mortality but mortality in the multiple antibiotic group was higher at 90 days (p = 0.03). In patients who received gentamicin, 4/16 (25%) developed renal dysfunction and 9/16 (56%) died by 90 days.
Conclusion: Highly variable prescribing practices for cirrhosis patients admitted to UK hospitals were evident from the number of antibiotics in varying combinations used empirically in this study. We have not identified a specific cause for a higher 90-day mortality in patients who received multiple agents empirically, as the groups were similar in respect to baseline characteristics. It is possible that the patients in the multiple antibiotic group had more severe disease not accounted for by our data, but may also reflect that use of multiple agents such as aminoglycoside antibiotics carries a risk of iatrogenic harm.

SAT-151
Mortality in patients hospitalised with decompensated cirrhosis and infection is associated with higher baseline measures of infection and organ dysfunction

Gemma Wells[1,2], Louise China[1,2], Alastair O'Brien[2]. [1]*Royal Free Hospital, London, United Kingdom;* [2]*University College London, London, United Kingdom*
Email: gemma.wells3@nhs.net

Background and aims: Infection is frequently diagnosed in patients presenting to hospital with decompensated liver cirrhosis, with systemic inflammation and immune dysfunction described in patients who develop organ failures and death. We examined characteristics and serum biomarkers of a large cohort of these patients admitted to hospitals across the United Kingdom (UK) to assess whether these findings held true in this cohort.
Method: We performed a post-hoc analysis of baseline characteristics, outcome data and serum biomarkers for patients diagnosed with infection at entry to the Albumin to Prevent Infection in Chronic Liver Failure (ATTIRE) trial. 211 patients with infection were identified from a total of 777 patients randomized to daily 20% human albumin infusions or standard of care during hospitalisation due to an acute decompensation of cirrhosis across 35 different UK hospitals between 2016–2019. Baseline demographics, admission medications and admission laboratory values were available for 206 patients and are presented as medians and 95% confidence intervals with the Mann-Whitney U test to detect differences between survivors and non-survivors at 90 days. Results of other serum biomarkers for infection, inflammation and cardiorenal function were available for a subcohort of 36 patients.
Results: 69/206 (33.5%) of patients diagnosed with infection at trial entry did not survive to 90 days. These patients were older (median age 58.9 vs 53.2, p = 0.0002), had higher baseline creatinine values (93 vs 67, p = 0.0003) and higher Model for End-stage Liver Disease scores (21.94 vs 18.87, p = 0.0003) than survivors. Non-survivors were more likely to have alcohol-related hepatitis (p = 0.007) and hepatic encephalopathy (p = 0.025), and to develop hospital acquired infections (p = 0.007) and renal dysfunction (p = 0.00073). 90-day mortality was not associated with prophylactic antibiotics or rifaximin, proton pump inhibitors or beta-blockers at trial entry. Baseline white cell count (WCC) (8.1 vs 11.3, p = 0.0005) and C-reactive protein (CRP) (38 vs 55, p = 0.037) were significantly higher in non-survivors. In a subcohort of 36 patients, there was no significant association between mortality at 90 days and other serum biomarkers of infection and inflammation, including procalcitonin (PCT). Serum syndecan-1 was significantly higher at trial entry (p = 0.0063) and day 5 (p = 0.004) in non-survivors.

Conclusion: Our data show that disease severity and organ dysfunction are significantly associated with 90-day mortality in this cohort of patients hospitalised with decompensated cirrhosis and infection. Conventional markers for infection (WCC and CRP) appear to be the most useful predictive laboratory tests for infection severity. The significant association between 90-day mortality, baseline creatinine and syndecan-1 levels suggests there is a role for further studies examining the cardiorenal axis in decompensated cirrhosis.

SAT-152

Optimising management of patients discharged from hospital following an acute decompensation of cirrhosis – a multicentre UK perspective

Giovanna McGinty[1], Benjamin Allen[2], Kate Simpson[3], Kelly De Stadler[2], Emily Boyd[3], Jessie Khoo[3], Kartikeya Khanna[3], Tareq Alhor[3], Luis Oliveira[3], Lancy Rodrigues[3], Anastasia Oates[1], James Maurice[1], Ankur Srivastava[1], Moby Joseph[3], Terence Farrant[2], Robbie Adamson[4], Mohsan Subhani[5], Kohilan Gananandan[6]. *[1]North Bristol Trust, Bristol, United Kingdom; [2]Royal United Hospital, Bath, United Kingdom; [3]Great Western Hospital, Swindon, United Kingdom; [4]University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom; [5]University of Nottingham, Nottingham, United Kingdom; [6]Royal Free Hospital, London, United Kingdom*
Email: gio.mcginty@nbt.nhs.uk

Background and aims: Following hospitalisation with acute decompensation (AD) of cirrhosis, patients experience significant morbidity with 90-day mortality rates reported over 50% in the sickest cohort. Significant variation in care exists with the British Association for the Study of Liver Disease (BASL) endorsing a discharge bundle to help standardise management. The aim of this study was to assess management and outcomes following hospitalisation with AD against these standards, and to elicit variations in care.
Method: A UK based multi-centre prospective study was conducted up to 90 days following discharge with AD as defined by Baveno VII criteria. Adult patients who were admitted with AD from 01/01/2024–31/03/2024 were identified at each site by a nominated site lead via electronic handover sheets and checked against their discharge letter. Patients who had died during the admission were excluded. Anonymised excel password-protected data sheets were used.
Results: A total of 48 patients across 3 sites were recruited with the median age being 63 (IQR 19). Aetiology of those included were alcohol-related (75.0%), MASLD (12.5%), cryptogenic (6.3%), PBC (2.2%), Hepatitis C (2.1%), and MetALD (2.1%). 54.2% of patients were admitted with ascites without spontaneous bacterial peritonitis (SBP), 14.6% with hepatic encephalopathy, 14.6% with variceal bleeding, 12.5% with SBP and 4.2% with hepatorenal syndrome -acute kidney injury. 7 patients (14.6%) were re-admitted to hospital during follow-up (5 due to further decompensation) with 13 (27.1%) patients dying within 90 days of discharge. No significant difference was noted in readmissions and mortality between specialist and non-specialist centres. With regards to decompensation management, 7 patients (100.0%) who were admitted with a variceal bleed were prescribed a beta blocker, but only 1 out of 7 patients had a repeat gastroscopy performed within the recommended 4-week period. Of the 6 patients that were diagnosed with SBP, 5 patients (83.3%) were prescribed secondary prophylaxis. Of the 36 patients with alcohol-related liver disease, only 17 (47.2%) were reviewed by the alcohol-care team as an inpatient. 15 (31.2%) patients were identified as not being future transplant candidates. Only 7 (46.6%) of these had appropriate treatment escalation plans documented in their discharge letter.
Conclusion: Despite the limited sample size of this pilot study, we highlight the parameters in post discharge care following AD that require urgent improvement with regards to optimising prescriptions, clinical reviews, interventions as well as advanced care planning. We will explore these concepts as well as variations in care more in the next phase of this program, which is a nation-wide based study through the UK hepatology trainee consortium (ToRcH-UK).

SAT-153

COVID-19 pandemic significantly increased anxiety and depression in patients with cirrhosis, but not in patients without liver disease

Greta Priebe[1], Lilith Kuballa[1], Thomas Brehm[2], Thomas Horvatits[3], Karoline Horvatits[3], Johannes Kluwe[4], Ansgar W. Lohse[1], Samuel Huber[1], Sven Pischke[1], Thorben Fründt[1]. *[1]University Medical Hospital Hamburg-Eppendorf, Hamburg, Germany; [2]University Medical Hospital Hamburg-Eppendorf, Forschungszentrum Borstel, Hamburg, Germany; [3]Gastromedics, Eisenstadt, Austria; [4]Evangelisches Amalie Sieveking Krankenhaus Hamburg, Hamburg, Germany*
Email: tfruendt@uke.de

Background and aims: The Coronavirus Disease 2019 (COVID-19) pandemic caused a significant increase of anxiety and depression, particularly in patients with chronic diseases like diabetes or hypertension. However, little is known about the prevalence of both disorders in patients with liver cirrhosis hospitalized during the pandemic. Furthermore, it's unclear if the prevalence of both diseases has changed in the post-COVID area or if there is a lasting effect of the pandemic.
Method: Retrospective analysis of three cohorts including patients with liver cirrhosis (LC) and without any liver disease who had been treated at the University Medical Center of Hamburg-Eppendorf at three different time periods: April to June 2019 (pre-COVID, cohort 1), April to June 2020 (COVID pandemic, cohort 2) and from April to June 2024 (post COVID, cohort 3). Patient Health Questionnaire-4 (PHQ-4) was used to diagnose depression and anxiety on admission. Demographic characteristics were extracted from patients electronical medical file. Patients with a history of mental disorders were excluded from the study.
Results: A total of n = 603 patients were analyzed, n = 294 with LC (cohort1/2/3: n = 110/129/55), n = 309 without any liver disease (non-LD; cohort 1/2/3: n = 104/101/104), n = 238 (40%) were female, median age 61 years (range: 18–94). In cohort 1, the prevalence of depression was 3.6% in LC patients and 2.8% in non-LD patients (p = 0.75), in cohort 2 it was 19% vs. 3.9% (p > 0.005), and in cohort 3 it was 3.5% vs. 2.8% (p = 0.81). The rate of anxiety was 4.5% in LC patients vs. 1% in non-LD patients (p = 0.11) in cohort 1, 21% vs. 3.9% (p > 0.0002) in cohort 2, and 1.8% vs. 1.9% (p = 0.9) in cohort 3. In a multivariate analysis that included age, gender, presence of LC, liver function, and exposure during the pandemic, only exposure was a significant risk factor for depression (OR: 4.6, 95% CI: 1.6–17.2; p = 0.03). For anxiety, higher age (OR: 1.05, 95% CI: 1.0–1.1; p = 0.04) and exposure to COVID (OR: 6.4, 95% CI: 1.8–29.3; p = 0.006) were significant risk factors.
Conclusion: In the pre-COVID era, the prevalence of depression and anxiety was comparable in LC and non-LD patients, but the COVID pandemic significantly increased the prevalence of both disorders only in LC patients, underlining the vulnerability of these patients to external stressors. Although the prevalence decreased in the post-pandemic period, these findings highlight the need for early psychological screening and targeted mental health interventions for patients with end-stage liver disease during future pandemics or other global health crises.

SAT-154

A metagenomics approach to frailty in patients with cirrhosis undergoing a multifactorial intervention

Email: gsoriano@santpau.cat

Background and aims: Frailty is a relevant prognostic factor in patients with cirrhosis, independently of the degree of liver failure. In a previous study, we observed an improvement in frailty and a decrease in emergency room consultation and falls in patients with cirrhosis during a multifactorial programme consisting of home-exercise, branched-chain amino acids and a multistrain probiotic. The aim was to study the fecal microbiota composition associated with frailty and its improvement in patients with cirrhosis.
Method: We analyzed fecal samples of 24 outpatients with cirrhosis included in a previous study (Román, Hepatol Commun 2024). Frailty was assessed by the Liver Frailty Index (LFI). Frail and prefrail patients (n = 22) were randomized to the multifactorial intervention (home-exercise, branched-chain amino acids and a multistrain probiotic) or control for 12 months. At baseline and at 12 months, we determined LFI, gait speed, fecal microbiota composition by metagenomic shotgun sequencing, and a battery of biomarkers in serum samples. A group of 15 age and gender-matched healthy controls was also included.
Results: Patients with cirrhosis showed a lower alpha diversity than controls. At baseline, the main differences between patients with cirrhosis and controls were increases in the abundance of Anaerotruncus massiliensis, Enterocloster bolteae, Streptococcus parasanguinis, Dialister invisus, Ruminococcus gnavus, Clostridium scindens, and 3 different Veillonella species in cirrhosis samples. In patients with cirrhosis, there was a positive correlation between the abundance of Rothia dentocariosa and LFI, and between Bacteroides faecis and gait speed. Streptococcus thermophilus showed a negative correlation with IL-6 and Lactobacillus acidophilus a positive correlation with mtDNA. Veillonella parvula and Veillonella dispar abundances positively correlated with ccK18. After the multifactorial intervention, LFI and gait speed improved, and the main changes in the microbiota composition were a decrease in the abundance of Akkermansia muciniphila, and an increase in Streptococcus thermophilus, Lactobacillus acidophilus and several species of Bifidobacterium.
Conclusion: Frailty in patients with cirrhosis was associated with a distinct microbiome signature that correlated with biomarkers of inflammation, mitochondrial dysfunction and liver damage. After a long-term multifactorial intervention, frailty improved in parallel with changes in microbiome composition. These results provide information useful to identify new therapeutic targets to improve frailty and its consequences in patients with cirrhosis.

SAT-155
Reduced COVID-19 vaccination effectiveness and clinical outcomes for decompensated cirrhosis: a nationwide population-based study

Won Sohn[1], Jae Yoon Jeong[2], Hyunwoo Oh[1], Jung Hee Kim[3], Ju-Yeon Cho[4], Yong Kyun Cho[1], Byung Ik Kim[1]. [1]*Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South;* [2]*Ewha Womans University College of Medicine, Seoul, Korea, Rep. of South;* [3]*Hallym University Dongtan Sacred Heart Hospital, Dongtan, Korea, Rep. of South;* [4]*Chosun University Hospital, Gwang-Ju, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: This study investigated the effectiveness of coronavirus disease 2019 (COVID-19) vaccination in decompensated cirrhosis.
Method: This study comprised a population-based cohort of 1,583,777 patients with chronic liver disease (CLD) including decompensated cirrhosis, from the National Health Insurance Service data in the Republic of Korea. The primary outcome was the risk of COVID-19 infection within 6 months after vaccination between 26 February 2021 and 31 December 2021. Hospitalisation and all-cause mortality rates were also investigated. Target trial specifications with propensity score matching were used to minimise the bias between the unvaccinated and vaccinated groups.
Results: The mean age of patients was 54.2 years and 54.5% of them were men. In total, 61,765 patients (3.9%) had decompensated cirrhosis. Compared to the unvaccinated group, the vaccinated group exhibited a lower risk of COVID-19 infection (hazard ratio [HR] = 0.94; 95% confidence interval [CI] = 0.91–0.97), hospitalisation (HR = 0.86; 95% CI = 0.83–0.89), and all-cause mortality (HR = 0.27; 95% CI = 0.20–0.36). However, there was no beneficial effect of the COVID-19 vaccination on the clinical outcomes of patients with decompensated cirrhosis. The multivariable analysis determined that COVID-19 vaccination reduced all-cause mortality (HR = 0.39; 95% CI = 0.32–49) in CLD and decompensated cirrhosis increased all-cause mortality in patients with COVID-19 infection (HR = 2.94; 95% CI = 2.15–4.02). These results were consistent during the pre-Delta and Delta-variant periods.
Conclusion: COVID-19 vaccination reduced the risk of COVID-19 infection, hospitalisation, and mortality in patients with CLD. However, patients with decompensated cirrhosis had a poor prognosis and diminished vaccination effectiveness. Early detection and antiviral treatment are warranted to manage COVID-19 infection effectively in patients with decompensated cirrhosis.

SAT-156
Role of renal biomarkers on sarcopenia and frailty in patients with cirrhosis

Won Sohn[1], Hyunwoo Oh[1], Jung Hee Kim[2], Ju-Yeon Cho[3], Jae Yoon Jeong[4], Yong Kyun Cho[1], Byung Ik Kim[1]. [1]*Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South;* [2]*Hallym University Dongtan Sacred Heart Hospital, Dongtan, Korea, Rep. of South;* [3]*Chosun University Hospital, Gwang-Ju, Korea, Rep. of South;* [4]*Ewha Womans University College of Medicine, Seoul, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: Sarcopenia and frailty are the risk factors for poor prognosis in patients with liver cirrhosis. This study was to investigate the role of renal biomarkers on sarcopenia and frailty in patients with cirrhosis.
Method: A total of 78 cirrhotic patients with serum creatinine < 1.5 mg/dL were analyzed with serum renal biomarkers (creatinine-to-cystatin C ratio, IL-18, KIM-1, and NGAL), sarcopenia, and liver frailty index (LFI). Sarcopenia was defined as a skeletal muscle index less than 36.54 cm^2/m^2 (male) and 30.21 cm^2/m^2 (female), respectively. LFI composed 3 performance-based tests (grip strength, chair stands, and balance). Frailty was categorized as frail (LFI >4.5), prefrail (LFI 3.2–4.5), or robust (LFI < 3.2). We analyzed the risk of sarcopenia and frailty according to a variety of renal biomarkers in patients with cirrhosis.
Results: The mean age was 59.2 years and females was 32%. Child-Pugh class A and B were 82% and 18%, respectively. Sarcopenia, prefrail, and frail were observed in 43 patients (55.1%). There was no significant difference in serum IL-18 (205.8 vs. 236.7 pg/mL, p = 0.285), NGAL (110.8 vs. 104.3 ng/mL, p = 0.537), and KIM-1 (224.6 vs. 250.5 pg/mL, p = 0.482) according to sarcopenia and frailty. However, serum creatinine-to-cystatin C ratio was significantly lower in

patients with sarcopenia and frailty compared to no sarcopenia and frailty (0.73 vs. 0.83, p = 0.002). A univariable analysis showed that sarcopenia and frailty were associated with age ≥60 years [odds ratio (OR) 2.42, p = 0.06], female (OR 2.88, p = 0.043), Child-Pugh class B (OR 14.73, p = 0.012), and creatinine-to-cystatin C ratio < 0.8 (OR 5.59, p = 0.001). A multivariable analysis indicated that the risk factors for sarcopenia and frailty were Child-Pugh class B (OR 9.04, p = 0.044), and creatinine-to-cystatin C ratio < 0.8 (OR 4.03, p = 0.008). Serum IL-18, NGAL, and KIM-1 were not associated with sarcopenia and frailty.
Conclusion: Serum creatinine-to-cystatin C ratio is associated with an increased risk of sarcopenia and frailty in cirrhotic patients with favorable renal function.

SAT-157

Identification of sarcopenia in patients with liver cirrhosis by combining anthropometry and ultrasound of thigh and psoas

Isabel Campos-Varela[1], Carlos Céspedes[2], Ester Palacio[2], Sergi Quiroga[2], Nuria Roson[2], Elena Vargas-Accarino[3], Macarena Simón-Talero[2], Victor Vargas Blasco[2], Lluis Castells[2]. *[1]Hospital Universitary Vall d'Hebron, Barcelona, Spain; [2]Hospital Universitary Vall d'Hebrón, Barcelona, Spain; [3]Hospital Universitary Vall d'Hebrób, Barcelona, Spain*
Email: icamposvarela@gmail.com

Background and aims: The gold standard for the diagnosis of sarcopenia in patients with cirrhosis is the evaluation of the skeletal muscle index (SMI) at the level of the third lumbar vertebra. We aimed at evaluating the usefulness of other techniques other than SMI for the diagnosis of sarcopenia in patients with cirrhosis.
Method: Unicentric prospective study. Patients with cirrhosis who underwent an abdominal computed tomography (CT) for any reason (June/2020–April/2024) were included. Sarcopenia was defined as SMI<39 cm^2/m^2 in women and < 50 cm^2/m^2 in men. Sarcopenia was evaluated by means of anthropometry, bioimpedance (BIA) and ultrasonography of thigh and psoas muscle. Thigh muscle thickness index (TMTI) and psoas muscle thickness index (PMTI) were measured. Thigh elastography was also measured. Biochemical markers were evaluated.
Results: 250 cirrhotics were included (74.4% men), median age 62 years. Pugh Child (A: 44.2%; B: 42.4%, C: 13.3); 43% with ascites. Sarcopenia was present in 95 (38%) patients (42% men vs. 27% women, P = 0.03). Median TMTI was lower in sarcopenic patients 0.89 cm/m^2 (IQR, 0.72–1.06) vs. 1.13 cm/m^2 (IQR, 0.95–1.33), P < 0.001. Median PMTI was lower in sarcopenic patients 1.16 cm/m^2 (IQR, 1.04–1.27) vs. 1.38 cm/m^2 (IQR, 1.17–1.51), P < 0.001. Regarding anthropometric evaluation, all measures were lower in sarcopenic patients (P < 0.05). Skeletal appendicular mass, body cell mass, body protein mass and muscle compartment evaluated by BIA were lower in sarcopenic patients (P < 0.05). Phase angle (PhA) was lower in sarcopenic patients, without statistical significance (P = 0.06). In the PhA segmental analysis, the right arm (P < 0.001) and the right leg (P = 0.002) were different in patients with sarcopenia. In patients with ascites only the PhA segmental analysis of the right leg was different (P = 0.03). The prevalence of myosteatosis by CT was higher in sarcopenic patients (55% vs. 41%. P = 0.03) and thigh elastography was not different (P = 0.52). In the univariate analysis, the significant measures for identifying sarcopenia for the entire cohort and by sex and with an AUROC >0.700 were: body mass index (BMI), calf and thigh circumferences, TMTI and PMTI. These were included in the multivariate analysis and a model was generated, which showed an AUROC of 0.839 (95% CI, 0.789–0.890). Other simpler models were designed, with 3 variables (BMI, calf circumference and TMTI or PMTI) with AUROC values of 0.819 and 0.812, respectively. There were no differences between both (P = 0.43). Nomograms were developed with the models of 3 variables. TMTI and PMTI cutoff points were evaluated for the diagnosis of sarcopenia.
Conclusion: Thigh and psoas muscle ultrasound combined with anthropometry are excellent alternatives for the evaluation of sarcopenia in patients with cirrhosis and could be an alternative to SMI for the identification of sarcopenia in those patients.

SAT-158

Factors predicting response to long-term albumin administration and impact on survival in patients with decompensated cirrhosis. A single-centre real-world experience

Isabel Payeras[1], Ana Clemente[2], María Sasía[1], Luis Alberto Pérez[1], Adriana Ahumada, Diego Rincón[2], Magdalena Salcedo[2], Ana Matilla[3], Rafael Bañares[2], Sonia Alonso Lopez[2]. *[1]Liver Unit, Department of Gastroenterology, Hospital General Universitario Gregorio Marañón, Madrid, Spain, Madrid, Spain; [2]Liver Unit, Department of Gastroenterology, Hospital General Universitario Gregorio Marañón, Madrid, Spain, Instituto de Investigación Sanitaria Gregorio Marañón (IiSGM), Madrid, Spain, Centre for Biomedical Research in Liver and Digestive Diseases Network (CIBERehd), Madrid, Spain, Madrid, Spain; [3]Liver Unit, Department of Gastroenterology, Hospital General Universitario Gregorio Marañón, Madrid, Spain, Instituto de Investigación Sanitaria Gregorio Marañón (IiSGM), Madrid, Spain, Madrid, Spain*
Email: isabel.payeras@salud.madrid.org

Background and aims: Although controversial, long-term albumin administration in patients with decompensated cirrhosis is very common. However, its efficacy in real clinical practice is not fully elucidated. We aimed at evaluating the efficacy of chronic albumin infusion and predictors of clinical response in this outpatient setting population.
Method: The cohort was comprised of all consecutive patients with decompensated cirrhosis under chronic albumin infusion [n = 69; (84% men); age 62 (9.9) years; etiology: (alcohol 33%, MASLD 8.7%, MetALD 15.9%, viral 14.5%, mixed 11.6%, other 15.9%); Median MELD: 16 (IQR:12–20)]. The indications were ascites [grade 2 or 3 (63.2%), refractory (23.5%)], hyponatremia (2.9%), and type 2 hepatorenal syndrome (2.9%). Twenty-eight patients (39.1%) had prior history of hepatocellular carcinoma (HCC) and nearly 64% had tumoral progression at baseline or throughout follow-up. Median treatment duration and albumin dose were 12 weeks (IQR: 6–27) and 30 g/week (IQR: 20–40), respectively. Clinical response (CR) was defined as i) decrease of number of paracentesis/thoracentesis, ii) natremia correction, iii) improvement in renal function. CR was achieved in 35 patients (50. 7%).
Results: Age, etiology, prior HCC and serum albumin >3.4 g/dl during treatment were associated with CR in univariate analysis. In multivariate analysis, only the absence of progressive HCC [OR: 25.35 (CI 95% 2.99–215.05)] and albumin >3.4 g/dl after one month of treatment [OR: 4.13 (CI 95% 1.27–13.46)] were associated with CR. Transplant or TIPS-free survival was significantly higher in responders compared with non-responders, regardless of the history of HCC (p-value log-rank test < 0.05). Heart failure occurred in 6 patients (8.7%), all with HCC (21.4% vs 0%; p = 0.008).
Conclusion: Clinical response to albumin administration in patients with decompensated cirrhosis is associated with significantly higher survival. Serum albumin concentration after 30-days is an early predictor of response allowing for therapy adjustment and resources optimization. The presence of HCC, especially if progressive, is associated with lower clinical response and higher risk of complications.

SAT-159

Increasing 'Liver Frailty Index' scores are associated with increased mortality and unplanned hospital admission in patients with cirrhosis: a retrospective cohort study

Isobel Phillips[1], Andrew Yeoman[1]. *[1]Gwent Liver Unit, Newport, United Kingdom*
Email: isobel.phillips2@wales.nhs.uk

Background and aims: The Liver Frailty Index (LFI) aims to identify cirrhosis-related sarcopenia and functional decline: increased LFI has

been associated with excess mortality in those patients awaiting transplant. It has also been shown to predict decompensation and admissions. At present, the evidence for its use is predominantly for transplant waitlist patients and further studies are required to validate the LFI for use in a 'non-transplant' cohort of patients with cirrhosis.
Method: LFI scores were routinely calculated in the outpatient liver clinic by a Hepatology nurse specialist. Hospital admissions in both the year before and after the point in time the LFI score was calculated were reviewed as was all-cause mortality rates from time of LFI to notes review.
Results: In total, LFI scores were calculated for 259 patients. Scores were 'frail' in 16% (n = 42), 'pre-frail' in 62% (n = 161) and 'robust' in just 22% (n = 56). Average number of unplanned hospital admissions in the 12 months prior to the LFI being obtained for frail, pre-frail and robust patients was 1.29 (0–10), 0.37 (0–4) and 0.14 (0–2) respectively. For the 12 months following the LFI, these figures were 1.09 (0–8), 0.64 (0–6) and 0.18 (0–3) respectively. At up to 36 months, all-cause mortality was 19% (n = 49) being 40% (n = 17) of frail patients, 16% (n = 25) in pre-frail patients and 13% (n = 7) among robust patients. Average number of months until death was 13 (3–34) in the frail cohort, 20 (4–39) in pre frail patients and 18 (4–38) in robust patients.
Conclusion: Higher LFI scores are associated with increased mortality and increased hospital admissions in the pre frail cohort. This data demonstrates the utility of LFI to predict adverse outcomes in a predominantly non-transplant listed cirrhosis cohort.

SAT-160
Phase angle as a predictive factor for mortality in hospitalized patients with cirrhosis
Fajardo Ordóñez Javier[1], Jordi Sánchez[2], Eva Roman[3,4], Mireia Miquel[2], Naujot Kaur[3], José Ferrusquía-Acosta[2], Maria Poca[1,4], Cristina Solé[2], Berta Cuyàs[1,4], Meritxell Casas[2], Edilmar Alvarado-Tapias[1,4], Teresa Monllor-Nunell[2], Alforcea Sheila[2], Ferrero Andreu[1], Anna Brujats[1], Mercedes Vergara[2], Àngels Escorsell[3], German Soriano[1,4]. *[1]Department of Hepatology, Hospital de la Santa Creu i Sant Pau., Barcelone, Spain; [2]Department of Hepatology, Corporació Sanitària Parc Taulí., Sabadell, Spain; [3]Department of Hepatology, Hospital de la Santa Creu i Sant Pau., Barcelona, Spain; [4]Centro de Investigación Biomédica en Red en Enfermedades Hepáticas y Digestivas (CIBEREHD), Instituto de Salud Carlos III (ISCIII), Madrid, Spain*
Email: javierfajardoordonez@hotmail.com

Background and aims: Phase angle (PA) measured by bioelectrical impedance analysis (BIA) is a valuable tool for assessing body composition, frailty, and prognosis in patients with chronic diseases, including cirrhosis. Most studies on PA in cirrhosis have focused on outpatient populations, with limited data available on hospitalized patients. The objective of this study was to assess the usefulness of PA in predicting adverse events (mortality, readmissions, and falls) in hospitalized patients with cirrhosis.
Method: Consecutive patients admitted with decompensated cirrhosis to the hepatology ward of two hospitals were included. PA was measured by BIA at admission, and patients were followed prospectively for one year to monitor the occurrence of death, readmissions, and falls.
Results: A total of 109 patients were included, with a mean age of 62 ± 11 years, 77% were male, and 69% with alcohol-related liver disease as the cause of cirrhosis. The mean MELD score was 15.7 ± 5.3. Ascites was the most common reason for hospitalization (58%). During a follow-up period of 265 ± 122 days, 33/109 (30.3%) patients died, 61/109 (56%) required at least one readmission, and 25/109 (23%) experienced one or more falls. Patients with a PA ≤4 (n = 47) had a significantly higher risk of mortality (adjusted for liver transplantation as a competing risk) during follow-up than patients with PA>4 (47% vs. 21%, p = 0.005). PA and the Charlson comorbidity index were identified as the independent predictive factors of mortality in the multivariable analysis (sHR 2.18, 95% CI 1.10–4.34, p = 0.026; and sHR 1.30, 95% CI 1.14–1.47, p < 0.001, respectively). However, PA did not show statistical significance in predicting readmissions or falls.
Conclusion: PA measured by BIA and the Charlson comorbidity index were the independent predictive factors of mortality during follow-up in patients with cirrhosis hospitalized in a hepatology ward. PA could serve as a useful tool for estimating prognosis in these patients.

SAT-161
Prevalence and prognosis of cirrhotic cardiomyopathy in hospitalized patients with decompensated cirrhosis
Cristina Solé[1], Judith Cortada[2], Francesca Castaldo[3], Jordi Sánchez[1], José Ferrusquía-Acosta[1], Meritxell Casas[1], Mireia Miquel[1], Mario Sutil[3], Laura Guillamón[3], Eva Guillaumet[3], Núria Casanovas[3], Andrés Ribas[3], Antonio Martínez[3], Mercedes Vergara[1]. *[1]Hepatology unit, Parc Taulí University Hospital, Parc Taulí research and innovation institute (I3PT-CERCA), Universitat Autonoma of Barcelona, CIBERehd, Sabadell, Spain; [2]Department of gastroenterology and hepatology, Parc Taulí University Hospital, Parc Taulí research and innovation institute (I3PT-CERCA), Universitat Autonoma of Barcelona, Sabadell, Spain; [3]Department of cardiology, Parc Taulí University Hospital, Parc Taulí research and innovation institute (I3PT-CERCA), Universitat Autonoma of Barcelona, Sabadell, Spain*
Email: csole@tauli.cat

Background and aims: Cirrhotic cardiomyopathy (CCM) is defined as cardiac dysfunction in patients with cirrhosis in the absence of pre-existing heart disease. Its prevalence and clinical implications remain controversial. This study aims to assess the prevalence of CCM, including both systolic and diastolic dysfunction, in patients with decompensated cirrhosis, and to investigate its correlation with prognosis.
Method: Retrospective analysis of a prospective cohort of hospitalized patients with decompensated cirrhosis from Parc Taulí Hospital (Barcelona) between October 2017 and January 2020. Clinical and laboratory data were collected at admission, and mortality, complications, and cardiac events within one year. Echocardiographic parameters obtained 3 months before or after inclusion were collected and reviewed by cardiologists.
Results: A total of 125 patients, predominantly male (77%), with alcohol-related cirrhosis (78%) were included. The median Child-Pugh and MELD score was 9 (7–10) and 15 (11–20), respectively. Among the entire cohort, 38 patients (30%) had an echocardiogram; six of these patients had pre-existing heart disease and were excluded from the analysis. No significant differences were found between those with and without an echocardiogram, except that the former had a higher incidence of acute kidney injury and hepatocellular carcinoma compared to the latter. The main indication for performing an echocardiogram was anasarca. Interestingly, no patient showed systolic dysfunction, either by LVEF (left ventricular ejection fraction) or GLS (global longitudinal strain). Nevertheless, 72% showed at least one parameter of diastolic dysfunction. Specifically, 9% had an E/e' ratio ≥15, 16% had a septal e' velocity < 7 cm/s or lateral e' velocity < 10 cm/s, 28% had a tricuspid regurgitation velocity (TRvel) >2.8 m/s, and 63% had a left atrial volume index (LAVI) >34 mL/m². A total of 16% met the criteria for CCM, although some echocardiographic data were lacking in 53% of patients. CCM was not associated with mortality, decompensation, or cardiovascular events. However, TRvel was associated with higher mortality, and LAVI >34 mL/m² with a higher risk of decompensation.
Conclusion: CCM is an underrecognized entity in clinical practice, with an estimated prevalence of 16% in decompensated cirrhosis. While no patients presented systolic dysfunction, 72% had at least one parameter of diastolic dysfunction, some of which were correlated with prognosis. Further studies are needed to better evaluate the clinical relevance of this condition.

SAT-162

Epidemiology and Risk factors for development of AKI-HRS based on the new consensus definition

Jeanette Pei Xuan Ng[1], Rahul Kumar[1], Jason Pik Eu Chang[2], Hiang Keat Tan[2], Marianne DeRoza, Chanda Ho[2], Yan Ling Ong[1].
[1]*Changi General Hospital, Singapore, Singapore;* [2]*Singapore General Hospital, Singapore, Singapore*
Email: jeanettengpx@hotmail.com

Background and aims: A new definition of AKI-HRS has recently been proposed by Acute Disease Quality Initiative (ADQI) and International Club of Ascites (ICA) for AKI. The main difference is addition of urine output and presence of pre-existing chronic kidney disease (CKD). The knowledge on epidemiology and risk factors for developing AKI-HRS based on the updated definition is limited. We aim to describe the epidemiology and risks factors for developing AKI-HRS.
Method: 288 inpatient admissions from Jan 2022 to March 2024 were included from an ongoing prospective study (REDUCE and SOLIDARITY-DAM). Retrospective data collection was carried out. Patients were categorized into those who developed AKI-HRS and those who did not (AKI-HRS (n = 57) Vs No AKI-HRS (n = 231)). Risks factors for the development of AKI-HRS was interrogated by standard statistical tests.
Results: The cohort mean age was 63.2 ± 10.1 years, BMI 25.6 ± 4.6 kg/m^2, majority were male (71.2%). MASLD/MASH was the most prevalent etiology of cirrhosis (39.2%) followed by alcohol (36.8%), viral (16.4%), and others (7.6%). AKI occurred in 83 (29%) of which 57 (19.7%) were classified as having AKI-HRS based on the updated definition. The updated definition allowed for an additional 16 (5.6%) patients to be classified as AKI-HRS. In patients who developed AKI-HRS, a higher proportion of MAFLD/MASH and lower of viral etiology was seen ($p = 0.043$). Patients with past decompensating events (hepatic encephalopathy, ascites), ischemic heart disease (IHD) and CKD developed AKI-HRS more frequently ($p < 0.05$). The use of diuretics and higher Child's-Pugh (CTP) score was associated with development of AKI-HRS. The use of non-selective betablockers was not associated with development of AKI-HRS. Patients with sepsis as a decompensating event developed AKI-HRS more often than variceal and non-variceal bleeding, alcoholic hepatitis, or HBV flare. No difference was observed in the preadmission creatinine, GFR, bilirubin, white cell count, markers of inflammation like neutrophil to lymphocyte ratio or platelet to lymphocyte ratio (p = NS for all). In the univariate analysis male gender ($p = 0.010$), decompensated cirrhosis ($p = 0.005$) (HE < 0.001) and Ascites ($p < 0.001$)), IHD ($p = 0.046$), use of diuretics ($p < 0.001$) and preadmission CTP score ($p < 0.001$) were significant predictors of development of AKI-HRS whereas CKD or current decompensating events were not (p = NS for both). In the multi-variate model, CTP score and IHD were significant predictors for the development AKI-HRS.
Conclusion: Preadmission CTP score and IHD independently predicts the development of AKI-HRS whereas markers of systemic inflammation and sarcopenia did not in this cohort.

SAT-163

Factors associated with AKI development and external validation of the AKI prediction score

Jeanette Pei Xuan Ng[1], Yan Ling Ong[1], Rahul Kumar[1], Nazia Chowdhury[1], Hiang Keat Tan[2], Marianne DeRoza[3], Chanda Ho[2], Jason Pik Eu Chang[2], Sakktivel Elangovan[1]. [1]*Changi General Hospital, Singapore, Singapore;* [2]*Singapore General Hospital, Singapore, Singapore;* [3]*Sengkang General Hospital, Singapore, Singapore*
Email: jeanettengpx@hotmail.com

Background and aims: Acute kidney injury (AKI) portends a worse prognosis in cirrhotics, and is associated with an higher morbidity, mortality and progression to chronic kidney disease. Early identification of patients who may develop AKI is important to mitigate the risk of development of AKI and improve outcomes. Higher MELD and Child Pugh score, low serum albumin and higher bilirubin levels are risk factors for development of AKI. The AKI prediction score was developed to predict AKI in cirrhotic patients, but it has not been externally validated, limiting its broader applicability. The aim of this study is to find out the predictors of AKI development in patients with cirrhosis and to examine the "AKI prediction score" by Patidar et al for external validation and wider applicability. Our other goal was to obtain a cut off score for MELD and MELD-Na to predict the risk of developing AKI.
Method: Patients for this study were recruited from our ongoing multicenter prospective study of "predictors of decompensation, ACLF and mortality in cirrhosis" (SoLiDaRity-DAM). A total of 294 inpatient admissions from Jan 2022 to March 2024 were included in the analysis. Cirrhosis was defined based on histology, biochemical or radiological investigations. AKI was defined as an increase in serum creatinine (SCr) ≥0.3 mg/dL within 48 hours or a percentage increase in SCr ≥50% from baseline as per KDIGO definition. Standard statistical tests were applied for group comparison and predictors of AKI was analyzed using cox-proportional hazard regression. ROC curves were analysed for statistical differences with Delong's test. Optimal cut off values were identified by maximization of Youden's index.
Results: The mean age of cohort was 63.2 ± 10.1 years, majority being male (71.0%). Alcohol was the most common etiology for cirrhosis (32.2%) followed by Metabolic dysfunction-associated liver disease (27.4%), viral hepatitis (22.6%) and other causes. The published AKI prediction score had an AUC of 0.7368 (95% CI: 0.6429–0.8307), while MELD had an AUC of 0.7265 (95% CI: 0.6342–0.8189), and MELD-Na had an AUC of 0.7066 (95% CI: 0.6105–0.8027). Although the AKI prediction score had the numerically highest AUROC, there was no statistically significant difference between the 3 ROC curves. DeLong's test for the two correlated ROC curves for the AKI prediction score, MELD, and MELD-Na showed a Z value of 0.56441 and a p-value of 0.5725. In our cohort, the optimal cutoff values for predicting AKI were determined as follows: an AKI prediction score of −2.01 (specificity 0.745, sensitivity 0.649), MELD of 18 (specificity 0.700, sensitivity 0.702), and MELD-Na of 23 (specificity 0.721, sensitivity 0.649).
Conclusion: A MELD cutoff of 18 and MELD-Na of 23 predict patients with decompensated cirrhosis at risk for AKI. The AKI prediction score had an AUROC of 0.7368 in our population. Utilization of the MELD, MELD-Na, and AKI prediction scores can aid in the early identification of patients at risk for AKI, helping to reduce the likelihood of its development.

SAT-164

Periodontal diseases in cirrhosis: prevalence, microbiome profile and dental assessment safety and tolerability

Ji Jade King[1], Naiwen Tan[2], Mohammed Alqarzaee[2], Joseph Ali[3], Alastair O'Brien[3], Dave Spratt[2], Francesco D'Aiuto[2], Louise China[3].
[1]*University College London, Institute of liver and digestive health, London, United Kingdom;* [2]*UCL Eastman dental institute, London, United Kingdom;* [3]*University College London, London, United Kingdom*
Email: jijadeking@gmail.com

Background and aims: Social determinants of health and healthcare practitioners' concerns about risk of cirrhosis represent major barriers to dental care access for liver patients. We compared prevalence of periodontal disease and microbiome profiles between cirrhotic patients (PTs) and healthy volunteers (HVs). Safety of oral assessments, perception of oral health and barriers to receiving dental care were also investigated.
Method: Adults with liver cirrhosis attending the Royal Free Hepatology Clinic were invited to participate. HVs were either patients' relatives or medical staff. Subgingival dental plaque samples were collected from 27 PTs and 24 HVs. DNA was extracted and processed with high-throughput sequencing technology (Illumina). Alpha and Beta diversity tests were performed to ascertain

similarities across samples and bacteria communities. Linear discriminant analysis effect size (LEfSe) was used to identify most prevalent taxa between the groups. A qualitative questionnaire was administered to all participants pre and post dental screening and answers were compared (Fisher). PTs received telephone follow-up at 1 week.
Results: 25/27 PTs had never experienced previous barriers to dental care, 1 did not answer and 1 found obstruction due to bleeding risk. Mean age differed significantly between the groups (57 PTs vs 35 HVs, $p < 0.0001$). On microbiome analysis, PTs exhibited a reduced presence of microbial species on alpha-diversity indices, with higher abundance of Lactobacillus and Limosilactobacillus and lower abundance of Cardiobacterium, Neisseria, Lautropia and Corynebacterium at phylum level ($p < 0.001$).
There were no differences between groups in time since last dental visit or deep clean, number of alcohol units per week, smoking history and frequency of flossing and mouthwash. PTs more frequently perceived to suffer from gum disease (40.7% vs 12.5%, $p = 0.01$), to have a "tooth that doesn't look right" (66.7% vs 20.8%, $p = 0.002$), and were more often diagnosed with periodontitis at our assessment (74% vs 17%, $p < 0.0001$). After the assessment, there was no substantial difference in occurrence of gum bleeding, infection and reported experience, compared to controls. 1 week later, 1 PT reported gum bleeding after leaving the hospital and 1 reported persistent gum discomfort.
Conclusion: Our cohort of cirrhotic patients had higher prevalence of periodontitis and lower microbial diversity than healthy controls, with distinct differences in subgingival microbiome, which may reflect a link between periodontal and liver health. There were no major immediate complications and no significant difference in reported experiences when cirrhosis patients were compared to HVs. Further studies evaluating the long-term safety and impact of periodontitis management are required to confirm our findings.

SAT-165

Oral health and microbiome: do they influence cirrhosis outcomes? A comparison of cirrhotic patients with periodontitis versus those with good oral health

Ji Jade King[1], Naiwen Tan[2], Mohammed Alqarzaee[2], Joseph Ali[1], Alastair O'Brien[1], Dave Spratt[2], Francesco D'Aiuto[2], Louise China[1].
[1]University College London, London, United Kingdom; [2]UCL Eastman dental institute, London, United Kingdom
Email: jijadeking@gmail.com

Background and aims: The role of gut translocation of bacteria in triggering systemic inflammation and predisposing to infective episodes in patients with liver disease is increasingly acknowledged. However, little is known about the relationship between periodontal health and risks of complications from cirrhosis. We assessed oral microbiomes and clinical outcomes of a cohort of cirrhotic patients undergoing a dental screening for periodontal disease.
Method: Adults with cirrhosis attending the Royal Free Hepatology Clinic who were able to travel, with no severe bleeding disorder, not pregnant and >10 teeth were invited to participate if able to consent. 27 participants underwent a 30-minute periodontal screening, followed by orthopantomogram and baseline biochemistry. DNA was extracted from subgingival samples and processed with high-throughput sequencing technology (Illumina). Alpha and Beta diversity tests were performed to ascertain similarities across samples and bacteria communities. Linear discriminant analysis effect size (LEfSe) was used to identify most prevalent taxa. Follow-up by case note review was performed at 1, 3 and 6 months and compared with Fisher exact test.
Results: 20 (74%) patients were diagnosed with periodontitis (P) at assessment, while 7(26%) were healthy (H). Patients with cirrhosis and periodontitis had significantly higher MELD (median MELD 12 vs 8, $p = 0.009$). Within the microbiome, there was no difference in alpha-diversity, but the P group had higher Beta-diversity on Unweighted UniFrac method and significantly lower abundance of Fusobacterium (genus level) on LEfSe. At 1 and 3-months follow-up, some patients from P group were admitted to hospital (5, 25% at 1-month; 1, 5% at 3-months), developed HE (2, 10% at 1- and 3-months) and variceal bleed (1, 5% at 1- and 3-months), compared to none in the H group. In the P group, new infection was seen in 6 (30%) patients at 1-month, 3 (15%) at 3-months, and 1 (5%) at 6. At 6 months, 2 (10%) Ps were inpatients and 2 (10%) had died, while all 7 (100%) Hs were outpatients.
Conclusion: Our study showed that most cirrhotic patients had periodontitis and that compared to those with no periodontitis their clinical outcomes were overall poorer, though numbers were too small to reach statistical significance. The severity of liver disease was also worse in those with periodontitis, which may explain more unfavourable outcomes. The periodontitis group had higher microbiome diversity and lower abundance of Fusobacteria. Further analysis is needed to elicit the prevalence of pathogenic species in each group. Main limitations to the interpretation of these results were sample selection bias, single-arm design, and small sample size. Further studies with larger randomised cohorts are required to confirm our conclusions.

Use of light-EEG to rule out covert hepatic encephalopathy in advanced chronic liver disease

Juliana Goediker[1], Isabel Korte[2], Johannes Chang[2], Abu-Omar Jasmin[2], Luisa Klotz[3], Sara Noemi Reinartz Groba[1], Markus Kimmann[1], Silvia Letmathe[1], Jörn Arne Meier[1], Jonel Trebicka[1], Michael Praktiknjo[1]. *[1]Department of Internal Medicine B, University Hospital Muenster, Muenster, Germany; [2]Department of Internal Medicine I, University Hospital Bonn, Bonn, Germany; [3]Department of Neurology, University Hospital Muenster, Muenster, Germany*
Email: michael.praktiknjo@ukmuenster.de

Background and aims: Hepatic encephalopathy (HE) is a common and severe complication of advanced chronic liver disease (ACLD), adversely affecting patient morbidity, mortality and quality of life. Early detection of minimal HE (MHE) is crucial for overall prognosis. Current diagnostic methods, including neuropsychometric tests and standard electroencephalography (EEG), are limited by accessibility, patient compliance, and resource constraints. This study aimed to evaluate the diagnostic accuracy of a low-cost, portable, and user-friendly light EEG system for ruling out MHE in patients with ACLD.
Method: A total of 97 patients with ACLD (60% alcohol-associated liver disease; 40% other etiology) or non-cirrhotic portal hypertension were prospectively included. Light-EEG recordings were performed, and spectral analysis identified parameters such as mean dominant frequency and power across δ, θ, α, and β bands. MHE diagnosis was based on neuropsychometric tests, including Number Connection Test and Critical Flicker Frequency. Receiver operating characteristics (ROC) were analyzed to determine ß-activity cut-offs for ruling in and ruling out MHE.
Results: A history of overt HE was present in 18% (n = 17) of the cohort and 64% (n = 62) presented with decompensated ACLD (21% variceal bleeding and 43% ascites). Patients with HE demonstrated significantly reduced β-activity in the temporo-occipital (10.0% vs. 14.8%) and parietal regions (10.4% vs. 16.9%) compared to those without HE ($p < 0.01$). A β-activity cut-off of < 6.1% was highly specific (100%) for ruling in MHE, while a cut-off of >22.9% was highly sensitive (100%) for ruling it out.
Conclusion: Light-EEG is a simple, reliable, and cost-effective alternative to standard EEG, enabling effective MHE exclusion in ACLD patients. Notably, the light EEG system achieved these results without requiring extensive training or patient cooperation, highlighting its practicality for clinical use.

SAT-167

Obesity decreases liver-related death in patients with cirrhosis: a retrospective, propensity score-matched study

Kei Endo[1], Takuya Watanabe[1]. [1]*Iwate Medical University School of Medicine, Yahaba, Japan*
Email: keiendo@iwate-med.ac.jp

Background and aims: The association between obesity and mortality in patients with cirrhosis remains controversial, probably due to the obscure criteria for obesity.
Method: This retrospective observational study enrolled 499 patients without hepatocellular carcinoma (HCC). The patients were evaluated for obesity during the subsequent 8-year follow-up period. Obesity was defined as a body fat percentage of ≥25.8% for men and ≥36.5% for women, as measured using a bioelectrical impedance analysis. After propensity score matching (PSM) was adjusted for age, sex, etiology, and severity of liver disease, 197 patients were assigned to either the obese or non-obese group. The prognostic impact of obesity in patients with cirrhosis was evaluated by differentiating between liver-related and non-liver-related deaths. All subsequent analyses used post-PSM data.
Results: The median observation period was 4.1 years. In both the obese and non-obese groups, there were 110 males (55.8%) with a median age of 68 years old. Sarcopenia was more common in the non-obese group than in the obese group (P < 0.01). A total of 113 patients died, and 3 patients underwent liver transplantation during the follow-up period. Of the 113 deceased patients, 66 died of liver-related events, and the remaining 47 died of non-liver-related events. The cumulative incidence of liver-related deaths was significantly higher in the non-obese group than in the obese group (P = 0.02), while there was no significant difference in the cumulative incidence of non-liver-related deaths between the obese and non-obese groups (P = 0.73). Multivariate competing risk analyses revealed that a non-viral etiology (hazard ratio [HR] 8.29; 95% confidence interval [CI], 2.99–22.9), decompensated cirrhosis (HR 6.12; 95% CI, 3.36–11.2), sarcopenia (HR 2.47; 95% CI, 1.21–5.04) and obesity (HR 0.49; 95% CI, 0.26–0.94) were independently associated with liver-related death. Among patients with a non-viral etiology, female patients, and patients with decompensated cirrhosis, the cumulative incidence of liver-related death was significantly higher in non-obese patients than in obese patients (P < 0.01, 0.03, and < 0.01, respectively).
Conclusion: Obesity decreased liver-related death in patients with cirrhosis, particularly in female patients, patients with a non-viral etiology, and patients with decompensated cirrhosis.

Email: jcarrion@psmar.cat

Background and aims: Postoperative mortality risk is higher in patients with advanced chronic liver disease (ACLD). However, the most recent score (VOCAL-Penn) seems to have lower accuracy in European patients [Canillas L. et al.; JCM2023]. The aim was to assess variables related to 90-day postoperative mortality in elective and emergent surgeries.
Method: Multicentric study including major surgeries (2010–2023) from 5 Spanish Hospitals in patients with ACLD according to 1) transient elastography >15 kPa, 2) thrombocytopenia and splenomegaly, 3) nodular liver surface, and 4) esophageal varices. Cox regression analyses were performed to identify predictors of mortality based on the type and urgency of surgery, comorbidities, liver function, and radiological or endoscopic signs of portal hypertension.
Results: We show the preliminary data (N = 2,031). The median age was 69, and 68.4% (n = 1,390) were men. Most of etiologies were alcohol (48.3%) and viral (32.6%). Emergent surgery was performed in 760 (37.4%) patients. Surgeries were abdominal (39.7%), orthopedic (21.8%), and abdominal wall (20.2%). Mortality at 90 days was 10.2% (n = 208) (18.4% in emergent and 5.4% in elective, p < 0.01). Surgeries were grouped by mortality in group 1 [abdominal wall (6.1%), abdominal-laparoscopic (5.8%) and vascular (7%) surgeries], group 2 [major orthopedic (10.2%) and cardiothoracic (11.2%)], and group 3 [abdominal-open (19.1%) and others (13.8%)]. In elective surgeries, mortality was significantly related to type of surgery (2.6% in group 1, 7.2% in group 2, and 9% in group 3), age (73 vs. 69 years), ASA-IV (42.6% vs. 10.6%), diabetes (47.1% vs. 31.8%), atrial fibrillation (20.9% vs. 9.6%), ascites (25.4 vs. 8.2%), and values of bilirubin (1.2 vs. 0.8 mg/dl), albumin (4.4 vs 4.2 g/dl), sodium (137 vs. 140 mmol/L) and platelets (96 vs. $131 \cdot 10^9$/L). Variables independently associated with mortality [HR (95% CI)] were surgery [group 1 (ref.), group 2: 2.1 (1.1–4.1), group 3: 4.0 (2.0–7.7)], age [1.0 (1.0–1.1)], bilirubin [1.1 (1.0–1.2)], ASA-IV [9.3 (2.1–40.7)], and ascites [2.4 (1.2–4.9)]. In emergent surgeries, mortality was significantly related to type of surgery (12.6% in group 1, 16.4% in group 2, and 29.3% in group 3), ASA-IV (56.5% vs. 27%), ascites (41.7% vs. 23.5%) and values of bilirubin (1.9 vs. 1.0 mg/dl), INR (1.4 vs 1.2), and platelets (110 vs. 125 10^9/L). Variables independently associated with mortality [HR (95% CI)] were the surgery [group 1 (ref.), group 2: 1.9 (1.2–3.0), group 3: 2.9 (1.9–4.5)], bilirubin [1.1 (1.1–1.1)], and ascites [1.8 (1.2–2.8)].
Conclusion: Our multicenter Spanish cohort of patients with ACLD has shown different variables associated with mortality in elective and emergent major surgeries. A new combined score could improve diagnostic accuracy for predicting surgical risk in European patients.

SAT-171

The novel classification as acute vs. non-acute decompensation provides prognostic value in cirrhosis patients developing ascites

Lucie Simonis, Lorenz Balcar, Anna Schedlbauer[1,2], Marta Tonon, Nikolaj Torp, Valeria Santori[3], Katharina Stopfer, Jan Embacher[1,2], Christian Sebesta[1,2], Leonie Hafner[1,2], Michael Trauner, Aleksander Krag, Salvatore Piano, Mattias Mandorfer, Thomas Reiberger, Georg Semmler. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [3]Unit of Internal Medicine and Hepatology, Department of Medicine, University of Padova, Padova, Italy, Padova, Italy*
Email: lucie.simonis@meduniwien.ac.at

Background and aims: Hepatic decompensation indicates a surge in morbidity and mortality in patients with cirrhosis. Baveno VII defined first and further decompensation and. Moreover, in an attempt to provide a more granular understanding of the path to/presentation of hepatic decompensation, a differentiation into acute decompensation (AD) and non-acute decompensation (NAD) has been proposed. We aimed to assess differences in the clinical course of AD vs. NAD in patients with ascites as first decompensation event.
Method: 543 cirrhosis patients developing ascites as first decompensation were included in this single-center longitudinal cohort study, and followed until further decompensation, liver transplantation (LT) or death. AD was defined as grade 3 ascites or ascites complicated by spontaneous bacterial peritonitis [SBP] or acute-kidney injury (AKI), while NAD was defined as grade 2 ascites. Hospitalization status was recorded.
Results: Mean age was 56.6 years, the majority of the patients (65%) were male with the most common etiology being alcohol-related liver disease (59.5%). 15% of patients had a cured etiology at baseline. 304 (56.0%) met the criteria for AD (20 [6.6%] with SBP, 19 [6.3%] with AKI), of which 218 (71.7%) were hospitalized while 86 (28.3%) were not hospitalized. Similarly, 234 (44.0%) were classified as NAD, of which 114 (48.7%) were hospitalized and 125 (51.3%) were not hospitalized. During a median follow-up of 4.1 years, further decompensation was observed in 348 patients (64.1%), ACLF occurred in 150 patients (27.6%), 33 (13.8%) underwent LT, and 125 patients (23.0%) died including 105 (19.3%) liver-related deaths. AD was associated with a significantly higher risk of subsequent further decompensation (subdistribution hazard ratio [SHR]: 2.02 [95% CI: 1.64–2.49], $p < 0.001$) and mortality (SHR: 1.37 [95% CI: 1.08–1.74], $p = 0.010$) vs. NAD. However, after stratifying according to hospitalization status, AD conferred only an increased risk when requiring hospitalization (SHR [all vs. non-hospitalized NAD] for hospitalized NAD: 1.23 [95% CI: 0.86–1.78], $p = 0.260$; non-hospitalized AD: 1.13 [95% CI: 0.74–1.72], $p = 0.570$; hospitalized AD: 1.69 [95% CI: 1.22–2.33], $p = 0.001$]. Of note, inflammation as assessed by C-reactive protein (CRP) was not associated with transplant-free mortality in NAD patients while it showed an independent association adjusting for age, sex, MELD, albumin and etiological cure at baseline in AD patients (adjusted SHR per log-change: 1.28 [95% CI: 1.08–1.51], $p = 0.005$).
Conclusion: Classifying patients according to AD vs. NAD identified subgroups of distinct risk for further decompensation and transplant-free mortality. Inflammation was an independent risk factor of mortality only in patients with AD.

SAT-172-YI

Branched-chain amino acids in liver cirrhosis and hepatic encephalopathy: a meta-analysis of clinical evidence

Luise Aamann[1], Neha Deshpande[2], Gitte Dam[3], Mette Borre[3], Giulio Marchesini Reggiani[4], Inigo Les[5], Niels Kristian Aagaard[3], Hendrik Vilstrup[3], Lise Lotte Gluud[1]. *[1]Copenhagen University Hospital Hvidovre, Copenhagen, Denmark; [2]University College London, London, United Kingdom; [3]Aarhus University Hospital, Aarhus, Denmark; [4]IRCCS-Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy; [5]Hospital Universitario de Navarra, Pamplona, Spain*
Email: luise.aamann@gmail.com

Background and aims: Hepatic encephalopathy (HE) is a brain dysfunction characterized by neurological and psychiatric changes associated with liver insufficiency or portal-systemic shunting, ranging from minor symptoms to coma. Nutrition plays a vital role in managing cirrhosis and HE, with branched-chain amino acid (BCAA) supplementation gaining attention for its potential to improve muscle protein synthesis, remove ammonia in muscle and reduce the risk of malnutrition and HE symptoms. The aim was to evaluate the beneficial and harmful effects of BCAA compared to any control intervention in individuals with HE and cirrhosis.
Method: We conducted a systematic search across multiple databases (April 2024). Randomized clinical trials (RCTs) comparing BCAA to any control intervention were included, irrespective of bias control, language, or publication status. Outcomes included all-cause mortality, improvement in HE, adverse events, quality of life, and nutritional status. Risk of bias was evaluated using the Risk of Bias 2 tool, and evidence quality was assessed using the GRADE approach. Meta-analyses (random-effects and fixed-effects) were performed, with subgroup and sensitivity analyses to explore heterogeneity and robustness of results.
Results: This meta-analysis included 18 RCTs (934 participants) with overt (13 trials) or minimal HE (5 trials). Nine trials assessed oral BCAA, and eight evaluated intravenous BCAA. Control interventions included no treatment/placebo, diets, lactulose, or neomycin. BCAA had no significant effect on mortality compared with controls (risk ratio (RR) 0.85, 95% CI 0.70 to 1.04; 867 participants; 17 trials; moderate quality). However, BCAA significantly reduced HE manifestations (RR 0.78, 95% CI 0.65 to 0.93; 934 participants; 18 trials; high quality). Sensitivity analyses confirmed this benefit in trials with a low risk of bias (RR 0.62, 95% CI 0.50 to 0.77). BCAA showed no notable effects on adverse events, quality of life, or nutritional parameters. Excluding trials with lactulose or neomycin as controls, BCAA maintained its beneficial effect on HE (RR 0.79, 95% CI 0.65 to 0.96), with no differences when compared directly to lactulose or neomycin (RR 0.81, 95% CI 0.46 to 1.42).
Conclusion: BCAA supplementation improves HE symptoms. We found no effect on mortality. Few trials reported adverse events, quality of life, or nutritional status. The interplay between BCAA supplementation, nutritional status, and newer established treatments like rifaximin for managing HE remains a subject of ongoing debate.

SAT-173-YI

History of overt hepatic encephalopathy is associated with worsen cognitive tests and cerebral atrophy in a prospective cohort of outpatients with cirrhosis with multimodal evaluation and brain magnetic resonance imaging with diffusion tensor imaging

Lyès Kheloufi[1], Philippe Sultanik[1], Clara Modolo[1], Charlotte Bouzbib[1], Sarah Mouri[1], Marika Rudler[1], Louis Puybasset[2], Damien Galanaud[3], Nicolas Weiss[1], Dominique Thabut[1]. *[1]AP-HP, Brain-Liver Pitié-Salpêtrière Study group (BLIPS), Paris, France; [2]APHP, Hôpital Pitié-Salpêtrière Hospital, Paris, France; [3]APHP, Pitié-Salpêtrière Hospital, Paris, France*
Email: lyes.kheloufi@aphp.fr

Background and aims: Hepatic encephalopathy (HE) is a severe complication of liver cirrhosis. It can take a range of forms according to its severity: Covert HE (CHE) is defined by subtle neurocognitive impairments (NI) whereas Overt HE (OHE) includes confusion, motor manifestations and can lead to coma and death. The consequences of OHE on human brain and cognitive function remains unclear but evidences of brain alterations have been identified in animal models. The aim of this study was to compare patients with liver cirrhosis

with history of OHE episodes and to identify its impact of brain function and morphology.
Method: Retrospective study of a prospective cohort of outpatients with cirrhosis (March 2018–June 2024) referred for cognitive complaints. Multimodal evaluation was conducted: neuropsychological evaluation (including HE detection tests: PHES, ANT), Electroencephalogram (EEG), Magnetic Resonance Imaging (MRI) with spectroscopy and Diffusion Tensor Imaging (DTI). The diagnosis of CHE was made based on an adjudication committee including a neurologist, a hepatologist and a neuropsychologist. OHE history was identified by the track on the medical file.
Results: 164 patients were included, the median age was 62 (55–67), 72% of males, aetiology of cirrhosis was alcohol/MASH/Viral/mixed for 65.2/52.4/14/39.6% of them. Median MELD was 12 (9–15) and Child Pugh index 8 (6–9). Overall, 75% had a history of OHE (HOHE) and 65.9% were diagnosed with CHE. In the HOHE group, Child Pugh, MELD score and ammonia were greater ($p = 0.01$, $p = 0.002$, $p = 0.003$) and cognitive tests were worse (MoCA, PHES, ANT, respectively $p = 0.042$, $p = 0.007$, $p = 0.007$). Memory evaluation (FCSRT, Rey's Figure) was worse ($p = 0.042$, $p = 0.174$) and was not influenced by CHE status. EEG tracks were slower ($p < 0.001$) and patients had more brain atrophy and T1 hypersignals of grey central nuclei at MRI ($p = 0.015$, $p = 0.043$). No differences were found for triphasic waves at EEG, vascular leukopathy or MRI spectroscopy ($p = 0.226$, $p = 0.565$, $p = 0.165$). Differences were found in DTI Fractional Anisotropy (FA) and Radial diffusivity (RD) ($p = 0.005$, $p = 0.028$) and this was not depending on CHE status. In the HOHE group, more patients were diagnosed with CHE ($p < 0.001$). Among patients diagnosed with CHE, HOHE was associated with brain atrophy and slower EEG tracks ($p = 0.016$, $p = 0.017$). DTI FA was also significantly different ($p = 0.027$) in CHE patients with HOHE.
Conclusion: History of OHE seem to have structural and functional long-term consequences on the brain independently from CHE. HOHE patients had more NI, brain atrophy, slower EEG background rhythm and markers of brain diffusivity. Cognitive tests evaluating memory were worse in these patients, and did not depend on CHE. Furthermore, in patients diagnosed with CHE, history of OHE was associated to morphological alteration on brain MRI and diffusivity variables. The occurrence of OHE episodes should be considered for the prognosis of neurological evolution in patients with liver cirrhosis.

SAT-174-YI

The impact of anticoagulant therapy on safety of variceal ligation in cirrhotic patients: a systematic review and meta-analysis

Background and aims: Banding ligation is a commonly used intervention for managing oesophageal varices. However, anticoagulant therapy is frequently prescribed in patients with cirrhosis for various reasons. The interaction between anticoagulant therapy and the safety of variceal banding in cirrhotic patients remains poorly understood. This systematic review and meta-analysis aims to evaluate whether anticoagulant therapy affects the outcome of variceal ligation in people with cirrhosis.
Method: Four databases (PubMed, Scopus, Embase and Web of Science) were searched for articles published until October 2024. Articles with data on non-cirrhotic patients were excluded. Major study variables included mortality, length of hospital stay, number of banding sessions, technical success rate of banding, type of anticoagulant, and risk of bleeding. The overall risk of bleeding and number of banding sessions was determined using a fixed-effect model for eligible studies.
Results: Out of 402 studies identified using our search strategy, eight underwent full-text review, with four records included in the systematic review and meta-analysis. Studies originated from France, USA, Switzerland, and Italy. A total of 388 patients were included. Warfarin and LMWH were the anticoagulants used, with portal vein thrombosis being the most common indication for anticoagulation. No significant difference was observed in MELD scores between groups ($p = 0.241$). One study reported band ligation success rates of 83% and 84% for patients with or without anticoagulation, respectively, with no statistically significant difference. Another study found mortality rates of 2 (2.5%) and 4 (2.2%) in the anticoagulant and non-anticoagulant groups, respectively, which were not significantly different. Hospital stay duration was statistically similar between groups (7.3 ± 2 vs 11.6 ± 6.4). Fixed-effect model analysis revealed no significant difference in the number of banding sessions between anticoagulant and non-anticoagulant groups ($p = 0.561$, p-heterogeneity = 0.678, $I^2 < 0.01$). The fixed-effect model demonstrated that continuing anticoagulants during oesophageal variceal ligation (EVL) was not associated with a higher pooled risk of bleeding (OR = 1.72 (CI: 0.59–5.02), $p = 0.319$; $I^2 < 0.01$).
Conclusion: Our meta-analysis shows anticoagulant therapy during banding of oesophageal varices in cirrhosis does not significantly increase adverse outcomes. Variables such as technical success rates, mortality, hospital stay, and banding sessions showed no statistically significant differences between patients on and off anticoagulants. These findings suggest that carefully monitored anticoagulant therapy can be safely maintained during EVL procedures. However, larger prospective studies are needed to establish these preliminary results and develop more precise treatment protocols.

Background and aims: Overt hepatic encephalopathy (OHE) is an important cause of hospitalization of patients with cirrhosis. OHE is potentially reversible but factors influencing progression, resolution and mortality of patients with OHE is not known particularly with confounders such as the presence or absence of acute on chronic liver failure (ACLF), use of specific therapies and lack of accurate follow up

data. Therefore, the aims of the study were to evaluate the natural history of an acute episode of OHE and to determine factors of progression, resolution and mortality.
Method: The data for this study were from the PREDICT study, which was a prospective, observational cohort study of patients with cirrhosis hospitalized for an acute decompensation or ACLF. Progression was defined as development of OHE (grade 2 or higher) or transition from grade 2 to grades 3 or 4 at week 1. Resolution was defined as the absence of OHE at week 1 in patients with OHE at admission. Univariable and multivariable logistic regression analyses were performed. Survival was evaluated with Kaplan Meier curves and the log-rank test. Post-hoc analysis of the interaction was adjusted for multiple comparisons using the Tukey method.
Results: 1273 cirrhosis patients were included [68% males; 59 (51–67) years; alcohol (56%)], 16% were admitted with OHE and 16% with ACLF. In multivariable analysis older age, MASLD etiology, previous history of OHE, treatment with lactulose at admission and Child-Pugh score were associated with OHE ($p < 0.05$). 3% (n = 31/913) had progression of OHE, which was associated with older age, alcohol consumption and Child-Pugh score at baseline ($p < 0.05$), with a significantly shorter time-to-death ($p < 0.001$, log-rank 18.7). 79% (n = 88/112) resolved OHE with significantly longer time-to-death ($p = 0.040$, log-rank 4.7). Interaction between OHE and ACLF to predict mortality at 28 days was significant ($p = 0.003$), with higher differences across all ACLF grades compared with HE grades.
Conclusion: Presence of ACLF and non-recovery from OHE are associated with higher short-term mortality rates, while resolution of OHE is associated with significantly better prognosis. Understanding the natural history of patients with an acute episode of OHE and the factors defining prognosis and response to therapy will have profound implications on the development of novel approaches to the management of this debilitating illness.
Acknowledgements: This research was made possible through access to data generated by the PREDICT study, promoted and funded by the European Foundation for the Study of Chronic Liver. Failure (EF CLIF), a private, non-profit research organization supported by unrestricted grants from Grifols and Genfit.

Minimal serum creatinine fluctuations impact on prognosis in acutely decompensated cirrhosis
Marco Tizzani[1], Chiara Lisi[1], Matteo Botta[1], Alberto Calleri[1], Maria Laura Robone[1], Mimma Bonomo[1], Giulia Pecorella[1], Elisa Bertoldi[1], Francesco Frigo[1], Daniela Campion[1], Antonio Ottobrelli[1], Alfredo Marzano[1], Elisabetta Bugianesi[1], Giorgio Maria Saracco[1], Carlo Alessandria[1]. [1]*Division of Gastroenterology and Hepatology, A.O.U. Città della Salute e della Scienza di Torino, University of Turin, Turin, Italy*
Email: marco.tizzani91@gmail.com

Background and aims: Renal dysfunction is common in cirrhosis, affecting prognosis. The impact of subtle increases in serum creatinine (sCr) on major clinical outcomes of patients hospitalized for acute decompensation (AD) remains unclear.
Method: Patients with cirrhosis hospitalized for AD from July 2022 to October 2024 were prospectively evaluated. Stable renal function (SRF) was defined as sCr equal or below patients' baseline value defined as per International Club of Ascites (ICA); minimal renal dysfunction (MRD) was defined as any sCr level exceeding the baseline without fulfilling acute kidney injury (AKI) or acute kidney disease criteria as per ICA definitions. Follow-up ended at liver transplantation (LT) or death.
Results: 304 patients were enrolled. Median age was 60 years. Ascites and alcohol-related liver disease were the most frequent cause of hospitalization (60%) and etiology (45%). Patients were classified as follows: 13% SRF, 39% MRD, 28% AKI, 12% chronic kidney disease (CKD) and 8% acute-on-chronic kidney disease. Median follow-up was 5.7 months (1.7–13.2). Median sCr values were: 0.79, 0.98, 1.68, 1.81 and 3.13 mg/dL, respectively. Median follow-up was 5.7 months [1.7–13.2]. Overall, 87 (29%) patients underwent LT and 79 (25%) died. Among the 105 patients with follow-up ≥3 months, 14 (13%) developed new-onset CKD. The incidence was 0/31 for SRF, 7/47 (15%) for MRD and 7/27 (26%) for AKI (MRD *vs* SRF, $p = 0.038$; MRD *vs* AKI, $p = 0.36$). 104/278 (37%) patients discharged from index hospitalization were re-hospitalized. The 3-month cumulative incidence of rehospitalization was comparable across groups (42%, 32%, and 39%; log-rank $p = 0.73$). The 6- and 12-month LT-free survival were respectively 97% and 94% in SRF, 88% and 78% in MRD, 64% and 52% in AKI (MRD *vs* SRF, $p = 0.028$; MRD *vs* AKI, $p < 0.001$).
Conclusion: MRD is very common among patients hospitalized for decompensated cirrhosis. Our preliminary results suggest that MRD is clinically meaningful as it entails intermediate prognosis between SRF and AKI, thus confirming the few data available in the literature so far. These patients may then need careful monitoring to prevent unfavorable clinical outcomes.

SAT-177
Specialist palliative care is under-utilized at end of life in chronic liver disease, especially in patients without liver cancer
Maria Valjus[1], Hanna-Riikka Lehto[2], Fredrik Åberg[3], Mikko Nuutinen[4], Tiina Saarto[1], Timo Carpén[1]. [1]*Helsinki University, Helsinki, Finland;* [2]*University of Turku, Turku, Finland;* [3]*Helsinki University, Helsinki University Central Hospital, Transplantation and Liver Surgery, Helsinki, Finland;* [4]*Nordic Healthcare Group, Helsinki, Finland*
Email: maria.valjus@hus.fi

Background and aims: The burden of liver disease in Finland is high and increasing. Traditionally, cancer patients have better access to palliative care services than patients with non-malignant diseases, although symptom burden is high in both groups. Thus, we aimed to examine the use of health care services and access to specialist palliative care (SPC) services among patients who died of either non-malignant liver disease or liver cancer.
Method: From the nationwide causes of death register, we identified all adults who died either of non-malignant or malignant (primary liver cancer) liver disease in Finland in 2019. We used National Care register to examine use of SPC and contacts to emergency department (ED). Primary outcome was an access to SPC services during the last 6 months of life, and secondary outcome the association of SPC services with the prevalence of ED contacts during the last of month of life.
Results: Overall, 896 (30.9% females, mean age 63.5 years) patients with non-malignant and 572 (32.7%; 75 years) with malignant liver disease died in 2019. Most of the patients died in-hospital (70.2% non-malignant and 82% malignant cases; $p < 0.001$). Non-malignant patients died more often at home (25.3% vs. 11.2%; $p < 0.001$, respectively).
During the last 6 months of life, SPC was provided for 7.5% (n = 67) of the patients with non-malignant, compared to 32.2% (n = 184) of the patients with malignant liver disease ($p < 0.001$). During the last month of life, respectively 5.0% (n = 45) and 27.8% (n = 159) of the patients received SPC ($p < 0.001$). Median time between the first contact with SPC service and death was 26.5 days (IQR 74) in non-malignant and 33 days (IQR 62) in malignant groups, respectively ($p = 0.695$). In the malignant group, the prevalence of ED contacts during the last month of life was lower among those who had received SPC contacts >30 days before death as compared to ≤30 days before death (53.8% vs. 76.6%; $p = 0.008$).
Conclusion: SPC services were utilized at the end of life in less than one in ten patients with non-malignant liver disease although one in four died at home. Initiatives to improve access to SPC in patients with liver disease are urgently needed.

Quantitative measurements of prothrombin in patients with cirrhosis and ascites: a validation study

Markus Maagaard[1,2], Nikolaj Torp[1,2], Cecilie Løbel[1,2], Katrine Bech[1,2], Helle Schnefeld[1,2], Georg Semmler[1,2], Katrine Lindvig[1,2], Katrine Thorhauge[1,2], Stine Johansen[1,2], Johanne Kragh Hansen[1,2], Camilla Dalby Hansen[1], Ida Falk Villesen[1], Peter Andersen[1], Mark Haastrup[3], Niels Foged[3], Maja Thiele[1,2], Mads Israelsen[1,2], Aleksander Krag[1,2]. [1]*Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark;* [2]*Institute of Health Sciences, University of Southern Denmark, Odense, Denmark;* [3]*Solsten Diagnostics International, Aarhus, Denmark*
Email: markus.maagaard@rsyd.dk

Background and aims: Prothrombin (coagulation factor II) is a coagulation cascade protein synthesized exclusively by the liver which results in decreased concentrations in patients with cirrhosis. The international normalized ratio (INR) is normally used to estimate prothrombin but is only an indirect measure, as INR also reflects coagulation factors VII and X, and can furthermore be affected by physiological factors and medications.
We aimed to validate a novel aptamer-based biosensor to quantify prothrombin as a potential point of care biomarker.
Method: We included 23 patients with cirrhosis and ascites together with 5 healthy individuals who served as controls. The endogenous molar concentration of prothrombin (C_{PT}) was quantified directly in EDTA-plasma stored at −80°C until sample analysis for the patients with cirrhosis. EDTA-plasma was taken from controls immediately ahead of analysis. Measurements were performed in a single 5 min reaction step by the aptamer-based electrochemical biosensor. We correlated C_{PT} levels with INR and albumin while assessing if C_{PT} was associated with liver disease severity. We followed patients from time of study inclusion (2014–2018) until November 2024.
Results: Mean age of patients with cirrhosis and ascites was 57 years (±8) while 30% were female. In the patients with cirrhosis and ascites median MELD-Na = 10 (IQR: 8–14) and Child-Pugh class distribution was B: 74% and C: 26%. Prothrombin levels were significantly lower in patients with cirrhosis (C_{PT} = 753 nM IQR: 531–961) compared to healthy controls (C_{PT} = 1654 nM IQR: 1511–1816, $p < 0.001$). In the patients with cirrhosis, prothrombin was negatively associated with INR ($r = -0.6488$, $p < 0.001$) and positively with serum albumin ($r = 0.6495$, $p < 0.001$). Similarly, INR exhibited a negative correlation with albumin ($r = -0.7408$, $p < 0.001$). There were lower prothrombin levels in patients with MELD-Na >10 (C_{PT} = 614 nM IQR: 499–753) compared to MELD-Na ≤10 (C_{PT} = 886 nM IQR: 696–1065, $p = 0.03$). Similarly, we observed a trend towards lower prothrombin levels in Child-Pugh C (C_{PT} = 503 nM IQR: 439–717) compared to Child-Pugh B (C_{PT} = 830 nM IQR: 696–960, $p = 0.0524$).
At end of follow up 8 of 23 patients were alive. 3 of these 8 (38%) scored low MELD-Na (≤10). Replacing INR with C_{PT} in MELD (MELD-Na_{PT}) resulted in 6 of 8 (75%) being classified with a low MELD-Na_{PT} (≤10).
Conclusion: Prothrombin levels measured using an aptamer-based biosensor were significantly reduced in patients with cirrhosis and correlated with established markers of liver function and disease severity. These findings suggest that the biosensor provides a fast and direct method for quantifying prothrombin as point of care diagnostics which in turn opens avenues for expanding home or remote testing of liver function in patients with cirrhosis.

SAT-179

The prognostic role of LiverRisk score in patients with compensated cirrhosis

Marta Tonon[1], Antonio Accetta[1], Simone Incicco[1], Roberta Gagliardi[1], Nicola Zeni[1], Valeria Santori[1], Valeria Calvino[1], Giulia Antonacci[1], Antonietta Romano[1], Carmine Gambino[1], Salvatore Piano[1]. [1]*Unit of Internal Medicine and Hepatology, Department of Medicine, University of Padova, Padova, Italy*
Email: salvatore.piano@unipd.it

Background and aims: The LiverRisk score is a non-invasive test that has been recently proposed for assessing the risk of compensated advanced chronic liver disease and liver-related events in the general population. Recently, its diagnostic and prognostic ability in tertiary settings was questioned. The aim of this study was the evaluation of the ability of LiverRisk score in predicting first decompensating event and mortality in outpatients with compensated cirrhosis.
Method: 271 outpatients with compensated cirrhosis and different etiologies evaluated at a single center from 2004 to 2023 were enrolled in the study. LiverRisk score was calculated for each patient using biochemical parameters at first visit. Patients were followed until death, liver transplantation or the end of follow up (October 2023).
Results: 271 outpatients (64% males, mean age 56.7 ± 13.0 years, mainly HCV cirrhosis [48.7%], median MELD = 8, median CTP = 6) were included in the study. During follow up, 60 patients developed ascites (22.1%), 30 hepatic encephalopathy (11.1%), 17 variceal bleeding (6.3%). Fifty-six patients died (20.7%, 33 for hepatic cause) and 31 were transplanted (11.4%). At multivariable analysis (adjusted for age, MELD, varices at inclusion and effective etiological treatment), LiverRisk score was associated with higher risk of developing decompensation of cirrhosis (HR 1.08, 95% CI 1.02–1.14, $p = 0.015$) and in particular with the risk of developing ascites (HR 1.07, 95% CI 1.02–1.13, $p = 0.012$). LiverRisk score was not indepently associated with the risk of mortality (HR 1.06, 95% CI 0.96–1.18, $p = 0.245$).
Conclusion: In patients with compensated cirrhosis LiverRisk score is associated with a higher risk of decompensation, but its association with mortality risk is weak.

SAT-180

Determinants of muscle mass in patients with liver cirrhosis

Martin Philipp[1], Karen Rischmüller[1], Veronika Kakouz[1], Theresia Blattmann[1], Georg Lamprecht[1]. [1]*Rostock University Medical Center, Department of Internal Medicine, Division of Gastroenterology and Endocrinology, Rostock, Germany*
Email: martin.philipp@med.uni-rostock.de

Background and aims: The interaction between liver function and muscle mass has a clinically and prognostically relevant impact on patients with liver cirrhosis (LC). In order to evaluate the effects of medication, diet, lifestyle and possible interventions on muscle mass, it is essential to have a precise understanding of the parameters that determine muscle mass in LC.
Method: We used skeletal muscle mass index (SMMI) determined by bioelectrical impedance analysis to investigate muscle mass in patients with LC. Complete data were available for 80 patients (68% male, median model of end-stage liver disease (MELD) 10, 84% with history of portal decompensation). A linear regression model was used to identify parameters influencing SMMI. The initial model included age, sex, presence of a transjugular intrahepatic portosystemic stent (TIPS), presence of tense ascites, hepatic encephalopathy based on Number Connecting Test (NCT), bilirubin, creatinine, albumin, INR and cystatin C.
Results: After stepwise backward elimination, sex, bilirubin, cystatin C, TIPS, INR, ascites and NCT remained in the final model with in decreasing order of relative importance. A negative correlation with SMMI was found for female sex ($p < 0.01$), cystatin C ($p = 0.01$), INR ($p = 0.03$), ascites ($p = 0.02$) and NCT ($p = 0.054$). TIPS ($p = 0.02$) and bilirubin ($p < 0.01$) had a significant positive correlation. Albumin, age and creatinine had only small effects. Using aggregated scores such as MELD or Child-Pugh instead of the separate parameters contained in each score resulted in a significantly worse model (multiple R-squared 0.44 or 0.42 vs. 0.54).
Conclusion: MELD and Child score have only a weak correlation with SMMI. Due to the involvement of creatinine in both renal and muscle metabolism and the positive correlation of bilirubin with muscle

mass, MELD and Child score should not be used to adjust for liver function in studies of muscle mass in LC. Parameters correlated with SMMI are sex, renal function (cystatin C), portal hypertension (ascites, TIPS), INR and NCT. Multivariate linear regression models based on these parameters will allow for a more accurate assessment of the impact of other factors (e.g. medication, lifestyle, diet) and interventions on muscle mass in patients with LC.

SAT-181

Attitudes towards exercise among patients with advanced chronic liver disease: a survey

Matthew McKenna-Barry[1,2,3], Ciara O'Connor[1,2], John Ryan[1,2], Karen Boland[1,2]. [1]*Royal College of Surgeons in Ireland, Dublin, Ireland;* [2]*Beaumont Hospital, Dublin, Ireland;* [3]*Bon Secours Hospital Group, Dublin, Ireland*
Email: matthewmckennab24@rcsi.com

Background and aims: Sarcopenia, the reduction of skeletal muscle mass and strength, is common for patients with advanced chronic liver disease (ACLD). This confers an increased risk of ascites, encephalopathy, hospital admission and mortality compared to patients with ACLD who do not have sarcopenia. A number of interventions have been proposed to reverse sarcopenia including diet and exercise interventions. In addition to its impact upon muscle function, exercise may have positive impact on patients' mood, body image and quality of life.
Method: A 21 point anonymised paper-based survey was distributed to patients attending a liver support clinic for patients with decompensated advanced chronic liver disease between July and November 2024. Questions included aetiology of chronic liver disease, age range, gender, current exercise times and modalities, attitudes towards exercise and limitations from exercise. All items were self-reported.
Results: 54 surveys were completed. 23 (42.6%) patients were aged between 45–60. 20 (37.0%) patients are female. 24 (44.4%) patients had alcohol related liver disease.30 (55.6%) patients reported current exercise. The median number of days exercised per week was 3 (IQR 2–5). The median cumulative weekly duration of exercise was 2 hours (IQR 0.71–5.35) and 22 (40.7%) exercise for 2.5 hours or greater per week in line with EASL guidelines. 30 (55.6%) patients attributed the maximum score (5/5) to the importance of exercise with a further 16 (29.6%) scoring it at 4/5. 39 (72.2%) patients walk for exercise, 11 (20.4%) swim and 5 (9.3%) use weights. 3 (79.6%) patients identified physical benefits from exercise, 40 (74.1%) patients experienced increased energy, 44 (81.5%) experienced improved mood and 41 (75.9%) experienced a reduction in anxiety. 28 (51.9%) patients would welcome advice on appropriate exercise and 31 (57.4%) patients would avail of a structured exercise program. The exercise habits of 23 (42.6%) patients were limited by a lack of energy and 16 (29.6%) patients were limited by pain.
Conclusion: This survey demonstrates that patients with ACLD greatly value exercise. Although the majority of patients with ACLD report exercising multiple times per week a sizeable proportion (44.4%) do not engage with regular exercise. The vast majority of respondents identify physical and mood benefits from exercise. Common symptoms of chronic illnesses limit the ability of patients to take part in exercise as they wish. Structured exercise programs should be made available to patients with liver disease in line with their preferences.

SAT-182-YI

Transjugular intrahepatic portosystemic shunt implantation is associated with resolution of hepatopulmonary syndrome

Email: tergast.tammo@mh-hannover.de

Background and aims: Hepatopulmonary syndrome (HPS) is a severe complication of portal hypertension, characterized by intrapulmonary vascular dilatations (IPVD) and elevated alveolar-arterial oxygen gradient (P(A-a)O2) leading to increased mortality. As of now, liver transplantation is the only curative treatment. While transjugular intrahepatic portosystemic shunt (TIPS) placement is an effective therapy for other complications of portal hypertension, its impact on HPS remains unclear. Some case reports suggest potential benefits, but concerns persist about exacerbating the pre-existing hyperdynamic circulation and aggravating HPS. Thus, this study aimed to evaluate the effect of TIPS placement on HPS.
Method: A prospective cohort study was conducted, including patients who underwent covered TIPS placement at MHH between 01/2021 and 01/2024. Patients were eligible for inclusion if they had contrast-enhanced transthoracic echocardiography (cTTE) and blood gas analysis (BGA) performed prior to TIPS placement (baseline; BL) and at least once at 6–18 months post-intervention (follow-up; FU). Patients with intracardiac shunt were excluded. Longitudinal effects of TIPS placement on HPS were assessed using linear mixed models (LMM).
Results: Forty-three patients (72% male, 74% TIPS indication refractory ascites) were included. The leading etiology was alcohol-related liver disease (60%) and the median MELD score was 10. At BL 30 patients (70%) had IPVD and 28 (68%) met HPS criteria. The median $P(A\text{-}a)O_2$ was 30.0 mmHg (interquartile range [IQR]: 23.0–39.9). At FU HPS prevalence significantly decreased to 12 patients ($p < 0.001$) while 27 still showed IPVD ($p = 0.581$). Nineteen patients (46%) reduced their $P(A\text{-}a)O_2$ by ≥10 mmHg. The median $P(A\text{-}a)O_2$ decreased to 23.5 mmHg (IQR: 9.0–35.2) ($p < 0.001$). Nineteen patients (67.9%) resolved their HPS: 11 via improvement in $P(A\text{-}a)O_2$, five by alleviation of IPVD, and three via improvements in both. HPS resolution was not associated with symptom control for TIPS indication (i.e. absence of ascites persistence or recurrence of portal hypertensive bleeding) at FU (74% vs. 77%, $p = 1.00$). Among patients without BL IPVD or HPS ($n = 13$), six (46%) developed IPVD, and five (38%) subsequently met HPS criteria. Notably, FU oxygenation improved even in patients without BL IPVD or HPS, as five (38%) achieved a reduction ≥10 mmHg in $P(A\text{-}a)O_2$. In LMM analysis, HPS prevalence was significantly reduced at 6 months post-TIPS ($p = 0.017$), along with a significant decrease in $P(A\text{-}a)O_2$ ($p = 0.013$). The presence of pathological $P(A\text{-}a)O_2$ was significantly lower at 6 months ($p < 0.001$) and 12 months ($p = 0.017$) compared to BL. Partial pressure of carbon dioxide did not differ significantly across time points.
Conclusion: TIPS implantation is associated with a significant improvement of $P(A\text{-}a)O_2$ and can lead to improvement or even resolution of HPS in a majority of patients.

SAT-183

The association between familial mediterranean fever and incidence liver cirrhosis: a population based matched cohort study

Michal Carmiel-Haggai[1,2], Rula Daud[3,4], Fadi Hassan[5], Helena Jeries[5,6], Dikla Dror-Zur[4,7], Kamal Abu Jabal[4,8], Mahmud Omar[9,10], Mohammad Naffaa[4,11]. *[1]Liver unit, Glilee Medical Center, Nahariya, Israel; [2]The Azrieli Faculty of Medicine, Bar-Ilan University, Safed, Israel; [3]Rheumatology unit, Galilee Medical Center, Nahariya, Israel; [4]The Azrieli Faculty of Medicine, Safed, Israel; [5]Rheumatology unit, Galilee Medical Center, Nahariya, Israel; [6]The Azrieli Aaculty of Medicine, Safed, Israel; [7]Liver unit, Galilee Medical Center, Nahariya, Israel; [8]Liver Unit, Galilee Medical Center, Nahariya, Israel; [9]Maccabi Healthcare Surviced, Tel AVIV, Israel; [10]The Sackler Faculty of Medicine, Tel Aviv, Israel; [11]Rheumatology unit, The Galilee Medical Center, Nahariya, Israel*
Email: michalc@gmc.gov.il

Background and aims: Familial Mediterranean Fever (FMF) usually does not involve the liver, although some evidence correlates FMF to cryptogenic cirrhosis. A previous work by our group, presented in the EASL congress 2022, showed that FMF was independently associated with incident cirrhosis among a cohort of chronic colchicine uses. The aim of this study is to examine the association between FMF and incident cirrhosis.
Method: Using the Maccabi Healthcare Services (MHS) computerized database, we extracted data of all patients aged ≥18 years, diagnosed with FMF according to ICD-9 code 277.31, between January 1, 2000 to December 31, 2022. A control group of patients was matched in 1:1 ratio by age and gender. Index date for FMF group was the date of diagnosis (or 18 if the diagnosis was made earlier in life) and for control group the date of study enrollment. We excluded patients with cirrhosis prior to index date as well as any chronic liver disease other than metabolic dysfunction-associated steatotic liver disease. Primary outcome was the incident cirrhosis, while event was defined by any of the following: incident cirrhosis, liver transplantation, end of follow-up, leaving MHS or death. We used cox proportional hazards models to assess the risk factors associated with cirrhosis and Kaplan-Meier curves to estimate the time to cirrhosis.
Results: Each group included 5236 patients, well matched in terms of age and gender. FMF group included higher proportion of obese patients (59.05% vs. 50.63%, $p < 0.01$) and higher proportion of diabetes (8.10% vs. 5.83%, $p < 0.01$). During follow-up, patients with FMF had higher incidence of cirrhosis compared to control group (2.10% vs 0.40%, p-value < 0.01). Cox proportional hazards model indicated that FMF was significantly associated with incident cirrhosis (HR = 2.60, 95% CI: 1.54–4.38, $p < 0.01$). Kaplan-Meier analysis demonstrated that cirrhosis free-survival rate in 7 years was significantly lower among FMF patients when compared to control (98.24% vs 99.66%, $p < 0.01$).
Conclusion: FMF patients have higher risk of incident cirrhosis, when compared to age and gender matched controls. The association between FMF and incident cirrhosis was irrespective to other metabolic risk factors for liver cirrhosis.

SAT-184-YI

Impact of diabetes mellitus on clinical outcomes in patients with acutely decompensated cirrhosis

Mimma Bonomo[1], Alberto Calleri[1], Marco Tizzani[1], Maria Laura Robone[1], Chiara Lisi[1], Giulia Pecorella[1], matteo botta[1], Francesco Frigo[1], Daniela Campion[1], Antonio Ottobrelli[1], Alfredo Marzano[1], Elisabetta Bugianesi[1], Giorgio Maria Saracco[1], Carlo Alessandria[1]. *[1]Division of Gastroenterology and Hepatology, A.O.U. Città della Salute e della Scienza di Torino, University of Turin, Turin, Italy*
Email: mimma.bonomo@gmail.com

Background and aims: Diabetes mellitus (DM) is common in patients with chronic liver disease, it is involved in the progression of fibrosis and significantly increases the risk of liver-related complications and mortality. However, its impact on decompensated hospitalized patients remains poorly addressed.
Method: Patients with cirrhosis hospitalized for acute decompensation (AD) between July 2022 and October 2024 were prospectively evaluated and followed-up until liver transplantation (LT) or death.
Results: 304 patients were included. One-third had DM (101/304, 33%). Compared to non-DM patients, DM patients were older (66 *vs* 57 years, $p < 0.001$) and with higher rates of arterial hypertension (45% *vs* 26%, $p = 0.002$); the prevalence of chronic kidney disease was similar (24% *vs* 19%, $p = 0.36$). The predominant etiology was metabolic dysfunction-associated steatotic liver disease (MASLD) in DM patients (30% vs. 8%, $p < 0.001$) and alcohol-related liver disease in non-DM patients (26% *vs* 54%, $p < 0.001$). The most common cause of hospitalization in each group was ascites (63% and 58%, respectively). Both groups had a median MELD-Na score of 20. Acute kidney injury (AKI) occurred in 36% in both groups during index hospitalization ($p = 0.89$). AKI stage ≥2 was more frequent in DM patients, although not significantly (47% *vs* 30%, $p = 0.09$). Among patients discharged from the index hospitalization (278), 33/93 (35%) of DM patients and 71/185 (38%) of non-DM patients experienced further hospitalizations ($p = 0.69$). The 3-month cumulative probability of rehospitalization was similar (25% *vs* 29%, log-rank $p = 0.84$). After a median follow-up of 5.7 (IQR 1.7–13.2) months, a comparable number of patients with- and without DM died (27% *vs* 26%, $p = 0.89$) or underwent LT (27% *vs* 30%, $p = 0.69$). The 6-month LT-free survival was 78.8% and 79.1%, respectively (log-rank $p = 0.99$).
Conclusion: Diabetes mellitus is frequently observed in patients with cirrhosis hospitalized for AD, particularly among older individuals and those with MASLD. In this high MELD cohort, DM did not significantly impact short- or medium-term outcomes, as evidenced by similar AKI rates, rehospitalization risk and 6-month LT-free survival.

SAT-185

Impact of PPIs, PCABs, and Rifaximin on SBP risk in cirrhotic patients with moderate-to-severe ascites

Satoshi Miuma[1], Satoshi Ishida[1], Satoshi Matsuo[1], Yasuhiko Nakao, Masanori Fukushima[1], Masafumi Haraguchi, Ryu Sasaki[1], Hisamitsu Miyaaki[1]. *[1]Department of gastroenterology and hepatology, Nagasaki university graduate school of biomedical sciences, Nagasaki, Japan*
Email: miuma1002@gmail.com

Background and aims: The role of acid-suppressive therapies, particularly proton pump inhibitors (PPIs) and potassium-competitive acid blockers (PCABs), in the risk of spontaneous bacterial peritonitis (SBP) among cirrhotic patients remains controversial. While rifaximin has been suggested to lower SBP incidence, its protective effect is unclear. This study aimed to evaluate the differential impact of these medications on SBP risk.
Method: This retrospective study analyzed 105 cirrhotic patients with moderate-to-severe ascites undergoing diagnostic paracentesis between April 2018 and March 2024. Patients on steroids or immunosuppressants were excluded. SBP was defined as an ascitic neutrophil count ≥250/mm^3 or positive ascitic fluid culture within 5 days of admission. Clinical factors, including medication use, were compared between SBP and non-SBP groups, and multivariate logistic regression was performed.
Results: The median age was 64 years, with 68 males and 37 females. Child-Pugh grade B and C were observed in 25 (23.8%) and 80 (76.2%) patients, respectively. SBP was diagnosed in 27 patients (22.9%). Significant differences between SBP and non-SBP groups were observed in Child-Pugh score ($p = 0.024$), leukocyte count ($p = 0.017$), prothrombin time ($p = 0.047$), and PCAB use ($p = 0.018$). The 90-day/180-day survival rates (excluding transplant cases) were 69.7%/50.8% for non-SBP and 46.2%/30.8% for SBP patients. Stratified by medication, the SBP incidence was 14.3% in the no-PPI/PCAB

group, 21.8% in the PPI group, and 46.7% in the PCAB group, with a significantly higher rate in the PCAB group. No significant difference was observed in SBP incidence based on rifaximin use (22.2% vs. 26.7%). Multivariate logistic regression identified PCAB use as the sole factor associated with SBP (Odds Ratio: 3.80, p = 0.030).
Conclusion: This study highlights the significant association between PCAB use and increased SBP risk in cirrhotic patients, while PPI and rifaximin use showed no such association. The findings underscore the importance of cautious prescribing of PCABs in this population to mitigate the risk of SBP. Tailored treatment strategies considering the differential effects of acid-suppressive therapies are warranted.

SAT-186-YI
Comparison of the animal naming test 1 minute versus 2 minutes for the screening of covert hepatic encephalopathy in a prospective cohort of outpatients with cirrhosis
Clara Modolo[1], Lyès Kheloufi[1], Philippe Sultanik[1], Sarah Mouri[1], Charlotte Bouzbib[1], Marika Rudler[1], Nicolas Weiss[1], Dominique Thabut[1]. [1]*AP-HP, Brain-Liver Pitié-Salpêtrière Study Group (BLIPS), Paris, France*
Email: modolo.clara@gmail.com

Background and aims: Hepatic encephalopathy (HE) is the most severe complication of cirrhosis. In its lightest form, "covert" HE (CHE) is characterized by isolated neurocognitive disorders (NCDs) that are difficult to diagnose, especially in patients with comorbidities (alcohol sequelae, obesity, diabetes) also affecting cognition. Several tools exist for screening, including cognitive tests like the Animal Naming Test (ANT). Conducted in 1 minute (ANT1), the French recommendation threshold is 20. However in neuropsychology, the test is validated for the general population in its 2-minute version (ANT2), standardized by age, sex, and education. This study aimed to compare ANT1 thresholds with ANT2 standards.
Method: We conducted a retrospective study on a prospective cohort of cirrhotic outpatients (March 2018-April 2024) referred for suspected CHE. NCD assessment included clinical exams (hepatologist, neurologist), neuropsychological tests (ANT1, ANT2, PHES), biomarkers, EEG, and brain MRI with spectroscopy. CHE diagnosis was established during multidisciplinary consultations by an adjudication committee based on examination results. Follow-up focused on clinical HE occurrence. Continuous values are medians, categorical values as numbers (%). Survival analysis used Kaplan-Meier and log-rank tests.
Results: 159 patients were included (71% male) aged 62 (55–67) years. Main causes of cirrhosis were: alcohol/metabolic/virus for 65/51/14%, 29% with ≥2 causes. Child-Pugh scores were: A/B/C for 26/63/11%; MELD score: 12 (9–15). Brain injury occurred in 10%, obesity in 30%, and TIPS in 25%. In total, CHE was diagnosed in 66% by the adjudication committee. Median ANT1, ANT2 and PHES scores in CHE patients were 14 (10–19), 21 (15–31) and −3 (−7; −1) vs. 18 (14–23), 29 (21–35) and −1 (−3; 0) in non-CHE patients (p = 0.002, p = 0.001, p = 0.002). ANT1, ANT2 and PHES were pathological in 69%, 21% and 33% of patients. 70% of patients with a pathological ANT1 had a normal ANT2, and 2% of patients with a normal ANT1 had a pathological ANT2. For CHE patient, ANT1threshold 20 had sensitivity (Se) and specificity (Sp) of 75% and 42%, while ANT2 (personalized thresholds) achieved Se 28% and Sp 92%. PHES (threshold: −4) had Se 39% and Sp 77%. Median follow-up was 60 months: 42% of patients experienced OHE. ANT1, ANT2 were significantly associated with the apparition of OHE (LR = 0.033, LR = 0.008), but not PHES (LR = 0.47).
Conclusion: In this study, only ANT1 and ANT2 are associated with Overt HE occurrence and not PHES. ANT1 and ANT2 seem to be better diagnostic tests for CHE than PHES, because they are correlated with the occurrence of OHE. There is a significant discordance between ANT1, whose threshold does not take into account age and education, which are known to impact verbal fluency, and ANT2, a robust and validated test in neuropsychology, for the screening of CHE. ANT1 is a good screening test because of its high Se, and ANT2 is more specific. A combination of the 2 tests would allow to refine the diagnosis of CHE using a rapid test.

SAT-187
Rehabilitation classes for sarcopenic cirrhotics, a proof of concept
Mariana Machado[1], Sandra Leitão[2], Célia Ricarte[2], Aida Macedo[2], Jorge Pinho[3], Sandra Lino[3], Cristina Noronha[2]. [1]*Gastroenterology Department, Hospital de Vila Franca de XIra, Faculdade de Medicina, Universidade de Lisboa, Lisbon, Portugal;* [2]*Physical Rehabilitation Department, Hospital de Vila Franca de Xira, Lisbon, Portugal;* [3]*Gastroenterology Department, Hospital de Vila Franca de Xira, Lisbon, Portugal*
Email: mverdelhomachado@gmail.com

Background and aims: Patients with liver cirrhosis present an estimated 40% prevalence of sarcopenia and 30% of frailty. Both sarcopenia and frailty are associated with greater risk for hepatic decompensation and mortality. There is a general consensus that patients with cirrhosis should engage rehabilitation programs with physical exercise to prevent and rescue from sarcopenia/frailty. However, it is still to be determined which would be the ideal rehabilitation program for patients with cirrhosis.
Method: Pilot study, with the enrolment of liver cirrhosis outpatients in a muscle rehabilitation program, with classes of 4 to 5 patients with cirrhosis, engaging physical exercise supervised by a physical rehabilitation therapist, with sessions of one hour, twice a week, for 10 weeks. All patients were advised to take a late evening snack with a high protein (20 g of protein) yoghurt. Before and after the intervention, 6-minute walk (6MW), 5-chair stand test (5-CST), handgrip strength, and bioimpedance measurements were done.
Results: 20 patients were enrolled (80% male, age 65 ± 6 years), 15 of whom already finished the program. Aetiology of cirrhosis was: 75% alcohol-associated, 15% MASLD, and 10% viral hepatitis; CPT class: A 50%, B 45% and C 5%, MELD3 was 13.1 ± 5.5 points. Adhesion rate to the program was 93%. At enrolment, the 6MW test was 336 ± 103 m, 5-CST 18 ± 20 s and handgrip strength 27 ± 2 kg. The performance of frailty tests was not associated with the severity of liver disease (assessed by Child-Pugh-Turcotte class, ALBI or MELD3). Evaluating patients that ended the program, we found an increase in muscle mass (48.8 ± 7.9 *vs.* 49.6 ± 7.8 kg, P = 0.038) and 6MW distance post intervention (361 ± 103 *vs.* 395 ± 94 m, P = 0.038), with a trend to lower proportion performing poorly (25% *vs.* 7% < 250 m, 65% *vs.* 64% 250–450 m, and 10% *vs.* 29% >450 m, P = 0.236). There was a trend to a decrease in 5-CST duration post intervention (20 ± 23 *vs.* 11 ± 3 s, P = 0.207), and to lower proportion performing poorly (26% *vs.* 7% >15 s, 42% *vs.* 57% 10–15 s, and 32% *vs.* 36% < 10 s, P = 0.353); no difference in handgrip strength (29.7 ± 8.7 *vs.* 30.8 ± 8.0 kg, P = 0.101), with a trend to lower proportion performing poorly, i.e. < 30 kg in men and < 15 kg in women (53% *vs.* 21%, P = 0.072).
Conclusion: A hospital class-based muscular rehabilitation program in patients with cirrhosis is feasible and associates with a high adhesion rate. The short-term effects of these programs seem promising, associating with improvement in frailty.

SAT-191-YI
Regulation and prognostic value of Fibroblast Growth Factor 23 in advanced chronic liver disease
Clemens Renhardt[1,2], Georg Kramer[1,2,3,4], Benedikt Hofer[1,2,3,4], Benedikt Simbrunner[1,2,3,4], Nina Dominik[1,2,3], Lorenz Balcar, Christian Sebesta[1,2,3], Paul Thöne[1,2,3], Albert Friedrich Stättermayer[1,2], Michael Trauner, Mattias Mandorfer, Thomas Reiberger. [1]*Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria;* [2]*Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria;* [3]*Clinical Research Group MOTION, Medical University of Vienna, Vienna, Austria;* [4]*Christian Doppler*

Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria
Email: n12028120@students.meduniwien.ac.at

Background and aims: Fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis linked to kidney disease and cardiovascular risk. We assessed FGF23 levels across stages of advanced chronic liver disease (ACLD) and its prognostic value.
Method: FGF23 levels were assessed in consecutive compensated (cACLD) and decompensated (dACLD) patients included in the Vienna Cirrhosis Study (VICIS; NCT03267615) characterized for portal hypertension (HVPG) and hepatic dysfunction (Child-Turcotte-Pugh: CTP-Score). Correlations of FGF23 with Creatinine (sCrea), Phosphate, Calcium, Vitamin D, PTH, and proBNP were tested. Patient characteristics and outcomes (first/further decompensation; overall survival) were compared between ACLD patients with elevated vs. non-elevated FGF23 levels.
Results: In 367 patients median FGF23 was higher in dACLD (n = 229; 51.4 pg/mL) vs. cACLD (n = 138, 46.1 pg/mL; p = 0.002) patients. FGF23 was elevated (>95.4 pg/mL) in n = 47 (12.8%; $FGF23^{high}$). Main characteristics of $FGF23^{high}$ patients were higher CTP-Score (p = 0.014), sCrea (p < 0.001; n = 11 [23.4%] with sCrea >1.5 mg/dL), phosphate (p < 0.001), proBNP (p < 0.001) and lower Vitamin D (p = 0.001), while no differences were found for PTH (p = 0.849). Accordingly, patients with abnormal sCrea (p < 0.001), phosphate (p = 0.004), calcium (p = 0.008), Vitamin D (p < 0.001) and proBNP (p = 0.001) had significantly higher FGF23 levels. Follow-up data (median 21.9 months) was available in 263 patients: $FGF23^{high}$ (n = 28) had no predictive value for decompensation (p = 0.12). While $FGF23^{high}$ patient showed higher mortality (log-rank p < 0.001), on multivariate analysis $FGF23^{high}$ was not independently associated with mortality (adjusted hazard ratio, aHR: 1.002, 95% CI: 0.9990–1.005; p = 0.197), while CTP (aHR: 1.489, 95% CI: 1.301–1.705; p < 0.001) and CRP (aHR: 1.294, 95% CI: 1.153–1.451; p < 0.001) remained independent risk factors for mortality.
Conclusion: FGF23 levels are higher in dACLD vs. cACLD and elevated FGF23 levels were linked to abnormal phosphate, calcium and Vitamin D levels and to renal and cardiac dysfunction. When adjusted for CTP, renal dysfunction and inflammation, elevated FGF23 did not impact on the risk for decompensation and mortality – indicating no independent prognostic value of FGF23 in ACLD.

SAT-192

Identifying potential baseline risk factors for further decompensation in patients with cirrhosis and early decompensation: analysis of data from a phase 2 randomized trial

Nancy S. Reau[1], Prasun Jalal[2], Marina Roytman[3], Zeev Heimanson[4], Christopher Allen[4], Robert J. Israel[5], Marcelo Kugelmas[6]. *[1]Rush University, Chicago, United States; [2]Baylor College of Medicine, Houston, United States; [3]University of California San Francisco, Fresno, United States; [4]Salix Pharmaceuticals, Bridgewater, United States; [5]Bausch Health US, LLC, Bridgewater, United States; [6]South Denver Gastroenterology, PC, Englewood, United States*
Email: nancy_reau@rush.edu

Background and aims: In patients with cirrhosis and ascites, additional decompensating events may occur; however, data characterizing further decompensation (DC) and associated risk factors in this population are limited. The aim of this analysis was to characterize a population with early decompensated cirrhosis who subsequently progressed (ie, further DC) vs those who did not, within a controlled trial setting.
Method: A phase 2, dose-ranging, randomized, double-blind trial (Bajaj et al. *Clin Gastroenterol Hepatol.* 2023;21[3]:723–731.e9) enrolled adults with cirrhosis and documented ascites (≥ grade 1; not medically refractory) and Conn score < 2, with no history of esophageal variceal bleeding (EVB), spontaneous bacterial peritonitis (SBP), or renal failure in the presence of comorbid ascites. Patients were randomly assigned to 24 weeks of treatment (6 arms; placebo/investigational rifaximin soluble solid dispersion tablets). A DC event was defined as a hospitalization for EVB, hepatic encephalopathy, hepatorenal syndrome, or SBP, or death due to liver complications during the 24-week period. Data were pooled across all treatment arms and stratified (with vs without DC event[s]); baseline demographic/baseline parameters were evaluated for the 2 subgroups post hoc.
Results: A total of 516 patients were included; 81.4% were aged < 65 y (median, 57.0 y [range, 26–83 y]), 61.0% were male, and 61.4% had a Conn score = 0. The mean (SD) MELD and MELD-Na scores were 11.5 (3.4) and 12.9 (3.9), respectively. Patients with (n = 61) vs without (n = 455) a DC event were more likely to have a higher baseline Child-Pugh (CP) class (A [0% vs 13.4%; p < 0.001], B [78.7% vs 80.9%; p > 0.05] or C [21.3% vs 5.7%; p < 0.001]), MELD score (≤10 [23.0% vs 45.1%; p < 0.001], 11–18 [70.5% vs 52.1%; p < 0.01], or 19–24 [4.9% vs 2.9%; p > 0.05), and MELD-Na score (≤10 [11.5% vs 31.6%; p < 0.001], 11–18 [68.9% vs 62.6%; p > 0.05], or 19–24 [14.8% vs 5.5%; p = 0.01). Significantly more patients with vs without a DC event had both a MELD score >10 and CP class B or C (77.0% vs 49.2%; p < 0.0001). Comorbid diabetes and cirrhosis etiology rates were similar between the 2 groups.
Conclusion: These trial data affirm that cirrhosis-related parameters, monitored to help determine patient prognosis (eg, MELD/MELD-Na score), identified patients with early DC at risk for further DC.

SAT-193-YI

Economic evaluation of LivR Well, a multidisciplinary, multimodal, home-based program for acute hepatic decompensation: interim analysis

Natalie Ngu[1,2], Thomas Worland[1], Stephanie Yung[1], Patricia Anderson[1,2], Joshua Abasszade[1], Bowen Xia[1], Jeremy Tse[1], Jo Hunter[1], Sophie Page[1], Edward Saxby[1], Benjamin Rogers[1,2], William Sievert[1,2], Adam Irving[2], Sally Bell[1,2], Suong Le[1,2]. *[1]Monash Health, Melbourne, Australia; [2]Monash University, Melbourne, Australia*
Email: natalielyngu@gmail.com

Background and aims: Chronic liver disease is a clinical and economic challenge with rates of mortality and re-admission greater than 30%. We compared LivR Well, a 28-day, home-based, program following acute hepatic decompensation to standard care, and herein report the economic evaluation.
Method: A randomized controlled trial was conducted at an Australian, non-liver transplant health service from February 2022 to May 2024. Patients with acute hepatic decompensation were recruited from inpatient or ambulatory care and randomized 1:1 to LivR Well, or standard care. The LivR Well group received weekly hepatology consultation, and physiotherapy, dietetics, pharmacy, social work, and/or addiction medicine when indicated. The program was delivered through Hospital in the Home (HITH) acute bed substitution model and both groups were coordinated by a liver clinical nurse consultant. We performed both a within-trial and modelled economic evaluation. Quality-adjusted life years (QALY) were calculated using utility weights extracted from EuroQoL-5 dimensions (EQ-5D-5L) at baseline, week 6, and week 12 with missing data imputed using multiple imputation. Costs included were HITH admission, unplanned, liver-related hospitalisation, regular albumin infusions, elective paracentesis and staff costs. The modelled evaluation took a lifetime horizon and used a Markov cohort structure with patients transitioning between 'compensated', 'decompensated', 'acute-on-chronic liver failure', and 'dead'. Transition probabilities were calculated using a historical cohort of patients with chronic liver disease. The primary outcome of both evaluations was incremental cost-effectiveness ratio (ICER).
Results: A total 106 patients were enrolled and randomized (n = 54 intervention, n = 51 control) with costs data available for 94 enrolled

to 7 April 2024. Ten intervention group patients dropped out (including 6 prior to program commencement), and 2 control group patients dropped out following randomization. EQ-5D-5L data were missing in 36%, 45%, and 59% at baseline, week 6, and week 12, respectively. The within-trial economic evaluation demonstrated median costs per patient for LivR Well and control were AU$1,542 (IQR: $381-$2,576) and AU$1,290 (IQR: $856-$2,969) respectively. Median QALYs generated per patient were 0.178 (IQR: 0.170–0.188) and 0.180 (IQR: 0.171–0.186) respectively resulting in a within-trial ICER of AU$356,402/QALY. The modelled evaluation had a deterministic ICER of AU$123,353/QALY. In the probabilistic sensitivity analysis LivR Well met the AU$50,000/QALY threshold in 0% of 2,000 iterations.

Conclusion: Interim results suggest that the existing protocol for LivR Well is unlikely to be cost-effective compared to standard care. Low rate of EQ-5D-5L completion may have contributed to the lack of difference in QALYs. A future adaptation which is simpler and cheaper may result in an ICER closer to the willingness-to-pay threshold.

SAT-194

Transcatheter closure of acquired portosystemic shunts for the management of refractory hepatic encephalopathy. A case-series

Natalie Ngu[1,2], Suong Le[1,2], Sally Bell[1,2]. [1]*Monash Health, Melbourne, Australia;* [2]*Monash University, Melbourne, Australia*
Email: natalielyngu@gmail.com

Background and aims: Hepatic encephalopathy (HE) occurs in 30–40% of patients with cirrhosis, and has a significant impact on quality of life, hospitalisation, and mortality. Transcatheter closure of large acquired portosystemic shunts (SPSS) may improve HE grading, overall performance status, and rates of rehospitalisation. We aim to describe characteristics and outcomes of patients with refractory HE following SPSS closure.

Method: We report a case series of 12 patients who underwent attempted angiographic obliteration of SPSS for treatment of refractory HE between January 2019 and November 2024 at a tertiary Australian hospital. Outcomes include radiological success, reduction in Westhaven HE grade at 4 weeks, and time to subsequent HE hospitalisation.

Results: A total of 12 patients were identified for inclusion. The median age was 64 years (Interquartile Range (IQR): 57–69), n = 7 were male, and n = 11 had cirrhosis, with portal hypertension attributed to chronic portal vein thrombosis in one patient (Type B). Baseline median Model for End-stage Liver Disease (MELD) score was 15 (IQR): 13–19) and median Child-Pugh score 9 (IQR: 8–11). One patient had no prior hospitalisation for HE and 2 had previously required intensive care unit support. Baseline Westhaven grades were 1 (n = 1), 2 (n = 8), 3 (n = 1), and 4 (n = 2) with 9 patients requiring assistance with self-care. All patients were prescribed lactulose and 11/12 were prescribed rifaximin at the time of the procedure. The main target shunt locations were splenorenal (n = 4), and left gonadal (n = 2). All SPSS were identified on four-phase computed tomography. Radiological closure of target SPSS was achieved in 10/12. Mean follow up was 450 ± 414 days with two deaths at 8 days and 199 days from SPSS closure. The first patient died during the index hospital admission with persistent grade 4 HE, the cause of the second is unknown, and both patients had successful obliteration of the target SPSS. At 4 weeks, 7 of the 11 surviving patients had documented resolution of overt HE, and the remaining 4 had grade 1 HE. Screening gastroscopy was performed post closure in 9 of which 6 had known varices. There were no procedure-related complications including subsequent variceal haemorrhage. A total 5 patients had subsequent admissions with HE at a mean 307 ± 226 days.

Conclusion: Transcatheter closure of large SPSS for refractory HE appears safe and effective in this small case-series. Whilst clinical success is difficult to establish retrospectively, positive results include readmission for HE in fewer than half and at a mean interval of 10 months. Findings support use of targeted imaging reviewed by an experienced radiologist to identify accessible SPSS in patients with portal hypertension and refractory HE in settings where shunt closure is available.

SAT-195

Daily step count using pedometer for sarcopenia management in patients with cirrhosis: a randomized controlled trial

Witchuta Niamsanit[1], Phunchai Charatcharoenwitthaya[1], Supot Nimanong[1], Tawesak Tanwandee[1], Watcharasak Chotiyaputta[1], Sapol Thepwiwatjit[1], Wimolrak Bandidniyamanon[1], Thanapat Atthakitmongkol[1], Siwaporn Chainuvati[1]. [1]*Division of Gastroenterology, Department of Internal Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand*
Email: niamsanit27@gmail.com

Background and aims: Sarcopenia, a condition characterized by reduced muscle mass and strength, affects nearly 40% of cirrhosis patients and is linked to increased mortality and hospitalization. Studies suggest that adequate nutrition and increased physical activity, as measured by daily step counts using pedometers, can improve muscle health in these patients. This study aims to compare the effectiveness of full pedometer recording (FPD) versus partial pedometer recording (PPD) on skeletal muscle index (SMI), sarcopenia resolution and mortality/hospitalization rates in patients with cirrhosis.

Method: In this prospective, open-label, randomized trial, sarcopenic cirrhotic patients were assigned to wear pedometer for 24 weeks (n = 27) or wearing pedometer for 12 weeks (n = 26). Both groups received standard medical care and protein supplements (16 grams) with albumin powder and soy-milk. Patients were encouraged to engage in active physical activity or walking for at least 30 minutes per day (minimum of 3000 steps/day) and all were remined twice per week via line app or by phone call. At baseline, 12 weeks, and 24 weeks complete blood count (CBC), serum creatinine, albumin (Alb), total bilirubin (TB) were collected. Anthropometric assessments and analysis of body fat percentage and measurement of skeletal muscle index (SMI) using bioelectrical impedance analysis (BIA). Standard frailty metrics were assessed, including the liver frailty index (LFI), handgrip strength, chair stand test, balance (3-positions), 6-minute walk test (6MWT), and gait speed test (GST).

Results: Total of 53 patients were enrolled (average age 65.2 years, 49.1% female, 39.6% with hepatitis C virus (HCV), 98% with Child-A cirrhosis. Both groups had similar demographics. At the 24-week follow-up, the change in SMI showed a slight improvement in the PPD group compared to the FPD group (1.45% ± 4.89% vs 1.22% ± 3.95%, p = 0.859). The daily step count was higher in the FPD group than in the PPD group (3992 steps [3042–7847] vs 2410 steps [1476–6466], p = 0.053). Thirteen (48.1%) patients in FPD and 10 (38.5%) patients in PPD group had resolution of sarcopenia (p = 0.47). The change in balance test in FPD group showed significant improvement compare to PPD group (0.00% [0.00–11.11] vs 0.00% [−0.83–0.00], p = 0.032). More than 72% of patients in both groups had stable or improved SMI. Two patients were hospitalized due to upper gastrointestinal bleeding, and no deaths were observed.

Conclusion: In sarcopenic cirrhotic patients who received nutritional supplements and continuous daily step count notifications via pedometer, no significant changes in SMI or resolution of sarcopenia were observed compared to the partial-monitor pedometer group. However, balanced test improvements were observed, reflecting improvements in liver frailty index. These findings suggest a trend toward improvement in sarcopenia in the FPD group.

SAT-196-YI

Prognostic performance of MELD and MELD 3.0 in 777 patients hospitalized with an acute decompensation of cirrhosis

Nikolaj Torp[1,2], Nicholas Freemantle[3], Mads Israelsen[1,2], Aleksander Krag[1,2], Alastair O'Brien[3,4]. [1]*Odense University Hospital, Odense, Denmark;* [2]*University of Southern Denmark, Odense, Denmark;*

[3]*Comprehensive Clinical Trial Unit, University College London, London, United Kingdom;* [4]*Royal Free Hospital, London, United Kingdom*
Email: a.o'brien@ucl.ac.uk

Background and aims: The Model for End-Stage Liver Disease (MELD) score prioritizes organ allocation for liver transplantation. While multiple prognostic scores exist for acute-on-chronic liver failure, clinicians often use MELD for ward-based management of complications to cirrhosis, despite its design for transplant allocation. We evaluated and compared the ability of MELD and MELD 3.0 to predict 90-day mortality in patients hospitalized with acute decompensation of cirrhosis.
Method: We analyzed data from the ATTIRE trial, which enrolled 777 patients with cirrhosis. Trial included patients admitted with acute decompensation and excluded those receiving palliative care or diagnosed with advanced hepatocellular carcinoma with a life expectancy of less than eight weeks. We calculated MELD and MELD 3.0 scores at randomization and evaluated their performance in predicting 90-day mortality using Akaike's Information Criterion for model fit. For prognostic discrimination, we used C-statistic, which is similar to time-dependent area-under-the-curve, and goodness of fit plots with Hosmer and Lemeshow tests for model calibration.
Results: Mean age was 53.8 years (±10.6) with 29% being female and with alcohol-related cirrhosis as the dominant etiology (90%). Majority of patients (97%) were admitted to the ward and 18 (3%) to the intensive care unit. Most admitted patients were due to new onset or worsening of ascites (67%), while the number of patients with organ dysfunction at admission was around 10%. At randomization, median MELD = 20 (IQR: 15–23) and MELD 3.0 = 23 (IQR: 18–27). The 90-day mortality was 24% and 4 patients (<1%) were transplanted during this period. The 90-day mortality C-statistic for MELD was 0.675 and 0.699 for MELD 3.0, which also had overall improved model fit (P = 0.0003). Model calibration for predicted and actual probability of 90-mortality was adequate for MELD, but poor for MELD 3.0 (p = 0.0295).
Conclusion: Our results highlight the limitations of MELD and MELD 3.0 when predicting mortality in hospitalized patients with predominantly alcohol-related cirrhosis where few were transplant candidates. In a ward-based setting, we recommend caution using these models in discussions with patients and relatives regarding prognosis, treatment escalation or palliation.

Smoking aggravates inflammation, fibrogenesis, angiogenesis and cancer risk in patients with cirrhosis
Nina Dominik[1,2], Benedikt Simbrunner[1,2,3], Bernhard Scheiner[1,2], Michael Schwarz[1,2], Lukas Hartl, Mathias Jachs, Lorenz Balcar, Georg Semmler, Georg Kramer[1,2,3], Christian Sebesta, Michael Trauner, Matthias Pinter[2], Mattias Mandorfer, Thomas Reiberger, Benedikt Hofer[1,2,3]. [1]*Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria;* [2]*Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria;* [3]*Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria*
Email: nina.dominik@meduniwien.ac.at

Background and aims: Smoking induces a proinflammatory state, yet the role of smoking in advanced chronic liver disease (ACLD) remains understudied. This study evaluated the impact of smoking on disease-driving mechanisms and clinical outcomes in ALCD patients.
Method: ACLD patients undergoing hepatic venous pressure gradient (HVPG) measurements from 2017–2021 were included. The association of smoking with biomarkers of inflammation, fibrogenesis, angiogenesis, and the incidence of hepatocellular carcinoma (HCC), extrahepatic malignancies, and mortality was examined.
Results: Among 339 ACLD patients (66.1% men, median age: 56.8 years, MELD: 11, HVPG: 17 mmHg), 62% (n = 210) were ever-smokers (n = 78 former, n = 132 active). Compared to never/former smokers, active smokers exhibited significantly higher white blood cell counts (5.49 vs. former: 4.74 vs. never: 4.25 G/L; p < 0.001) and C-reactive protein levels (CRP: 0.36 vs. former: 0.29 vs. 0.21 mg/dL; p = 0.035). Active smokers showed upregulated fibrogenesis (TIMP-1: 364 vs. former: 324 vs. never: 278 ng/mL, p < 0.001; P3NP: 20.9 vs. former: 15.6 vs. never: 17.2 µg/L, p = 0.008) and angiogenesis (PLGF: 21.7 vs. former: 18.2 vs. never: 19.0 pg/mL, p = 0.004) markers. Over a median follow-up of 30.4-months, ever-smokers exhibited a higher incidence of extrahepatic malignancies (HR: 11.04; p = 0.020) and numerically higher HCC incidence (HR: 2.28; p = 0.147; mostly evident in Child-Pugh A patients: HR: 7.34, p = 0.056). All-cause or liver-related mortality risk did not differ significantly between ever-smokers and never-smokers.
Conclusion: Smoking is linked to an upregulation of disease-driving mechanisms in ACLD and increases the risk of extrahepatic malignancies and potentially HCC. These findings underscore the importance of strategies supporting smoking cessation in ACLD patients.

SAT-198
Clinical and hemodynamic factors associated with hemoglobin levels in patients with liver cirrhosis
Jùlia Vidal-Sánchez[1], Natalia Jimenez-Esquive[1], Anna Baiges, Josep Marti Sanahuja[1], Fanny Turon, Virginia Hernández-Gea[2], Juan Carlos García-Pagán, Annabel Blasi[1], Enric Reverter[3]. [1]*Hospital Clinic Barcelona, Anaesthesiology and Critical Care Department, Barcelona, Spain;* [2]*Hospital Clinic Barcelona, Hepatic Hemodynamics, Hepatology Department, Barcelona, Spain;* [3]*Hospital Clinic Barcelona, Liver and Digestive ICU, Hepatology Department, Barcelona, Spain*
Email: ereverte@clinic.cat

Background and aims: Liver cirrhosis with portal hypertension leads to hemodynamic alterations including hydrosaline retention, increased plasma volume and cardiac index (CI) and decreased systemic vascular resistance (SVR). The effect of these hemodynamic changes on haemoglobin (Hb) levels has not been specifically assessed. Though cross-sectional studies suggest that anemia may worsen hyperdynamic circulation, it is unclear whether anemia is a cause or consequence of this condition. We aimed was to study the association between Hb levels and hepatic and systemic hemodynamic variables, as well as clinical variables in cirrhotic patients, both at baseline and in relation to temporal changes in these variables.
Method: retrospective cohort study of cirrhotic patients who underwent two serial hemodynamic studies (hepatic and systemic) separated by at least 3 months. Between these two assessments, most patients received treatments known to modulate systemic and hepatic hemodynamics. Baseline clinical and hemodynamic variables associated with Hb levels were studied, as well as the association of temporal changes in these variables with changes Hb levels.
Results: 242 patients were included: 88 with HCV eradication, 71 with TIPS placement, 33 with β-blocker initiation, and 50 with no significant events between assessments. At baseline, several clinical and liver function variables (prothrombin, albumin, Child score, MELD score, sodium, ascites), systemic hemodynamics (CI, SVR, mean arterial pressure-MAP, and hepatic hemodynamics (HVPG, wedge hepatic venous pressure (WHVP) were correlated with Hb levels. At multivariate analysis only albumin (β = 0.41), ascites grade (β = −0.24), and CI or indexed SVR (β = −0.20 and β = 0.23, respectively) were correlated with Hb (adjusted $R^2 = 0.38$). When analyzing temporal changes between hemodynamic studies, changes in Hb correlated with changes in albumin (β = 0.45), CI (β = −0.21), and MAP (β = 0.13) (or indexed SVR, β = 0.24); global adjusted $R^2 = 0.34$. Changes in hepatic hemodynamics did not independently correlate with changes in Hb. Subgroup analysis showed similar results.

Albumin had the strongest correlation with Hb and its changes across all comparisons.
Conclusion: Haemoglobin levels and their temporal changes in cirrhotic patients are largely correlated with albumin levels and variables related to hyperdynamic circulation and hydrosaline retention, suggesting a significant dilutional component in its values.

SAT-199-YI
A systematic review and meta-analysis of the ability of novel biomarkers to differentiate subtype of acute kidney injury and predict response to terlipressin treatment
Olivia Greenham[1], Amaan Ali[1], Kohilan Gananandan[1], Rajeshwar Prosad Mookerjee[1]. [1]*Liver Failure Group, University College London, London, United Kingdom*
Email: olivia.greenham@nhs.net

Background and aims: Acute kidney injury (AKI) in patients with cirrhosis carries significant morbidity and mortality and accounts for 20% of acute decompensation admissions. Plasma creatinine (pCr) is used to measure severity of kidney dysfunction but is not a sensitive marker for early AKI detection and overestimates glomerular filtration rates in cirrhosis patients. pCr is also unable to differentiate between subtypes of AKI; pre-renal, acute tubular necrosis (ATN) and hepatorenal syndrome (HRS-AKI), which have different treatment options and prognoses. Current guidelines advise assessing response treatment over an initial 24–48 hours of AKI diagnosis to differentiate between subtypes. However, response to terlipressin in patients with HRS-AKI is reported as low as 35–50% with contributing factors being incorrect diagnosis and delayed treatment. We performed a literature search and metanalysis to assess the ability of novel biomarkers to diagnose subtype of AKI and predict response to terlipressin in HRS-AKI.
Method: Searches of OVID EMBASE and MEDLINE databases from inception to 6th June 2024. The search strategies included terms for cirrhosis, biomarkers and outcomes of interest. We included prospective and retrospective studies including cohort studies and randomised control studies and excluded conference abstracts, letters, reviews, experimental studies and case studies. Our primary outcome was the ability of a novel biomarker to predict the subtype of AKI in patients with cirrhosis. The secondary outcome was the ability of a novel biomarker to predict patients' response to terlipressin in HRS-AKI. 657 records were identified with 506 abstracts screened and 109 papers assessed for eligibility. 25 papers were found which fulfilled this study's objectives.
Results: 25 studies assessed the ability for biomarkers to diagnose subtype of AKI. 46 plasma and urinary biomarkers were assessed in 17493 patients. Urinary neutrophil gelatinase-associated lipocalin (NGAL) was the most investigated biomarker in 19 papers. A metanalysis was performed on the ability of 4 urinary biomarkers to predict ATN using the Area Under the Receiver Operating Characteristic curve (AUROC) with 95% CI values; NGAL 0.88 (0.85–0.91), interleukin 18 (IL-18) 0.92 (0.88–0.95), kidney injury molecule 1 0.66 (0.57–0.76), and B2-microglobulin 0.71 (0.63–0.91). 15 plasma and urinary biomarkers were assessed in 1717 patients in 8 studies to predict a response to terlipressin. The studies were unable to show a statistically significant correlation for any biomarker studied.
Conclusion: Urinary NGAL and urinary IL-18 demonstrate a strong ability to differentiate AKI subtypes which provides an opportunity for directing therapy earlier. However current biomarkers lack predictive utility for response to terlipressin. A limited number of studies with low patient numbers likely contribute to a lack of positive findings. Better diagnostic tools are required to improve early diagnosis and treatment of AKI in cirrhosis.

SAT-200
Effect of human albumin solution on coagulation parameters in decompensated cirrhosis (CoPA-D): an open-label randomized control trial
Omkar Rudra[1], Vinod Arora[1], Dr Babu Lal Meena[1], Manoj Kumar[1], Ayush Jain[1], Akhil Deshmukh[1], Imran Khan[1], Satyakam Pandey[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: shivsarin@gmail.com

Background and aims: Albumin is commonly used in cirrhosis for multiple indications and is a disease modifying agent. Due to rapid transformation of exogenous albumin into nitroso-albumin and its effects on platelets, albumin infusion may alter the coagulation system. Since cirrhosis is a state of dysregulated clotting and bleeding, we evaluated the effect of serial human albumin solution (HAS) infusion on coagulation parameters in decompensated cirrhosis.
Method: Decompensated cirrhosis patients (18–70 years) with serum albumin ≤2.5 g/dl were randomised to standard-of-care (SOC) arm or SOC + HAS (Albumin) arm. Patients in albumin arm received standard medical treatment (SMT) with 20% HAS daily to raise and maintain serum albumin levels ≥3 g/dl. Those in SOC arm received SMT without HAS. Derangement of coagulation was assessed by battery of coagulation tests and serial rotational thromboelastometry (ROTEM) at day 0, 1 and 3. Data analysed using independent t-test, repeated measures and paired t-test.
Results: 90 patients completed the study, 50 in albumin and 40 in SOC arm. Baseline parameters including MELD [17.18 ± 4.94 in albumin and 17.15 ± 4.74 in SOC group (p = 0.980)] were comparable. 9 patients achieved target serum albumin ≥3 g/dl on day 1 and 38 by day 3. In the albumin arm, within the first 24 hours, an increase was seen in activated partial thromboplastin time test (apTT) (seconds) from 39.4 ± 9.6 to 43.4 ± 10.2 (p < 0.001), international normalized ratio (INR) from 1.77 ± 0.4 to 1.88 ± 0.44 (p = 0.001), clotting time (CT) of extrinsically activated thromboelastometric test (EXTEM) (seconds) from 82.64 ± 27 to 98.18 ± 33 (p < 0.001), clot formation time (CFT) EXTEM (seconds) from 210.9 ± 117.17 to 263.34 ± 130.67 (p < 0.001). Significant reduction seen in fibrinogen (mg/dl) from 165.1 ± 101.2 to 140.96 ± 86.56 (p < 0.001), maximum clot firmness (MCF) EXTEM (mm) from 45.14 ± 12.10 to 42.58 ± 11.70 (p < 0.001), A10 fibrinogen-based thromboelastometry (FIBTEM) (mm) from 10.6 ± 6.14 to 8.54 ± 5.69 (p < 0.001), A20 FIBTEM (mm) from 11.18 ± 6.31 to 9.02 ± 5.63 (p < 0.001) and MCF FIBTEM (mm) from 11.32 ± 6.97 to 9 ± 6.06 (p < 0.001). Subsequent albumin transfusions on day 2 and 3 showed further worsening of coagulation parameters. Human von-Willebrand factor (ng/ml) was unchanged on day 1 [43.19 ± 19.27 and 43.80 ± 21.21 (p = 1)] but subsequently reduced to 31.60 ± 14.70 at 72 hours (p < 0.001). ADAMTS levels remained unchanged at 24 and 72 hours. No similar significant changes seen in coagulation parameters in SOC arm. Total of 9 (10%) patients required coagulation correction for therapeutic interventions, 6 (12%) in SOC and 3 (7.3%) in albumin arm (p = ns), but none had clinically significant bleeding.
Conclusion: Human albumin solution in standard doses causes significant derangement in ROTEM-based coagulation parameters within 24 hours. Monitoring of coagulation parameters is advisable for decompensated cirrhosis patients receiving HAS.
[Trial registration - NCT05937048].

SAT-205
Dynopenia predicts mortality in patients with liver cirrhosis and hepatocellular carcinoma
Paolo Gallo[1], Valentina Flagiello[1], Antonio De Vincentis[2], Simone Di Cola[3], Francesca Terracciani[1], Andrea Falcomata'[1], Antonio Picardi[1], Umberto Vespasiani-Gentilucci[1]. [1]*Clinical Medicine and Hepatology Unit, Campus Bio-Medico University, Rome, Italy;* [2]*Internal Medicine Unit, Campus Bio-Medico University, Rome, Italy;* [3]*Department of Translational and Precision Medicine, Sapienza*

University of Rome, Rome, Italy
Email: paolo.gallo@policlinicocampus.it

Background and aims: Sarcopenia is a common complication in patients with liver cirrhosis and hepatocellular carcinoma (HCC). Recent advances in geriatric research have led to a paradigm shift, identifying low muscle strength as the primary determinant of negative outcomes in sarcopenia. However, few studies have thoroughly investigated the clinical impact of muscle strength in liver disease. The aim of this study was to evaluate the role of dynopenia (reduced muscle strength) in predicting mortality among patients with liver cirrhosis and HCC.
Method: The study included consecutive adult outpatients attending the Hepatology Unit of the Fondazione Policlinico Campus Bio-Medico of Rome. Muscle strength was assessed using handgrip dynamometry, following the recommendations of the EWGSOP 2019 (<27 kg for men and < 16 kg for women). Diaphragmatic excursion was assessed with ultrasound and considered a proxy of low muscle strength. In a subgroup of population, we assessed muscle mass by bioimpedance analysis (appendicular skeletal muscle mass calculated according to the Sergi equation - EWGSOP 2019). The associations between sarcopenia proxies and 24-month all-cause mortality were evaluated using both crude and adjusted Cox regression models. Survival was estimated through Kaplan–Meier estimates, and survival curves were compared using the log-rank test.
Results: A total of 158 patients were included in the analysis [mean age 73.1 years (SD 7.4), 77% male, median BMI 27.3 kg/m^2 (IQR 24.6–29.8)]. Viral cirrhosis was the most common etiology (37%), with 77% of patients classified as Child-Pugh class A. Active HCC was observed in 61% of patients, most of whom were classified as BCLC stage A or B (74%). Low muscle strength and diaphragmatic excursion were independently associated with 24-month mortality [aHR 1.66 (1.22–2.27), p = 0.001, and aHR 0.64 (0.42–0.98), p = 0.042, respectively] after adjustment for age, gender, and MELD. Kaplan–Meier analysis showed significantly reduced survival in patients with dynopenia compared to those without (60% vs 78%; log-rank test, p = 0.0047). In the subgroup analysis of 65 patients, low muscle strength was the only factor independently associated with 24-month mortality [aHR 1.96 (1.15–3.35), p = 0.014], while diaphragmatic excursion showed a trend toward significance [HR 0.48 (0.22–1.04), p = 0.06]. Conversely, muscle mass indices were not associated with all-cause mortality. Finally, Kaplan–Meier analysis confirmed a significantly reduced survival in patients with dynopenia compared to those without in this subgroup (log-rank test, p = 0.0068).
Conclusion: Dynopenia has emerged as a key prognostic determinant in cirrhotic patients with HCC, particularly in the earlier stages of the disease. In our small cohort, it was identified as the only muscle-related parameter significantly associated with mortality. If validated in larger, independent cohorts, dynopenia could serve as a robust early marker to identify patients at higher risk of poor outcomes.

SAT-206

Hepatic perfusion measured with 15Oxygen-water-Positron emission tomography/computed tomography correlates with severity of cirrhosis

Paul Runeson[1], Johan Vessby[1], Mark Lubberink[2], Gunnar Antoni[3], Fredrik Rorsman[1]. *[1]Uppsala University, Department of Medical Sciences, Akademiska University Hospital, Uppsala, Sweden; [2]Uppsala University, Department of Surgical Sciences, Akademiska University Hospital, Uppsala, Sweden; [3]Uppsala University, Department of Medicinal Chemistry, Akademiska University Hospital, Uppsala, Sweden*
Email: paul.runeson@medsci.uu.se

Background and aims: There is a need for accurate non-invasive diagnostic tools for evaluation of liver function and prognosis in liver cirrhosis. As intravenously administered water follows blood flow, radioactive ^{15}O-water serves as a reliable tracer for perfusion studies. In this study we investigated liver perfusion in patients with cirrhosis using ^{15}O-water-PET/CT aiming to correlate the resulting quantitative hemodynamic parameters with clinical parameters relating to the severity of cirrhosis.
Method: Twenty-three patients with varying degrees of liver cirrhosis and three controls without cirrhosis were examined using dynamic ^{15}O-water-PET/CT. The quantitative perfusion measurements calculated included total hepatic perfusion, portal hepatic perfusion, arterial hepatic perfusion, portal hepatic flow, and arterial hepatic flow. The severity of cirrhosis was assessed by Child-Pugh score and model of end-stage liver disease (MELD) score, liver stiffness measurement (LSM) by transient elastography, and the presence or absence of esophageal varices on gastroscopy. Spearman's correlation coefficient was used to calculate the correlation of the perfusion measurements with clinical factors.
Results: Total hepatic perfusion negatively correlated with Child-Pugh score (r = –0.609, p = 0.002), MELD-score (r = –0.449, p = 0.032) and LSM (r = –0.483, p = 0.019). Portal hepatic perfusion negatively correlated with Child-Pugh score (r = –0.614, p = 0.002) and MELD-score (r = –0.548, p = 0.007) and LSM (r = -0.422, p = 0.045). Portal hepatic flow also negatively correlated with Child-Pugh score (r = –0.681, p = <0.001) and MELD-score (r = –0.584, p = 0.003), but not with LSM. No correlation was found between clinical parameters and arterial hepatic perfusion or arterial hepatic flow. Total hepatic perfusion (r = –0.597, p = 0.004), portal hepatic perfusion (r = –0.604, p = 0.004) and portal hepatic flow (r = –0.540, p = 0.011) negatively correlated to presence of esophageal varices on gastroscopy.
Conclusion: Hepatic hemodynamic parameters in liver cirrhosis measured with ^{15}O-water-PET/CT correlated with Child-Pugh score, MELD-score, LSM, and the presence of esophageal varices. PET measurements of total hepatic perfusion, portal hepatic perfusion, and portal hepatic flow decreased with increasing severity of cirrhosis and with presence of esophageal varices. Future studies will further develop this technique and explore its clinical potential.

SAT-207

High mortality of further decompensation of liver cirrhosis: validation study

Petra Dinjar Kujundžić[1], Frane Pastrovic[1,2], Mislav Barišić-Jaman[1], Marko Milosevic[1], Stela Bukvić Milosevic[1], Josip Stojic[1], Viktoria Skurla[1], David Dohoczky[1], Stjepan Budisa[3], Alan Ayoub[1], Sandro Kukic[4], Ivica Grgurević[1,4]. *[1]University Hospital Dubrava, Zagreb, Croatia; [2]Faculty of Pharmacy and Biochemistry, University of Zagreb, Zagreb, Croatia; [3]Community Health Centre of the Zagreb County, Samobor, Croatia; [4]School of medicine, University of Zagreb, Zagreb, Croatia*
Email: ivicag72@gmail.com

Background and aims: To validate the concept of further decompensation (FD) as a more severe stage in the progression of cirrhosis and its association with outcomes in a cohort of hospitalized patients experiencing their first decompensation of liver cirrhosis.
Method: A retrospective analysis of patients hospitalized with their first episode of decompensation at a tertiary center over a 5-year period. Diagnosis of liver cirrhosis relied upon histology or a combination of clinical criteria in patients with a history of chronic liver disease. We analyzed clinical, laboratory, imaging features and mortality of the first decompensation and outcomes of patients who survived the first decompensation, based on the development of FD. Patients were followed until death or liver transplantation, which were considered composite adverse outcome, or until the censored date.
Results: The analysis included 247 patients hospitalized for their first decompensation of cirrhosis (average age 60 years, 74.1% male, 77.7% alcohol-associated liver disease, 10.1% metabolic dysfunction-associated steatotic liver disease, MELD-Na 19, Child-Pugh score (CPS) 10), without concomitant chronic heart disease, respiratory or renal failure, or malignancy, who were followed for an average (median) 28 months. Of them, 58 (23.8%) presented with non-acute (NAD), and 186 (76.2%) with acute decompensation (AD). During the first

hospitalization, 44 (17.8%) patients died. Out of 203 surviving patients, 102 (50.2%) developed FD. During the follow-up adverse outcome occurred in 59/102 (57.8%) patients who experienced subsequent decompensation, compared to 28/101 (27.7%) patients who did not have additional decompensation ($p < 0.001$). The risk of 3-year mortality was significantly higher for patients who developed FD (HR = 1,712, 95% CI 1,012–2,97, p = 0,04), whereas the type of initial decompensation (AD vs. NAD) did not influence survival. In univariate logistic regression none of the tested clinical, laboratory, or imaging features from the first decompensation were associated with the risk of developing FD. Higher initial CPS, MELD-Na scores, and occurrence of FD, were associated with the increased 3-year risk of dying. In multivariate analysis only CPS (HR 1.420, CI 1.093–1.844, p = 0.008) remained independently associated with the 3-year mortality. Patients with CPS>8 at initial decompensation who subsequently developed FD experienced adverse outcome more frequently compared to patients who did not develop FD (64.3% vs 29.6%, $p < 0.001$).

Conclusion: Further decompensation represents an advanced stage of cirrhosis with high mortality. It is essential to define risk factors for the development of this disease stage and further investigate its relationship with conventional indicators of liver function, such as CPS and MELD score.

SAT-208

Elevated serum ammonia is a poor prognostic marker for 1 year liver related outcomes and external validation of AMMON-OHE prediction model in stable outpatient cirrhosis

Pooi Ling Loi[1], Yan Ling Ong[1], Sakktivel Elangovan[1], Marianne DeRoza[2], Hiang Keat Tan[3], Chanda Ho[3], Jason Pik Eu Chang[3], Rahul Kumar[4]. *[1]Changi General Hospital, Singapore, Singapore, Singapore; [2]Sengkang General Hospital, Singapore, Singapore, Singapore; [3]Singapore General Hospital, Singapore, Singapore, Singapore; [4]Changi General Hospital, Singapore, Duke-NUS Medical School, Singapore, Singapore, Singapore*
Email: pooiling.loi@mohh.com.sg

Background and aims: Prediction of the liver related outcomes in stable cirrhosis patient poses a challenge. Traditional scores like MELD and Child-Pugh (CTP) score perform poorly. Ammonia is central to the pathogenesis of hepatic encephalopathy (HE). Although CTP score includes HE, it is limited by interobserver variability. Recently serum ammonia has been reported to predict the long-term outcomes in stable cirrhosis patients and a new "AMMON-OHE" score has been proposed to predict the liver related outcomes (LRE) of these patients. The aim of this study is to test the hypothesis whether serum ammonia can predict the liver related outcomes and to externally validate AMMON-OHE score.

Method: In this ongoing multi-centre study to predict the decompensation, acute on chronic liver failure and mortality in cirrhosis (SoLiDaRity), 206 stable out-patient cirrhotic were recruited since January 2023. Patients were censured at liver related clinical outcomes (LRE), liver transplant or death. The primary endpoint was all non-elective admissions for LRE defined as worsening ascites requiring admission, HE, variceal bleeding or infection at 1 year. The 1-year clinical outcomes were reviewed from 1st ammonia measurement. Standard statistical tests were applied.

Results: The median follow up duration of the cohort was 373 (IQR: 193–467) days. Majority of the patients were male (59.2%) with mean age of 66 ± 10.3 years. MASLD was the most common aetiology (47.6%) followed by HBV (23.8%). A total of 37.4% patients had decompensated cirrhosis, rest were in compensated stage. Patients with CTP classes A/B/C were 75%, 21% and 4% respectively. The median MELD of the cohort was 8 (IQR: 6–11). A total of 31 (15%) patients developed LRE within 1 year of ammonia measurements. The median ammonia in patients who achieved LRE and those who did not was 53 (IQR:38–63) and 25 (IQR:18–39) respectively. Similarly, the median AMMON-OHE scores were 0.17 (0.08–0.20) and 0.02 (IQR: 0.01–0.10) ($p < 0.001$ for both). The MELD and CTP score as well CRP and white cell count were higher in patients developing LRE ($p < 0.05$ for all). The univariate cox regression showed MELD, CTP, CRP, WCC, ammonia and AMMO-OHE score as predictors of LRE. Ammonia and OHE scores remained an independent predictor or 1-year LRE in multivariable analysis. Performance of MELD, AMMON-OHE score and ammonia in predicting 1-year LRE was then assessed based on area under receptor operator curve (AUROC). CTP score had the best AUROC of 0.837 followed by AMMON-OHE score of 0.818 followed. Ammonia and MELD had AUROC of 0.799 and 0.734 respectively. The best cut off to predict LRE at 1 year for ammonia was 33 umol/L with 84% sensitivity and 71% specificity.

Conclusion: Measurement of ammonia for outpatient stable cirrhosis patients may aid in the prediction of LRE within 1 year. AMMON-OHE score fairs well in predicting 1-year LRE in this external cohort and can be used as a tool for patient monitoring.

SAT-209

Randomized, open-label, phase 2a comparator study to assess the pharmacodynamics, safety and pharmacokinetics of oral administration of mnk6106 (l-ornithine phenylacetate) vs. rifaximin in subjects with hepatic cirrhosis and a previous history of hepatic encephalopathy

Darren Rubin[1], Tarek Hassanein[2], Peter Winkle[3], Eric J. Lawitz[4], Roxanna Stoici[5], Zeid Kayali[6], Grisell Ortiz Lasanta[7], Rajiv Jalan. *[1]Yaqrit Discovery Limited, London, United Kingdom; [2]Southern California GI & Liver Centers (SCLC), San Diego, United States; [3]CenExelAct, Anaheim, United States; [4]Texas Liver Institute, San Antonio, United States; [5]GCP Research, St. Petersburg, United States; [6]Inland Empire Liver Foundation, Rialto, United States; [7]FDI Clinical Research, San Juan, Puerto Rico*
Email: darren@yaqrit.com

Background and aims: Ammonia plays a central role in the pathogenesis of hepatic encephalopathy (HE). There are no approved treatments targeting ammonia. L-Ornithine Phenylacetate (L-OPA) has a unique mechanism of action involving its permanent excretion as phenylacetylglutamine (PAGN). It lowers ammonia rapidly when administered by iv. The aims of this dose response study were to evaluate the efficacy of oral L-OPA on reducing plasma ammonia (AMM). Safety, tolerability, pharmacokinetics and exposure response relationships were also evaluated.

Method: 48-decompensated cirrhosis patients with previous history of overt HE (28 male, mean 57.2 years; mean MELD (range): 8.8–12.1; Pugh (range): 7–8) were randomized 1:1:1:1 to receive 1 of the 3 dosing regimens of L-OPA [Group A, 2 g TID; Group B, 4 g BID, Group C, 4 g TID], or rifaximin (Group D, 550 mg bd), for 5-days. Subjects were assessed for clinical functional scoring and liver scores. All biochemical variables were measured in a central laboratory. Adverse events (AEs) were recorded.

Results: AMM levels decreased significantly more in Groups B and C compared with the rifaximin, Group D. The levels between baseline and Day 5 [umol/L; mean (SD)] were; Group A: 68.1 (26.8) to 75.2 (27.3); Group B: 88.9 (34.4) to 59.3 (13.6); Group C: 87.5 (33.8) to 74.1 (11.6); Group D: 81.5 (23.8) to 75.4 (29.7). Percentage change from baseline to Day 5 were +2.04 (35.6); −26.3 (27.0); −11.9 (30.6); and −4.20 (26.8) in Groups A, B, C and D respectively. In general, in the L-OPA groups, mean increases in plasma L-ornithine, phenylacetate and PAGN concentrations were observed with increase in dose and dosing regimen. Cumulative amount of urinary excretion of PAGN in general was similar on all days for each group. Overall, 20 (55.6%) patients who received L-OPA and 5 (41.7%) subjects who received rifaximin had at least 1 treatment-emergent adverse event. No significant differences in adverse events (AEs) were observed between groups. No significant trends were seen in laboratory results, neuropsychiatric tests, vital signs or ECGs (no subject had a QT or QTcF interval >500 ms or increased by >60 ms) between groups. Overall, the

subjects reported improvement in clinical function during treatments.
Conclusion: Group B (L-OPA 4 g BID) showed the highest decrease in plasma AMM concentrations which was about 6 times greater than Rifaximin and this dose may be selected for future trials. All doses of L-OPA were safe and well tolerated.

SAT-210
Development and validation of the modified hepatic encephalopathy staging tool (mHEST) for grading of hepatic encephalopathy for accurate assessment and regulated clinical trials
Caterina Chesta[1], Darren Rubin[2], Brooke M. Currie[3], Marissa Walsh[3], Saifra Sohail[3], Karin Coyne[3], Rajeshwar Prosad Mookerjee[4], Tarek Hassanein[5], Rajiv Jalan. *[1]1Liver Failure Group, Institute for Liver and Digestive Health, University College London, London, United Kingdom; [2]Yaqrit Discovery Limited, London, United Kingdom; [3]Evidera Limited, Bethesda, United States; [4]University College London, London, United Kingdom; [5]Southern California GI & Liver Centers (SCLC), San Diego, United States*
Email: cchesta@uchile.cl

Background and aims: Hepatic encephalopathy (HE) is one of the most common complications of liver cirrhosis for which treatment options are limited. Although the West Haven (WH) scale is recommended by guidelines for defining severity, it is considered inadequate by regulatory bodies such as the FDA due to significant intra- and inter-rater variability between observers. Therefore, the Hepatic Encephalopathy Staging Tool (HEST) test was developed but considered inadequate due to inclusion of asterixis as a variable. Therefore, the modified HEST (mHEST) was developed, which excludes asterixis and includes variables that are unlikely to be influenced through interpretation. The aims of this study were to determine the inter-rater and intra-rater agreement of the mHEST test.
Method: 49-healthcare workers including doctors, nurses and physician assistants from 6 countries participated in the study. 6-brief video vignettes of actors in various stages of HE were created. Two rounds of evaluations were conducted. In the first round, a mHEST introductory video was shown, and then participants were asked to assess the video vignettes and stage them according to mHEST. Second round was 5 to 10 days later, whereby participants reassessed the same videos and staged them again.
Results: For the inter-rater reliability results in Round 1, 44 participants (89.8%) correctly rated Vignette A as Stage 0/1 and Vignette C as Stage 3; 45 participants (91.8%) correctly rated Vignette B as Stage 2; 49 participants (100%) correctly rated Vignette D as Stage 4; and 46 (93.9%) correctly rated Vignettes E and F as Stage 2 and Stage 3, respectively. For intra-rater (test-retest) reliability, concordance between participants' Round 1 responses and their Round 2 responses was as follows: 88.1% (Vignette A, Stage 0/1); 81.0% (Vignette B, Stage 2); 88.1% (Vignette C, Stage 3); 100% (Vignette D, Stage 4); 90.5% (Vignette E, Stage 2); and 92.9% (Vignette F, Stage 3).
Conclusion: mHEST demonstrated excellent inter-rater and intra-rater reliability. Specifically, results from the current study suggests that clinical support staff, irrespective of experience, can accurately and consistently identify the HE severity of cirrhosis patients using the mHEST grading system. This HE staging system has been approved by the regulators such as the FDA, EMA and PMDA for use as an end point for Phase-3 trial of ornithine phenylacetate in cirrhotic patients with overt HE.

SAT-211
Risk of hepatocellular carcinoma and cirrhosis decompensation in a large retrospective cohort of cirrhotic patients with autoimmune hepatitis
Mifleh Tatour[1], rawi hazzan[2], Tarek Saadi[3], Fadi Abu Baker[4]. *[1]Clalit Health Services, Northern Region, Israel, Department of Family Medicine, Clalit Health Services, Northern Region, Israel, Afula, Israel, Israel; [2]Clalit Health Services, Northern Region, Israel, Azrieli Faculty of Medicine, Bar-Ilan University, Safed, Israel, Afula, Israel, Israel; [3]Liver Unit, Rambam Health Care Campus, Haifa, Israel, Bruce Rappaport Faculty of Medicine, Technion – Israel Institute of Technology, Haifa, Israel, Haifa, Israel; [4]Department of Gastroenterology and Hepatology, Hillel Yaffe Medical Center, Hadera, Israel, Bruce Rappaport Faculty of Medicine, Technion – Israel Institute of Technology, Haifa, Israel, Hadera, Israel*
Email: Mifleh.rt.1989@gmail.com

Background and aims: Autoimmune hepatitis (AIH) is a chronic inflammatory liver disease that can lead to cirrhosis in up to 30% of patients. Cirrhotic patients are at risk of high morbidity and mortality due to cirrhosis decompensation and hepatocellular carcinoma (HCC). This retrospective study aimed to assess the rates of decompensated cirrhosis and HCC in patients with AIH- related cirrhosis.
Method: This retrospective population-based study included adult patients diagnosed with AIH between the years 2000 and 2020 in a cohort of approximately 2.7 million adults. We investigated the rates of cirrhosis development, cirrhosis decompensation, and HCC among 774 AIH patients. The primary outcomes were rates of decompensated cirrhosis and HCC in patients who developed cirrhosis.
Results: Among the 774 AIH patients, 40% developed cirrhosis. During a median follow-up of 8.2 years (IQR 2.9–12.3), the annual incidence of decompensated cirrhosis was 4.25%, with a mean time of 8.2 years from cirrhosis diagnosis to decompensation. Nineteen cirrhotic patients (6.2%) developed HCC, with a yearly incidence rate of 0.63%. Most HCC cases occurred within the first years of cirrhosis diagnosis.
Conclusion: The rate of decompensated cirrhosis in AIH patients was lower than in other cirrhotic liver diseases, suggesting AIH may follow a different clinical course. The annual incidence of HCC was also significantly lower than the threshold for HCC surveillance, indicating the need to reassess current surveillance guidelines, particularly in the late years following cirrhosis diagnosis.

SAT-212-YI
Lipopolysaccharide-binding protein indicates risk for infections and liver-related death in patients with compensated and decompensated liver cirrhosis
Rhea Veelken[1,2], Benedikt Simbrunner[1], Georg Kramer[1], Nina Dominik[1], Benedikt Hofer[1], Lorenz Balcar[1], Christian Sebesta[1], Paul Thöne[1], Lukas Hartl[1], Mathias Jachs[1], Michael Trauner[1], Albert Friedrich Stättermayer[1], Thomas Berg[2], Florian van Bömmel[2], Mattias Mandorfer[1], Thomas Reiberger[1]. *[1]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Division of Hepatology, Department of Medicine II, University Hospital of Leipzig, Leipzig, Germany*
Email: rhea.veelken@medizin.uni-leipzig.de

Background and aims: Translocation of bacteria or endotoxins represent an important mechanism contributing to hepatic decompensation in cirrhosis. Lipopolysaccharides (LPS) are components of the cell envelope of gram-negative bacteria, and LPS-binding protein (LBP) is a stable marker of bacterial translocation (BT) that may hold prognostic value in patients with cirrhosis. BT and infections indicate immune dysfunction in cirrhosis, which hold a high risk for mortality, underlining the unmet clinical need for an accurate and early risk prediction for infections in this population. Thus, the aim of our study was to investigate the association of LBP with development of infections or death in patients with liver cirrhosis.

Method: Patients with cirrhosis w/o infections or malignancies undergoing hepatic venous pressure gradient (HVPG) measurement at the Medical University of Vienna between 2017–2023 and with available LBP results were prospectively enrolled (VICIS; NCT03267615). Infections, liver-related deaths and transplant-free survival were recorded. Spearman correlation analysis and Kaplan-Meier estimation were performed.
Results: A total of 413 patient (median age of 57 years; 138 [33%] women) with a median MELD of 11 (IQR 9–15) and median LBP of 6.75 (IQR 5.16–8.77) µg/mL were included. The 216 (52.3%) compensated cirrhosis (CC) patients showed no difference in median LBP levels compared to the 197 (47.7%) decompensated cirrhosis (DC) patients (6.99 vs 6.66 µg/mL; p = n.s.). LBP levels showed direct correlations of weak (Spearman $\rho = 0.32$; $p < 0.001$) and moderate ($\rho = 0.504$; $p < 0.001$) strength with IL-6 and CRP, respectively, while there was no correlation between LBP and HVPG ($\rho = -0.083$, $p = 0.096$). Based on LBP tertiles, patients were categorized into groups with different risks for BT: low-LBP (n = 139; 45.3% CC), median LBP 4.67 [range, 1.57–5.61] µg/mL; mid-LBP (n = 137, 61.3% CC), median LBP 6.76 [range, 5.63–7.93] µg/mL; high-LBP (n = 137; 50.4% CC) median LBP 10.2 [range, 7.94–32] µg/mL. Patients with low and mid-LBP levels had longer median OS of 25 [95CI 45.07–54.8] months and 28 [95% CI 47.9–56.6] months, as compared to those with high-LBP levels with a median liver-related transplant-free survival of 19 [95% CI 46.8–52.7] months (log-rank p = 0.004). Patients with high-LBP showed a significantly shorter time to develop an infection or to liver-related death (median 15 [95% CI 33.5–45.2] months) than patients with low-LBP (21 [95% CI 39.6–49.9] months) or mid-LBP (26 [95% CI 40.8–49.79] months; log-rank p = 0.014).
Conclusion: LBP levels were linked to severity of systemic inflammation but not to PH severity nor to decompensated state (DC), suggesting that LBP may reflect BT as a pathomechanism rather than disease severity. Importantly, ACLD patients with high-LBP (also including 50% CC patients) had an increased risk for infections and liver-related mortality.

SAT-213-YI
Muscle mass assessed by rectus femoris ultrasound predicts clinical outcomes in cirrhosis: a step beyond the "black-and-white" classification of sarcopenia

Roberta Gagliardi[1], Paola Campadello[1], Silvia Brocco[1], Simone Incicco[1], Valeria Calvino[1], Beaudelaire Sikadi[1], Marta Tonon, Carmine Gambino[1], Nicola Zeni[1], Anna Barone[1], Giorgio De Conti[2], Chiara Giraudo[2], Paolo Angeli[1], Salvatore Piano. *[1]Unit of Internal Medicine and Hepatology, Department of Medicine, University and Hospital of Padova, Padova, Italy, Padova, Italy; [2]Radiology Unit, Department of Medicine, University and Hospital of Padova, Padova, Italy, Padova, Italy*
Email: salvatore.piano@unipd.it

Background and aims: Sarcopenia is common in patients with cirrhosis and is strongly linked to adverse clinical outcomes. Traditionally, sarcopenia is viewed as a binary condition - either present or absent. However, the degree of muscle loss may significantly influence clinical outcomes, highlighting the need to consider muscle mass as a continuous variable rather than a dichotomous one. Despite this, few studies have yet evaluated muscle loss in a linear context. The ultrasound measurement of rectus femoris cross-sectional area (RF-CSA) has demonstrated excellent accuracy in assessing sarcopenia in patients with cirrhosis. This study aimed to evaluate: (a) the prognostic significance of the RF-CSA in patients with cirrhosis hospitalized for an acute decompensation (AD) of the disease.
Method: Thigh ultrasound was performed at bedside in 203 consecutive patients hospitalized for an AD of cirrhosis. RF-CSA was measured at two-thirds of the distance from the anterior superior iliac spine to the superior patellar border; three measurements were collected, and the mean value was calculated. RF-CSA was considered as a continuous variable. Patients were followed up until death, liver transplant or 90 days and data about complications during hospitalization and mortality were recorded.
Results: Among hospitalized patients (mean age: 64 ± 10 years, median MELD 17), median RF-CSA was 3.09 cm^2. During hospitalization, 32 patients (16%) died. RF-CSA was significantly lower in patients who died compared to survivors (2.64 cm^2 vs 3.20 cm^2; p = 0.005). In multivariable analysis (adjusted for age, gender, MELD and infections) RF-CSA was an independent predictor of 90-day mortality (sHR = 0.57; p = 0.006), along with MELD (sHR = 1.11; p < 0.001). Stratification of RF-CSA in tertiles demonstrated that greater severity of muscle loss was associated with a higher cumulative incidence of 90-day mortality (first tertile 39% vs second 26% vs third 12%; p = 0.001). Additionally, RF-CSA was an independent predictor of in-hospital complications, including sepsis (OR = 0.59; p = 0.001), shock (OR = 0.60; p = 0.005), AKI (OR = 0.75; p = 0.019) and hepatic encephalopathy (OR = 0.78; p = 0.023).
Conclusion: Sarcopenia represents a spectrum, with greater muscle loss leading to worse outcomes and higher in-hospital and 90-day mortality. Ultrasound assessment can aid in risk stratification, enabling targeted interventions to slow or prevent muscle loss and potentially improve clinical outcomes.

SAT-214
Micronutrients supplementation in patients with liver cirrhosis: a single-arm prospective cohort study

Yiran Wang[1,2], James Williams[3], Emily Schembri[1], Steven Trinh[3], Stephen Bloom[1,2,3], Rohit Sawhney[1,2,3]. *[1]Eastern Health Clinical School, Melbourne, Australia; [2]Monash University, Melbourne, Australia; [3]Eastern Health, Melbourne, Australia*
Email: ywan0355@student.monash.edu

Background and aims: Patients with cirrhosis have an increased risk of malnutrition and sarcopenia, which is associated with worse prognosis. Deficiencies of micronutrients specifically have been well described and are associated with complications such as decompensation and death. However, the clinical implications of micronutrient deficiencies in cirrhosis as well as the benefits of supplementation remain incompletely understood. The aim of this study was to investigate the prevalence of micronutrient deficiencies as well as the effects of supplementation on cirrhosis severity, nutritional status, symptoms, function and quality of life (QoL) in a cohort of Australian patients with cirrhosis.
Method: Patients with cirrhosis were recruited between January 2022 to June 2024 from the outpatient liver clinics of 3 tertiary hospitals. Baseline assessments incorporating clinical, nutritional and functional measures included routine blood tests and micronutrient levels, the 36-item short form survey (SF-36), Royal Free Hospital Nutritional Prioritising Tool (RFH-NPT) to stratify nutritional risk, Subjective Global Assessment (SGA) for QoL and handgrip strength (HGS). Patients with any specific deficiencies on blood tests were given supplementation according to a pre-defined protocol for six months, before returning for a final follow-up to repeat all assessments. Statistical analysis was conducted using multilevel linear mixed models, adjusting for age, sex, body-mass-index and other supplements taken concurrently, to determine the impact of supplementation on outcomes variables.
Results: A total of 152 cirrhotic patients were recruited. The median age was 63 (55–69.5) years, and 36% were female. The cohort primarily consisted of Child-Pugh (CP) class A patients (68%) with some B (27%) and C (5%) patients. Micronutrient deficiencies were very common with 87% having at least 1 and 41% >2 deficiencies. The most common deficiencies overall were zinc (70%), vitamins A (43%), C (35%) and D (30%). Supplementation with vitamins A and D correlated with a decrease in CP score of 1.2 (p = 0.005) and 0.53 (p = 0.044), respectively. Vitamin D, magnesium, and iron supplementation were associated with an increase in HGS by 2.09 kg (p = 0.019), 3.7 kg (p = 0.029), and 4.35 kg (p = 0.041), respectively. Magnesium

supplementation was related to improved emotional well-being (p = 0.004), but other supplements, such as B-group vitamins, vitamin C, vitamin D, and iron, were associated with decreased QoL metrics in the SF-36.
Conclusion: This study confirms the prevalence of micronutrient deficiencies in cirrhosis and further evaluated the benefits of relevant supplementation. Vitamins A, D, magnesium and iron supplements were generally associated with improvements in cirrhosis severity, nutritional and functional status. Further study is needed to confirm these findings and determine the role of micronutrient supplementation on clinical outcomes.

SAT-215
A retrospective review of reduced dose argatroban in liver impairment
Sarah Sawieres[1], Francesca Trovato[1], Melanie Dalby[1,2], Julia Czuprynska[1], William Bernal[1]. *[1]Kings College Hospital, Denmark Hill, London, United Kingdom; [2]Kings College London, School of Cancer and Pharmaceutical Sciences, London, United Kingdom*
Email: s.sawieres@nhs.net

Background and aims: Heparin induced thrombocytopenia (HIT) is a rare serious, potentially life-threatening adverse reaction to heparin. Argatroban is an alternative anticoagulant for patients with suspected or confirmed HIT. Guidance suggests reduced dosing of argatroban for patients with liver impairment as there may be increased risk of bleeding. We retrospectively investigated the efficacy and safety of reduced dose argatroban in critically ill patients with suspected or confirmed HIT and varying degrees of liver impairment.
Method: Patients treated with intravenous argatroban were identified using dispensing system records between 2017 and 2023. Patients in critical care with a suspected or confirmed HIT, aged ≥18 years were included. Doses were defined as the critical care standard of 0.5 µg/kg/min or reduced dose of 0.2 µg/kg/min. Efficacy was defined as achieving steady-state concentration within 4 dose changes and absence of thrombotic complications during critical care. Safety was assessed by the absence of haemorrhage as defined by International Society of Thrombosis and Haemostasis.
Results: 139 patients received argatroban of whom 52 met eligibility criteria. Nineteen had liver impairment and 33 did not. In the liver group, 11 were post-liver transplant, 3 had decompensated chronic liver disease, 1 had Budd-Chiari Syndrome, 3 had acute liver failure, and 1 had a liver abscess. The non-liver group included 6 with COVID-19 pneumonitis, 6 with sepsis, 7 with cardiovascular disease, and 14 with other critical care indications. There was no significant difference in the SOFA scores between the liver group (median 10, IQR 4) and the control group (9, IQR 4) (p = 0.83)). Median MELD score for liver patients was 30 (11.5). Groups did not differ in sex, type of heparin, platelet count or baseline APTT but Liver patients were younger (43 (21) vs 63 (26) years, p < 0.001), had higher bilirubin (40 (47) vs 11 (8) mmol/L p < 0.0015) and INR (1.58 (1.685) vs 1.23 (0.34) p = <0.003. In the liver group, 2 (11%) patients did not reach steady state within 4 dose changes, compared to 5 (15%) patients in the non-liver group (p = 1). Two (11%) liver group patients developed thrombosis after starting argatroban, compared to 3 (9%) patients in the non-liver group (p = 1). Three (16%) liver group patients and 1 (3%) non-liver group patient had bleeding events after starting argatroban, but this difference was not statistically significant (p = 0.132).
Conclusion: In this retrospective study of critically ill patients with liver impairment, a reduced dose of argatroban starting at 0.2mcg/kg/min was effective as an anticoagulant in HIT without significant increase in bleeding events.

SAT-216
The most common bacterial isolates in spontaneous bacterial peritonitis in a tertiary hospital center in Croatia and their antibiotic resistance
Sanja Stojsavljevic Shapeski[1], Lucija Virović Jukić[2], Mario Živković[1], Jelena Lucin[1], Branka Đuras Cuculić[1], Neven Ljubičić[2], Neven Baršić[2], Alen Bišćanin[1], Tajana Pavić[1], Ivan Lerotić[1], Vedran Tomašić[1], Ivan Budimir[1], Davor Hrabar[1], Marija Perić Bešlić[1]. *[1]Sestre Milosrdnice University Hospital, Zagreb, Croatia; [2]Sestre Milosrdnice University hospital, University of Zagreb School of Medicine, Zagreb, Croatia*
Email: lucija.jukic@gmail.com

Background and aims: Spontaneous bacterial peritonitis (SBP) is a common infection in patients with decompensated liver cirrhosis. The choice of empirical antibiotic treatment is based on the severity and the environment of the infection as well as on local resistance profiles. The aim of this study was to investigate the most common bacteria isolated in ascites of patients with SBP at our institution and their antibiotic resistance profile.
Method: In this retrospective study, we analyzed electronic medical records of patients with SBP and positive ascitic fluid culture hospitalized in a tertiary hospital center in the period between September 1, 2020 and October 1, 2024. There were 20 positive ascitic fluid cultures in patients diagnosed with SBP, with 22 organisms isolated in 17 patients. In the majority of cases (18/20) a single organism was isolated, and 2 organisms were isolated in 2 cases. Two patients had the same organism isolated in 2 or 3 ascites cultures during the same episode of SBP, and these isolates were excluded from antimicrobial resistance analysis.
Results: The most common organisms isolated were Escherichia coli (n = 6), Escherichia coli ESBL (n = 3), Streptococcus viridans (n = 5) and Enterococcus faecalis (n = 2). Other organisms were occasionally isolated: Acinetobacter species, Pseudomonas species, Staphylococcocus aureus, methicillin-resistant Staphylococcus aureus, beta-hemolytic Streptococcus and Bacteroides species. Five patients (29.4%) were considered to have nosocomial or health care-associated infections, while 12 patients (70.1%) had community-acquired SBP. Twelve of 19 isolated organisms (63.2%) were sensitive to a third-generation cephalosporin, ceftriaxone, which represents the standard empirical antibiotic treatment for SBP at our institution. Among these, 15.7% had nosocomial or health care-associated SBP. Sixteen organisms (84.2%) was sensitive to piperacillin/tazobactam, 15.7% of which were nosocomial or health care-acquired infections. Thirteen organisms (68.4%) were sensitive to meropenem; 10.5% of these were not community acquired. Resistance to ceftriaxone was found in 7 (36.8%) organisms, 5 of which were community acquired and 2 were considered nosocomial or health care-associated SBP.
Conclusion: Clinical Practice Guidelines issued by the European Association for the Study of the Liver recommend a third-generation cephalosporin as an empirical antibiotic treatment of community-acquired SBP, assuming a low risk of antimicrobial resistance. In our cohort of patients with SBP, 63.2% of isolated organisms were sensitive to ceftriaxone, while sensitivity to carbapenems and piperacillin/tazobactam was higher (68.4% and 84.2%, respectively).

SAT-221
High incidence of diuretic derived complications among patients with refractory ascites undergoing either TIPS implantation or insertion of tunneled peritoneal catheter
Sarah Lisa Schütte[1], Anja Tiede[1,2], Jim Benjamin Mauz[1], Hannah Schneider[1], Bernhard Meyer[3], Benjamin Heidrich[1,2,4], Heiner Wedemeyer[1,2,4], Benjamin Maasoumy[1,2], Tammo Lambert Tergast[1]. *[1]Hannover Medical School, Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover, Germany; [2]German Center for Infection Research (DZIF), Hannover, Germany; [3]Hannover Medical School, Department of Diagnostic and Interventional Radiology, Hannover, Germany;*

[4]*Hannover Medical School, Excellence Cluster Resist, Hannover, Germany*
Email: schuette.sarah@mh-hannover.de

Background and aims: Onset of refractory ascites (RA) is a severe complication of chronic liver disease. According to the International Ascites Club guidelines, two categories are defined. The first is diuretic-resistant (DR) RA, marked by a lack of response to diuretic therapy. The second is diuretic-intractable (DI) RA, where complications, such as renal impairment, emerge from diuretic treatment. Placement of a transjugular intrahepatic portosystemic shunt (TIPS) or, if contraindications against TIPS arise, tunneled peritoneal catheters (PeCa) offer an additional therapeutic approach to diuretic therapy. As of now, the exact prevalence and the potential relevance of classifying the ascites as either DR or DI remains unclear. Hence, this study aims to assess the clinical outcomes of patients with DR and DI ascites undergoing either TIPS or PeCa implantation.
Method: We evaluated all patients with RA and cirrhosis undergoing TIPS or PeCa insertion from 2009 to 2023. Exclusion criteria were malignancies or missing informed consent. Study endpoints were mortality, acute kidney injury (AKI) and hyponatremia < 130 mmol/l within 365 days after implantation. Analysis was conducted utilizing univariable and multivariable competing risk analysis, treating death and liver transplantation as competing events. All parameters demonstrating a significant association with the outcome of interest in a univariable analysis were included into the multivariable model.
Results: Two separate analyses were conducted. First, 256 patients undergoing TIPS insertion were analyzed. Only 20% (n = 51) patients displayed DR ascites, while 205 (80%) had DI ascites. No significant differences were observed between DR and DI groups in terms of mortality (HR 0.87, p = 0.73), AKI (HR 1.18, p = 0.61), or hyponatremia (HR 1.18, p = 0.66). Mortality was independently associated with age (HR 1.06, p < 0.001) and MELD score (HR 1.10, p = 0.006), while cholinesterase (HR 0.71, p = 0.04) and potassium (HR 0.60, p = 0.02) were protective factors. The second analysis included 177 PeCa patients with PeCa. Again, only 18% (n = 31) classified as DR and 72% (n = 146) as DI. Here, classification as DR or DI was also not associated with mortality (HR 0.97, p = 0.95) or AKI (HR 0.98, p = 0.93), but was independently linked to the risk of hyponatremia (HR 0.51, p = 0.04). Mortality was predicted solely by MELD score (HR 1.07, p = 0.03). Besides the classification into DR or DI, hyponatremia in PeCa patients was linked to cholinesterase (HR 0.65, p = 0.02) and sodium levels (HR 0.94, p = 0.003). Interestingly, presence of diuretics post PeCa implantation was linked to a lower AKI risk (HR 0.63, p = 0.04).
Conclusion: Only few patients with refractory ascites achieve maximum doses of diuretic treatment without complications and can be classified as DR. However, prognosis seems to be overall comparable between those with DR and DI.

SAT-222

Liver cirrhosis detection by canine olfaction using randomized controlled blinded testing: a proof-of-concept study

Suwadee Aramwittayanukul[1], Susan Redmond[2], Phunchai Charatcharoenwitthaya[3], Sarita Ratana-Amornpinm[1], Taya Kitiyakara[1]. *[1]Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; [2]Independent K9 trainer/handler, Bangkok, Thailand; [3]Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand*
Email: shusherry18@gmail.com

Background and aims: Cirrhosis is often diagnosed late as it is initially asymptomatic. Early diagnosis is essential for preventing disease progression and subsequent complications. This study explores whether dogs can detect cirrhosis through scent detection of volatile organic compounds from the breath and urine of patients.
Method: The study, conducted from February 2023 to January 2024, collected breath and urine specimens from cirrhotic patients and non-cirrhotic controls from Ramathibodi Hospital's and Siriraj Hospital's outpatient clinics in Thailand. These specimens were sent to train two scent-detection dogs until the trainer was confident of scent imprinting. One was an experienced scent-detection dog (Dog 1), while the other was newly trained (Dog 2). New specimens were used to test the dogs in a randomized controlled blinded fashion with non-cirrhotic controls (cirrhosis: control ratio of 1:3 per test). The dogs were trained to signal the specimen they thought were from cirrhotic patients.
Results: The study tested 26 sets (cirrhosis n = 26, control n = 78). Dog 1 consistently showed higher accuracy than Dog 2, with diagnostic accuracy of 94.23% (95% CI: 87.86–98.93) for mask samples and 98.08% (95% CI: 93.23–99.77) for urine samples, with an area under the curve (AUC) of 0.92 and 0.97, respectively. In contrast, Dog 2 had a diagnostic accuracy of 73.08% (95% CI: 63.49–81.31) for mask samples and 75% (95% CI: 65.55–82.97) for urine samples, with an AUC of 0.64 for masks and 0.67 for urine samples. The higher accuracy for urine samples compared to masks was not statistically significant (p = 0.2782).
Conclusion: The experienced scent-detection dog demonstrated high diagnostic accuracy of 94.23% for masks and 98.08% for urine samples with AUC of 0.92 and 0.97, respectively. This suggests it is possible to distinguish between cirrhotic and non-cirrhotic patients using scent-detection.

SAT-223

Novel sex-specific cut-offs for subcutaneous adipose tissue radiointensity in patients with cirrhosis: a post-hoc analysis

Simone Di Cola[1], Gennaro D'Amico[2], Manuela Merli[3]. *[1]Department of Translational and Precision Medicine, Sapienza university of Rome, Italy, Rome, Italy; [2]Gastroenterology Unit, Ospedale V. Cervello, Palermo, Italy; [3]Department of Translational and Precision Medicine, Sapienza University of Rome, Rome, Italy*
Email: simone.dicola@uniroma1.it

Background and aims: While several recent studies have addressed the prognostic impact of sarcopenia and myosteatosis in cirrhosis, less is known about the role of subcutaneous adipose tissue radiointensity (SAT-r). From a retrospective study Ebadi suggested that higher SAT-r (>-83 Hounfield Unit - HU - for men and ≥74 HU for women) may be associated with higher mortality in liver transplant wait-listed patients with cirrhosis. The aim of this study is to prospectively assess the prognostic value of high SAT-r in a heterogeneous cohort of patients with cirrhosis.
Method: This is a post-hoc analysis of the prospective multicentre *EpatoSarco* study, in which 433 patients with cirrhosis were enrolled after CT scan for clinical indication. SAT-r was evaluated using SliceOmatic software at the L3-L4 level and its prognostic impact was assessed by the Fine and Gray model for competing risks.
Results: The median SAT-r was 95 HU (IQR −115 to −83 HU), significantly lower in patients with no muscle changes than in those with other muscle changes (−96 ± 13 vs −90 ± 15, p = 0.0015). Fifty-one patients died during the 1-year follow-up: mean SAT-r was significantly lower in alive than in deceased patients (−92 ± 15 vs −87.1 ± 15, p 0.025). We failed to validate the Ebadi's cutoffs and found that in our population the best discriminant cutoff for death-risk was −89.5 HU for men and −98.4 HU for women. With these cut-offs, 188 patients had high-risk RSAT-r, with a significantly higher cumulative incidence of death (p = 0.006; death and OLT competing. The SHR for mortality of high-risk SAT-r, adjusted for the MELD score was 1.9 (CI 1.006 to 3.6). When type of muscle damage and its interaction term with high-risk SAT-r was added to the model, the interaction was almost significant (p. 0.06) and allowed to identify 4 different risk groups.
Conclusion: New sex-specific cut-offs for high SAT-r may identify patients at high risk of death, especially when combined with other muscle changes.

SAT-224

Management of ascites in elderly patients with cirrhosis: results of an italian survey

Simone Di Cola[1], Lucia Lapenna[2], Margherita Spigaroli[2], Manuela Merli[1]. [1]*Department of Translational and Precision Medicine, Sapienza university of Rome, Italy, Rome, Italy;* [2]*Department of Translational and Precision Medicine, Sapienza University of Rome, Rome, Italy*
Email: simone.dicola@uniroma1.it

Background and aims: The management of ascites in elderly cirrhotic patients is challenging, given comorbidities and frailty that limit therapies, interventions, and transplantation. We assessed how physicians in Italy manage ascites decompensation in elderly patients (>70 years) with cirrhosis.
Method: AISF members received a 49-question survey addressing care settings, centre expertise, radiology and transplant services, patient comorbidities, ascites therapies, and management challenges. Respondents also identified the main problem in managing these patients.
Results: Twenty-two centres (54.5% from university hospitals) responded. Half of the respondents were gastroenterologists. Day hospital services were available in 90.9% of centres, but only 45.5% performed TIPS directly. A total of 1,064 elderly patients with ascites were included. Alcohol was the main etiology. Two hundred and forty-two (22.7%) patients had refractory or intractable ascites, with kidney injury being the leading cause, followed by hepatic encephalopathy and electrolyte imbalance. Diuretics were the main therapy (63.2%), while 21.7% required periodic paracentesis; procedural complications occurred in 17% of patients. Spontaneous bacterial peritonitis (61 cases) and hepatorenal syndrome (42 cases) were common complications, but the majority of physicians (81%) avoided vasopressor therapy due to age and comorbidities. TIPS was evaluated in 50 patients, but were denied in 26 cases; nine patients underwent transplantation despite their age. Forty-six patients required long-term care, and 209 (19.6%) died, with infections and ACLF as leading causes. Over half were dependent on caregivers, and 566 (53.2%) were malnourished, though only 259 received nutritional support. Respondents highlighted insufficient community medical support and undervalued caregiver roles as key issues.
Conclusion: Elderly patients with ascites face limited therapeutic options. Comprehensive care strategies, enhanced community support, caregiver integration, and targeted nutritional programmes are crucial to improving outcomes in this vulnerable population.

Email: cristina_ripoll@yahoo.es

Background and aims: The development of first decompensation is a landmark in the natural history of compensated advanced chronic liver disease (cACLD) with a worsening of prognosis, but most data was obtained for over 30 years. This study examines in a contemporary population of cACLD: (i) the incidence of decompensation, (ii) the most prognostically relevant combination of events defining decompensation, and (iii) the effects of aetiological therapy and hepatocellular carcinoma (HCC) development on decompensation.
Method: Individual patient data meta-analysis of prospective observational studies or RCTs in cACLD with patients included after 2006. To account for heterogeneity, an "individual study term" was added to the multivariate analysis. Aetiological therapy was defined as: viral hepatitis treatment, alcohol abstinence or >10% weight loss. The cumulative incidence function (CIF) of ascites, variceal bleeding, hepatic encephalopathy (HE) and jaundice, and hepatocellular carcinoma (HCC) were assessed with death and liver transplantation as competing events. The specific impact of ascites, bleeding, HE, jaundice and HCC (as time varying covariates) on survival was assessed by Cox proportional hazards model, including Child-Pugh score, oesophagogastric varices, non-selective beta-blocker exposure, cirrhosis aetiology, aetiological treatment and obesity.
Results: A total of 9 studies including 1308 cACLD patients were selected (main etiologies: 26% metabolic dysfunction-associated

steatotic liver disease (MASLD), 51% viral hepatitis, 15% alcohol-related liver disease (ALD), mean age 54 (12), sex female 37%, with a median follow-up of 3.2 (IQR 0.5–5.0) years. Overall, 240 patients (18.3%) developed decompensation and 117 HCC, in 80% HCC developed prior to decompensation. The first decompensating events were: ascites (130, 54%, CIF 0.133), variceal bleeding (48, 20%, CIF 0.048), HE (25, 10.4%, CIF 0.021), jaundice (15, 6.2%, CIF 0.016), and combined events (22, 9%, CIF 0.021). The adjusted hazards ratio (aHR) of decompensation for mortality was 11.6 (95% CI 7.9 to 16.9); specifically for: ascites 5.7 (95% CI 3.6–9.1), bleeding 3.0 (95% CI 1.5–6.1), HE 4.7 (95% CI 1.5–15.3), jaundice 3.7 (95% CI 0.9–15.3), and any combination 30.5 (95% CI 16.5–53.5). HCC increased the risk of decompensation (aHR 2.3, 95% CI 1.8–4.4) and death (aHR 6.6, CI 4.1–10.4). Aetiological treatment significantly reduced the risk of decompensation (aHR 0.68, CI 0.54–0.87).

Conclusion: Ascites and bleeding remain the most common first decompensating events in cACLD and both significantly increase mortality. HE and jaundice are infrequent as sole first decompensating events. Aetiological therapy significantly reduces decompensation risk, whereas HCC development significantly elevated the risk for both decompensation and death.

SAT-226

Impact of infections on the natural history of compensated advanced chronic liver disease: data from an individual patient data meta-analysis

Cervello, Palermo, Italy, Palermo, Italy; [19]Department of Internal Medicine IV, Jena University Hospital, Jena, Germany, Jena, Spain*

Email: cristina_ripoll@yahoo.es

Background and aims: The impact of bacterial infections (BIs) in compensated cirrhosis remains poorly understood. This study aimed to assess the incidence of infections in compensated advanced chronic liver disease (cACLD) and their influence on the risk of decompensation (ascites, variceal bleeding, overt encephalopathy, and jaundice) and mortality.

Method: An individual patient data meta-analysis was conducted using prospective observational or interventional trials from 2006 onward, involving patients with cACLD. Clinically relevant BIs were defined as those treated with antibiotics. The cumulative incidence of BIs and their adjusted impact on decompensation and mortality were evaluated using competing-risk, time-dependent regression analysis.

Results: Data from 1,308 patients with cACLD extracted from nine studies (51% viral hepatitis, 26% metabolic dysfunction-associated steatotic liver disease (MASLD), 15% alcohol-related liver disease (ALD); mean age 54 ± 12 years; 37% female) followed for a median of 3.2 (IQR 0.5–5.0) years were analysed. Of these, 126 patients (10%) developed BIs before/at time of decompensation, 50 (4%) after decompensation, while 543 (42%) remained infection-free, and 589 had missing infection data, but displayed similar outcomes to the non-infected group. Patients who developed infections were more likely to have ALD (46% vs. 9%, $p < 0.001$) and Child B cirrhosis (39% vs. 25%, $p = 0.003$). In BI-associated decompensation, more patients had ALD aetiology (64% vs. 36%, $p = 0.016$) and a higher prevalence of varices ($p = 0.003$) was observed. Infection site was associated with risk for decompensation ($p = 0.002$). Respiratory infections were more common in patients that developed decompensation (37% vs. 23%). Decompensation occurred in 37% of patients with BIs compared to 15% of those without BIs ($p < 0.0001$), primarily as ascites (21% vs. 9%) and hepatic encephalopathy (13% vs. 3%). BIs significantly increased the risk of decompensation (subdistribution hazard ratio [sHR] 3.5, 95% CI: 2.4–5.1, $p < 0.001$) and mortality (sHR 2.6, 95% CI: 1.7–3.8, $p < 0.001$).

Conclusion: Decompensation following BIs occurs frequently, particularly in patients with more advanced stages of cACLD and markedly increases the risk of decompensation and mortality. Future studies should explore preventative strategies for infections to improve outcomes in this population.

SAT-227

Cirrhotic cardiomyopathy: Prevalence and clinical impact on liver cirrhosis outcomes

Takashi Kitagataya[1], Goki Suda[1], Takatsugu Tanaka[1], Shoichi Kitano[1], Naohiro Yasuura[1], Akimitsu Meno[1], Takashi Sasaki[1], Risako Kohya[1], Masatsugu Ohara, Masato Nakai[1], Takuya Sho[1], Kosuke Nakamura[2], Suguru Ishizaka[2], Naoya Sakamoto[1]. *[1]Department of Gastroenterology and Hepatology, Graduate School of Medicine, Hokkaido University,*

Sapporo, Japan; [2]Department of Cardiovascular Medicine, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, Sapporo, Japan
Email: takashi.kitagataya@pop.med.hokudai.ac.jp

Background and aims: Cirrhotic cardiomyopathy (CCM) is a significant complication of liver cirrhosis, but its prevalence and impact remain unclear. This study aimed to assess the prevalence of CCM in patients with liver cirrhosis and evaluate its impact on clinical outcomes.
Method: This retrospective study included 80 patients with liver cirrhosis confirmed by transient elastography (liver stiffness ≥12.5 kPa) at Hokkaido University Hospital between January 2014 and April 2024. CCM was diagnosed using the 2019 Cirrhotic Cardiomyopathy Consortium criteria. Patient characteristics, survival, and incidence of decompensation and cardiovascular events were analyzed. Propensity score matching was performed to adjust for potential confounding factors between groups with and without CCM.
Results: The prevalence of CCM was 46.3% (37/80), with 78.4% of CCM patients showing isolated systolic dysfunction based on global longitudinal strain. Patients with CCM were significantly older and had lower serum ammonia and bilirubin levels, as well as higher platelet counts. CCM was associated with a significantly higher incidence of decompensation events (HR 3.97, 95% CI 1.64–9.61, p = 0.003) and was an independent risk factor for decompensation in multivariate analysis (HR 3.24, 95% CI 1.29–8.11, p = 0.012). No significant differences were observed in overall survival or cardiovascular events between patients with and without CCM. The analysis of CCM subgroups revealed a statistically significant difference in the cumulative incidence of decompensation events between patients with isolated systolic dysfunction and those without CCM (p < 0.003).
Conclusion: CCM is prevalent among patients with liver cirrhosis and is associated with an increased risk of hepatic decompensation. These findings highlight the importance of cardiac evaluation in cirrhotic patients and suggest that CCM should be considered in the management of liver cirrhosis to potentially improve patient outcomes. The high prevalence of isolated systolic dysfunction based on global longitudinal strain measurements emphasizes the importance of incorporating this parameter into the diagnostic criteria for CCM.

SAT-228

L-ornithine-L-aspertate improves quality of life and ammonia levels but not microbiome dysbiosis in cirrhosis: results of a phase 4 study

Angela Horvath[1,2], Daniel Habich[2], Nicole Feldbacher[1,2], Lavra Celcer[2], Vanessa Stadlbauer[1,2]. *[1]Medical University of Graz, Graz, Austria; [2]Center of Biomarker Research in Medicine, Graz, Austria*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: Liver cirrhosis is associated with gut microbiome dysbiosis, intestinal inflammation and gut barrier dysfunction, contributing to reduced quality of life and the development of complications. In a recent retrospective study, we showed that L-ornithine-L-aspartate (LOLA) was associated with less dysbiosis. We aimed to study whether LOLA can improve gut microbiome dysbiosis, sarcopenia, frailty, ammonia levels and quality of life.
Method: In a monocentric, open-label, phase 4 study, patients with liver cirrhosis and hepatic encephalopathy grade 0–2 (assessed by either number connection test or critical flicker frequency or Westhaven criteria) received LOLA 18 g/day orally for 3 months. Endpoints were gut microbiome composition (16 s rRNA sequencing, analysis of alpha and beta diversity, taxonomic differences assessed by ANCOM and LEfSe, Tax4fun to predict function), quality of life (short form 36 questionnaire, SF36), serum ammonia, measurements of sarcopenia and frailty (appendicular lean muscle mass, anthropometric measures, liver frailty index, SARC-F) and biomarkers of sarcopenia (myostatin, irisin, fibroblast growth factor (FGF)-21, insulin like growth factor (IGF-1)).
Results: 193 patients were screened, 65 included and 52 patients (40.4% female, age 62 (58; 65)) completed the study. LOLA did not alter microbiome diversity, taxonomic composition nor predicted function. LOLA significantly improved the SF36 dimension vitality (from 45 (35; 60 to 50 (45; 60), p = 0.019). LOLA also decreased serum ammonia in patients with elevated baseline values (n = 10; from 69.5 (54; 225) µmol/L to 46.0 (22; 66) µmol/L, p = 0.004). Muscle mass declined over the study period, but not in the subgroup of patients with elevated and subsequently improved ammonia levels. Sarcopenia, frailty scores and muscle biomarkers did not improve either.
Conclusion: LOLA improved vitality in patients with cirrhosis, a clinically relevant patient reported outcome parameter but did not alter gut microbiome composition and function and could not prevent cirrhosis associated muscle loss in the majority of the patients. LOLA may be a useful adjunct treatment to improve quality of life in cirrhosis and may prevent muscle loss in patients with elevated ammonia levels.

SAT-229

Urinary microbiome alterations in patients with cirrhosis: a link to an increased urinary tract infection risk

Johannes Woltsche[1], Christian Pacher-Deutsch[1,2], Nicole Feldbacher[1,2], Maximilian Nepel[1], Stefan Fürst[1], Lukas Gulden[1], Jakob Schwarzl[1], Angela Horvath[1,2], Vanessa Stadlbauer[1,2]. *[1]Medical University of Graz, Graz, Austria; [2]Center of Biomarker Research in Medicine, Graz, Austria*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: The pathophysiology of cirrhosis is closely linked to changes in microbiome composition. Cirrhosis-related dysbiosis is not confined to the gut but is also evident on the skin, in saliva, and in serum. This study aimed to characterize the urinary microbiome (UMB) of patients with cirrhosis to explore its connection to an increased susceptibility to urinary tract infections (UTIs).
Method: Midstream urine samples from 137 patients were analyzed via 16S rRNA gene sequencing. After excluding 29 patients who did not meet the inclusion or quality criteria, the UMB of 76 patients with cirrhosis (age 64.0 ± 13.5, 25% female) and 32 non-cirrhotic controls (58.5 ± 16.5, 47% female) was compared in terms of alpha and beta diversity, linear discriminant analysis effect size, and analysis of composition of microbiomes. Further analysis distinguished differences in UMB composition between patients with cirrhosis who developed a UTI within three years of sampling (dUTI group; n = 21) and those who remained free of UTI (no_UTI group; n = 24).
Results: Microbiome profiles of patients with cirrhosis differed significantly from those of non-cirrhotic controls: Alpha diversity was markedly reduced in the urine of patients with cirrhosis. The UMB of controls was predominantly associated with *Streptococcus*. Analysis of differences in UMB composition between dUTI and no_UTI groups demonstrated that the UMB of dUTI patients was strongly associated with Firmicutes and *Enterococcus*, while no_UTI patients displayed higher abundances of Bacteroidetes, *Prevotella* and *Corynebacterium 1*. Analysis of pathogens identified in microbiological examinations in the context of UTI in patients with cirrhosis revealed *Enterococcus* as highly common causative agent (23.3%).
Conclusion: The UMB of patients with cirrhosis shows a significantly altered composition compared to non-cirrhotic controls. Decreases in alpha diversity and *Streptococcus* abundance in the UMB of patients with cirrhosis might support understanding of the increased susceptibility to UTIs in this population. Patients of the no_UTI group exhibited higher abundances of bacteria typically found in a healthy UMB, such as *Prevotella* and *Corynebacterium 1*, whereas patients in the dUTI group exhibited significantly increased counts of *Enterococcus*, a genus containing species which commonly cause UTIs in patients with cirrhosis.

SAT-230

Biomarker-based profiling of pathomechanisms across distinct clinical stages of cirrhosis

Email: vlad.taru@meduniwien.ac.at

Background and aims: Disease-driving pathomechanisms in cirrhosis involve bacterial translocation (BT), macrophage activation, inflammation, endothelial dysfunction and fibrogenesis but their relative contribution may vary by disease stage and etiology.
Method: This study analyzed biomarkers of well-characterized cirrhosis patients of alcohol-related (ALD), metabolic liver disease (MASLD) and chronic viral hepatitis (VIRAL) recruited in the prospective Vienna Cirrhosis Study (VICIS) with data on hepatic venous pressure gradient (HVPG). Blood levels of 10 biomarkers were compared between compensated (CC) and decompensated (DC) patients and across etiologies. Multivariable linear regression models were used to evaluate the independent association between biomarkers, adjusting for liver disease severity.
Results: A total of n = 120 cirrhosis patients (ALD: 60; MASLD:30; VIRAL:30) with CC (n = 60; MELD: 10 (5); HVPG: 14 (8)) and DC (n = 60, MELD: 12 (6); HVPG: 19 (6)) were included. The soluble CD14 (sCD14), responsible for sensing circulating lipopolysaccharide (LPS) and activating toll-like receptor 4 (TLR4), was increased in DC vs. CC (sCD14: 1.95 (0.83) vs. 1.56 (0.51) µg/mL, $p < 0.001$) and correlated with the LPS-binding protein (LBP) levels in DC (rho = 0.52, $p < 0.001$) and in all etiologies, indicating a key role of BT-mediated TLR4 activation in DC. Macrophage activation was pronounced in DC compared to CC (CXCL9: 0.14 (0.10) vs. 0.22 (0.11) $p = 0.008$) and correlated with sCD14 (CXCL9: rho = 0.37, $p < 0.001$). Systemic inflammation (IL-6, TNF-α) was more pronounced in DC compared to CC and strongly correlated with sCD14 (IL-6, rho = 0.47; TNF-α, rho = 0.42; both $p < 0.001$). Importantly, sCD14 independently associated with biomarkers of endothelial dysfunction (von Willebrand factor antigen: VWF-Ag) and liver fibrogenesis (tissue inhibitor of metalloproteinases 1: TIMP1; Enhanced Liver Fibrosis (ELF) score) on multivariable linear regression analysis adjusted for HVPG and MELD (VWF: $\beta = 0.41$, $p = 0.007$; TIMP1: $\beta = 238.6$, $p < 0.001$; ELF: $\beta = 34.6$, $p = 0.045$).
Conclusion: Biomarkers reflecting specific disease-driving pathomechanisms in cirrhosis such as bacterial translocation and macrophage activation increase in patients with decompensated cirrhosis across common etiologies. Elevated sCD14 was independently linked to endothelial dysfunction and liver fibrogenesis and emphasizes the important role of innate immune system activation related to BT.

SAT-231

Improved glycaemic control over time in patients with type 2 diabetes mellitus (T2DM), with and without cirrhosis: a territory-wide cohort study of 1.2 million patients in Hong Kong

Mary Yue Wang[1,2], Sherlot Juan Song[1,2], Grace Wong[1,2], Vincent Wai-Sun Wong[1,2], Terry Cheuk-Fung Yip[1,2]. *[1]Medical Data Analytic Center, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China, Hong Kong, Hong Kong; [2]State Key Laboratory of Digestive Disease, Institute of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, China, Hong Kong, Hong Kong*
Email: wangyue0730888@gmail.com

Background and aims: Patients with cirrhosis are at increased risk of both hyperglycaemia and hypoglycaemia. Meanwhile, there have been major developments in anti-diabetic treatments in the past two decades. This study aimed to examine secular trends of glycaemic control in T2DM patients without cirrhosis and those with compensated and decompensated cirrhosis.
Method: This retrospective study included patients with T2DM aged ≥18 years at the time of T2DM diagnosis in Hong Kong from 2000–2023. Cirrhosis was defined by diagnosis or procedure codes, Fibrosis-4 index >3.25, or aspartate aminotransferase-to-platelet ratio index >2. Decompensated cirrhosis was defined by the presence of hepatic decompensating events. Serial laboratory measurements in each of the five consecutive periods (2000–2004, 2005–2009, 2010–2014, 2015–2019, and 2020–2023) were summarised by time-weighted average. The percentage of patients who achieved time-weighted average haemoglobin A1c (HbA1c) < 7% was compared in the five periods. Mixed effects logistic regression was employed to examine the impact of the period on the achievement of HbA1c < 7%.
Results: Of 1,206,233 patients with T2DM identified (mean age 63.1 years, 52.0% males), 63,200 (5.2%) had cirrhosis, among whom 17,992 (28.5%) had decompensated cirrhosis. The proportion of patients achieving HbA1c < 7% increased over time regardless of cirrhosis status. A higher percentage of patients with compensated cirrhosis achieved HbA1c < 7% (from 2000–2004 to 2020–2023, 49.3% to 75.8% in compensated cirrhotic group vs 47.6% to 64.6% in decompensated cirrhotic group vs 39.2% to 65.9% in non-cirrhotic group, $p < 0.001$). After adjusting for age, sex, body mass index, T2DM duration, aetiologies of liver disease, and important comorbidities, laboratory results and medication use, the compensated cirrhosis group had the biggest increase in the proportion of patients achieving HbA1c < 7% (2020–2023 vs 2000–2004, compensated cirrhotic group: OR 3.95, 95% CI 3.57–4.39; decompensated cirrhotic group: OR 3.71, 95% CI 3.11–4.42; non-cirrhotic group: OR 3.14, 95% CI 3.09–3.20).
Conclusion: After adjusting for confounding factors, patients with compensated cirrhosis had the largest improvement in glycaemic control. From 2000 to 2023, patients with T2DM had improved glycaemic control irrespective of their cirrhosis status, suggesting a universal improvement in diabetes care. Future analysis is needed to clarify the importance of glycaemic control in improving hepatic and extrahepatic outcomes and to establish the optimal glycaemic target for patients with T2DM and cirrhosis.

SAT-232

Direct oral anticoagulants for Budd-Chiari syndrome following percutaneous angioplasty in a chinese cohort

Chengjian Wu[1], Zhaoyan Gao[2], Yi Shen[1], Luo Xuefeng. *[1]Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, Sichuan Province, China; [2]Sichuan University, Chengdu, Sichuan Province, China*
Email: wuchengjian@stu.scu.edu.cn

Background and aims: Direct oral anticoagulants (DOACs) have been widely used to treat various thrombotic disorders. However, data regarding their use in patients with Budd-Chiari syndrome (BCS) are

limited. The present study was designed to assess the efficacy and safety of DOACs in a Chinese population with BCS.
Method: Between August 2020 and August 2024, patients with BCS who received DOACs following percutaneous transluminal angioplasty (PTA) were retrospectively evaluated. The primary outcome was the proportion of patients free from restenosis; secondary outcomes included bleeding and death.
Results: A total of 88 patients who received DOACs following PTA were included in the analysis, with a mean age of 46.4 ± 13.1 years. 44 patients received rivaroxaban, and the other 44 patients received dabigatran. 67 patients (76%) had cirrhosis, and 11 patients (13%) had a history of variceal bleeding. The median duration of DOAC therapy was 20.3 (interquartile range, 8.6 to 28.6) months. The median follow-up time was 22.6 (interquartile range, 14.4 to 31.6) months. The 1- and 3-year accumulative patency rates were 77.8% and 68.7%, respectively. 5 major bleedings (5.7%; incidence rate 3.4 per 100 patient-years; n = 4 upper gastrointestinal bleeding, n = 1 severe epistaxis with a decrease in hemoglobin by more than 2.0 g/L), 9 minor bleedings (10.2%; incidence rate 6.0 per 100 patient-years; n = 5 gingival bleeding, n = 2 epistaxis, n = 2 menorrhagia) occurred during DOAC therapy. Two patients died during follow-up (one from hepatocellular carcinoma and another from hepatorenal syndrome).
Conclusion: DOACs are safe and effective in patients with BCS following PTA. Further study is required to compare them with traditional anticoagulants.

SAT-237

A study of clinical characteristics in 43 patients with porto-sinusoidal vascular disease

Chengjian Wu[1], Yi Shen[1], Luo Xuefeng. [1]*Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, Sichuan Province, China*
Email: wuchengjian@stu.scu.edu.cn

Background and aims: Since the introduction of the term 'Porto-sinusoidal vascular disease' (PSVD) in 2019, understanding of this disease has been limited. It has been reported that PSVD patients have a higher risk of developing portal vein thrombosis (PVT), but it is unclear whether PVT affects the progression of PSVD.
Method: This study retrospectively included patients diagnosed with PSVD at West China Hospital, Sichuan University, from 2019 to 2024. All patients were confirmed not to have liver cirrhosis through liver biopsy. Patient medical records were obtained through the electronic medical record system, collecting basic information, laboratory tests, imaging examinations, gastroenterological endoscopy, and pathological examination data, as well as treatment and prognosis information. Patients were divided into two groups based on the presence or absence of PVT: (1) PVT group, (2) non-PVT group, and then the clinical characteristics of the two groups were compared.
Results: A total of 43 PSVD patients were included in this study, with 26 males (60.5%) and 17 females (39.5%), and the average age was 46 ± 17 years. Among them, 11 (25.6%) patients had PVT. Comparing the two groups of patients with and without PVT, we found no statistically significant differences in age, total bilirubin, transaminase, alkaline phosphatase, and γ-glutamyl transpeptidase levels. Additionally, there were no significant differences in the manifestations of portal hypertension or pathological manifestations between the two groups. Patients with PVT tended to have longer spleen lengths (16.08 ± 3.97 cm, 14.16 ± 2.63 cm, P = 0.097), and pathological examinations found a higher proportion of non-regional sinusoidal dilation (72.7%, 40.6%, P = 0.088). Interestingly, we found that the proportion of males in the PVT group was significantly higher (90.9%, 50%, P = 0.029), and the albumin levels in this group of patients were lower than those without PVT (32.3 ± 12.2 g/L, 40.4 ± 6.9 g/L, P = 0.011), while the INR levels were higher (1.30 ± 0.16, 1.16 ± 0.15, P = 0.020). A total of 13 patients underwent transjugular intrahepatic portosystemic shunt surgery, but there was no difference in the proportion of patients between the two groups, with 5 (45.5%) in the PVT group and 8 (25%) in the non-PVT group, P = 0.262. There have been no deaths in either group to date.
Conclusion: We found that PSVD patients with PVT are predominantly male, and these patients have lower serum albumin levels and higher INR levels, suggesting a potentially more severe condition.

SAT-238

To construct a prediction model of recompensation in HBV-related decompensated cirrhosis patients combined with the inflammation index MLR

Xu Huaqian[1], Tang Shanhong[1]. [1]*Department of Gastroenterology, The General Hospital of Western Theater Command, Chengdu 610083, Sichuan, China*
Email: xuhuaqian98@163.com

Background and aims: Systemic inflammation plays an important role in the progression of end-stage liver disease. On the basis of effective antiviral therapy, some patients with decompensated hepatitis B cirrhosis can have a certain reversal of liver function, that is, recompensation, but the relationship between systemic inflammation and recompensation in patients with decompensated cirrhosis is still unclear. Therefore, this study aims to further explore the effect of inflammatory factors on liver recompensation in patients with hepatitis B virus-related decompensated cirrhosis.
Method: This is a single-center retrospective observational study. Patients with decompensated hepatitis B cirrhosis were divided into the non-recompensation group and the recompensation group according to the occurrence of recompensation. The differences between the groups were compared, and logistic regression analysis was used to screen the influencing factors. Based on the results of the influencing factors, we constructed a nomogram model and verified the value of the model.
Results: A total of 707 patients were enrolled in this study, 270 patients were excluded according to the exclusion criteria. According to whether recompensation occurred within 2 years, patients were divided into recompensation group (n = 180) and non-recompensation group (n = 257), and the incidence of recompensation was 41.19% (180/437). By comparing the baseline characteristics between the two groups, it was found that there were significant statistical differences in inflammation-related indicators between the two groups. Logistic regression multivariate analysis showed that the occurrence of liver failure, MLR and Child-Pugh score were independent influencing factors for the occurrence of recompensation in the training set. The nomogram model was constructed by combining the multivariate results. The model calibration curve of the training set and the validation set had a good consistency with the clinical decision curve. The area under the ROC curve of the training set and validation set was 0.815 (95% CI: 0.767–0.863) and 0.823 (95% CI: 0.767–0.863), respectively, which was better than MLR, Child-Pugh score, MELD, MELD-Na, iMELD, and ALBI score (P < 0.05).
Conclusion: High inflammation level is a risk factor for recompensation in patients with decompensated hepatitis B cirrhosis. Among the common inflammatory indicators, MLR is an independent influencing factor for patients' recompensation, and the Nomogram model combined with MLR can better predict patients' recompensation.

SAT-239

Comparative study on the efficacy of TIPS versus Non-TIPS treatments for hepatic portal vein thrombosis complicated by upper gastrointestinal hemorrhage

Rongjiong Zheng[1], Tongtong Shao[1], Jingli Zhang[1], Li Yang[1], Xinting Li[1], Ziyi Zhang[1], Keying Xu[1], Xiaobo Lu[1]. [1]*The First Affiliated Hospital of Xinjiang Medical University, Urumchi, China*
Email: 392213109@qq.com

Background and aims: Portal vein thrombosis (PVT) and upper gastrointestinal bleeding are prevalent complications in patients with liver cirrhosis. PVT can elevate the risk of upper gastrointestinal

bleeding. The objective of this study is to further validate the efficacy of transjugular intrahepatic portosystemic shunt (TIPS) treatment in this patient population.
Method: The clinical data of 72 patients with liver cirrhosis complicated by portal vein thrombosis (PVT) and upper gastrointestinal bleeding were analyzed retrospectively. Twenty-two patients in the transjugular intrahepatic portosystemic shunt (TIPS) group received TIPS treatment along with postoperative anticoagulant therapy, while the non-TIPS group received symptomatic hemostatic therapy and anticoagulant therapy. There were no significant differences in age, gender, or baseline characteristics between the two groups, and the procedures were technically successful for all patients in the TIPS group. The patients were followed up for a median of 13 months, during which the prognosis was assessed based on recanalization rate, rebleeding rate, and survival rate.
Results: The median age of the 72 patients included in the study was 54.5 years (range: 23 to 85 years), with a male-to-female ratio of 1.4:1. In the TIPS group, complete recanalization of portal vein thrombosis (PVT) occurred in 72.3% (16/22) of patients, while rebleeding was observed in 15.8% (3/22) of patients, and no patients died. In the non-TIPS group, complete recanalization of PVT occurred in 28% (14/50) of patients, partial recanalization was noted in 12% (6/50) of patients, and stable PVT was present in 58% of patients. Additionally, one patient died, and rebleeding occurred in 38% (19/50) of patients. The rate of PVT recanalization in the TIPS group was significantly higher than that in the non-TIPS group (72.3% vs. 28%, $P < 0.01$), and the rate of upper gastrointestinal rebleeding in the TIPS group was significantly lower than that in the non-TIPS group (15.8% vs. 38%, $P < 0.05$). In the TIPS group, the bilirubin level was (27.31 ± 10.98) before treatment and (30.62 ± 10.90) after treatment, and there was no statistically significant difference observed between the two groups ($t = -1.11$, $P = 0.28$). INR was (1.47 ± 0.22) before treatment and (1.55 ± 0.18) after treatment, also showing no significant difference between the two groups ($t = -1.36$, $P = 0.19$).
Conclusion: TIPS (Transjugular Intrahepatic Portosystemic Shunt) treatment for patients with liver cirrhosis and portal vein thrombosis, complicated by upper gastrointestinal bleeding, demonstrates a high rate of thrombosis recanalization, a low incidence of rebleeding, and does not exacerbate liver function impairment.

SAT-240-YI
Evaluation of the clinical utility of wearable fitness tracking devices to diagnose frailty in patients with liver cirrhosis – A proof-of-concept study

Jonna Friederike Zimmermann[1], Martin Kabelitz[1], Sophia Geißelbrecht[1], Liv Ahl[1], Lea Wagner[1], Heiner Wedemeyer[1,2,3], Benjamin Maasoumy[1,2,3], Lisa Sandmann[1,2,3]. *[1]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [2]German Center for Infection Research (DZIF), Hannover/Braunschweig, Germany; [3]Excellence Cluster RESIST, Excellence Initiative Hannover Medical School, Hannover, Germany*
Email: zimmermann.jonna@mh-hannover.de

Background and aims: Frailty is prevalent among patients with liver cirrhosis and clinically relevant as it negatively impacts quality of live and long-term clinical outcome. Diagnosis of frailty based on the Liver Frailty Index (LFI) is limited in the clinical routine due to the personnel- and time-consuming assessment. Wearable fitness tracking devices (WFTD) have the potential to serve as a resource-efficient alternative to diagnose frailty. This proof-of-concept study aims to evaluate the ability of accelerometer data from WFTD to diagnose frailty in patients with liver cirrhosis.
Method: From 03/2022 to 11/2024, patients with liver cirrhosis were prospectively enrolled in the study. All patients performed frailty assessment by LFI and walking of a predefined distance while wearing the standardized WFTD. Laboratory and clinical data were collected at the study time point. A random forest model was employed with model evaluation conducted using weighted F1 scores and five-fold cross-validation. Prior to model fitting, the data was scaled, and the dataset was split into 70% training and 30% test subsets. In addition to the WFTD data, Model of endstage liver disease (MELD) Score, MELD 3.0 and the Freiburg index of post-TIPS survival (FIPS) were added to the random forest analysis. Due to the unequal size of the frail and not-frail group, a weighted F1 score was used to evaluate the model.
Results: 121 datasets of 115 individual patients qualified for final analysis after exclusion of patients without representative walking distance or insufficient baseline data on LFI, with Budd-Chiari syndrome or HCC outside the Milan criteria. The majority of patients were male (59%) at a median age of 61 years (IQR 54–66). Median MELD, MELD 3.0 and FIPS were 10 (IQR 8–14), 13 (IQR 9–16) and −0.28 (IQR −0.97–0.25), respectively. Based on the LFI, the majority of patients were classified as pre-frail (69.4%, n = 84/121), while only 24.8% (30/121) of patients were frail and 5.8% (7/121) robust at the time point of assessment. With the addition of MELD, the model achieved a weighted F1 score for the random forest analysis on the test data of 0.67. The model further improved when including MELD 3.0 (weighted F1 score: 0.69) or FIPS (weighted F1 score: 0.74). In order to analyze a cohort-adjusted classification of the LFI, the LFIs of the total cohort were divided into quartiles and the lowest quartile representing the most robust patient subset was compared to the remaining three. In doing so, weighted F1 scores for the random forest analysis further improved with the combination of accelerometer data and MELD 3.0 achieving the most accurate results (weighted F1 score: 0.837).
Conclusion: This proof-of-concept study demonstrated that predicting LFI from WFTD data is not only feasible but a time- and personnel-efficient approach to diagnose frailty in patients with liver cirrhosis. Training and testing in larger cohorts is ongoing and certainly needed to further evaluate its accuracy and ability to predict clinical outcomes.

SAT-241
Over the years, diagnostic problems in cirrhosis continue, but its etiology changes: chronic viral hepatitis is decreasing, steatotic liver disease is increasing

Zülal İstemihan[1], Ahmet Oğuz Çelik[2], Arzu Taş[2], Dilek Deniz[2], Çağrı Muratoğlu[2], Kanan Nuriyev[1], Sezen Genç Uluçeçen[1], Aynure Rustamzade[1], Gizem Dağcı[1], Mehmet Akif Yağlı[1], Bilger Çavuş[1], Aslı Çifcibaşı Örmeci[1], Filiz Akyuz[1], Kadir Demir[1], Fatih Beşışık[1], Sabahattin Kaymakoğlu[1]. *[1]Istanbul University, Istanbul Faculty of Medicine, Department of Internal Medicine, Division of Gastroenterohepatology, Istanbul, Türkiye; [2]Istanbul University, Istanbul Faculty of Medicine, Department of Internal Medicine, Istanbul, Türkiye*
Email: kaymakoglus@hotmail.com

Background and aims: To investigate the characteristics of cirrhosis etiology, diagnostic methods, and complications with a 1-decade interval.
Method: The clinical and demographic characteristics of patients with cirrhosis at the time of diagnosis at a tertiary university hospital between 2005–2009 (first period) and 2019–2023 (second period) were retrospectively investigated.
Results: A total of 1068 patients (64.5% men, mean age 55.5 ± 12.6 years) were diagnosed with cirrhosis (709 (66.4%) patients in the first period, and 359 (33.6%) in the second period). In the first period, patients were younger ($p = 0.000$). The mean MELD-Na was 12 ± 5.2. MELD-Na was not different between the periods ($p = 0.061$). In the first and second periods, 57.7% and 61.3% of the patients were in Child-Pugh A, 31.6% and 32.4% in B, 10.7% and 6.3% in C, respectively. While there was no difference in Child-Pugh stages A and B between the periods, the rate of patients diagnosed in stage C was significantly less in the second period ($p = 0.025$). In the first period 191 (26.9%) patients, and in the second period 95 (26.5%) patients were diagnosed with complications in the emergency department. The

others were diagnosed in the outpatient clinic under elective conditions. There was no difference in where cirrhosis was diagnosed between periods (p = 0.868). 587 (55%) patients were decompensated at diagnosis. There was no difference between periods (p = 0.109), but the patients diagnosed in the emergency clinic had a higher rate of decompensated cirrhosis (p = 0.000). The causes of cirrhosis were, in order, 246 (23%) HBV, 196 (18.4%) cryptogenic, 188 (17.6%) MASLD, 143 (13.4%) alcohol, 126 (11.8%) HCV, 83 (7.8%) autoimmune liver diseases, 45 (4.2%) HDV, 23 (2.2%) other causes, and 18 (1.7%) genetic diseases. In the second period, while the frequency of cirrhosis caused by HBV, HCV, and HDV decreased (p = 0.000, p = 0.000, and p = 0.022, respectively), the frequency of MASLD and alcohol-related liver disease (ALD) increased (p = 0.000, and p = 0.023). In respect to the clinical stage 251 (23.5%) patients were diagnosed as stage 1, 260 (24.3%) as stage 2, 114 (10.7%) as stage 3, 402 (37.6%) as stage 4, 36 (3.4%) as stage 5, and 5 (0.5%) as stage 6. The frequency of diagnosis in stage 1 was higher in the second period (p = 0.000). While the frequency of using clinical features in the diagnosis of cirrhosis was higher in the first period (p = 0.000), the frequency of using the radiological methods and fibroscan was higher in the second period (p = 0.000, and p = 0.000). 120 (11.2%) patients had hepatocellular carcinoma at the time of diagnosis, there was no difference between periods (p = 0.494).

Conclusion: There is still a problem with diagnosing cirrhosis, as most patients are diagnosed after decompensation and in the emergency clinic. Over the years, viral factors in the etiology of cirrhosis have gradually decreased, however MASLD and ALD have progressively increased.

Cirrhosis and its complications – Portal Hypertension

Endoscopic ultrasound-guided portal pressure gradient predicts hepatic decompensation in compensated cirrhosis

Michael Yu[1,2], Bryant Le[1], Andy Lin[1], Frances Dang[1], Avni Jain[1,2], Harry Nguyen[1], Kenneth Chang[2], Ke-Qin Hu[1], Jason Samarasena[1].
[1]University of California, Irvine, Orange, CA, United States; [2]Hoag, Newport Beach, CA, United States
Email: 1yuma1688@gmail.com

Background and aims: Endoscopic ultrasound guided-portal pressure gradient (EUS-PPG) has emerged as an alternative method for obtaining direct portal pressure measurements for assessing portal hypertension. Transjugular hepatic venous portal gradient (HVPG) is the gold standard for measuring portal hypertension and is the basis for defining clinically significant portal hypertension, defined as ≥ 10 mmHg. Though EUS-PPG has been shown to correlate with HVPG, clinical parameters, FIB4 score, and fibrosis staging, associations with downstream clinical outcomes such as hepatic decompensation are lacking. We aimed to evaluate the utility of EUS-PPG in predicting new hepatic decompensation in patients with compensated cirrhosis.
Method: This was a single-center retrospective study at a tertiary endoscopy center of patients who had EUS-PPG measured from 2014 to 2023. Subjects with cirrhosis without a prior decompensating event were included. A new decompensating event defined as variceal bleeding, ascites, or hepatic encephalopathy was the primary endpoint. Baseline characteristics were compared between patients with and without new decompensation. Univariate and multivariate logistic regression analyses were conducted to determine potential associations between predictors including MELD-Na, Child-Pugh score, platelet count, and PPG, with new decompensation. Receiver operating characteristic curve was constructed with PPG as predictor for hepatic decompensation and Kaplan-Meier curve was constructed according to cut-off level of PPG ≥ 10 mmHg. Post hoc analysis was done to establish optimal PPG cut off with maximal negative predictive value.
Results: 202 patients had EUS-PPG, of which 103 had a diagnosis of cirrhosis. 65 of these had no prior hepatic decompensation at time of EUS-PPG and were included in the study. Median age was 62.0 (IQR 56.0–68.0). 46% were male. Median MELD-Na was 9 (7–11) and 87.7% were Child-Pugh Class A. Liver disease etiologies included viral hepatitis (16.9%), MASLD (44.6%), ALD (15.4%), and others (23.1%) which included AIH, PSC, and PBC. 13 patients (20%) developed new hepatic decompensation. Median PPG in the decompensated group was 9.6 mmHg (6.6–13.6) compared to 6.0 mmHg (3.2–10.0) in the compensated group. 46% of the decompensated group had PPG ≥10 mmHg, compared to 26.9% in the compensated group. In crude and adjusted analyses, PPG was significantly associated with decompensation (OR 1.12, 95% CI 1.01–1.23; aOR 1.17, 95% CI 1.02–1.35). PPG ≥10 mmHg trended towards an association with new decompensation (OR 2.33, 95% CI 0.67–8.13) but was not statistically significant. Post hoc analysis identified PPG value of <8 mmHg as having the greatest negative predictive value of 89% for developing decompensation.
Conclusion: In patients with compensated cirrhosis, higher EUS-PPG had a greater likelihood of new hepatic decompensation. This study supports EUS-PPG as a reliable tool for assessing portal hypertension and possibly predicting clinical decompensation.

Background and aims: TIPS is a highly effective treatment for complications of portal hypertension but carries a substantial risk (20–40%) of hepatic encephalopathy (HE) post-TIPS. Sarcopenia has been also identified as a contributing factor to HE given the role of skeletal muscle in ammonia metabolism. We aimed to evaluate whether a 12-week intervention (2 weeks pre-TIPS and 10 weeks post-TIPS) consisting of physical exercise and protein-enriched oral nutritional supplements reduces sarcopenia and lowers HE incidence within 6 months post-TIPS.
Method: Prospective, open-label, randomized study including cirrhotic patients scheduled for elective TIPS in two centers. Patients were randomized 1:1 to control group or intervention group. The primary endpoint was the development of HE within 6 months post-TIPS. The secondary endpoint was the intervention's impact on sarcopenia. This is an interim analysis focused on the primary endpoint.
Results: Forty-five patients were included (23 control, 22 intervention). Baseline characteristics, including sex, age, Child-Pugh score, MELD, prior HE, HE treatments, baseline ammonia levels, Liver Frailty Index (LFI), and TIPS indications, were similar between groups. Portal pressure gradients at 24 hours and 1 month post-TIPS were comparable among the two groups. No post-TIPS variceal bleeding occurred, and ascites control was equivalent also in the control and intervention group. Nineteen patients (86%) in the intervention group adhered to >50% of prescribed sessions. 18 patients (40%) developed HE: 14 (77%) in the control group and 4 (22%) in the intervention group. Cumulative HE incidence at 1, 3, and 6 months was 44%, 60%, and 65% in controls versus 14%, 20%, and 20% in the intervention group (log-rank 8.7, $p < 0.01$). Per-protocol analysis revealed an even greater benefit (log-rank 15.4, $p < 0.001$). Among 24 patients with baseline and 6-month LFI assessments (12 per group), 5 intervention patients improved LFI compared to none in the control group ($p = 0.04$).
Conclusion: A 12-week intervention of physical exercise and nutritional support effectively reduces post-TIPS HE incidence and improves frailty parameters, highlighting the value of targeting sarcopenia in cirrhotic patients undergoing TIPS.

Background and aims: Sustained alcohol abstinence improves the prognosis of patients with alcohol-related cirrhosis (ArLD) and may even facilitate hepatic recompensation in decompensated patients. However, more evidence is needed on the incidence, predictors and prognostic implications of recompensation in ArLD.
Method: This Baveno Cooperation-endorsed multicentre study included patients with decompensated ArLD who achieved alcohol abstinence between 2001 and end of 2022. Following Baveno VII criteria, recompensation was defined as (i) the resolution of ascites and encephalopathy (including cessation of medical therapy) and absence of variceal bleeding and (ii) improved hepatic function (Child-Pugh A or MELD < 10). Patients were censored upon alcohol relapse or liver transplantation.
Results: A total of 418 patients with decompensated ArLD from 13 centres were included at the time of alcohol abstinence (median age: 55 years; 71.1% male). The median MELD at inclusion was 19 (IQR: 13–24) and 68.2% had experienced further decompensation prior to abstinence. The median duration from first decompensation to abstinence was 1.0 month (IQR: 0.0 – 11.7). Over a median follow-up of 34.3 months (IQR: 15.7 – 63.2), 101 patients achieved recompensation with a cumulative incidence of 7.5% after 1 year, 18.9% after 2 years and 27.2% after 5 years. With regard to predictors of recompensation (including centre as random effect), recompensation probability decreased with a longer duration to alcohol abstinence after first decompensation (subdistribution hazard ratio [SHR] per month: 0.97; p = 0.004). Neither MELD (SHR: 0.98; p = 0.353) nor albumin (SHR per mg/dL: 0.98; p = 0.145) at abstinence significantly impacted subsequent recompensation. However, there was a higher likelihood in patients with a higher platelet count (SHR per 10 G/L: 1.03; p < 0.001) and in patients presenting with alcohol-related hepatitis at abstinence (SHR: 2.05; p = 0.095). Liver-related death (LRD) occurred in 59 patients (14.1%) and de novo hepatocellular carcinoma (HCC) was diagnosed in 7 patients (1.4%). Not a single patient who had recompensated and remained abstinent progressed to LRD or HCC over a median follow-up of 22.3 months after recompensation. In contrast, the cumulative incidence of LRD/HCC in abstinent patients who remained decompensated was 11.8%/1.2% after 1 year, 16.5%/2.1% after 2 years and 21.1%/2.8% after 5 years. Of note, of the 16 patients who relapsed to alcohol consumption after recompensation (15.8% of recompensated cohort), 4 progressed to LRD and 1 to HCC.
Conclusion: Hepatic recompensation can be achieved in a significant proportion of decompensated ArLD patients, particularly when abstinence is achieved early after decompensation and platelet count is higher. Recompensation in ArLD cirrhosis significantly improves clinical outcomes, with a negligible risk of liver-related mortality.

TOP-189-YI

Vibration-controlled transient elastography of the liver and the spleen for hepatic decompensation risk stratification in a european multicentre study of contemporary cACLD patients

Email: mattias.mandorfer@meduniwien.ac.at

Background and aims: The recently introduced Non-**I**nvasive Clinically Significant Portal Hypertension (CSPH) Estimated Risk ('NICER') model comprising liver (LSM) and spleen stiffness measurement (SSM; at 100 Hz) by transient elastography, platelet count (PLT), and body mass index (BMI) outperformed ANTICIPATE ± NASH (LSM & PLT ± BMI) for the non-invasive diagnosis of CSPH in compensated advanced chronic liver disease (cACLD).

Herein, we present follow-up data from the Baveno Cooperation study leading to the NICER model, and compare the prognostic utility of non-invasive strategies and hepatic venous pressure gradient (HVPG).

Method: Child-Pugh stage A cACLD (LSM ≥10 kPa and/or F3/4) patients from 16 specialized European centres who underwent paired assessment of HVPG, SSM (at 100 Hz), and LSM from 2020–2023 and had lab and follow-up data available were included into the study.

Results: 393 cACLD patients (MASLD: 40.7%, MetALD/ALD: 32.1%) with CSPH (HVPG ≥ 10 mmHg) prevalence of 59.3% were included. Patients were followed for a median of 1.3 (0.8–1.9) years until the occurrence of hepatic decompensation, hepatocellular carcinoma, liver transplantation, death, or last visit. Hepatic decompensation incidence rates were 8.3% (n = 28, 95% CI: 5.0–10.7%) and 13.4% (n = 37, 95% CI: 8.7–17.8%) at 1 and 2 years of follow-up, respectively. HVPG (AUC: 0.755, 95% CI: 0.662–0.849), ANTICIPATE ± NASH (AUC: 0.751, 95% CI: 0.654–0.848), and NICER (AUC: 0.739, 95% CI: 0.635–0.844) conferred similar time-dependent discriminative ability for hepatic decompensation at 2 years. The presence/absence of CSPH (Y1 decompensation rate: 10.9% vs. 3.4%, Y2: 20.0% vs. 3.4%, log-rank test: $p < 0.001$), or a non-invasively predicted CSPH probability of ≥60%/<60% according to ANTICPATE ± NASH (Y1: 11.6% vs. 4.3%, Y2: 19.9% vs. 7.2%, $p = 0.003$) or NICER (Y1: 10.1% vs. 5.0%, Y2: 18.0 vs. 7.4%, $p = 0.010$) all similarly distinguished high-risk cACLD patients from those with a more favourable prognosis. In Cox regression analysis, serum albumin level was identified as a key predictor of hepatic decompensation (hazard ratio [HR]: 0.83 per g/L, $p < 0.001$) besides portal hypertension as evaluated by either HVPG (albumin-adjusted HR [aHR]: 1.10 per mmHg, $p = 0.002$) or by ANTICIPATE ± NASH (aHR: 1.13 per 10% CSPH probability, $p = 0.049$) or NICER (aHR: 1.14 per 10% CSPH probability, $p = 0.042$). Consideration of albumin increased discrimination in comparison to HVPG/NICER/ANTICIPATE ± NASH alone ($p < 0.001$ for all; Harrel's C: 0.764–0.775 for albumin-containing models).

Conclusion: In our multicentre study of contemporary European cACLD patients, non-invasively estimated CSPH risk was similarly predictive for hepatic decompensation as HVPG. Consideration of serum albumin increased the discriminative ability, while the addition of SSM-100 Hz *per se* did not improve hepatic decompensation risk stratification.

Email: georg.semmler@meduniwien.ac.at

Background and aims: Our prospective study (VICIS; NCT03267615) investigated biomarkers of key pathophysiological mechanisms involved in advanced chronic liver disease (ACLD) progression throughout different clinical stages and evaluated their stage-specific ability of identifying progressive disease.
Method: 464 ACLD patients with portal hypertension (PH; hepatic venous pressure gradient [HVPG] >5 mmHg) were characterized at the time of HVPG measurement from 2017–2021 and prospectively followed. Clinical stages were defined as cACLD, first decompensation, further decompensation, ACLF, liver-related death, and recompensation. The following pathophysiological mechanisms were assessed: PH/endothelial dysfunction (HVPG/von Willebrand Factor [VWF]), extracellular matrix (ECM) remodeling/fibrogenesis (enhanced liver fibrosis score [ELF]), systemic inflammation (SI; C-reactive protein [CRP], interleukin-6 [IL-6], and procalcitonin), circulatory dysfunction (proBNP, copeptin), hepatic impairment (MELD, albumin, and bile acids [BA]). Endpoints: First decompensation in cACLD, further decompensation/ACLF in first decompensation, and liver-related death in further decompensation.
Results: All biomarkers showed significant differences between cACLD and decompensated cirrhosis. Interestingly, HVPG reached a plateau with first decompensation, while VWF, CRP & IL-6, copeptin, and albumin & BA were significantly increasing between patients with first and further decompensation. During a median follow-up of 28.8 months, 35/179 (19.6%) cACLD patients developed first decompensation; 60/168 (35.7%) first decompensation patients developed further decompensation/ACLF; 40 (34.2%) of further decompensated patients experienced liver-related death. Investigating differences between progressors and non-progressors within 24 months (cACLD) and 12 months (first/further decompensation) in sub-stages, the most profound differences were found for PH/endothelial dysfunction (HVPG/VWF), ECM remodeling/fibrogenesis (ELF), and liver function (MELD, albumin, and BA) in cACLD, while SI (CRP, PCT, and IL-6) was the key driver of progression after first decompensation. Profound systemic inflammation (PCT & IL-6) and circulatory dysfunction (copeptin) were hallmarks of adverse outcomes among those with further decompensation.
Conclusion: PH/endothelial dysfunction are the main druggable targets (i.e., HVPG-lowering medications & statins) in cACLD, while modulating SI (e.g., antibiotics & albumin) seems key for preventing progression from first to further decompensation. In those with further decompensation, improving circulatory dysfunction (e.g., albumin) is becoming increasingly relevant. Notably, even within these stages, there was profound interindividual variation of pathophysiology-related biomarkers that can be visualized by spider diagrams and may help to guide personalized therapy in future trials.

Email: gudwns21@korea.ac.kr

Background and aims: Acute esophageal variceal bleeding (AVB) is one of the most serious complications of liver cirrhosis. For the emergent management of variceal bleeding, administration of a vasoconstrictor is essential for hemostasis together with endoscopic variceal ligation (EVL). Standard-dose repeated bolus injection (SDRBI) of terlipressin 4–6 times daily is most widely employed before and after EVL, but the adverse effects of terlipressin cannot be overlooked. To minimize the ischemic side effect, low-dose continuous infusion (LDCI) of terlipressin has been proposed for hepato-renal syndrome in patients with liver cirrhosis. However, data from prospective comparisons between the two methods for AVB are sparse. This study aims to compare the safety and efficacy of the two methods for the management of AVB.
Method: This study is a randomized controlled trial to compare SDRBI and LDCI of terlipressin in patients with AVB. A total of 125 patients were enrolled and randomly assigned to the SDRBI group (n = 63, 1 mg bolus injection every 6 hours after initial 2 mg of terlipressin) or LDCI group (n = 62, 2 mg/day of terlipressin infusion) after EVL. Patients with gastric varices on the fundus, failure of initial endoscopic therapy, or advanced hepatocellular carcinoma were excluded.
Results: The baseline characteristics of the patients were not significantly different. Re-bleeding incidence after initial successful EVL was observed for 5 days. The success rate of maintaining hemostasis was 98.4% in both groups (Crude odd ratio = 0.98 [0.06–6.09], P = 0.991). One patient died in the SDRBI group. Decrease of Hb more than 3 g/dL or adjusted blood requirement index over 0.75 to maintain Hb>8.0 g/dL were observed in 7 patients (11.1%) in the SDRBI and 9 (14.5%) in the LDCI group (P = 0.763), respectively, without newly developed hematemesis or melena. The overall incidence of gastrointestinal, cardiovascular, metabolic, or neurologic adverse events was significantly higher in the SDRBI group than in the LDCI group during 5 days (P < 0.05).
Conclusion: Compared with SDRBI, LDCI of terlipressin shows comparable efficacy and better safety for managing AVB in patients with liver cirrhosis.

WED-158
A metabolomic model based on portal venous functional metabolites for predicting post-TIPS overt hepatic encephalopathy using machine learning methods

Xiaoze Wang[1], Kunyi Ba[1], Guofeng Liu[1], Luo Xuefeng, Li Yang.
[1]Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, China
Email: wang_xiaoze@wchscu.cn

Background and aims: The occurrence of overt hepatic encephalopathy (OHE) after transjugular intrahepatic portosystemic shunt (TIPS) is associated with poor outcomes but cannot be predicted accurately. The identification of serum biomarkers from portal vein for predication and patient risk stratification remains underexplored. We aimed to determine the portal venous functional metabolites to predict the development of OHE after TIPS establishment.
Method: Prospective TIPS cohorts including 332 patients underwent preoperative serum collection and follow-up evaluation. Serum metabolomics was analyzed to predict OHE on random forest analysis. A training cohort (n = 221) was used to build the prediction model and a validation cohort (n = 111) was used to test the model. Cell experiments were conducted to test the functions of the selected metabolites.
Results: A total of 71 patients (21.4%) developed OHE after TIPS. By metabolomic profiling, 668 portal venous plasma metabolites are identified. Our machine learning analysis reveals a 7-metabolite OHE predictive model, which is validated in a test set, yielding an area

under the receiver operating characteristic (AUROC) of 0.911. We stratified patients into high-risk and low-risk groups based on the predictive model cutoff. The hazard ratio for the occurrence of post-TIPS OHE in the high-risk group was 16.82 times that of the low-risk group (95% confidence interval 4.02–70.33, $p < 0.001$). Moreover, we individually applied these metabolites from the model to stimulate the astrocyte and found that citrate and taurolithocholic acid could inhibit cell proliferation and promote astrocyte senescence.
Conclusion: Collectively, our findings reveal the metabolic landscape of post-TIPS OHE and identify a distinct biomarker panel that enables prediction, thus facilitating precision prevention for OHE.

WED-159

The role of hepatic venous pressure gradient in patients with porto-sinusoidal vascular disease

Xiaofeng Zhang[1]. [1]*Nanfang hospital, Southern Medical University, Guangzhou, China*
Email: 1282614092@qq.com

Background and aims: The hepatic venous pressure gradient (HVPG) is commonly used as a surrogate for direct portal pressure gradient (PPG) measurement. However, its suitability in patients with porto-sinusoidal vascular disease (PSVD) remains unclear. This study aims to evaluate the correlation between HVPG and direct PPG in these patients.
Method: We conducted a "proof-of-concept" study to evaluate the HVPG and ultrasound-guided percutaneous portal pressure gradient (US-PPG) measurements in patients with PSVD. Prior to this, we assessed the stability of US-PPG by enrolling 21 patients with decompensated cirrhosis who underwent both US-PPG and pre-transjugular intrahepatic portosystemic shunt (TIPS) PPG measurements on the same day. Agreements between HVPG and US-PPG in PSVD patients, as well as US-PPG and pre-TIPS PPG in decompensated cirrhotic patients, were analyzed using the intra-class correlation coefficient (ICC) and the Bland-Altman method.
Results: Among the 21 patients, US-PPG demonstrated a good correlation with pre-TIPS PPG ($R = 0.85$, 95% CI: 0.65–0.94), with an ICC of 0.85 (95% CI: 0.67–0.94). Similarly, a good agreement was observed between ultrasound-guided portal pressure (PP) and pre-TIPS PP ($R = 0.91$, ICC = 0.88; $p < 0.001$). For the primary evaluation, 8 patients with biopsy-proven PSVD were included. Among them, only one patient was decompensated, and HVPG measurement failed in this case due to extensive hepatic venous-to-venous communications; the US-PPG in this patient was 34 mmHg. In the remaining 7 patients, the median US-PPG was 9.0 mmHg (IQR: 9.0–24.0), while the median HVPG was 8.0 mmHg (IQR: 4.0–9.0). However, the agreement between US-PPG and HVPG was poor, with an ICC of 0.73 (95% CI: 0.06–0.95) and a correlation coefficient (R) of 0.75 (95% CI: 0.07–1.0). Similarly, a poor agreement was observed between ultrasound-guided portal pressure (PP) and Wedge hepatic vein pressure ($R = 0.53$, ICC = 0.63). The median platelet count was 95.0×10^9/L (IQR: 46.3–238.0), the median liver stiffness measurement was 9.7 kPa (IQR: 5.6–13.4), and the median spleen stiffness measurement was 43.5 kPa (IQR: 23.9–73.9).
Conclusion: HVPG demonstrated poor accuracy in reflecting portal pressure values in patients with PSVD. Further studies are warranted to explore non-invasive tools for evaluating portal hypertension in PSVD individuals.

WED-160

Long-term outcome of interventional radiological management of Budd-Chiari syndrome: a retrospective, multicenter survey of 10 years

Email: xiadongdong1026@163.com

Background and aims: Large cohort study on radiological interventional management, including percutaneous angioplasty recanalization (PTA)/thrombolysis, transjugular intrahepatic portosystemic shunting (TIPS), for symptomatic patients with Budd-Chiari syndrome (BCS) are lacking. We aimed to depict characteristics and treatment allocation of BCS patients, and intensively assess its long-term outcomes and complications.
Method: Consecutive patients diagnosed as BCS from 6 Chinese tertiary centres were retrospectively screened for eligibility between Jul-2010 to May-2019. Unadjusted, propensity score match (PSM) adjusted, and competing risk analyses with death as a competing event were conducted.
Results: A total of 997 patients were enrolled, including inferior vena cava (15.7%), hepatic vein (16.2%), and combined (68.1%) types. All patients received anticoagulation. Medical treatment alone sufficed in 117 (11.7%) patients, and 22 (2.2%) patients received thrombolysis for acute thrombosis. PTA was used in 834 (83.7%) patients, 268 with and 566 without initial stenting. Initial stenting reduced competing risk adjusted restenosis rate in patients underwent PTA, but not improved survival before and after PSM in all three types of BCS, and patient with unsolved restenosis had a worse prognosis, compared to these solved restenosis or non-restenosis (hazard ratio: 3.0 [1.14–7.63], $p < 0.001$). TIPS was performed in 90 (0.9%) patients (46 initial and 44 converted TIPS). Overall, the 3-year shunt dysfunction and 3-month hepatic encephalopathy rates were 52.3% (40.8%–63.8%) and 20% (11.7%–28.3%), respectively, with no differences between initial TIPS and converted TIPS. Anticoagulation-related, PTA-related, and TIPS-related complications occurred in 152/997, 11/834, and 1/90 patients. The 5-year orthotopic liver transplantation (OLT)-free survival rate was 90.2% (88.2%–92.3%) in the whole cohort with 103 (10.5%) patients died after a median follow-up of 57.3 months, which was similar among different BCS types patients.
Conclusion: With predominantly IVC-obstruction presented and angioplasty used, interventional radiological treatment could also achieve a good long-term outcome in Chinese patients with BCS.

WED-161

Dedicated stent decreases the risk of hepatic encephalopathy after transjugular intrahepatic portosystemic shunt in cirrhotic patients

Shu Mei Du[1], Luo Xuefeng[1]. [1]*Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, Sichuan Province, China*
Email: 2022224025270@stu.scu.edu.cn

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is a minimally invasive interventional procedure to relieve the symptomatic complications of portal hypertension, and HE is the most common and often severe complication following TIPS, previous research had found that polytetrafluoroethylene (ePTFE) stents and bare stents had a comparable post-TIPS HE rates. The Fluency (Bard, Murray Hill, USA) and the Viatorr (W.L. Gore & Associates, Flagstaff, AZ, USA) are two types of ePTFE-covered stents, Despite the ePTFE-covered stent was widely recommended by the guidelines, the effect of different ePTFE-covered stents on patients` outcomes remains controversial. This study aimed to investigate the incidence of hepatic encephalopathy (HE) following transjugular intrahepatic portosystemic shunt (TIPS) using different types of stent grafts in patients with cirrhosis.
Method: Consecutive patients with cirrhosis who underwent TIPS from January 2012 to December 2022 in our center were considered to be included in the study. Patients were divided into the Viatorr group and Fluency group. Case-control matching was performed to control potential confounding variables at baseline. Kaplan-Meier and Cox regression analyses were used to identify the cumulative rates and independent risk factors of post-TIPS HE.
Results: 1077 patients were included in this study, 340 patients in the Viatorr group and 737 in the Fluency group. The 2-year cumulative incidence of HE was significantly lower in the Viatorr group compared with Fluency group (26.4% vs. 34.3%, p = 0.018). The 2-year cumulative rate of shunt dysfunction was also lower in the Viatorr group (2.2% vs. 7.5%, p = 0.037). However, the 2-year cumulative rate of transplant-free survival (93.4% vs. 90.1%, p = 0.428) was comparable between two groups.
Conclusion: TIPS creation using the Viatorr stent-grafts showed a lower risk of HE and better patency compared with the Fluency stent-grafts. Therefore, dedicated stent-graft should be preferred for the TIPS creation in patients with cirrhosis.

WED-162

Cardiac failure following transjugular intrahepatic portosystemic shunt patients with cirrhosis

Shu Mei Du[1], Luo Xuefeng. [1]*West China Hospital of Sichuan University, Chengdu, China*
Email: 2022224025270@stu.scu.edu.cn

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is effective in alleviating the complications of portal hypertension. Post-TIPS cardiac failure has become one of the main concerns recently. It is as high as 20% after TIPS insertion in the Western population. This study was designed to evaluate the incidence of post-TIPS cardiac failure and predisposing factors in patients with cirrhosis.
Method: Between September 2022 and April 2024, consecutive cirrhotic patients who underwent elective TIPS were prospectively screened for inclusion. Patients were excluded if they had (1) a history of previous TIPS or surgical shunt; (2) medium to severe pulmonary hypertension; (3) heart failure; (4) End-stage renal disease requiring hemodialysis; (5) respiratory failure; (6) malignancies with a life expectancy of less than 6 months. A systematic cardiac assessment was conducted in each patient, including biological parameters and transthoracic echocardiography. The primary endpoint was the incidence of cardiac failure.
Results: 238 patients underwent TIPS during the study period, 210 met inclusion criteria [aged 54.0 (47.0–61.0) years, 68.0% man]. Etiologies of cirrhosis were hepatitis B viral infection in 120 (57.1%) patients, and the indication for TIPS was secondary prophylaxis in 166 (79.0%) patients. Baseline echocardiography showed the ejection fraction was 68.0% (63.0%–72.0%), E/A was 1.0 (0.8–1.3), and Pro-BNP was 103.0 (48.0–194.3) respectively. After a median follow-up of 12.0 (8.0–17.0) months, only one patient (0.47%) experienced post-TIPS cardiac failure. 104 (49.6%) patients had post-TIPS echocardiography, end-systolic diameter (ESD), left ventricle (LV) diameter, and stroke volume (SV) were slightly increased after TIPS (ESD, 30.0 vs 31.0, p = 0.001; LV diameter, 48.0 vs 50.0, p = 0.000; SV, 72.0 vs 82.0, p = 0.000). Diastolic function parameters, including left atrial volume index (LAVI), left ventricular mass index (LVMI), and Mean E/e' also showed a slight increase after TIPS (LAVI, 36.7 vs. 41.1, p = 0,000; LVMI, 91.4 vs. 98.5, Mean E/ e', 8.9 vs. 9.5, p = 0.014). However, 155 (73.8%) patients had edema, and 13(6.2%) patients needed liver transplantation or died.
Conclusion: Post-TIPS cardiac failure is rare in the current Chinese cohort. The following echocardiography revealed that despite diastolic function being impaired, patients with cirrhosis can increase cardiac contractility to compensate for the increased volume load shunted to the heart after TIPS.

WED-163

Prevention of hepatic encephalopathy following transjugular intrahepatic portosystemic: lactulose plus rifaximin vs. lactulose monoprophylaxis

Shu Mei Du[1], Luo Xuefeng[1]. [1]*Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, Sichuan Province, China*
Email: 2022224025270@stu.scu.edu.cn

Background and aims: Hepatic encephalopathy (HE) is the most common complication after transjugular intrahepatic portosystemic shunt (TIPS). Rifaximin and lactulose are effective in preventing HE in patients with cirrhosis and TIPS. There is a lack of evidence concerning whether a combination of rifaximin and lactulose is better than lactulose monoprophylaxis. The present aims to compare the efficacy of lactulose plus rifaximin with lactulose monoprophylaxis in preventing post-TIPS HE.
Method: Consecutive patients with cirrhosis who underwent TIPS successfully from May 2019 to May 2024 in our center were included in the study. Patients were divided into group A and group B (A: lactulose monoprophylaxis; B: lactulose plus rifaximin). Propensity score matching (PSM) was performed to control potential confounding variables at baseline, and the Child-Pugh score, MELD score, PT and age were defined as covariates. Patients were prescribed rifaximin 600 mg two times daily and lactulose 15 ml three times daily (the starting dose) or lactulose 15 ml three times daily for six months after TIPS placement.
Results: 608 patients were included in this study, 527 patients treated with lactulose, and 81 patients treated with lactulose plus rifaximin. After PSM, there were 74 fuzzy-matched patients in group A and group B. The Child-Pugh score was 10.5, and MELD score was 7.0 in group A versus 9.8 and 7.0, respectively, in group B (p = 0.943; p = 1.000). The median follow-up was 22 (12–35) and 7 (6–9) months in groups A and B, respectively. The 1-year cumulative rate of overt HE was comparable between the two groups (22.0% vs. 22.4%, Grays test, p = 0.537). 58.0% and 64.2% of patients had only one episode of overt HE in groups A and B. No statistically significant difference was found in the 1-year cumulative rate of transplant-free survival (80.6% vs. 90.0%, Grays test, p = 0.269).
Conclusion: Our data show that adding rifaximin to lactulose monoprophylaxis is not effective in the prevention of overt HE following TIPS.

WED-164

Cirrhotic patients with acute variceal bleeding and an indication for preemptive-TIPS: real-life results

Jiajia He[1], Luo Xuefeng. [1]*Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, Sichuan Province, China*
Email: 2023224025279@stu.scu.edu.cn

Background and aims: Acute variceal bleeding is a severe complication of portal hypertension in patients with cirrhosis. Patients who had a Child-Pugh C (<14 points) or child B >7 points with active bleeding at endoscopy were at high risk of treatment failure and mortality. Pre-emptive transjugular intrahepatic portosystemic shunt (pre-emptive TIPS) is indicated in these patients and widely recommended by guidelines. However, the actual implementation of pre-emptive TIPS varied significantly between different centers. The present study was designed to assess the application of pre-emptive TIPS in real clinical practice.
Method: This was a retrospective cohort study. From December 2019 to November 2022, cirrhotic patients with acute variceal bleeding admitted to West China Hospital who met the indication of pre-emptive TIPS were included. Those treated with TIPS were included in group A, and the remaining patients were included in group B. The primary outcomes were 5-day treatment failure and 6-week mortality.
Results: A total of 709 patients with cirrhosis and acute variceal bleeding were admitted to our hospital, among whom 126 patients (17.77%) met the criteria of high-risk. Twelve patients were child B >7 points with endoscopic active bleeding, and 114 patients were child C (<14 points). TIPS was performed in only 37 patients (29.37%). TIPS was not carried out due to refusal by the patient or the relatives (n = 42), hepatic encephalopathy (HE) (n = 6) and poor liver function (n = 10), hemodynamic instability (n = 2), prior TIPS (n = 2), hepocellular carcinoma (HCC) (n = 22) and balloon-occluded retrograde transvenous obliteration therapy (n = 5). Patients' characteristics such as age, sex ratio, etiology, ascites, and the proportion of patients with HE, ascites, and portal vein thrombosis were similar in the two groups. Chronic viral infection was the main cause of cirrhosis, accounting for 65.87% of all patients. Child-Pugh class varied significantly between these two groups, with the proportion of child B patients being 21.62% in group A and 7.87% in group B (P = 0.03), but there was no significant difference in Child-Pugh scores between the two groups (P = 0.19). The proportion of patients with HCC is higher in group B (18.92% vs 41.57%, P = 0.02). The 5-day treatment failure were 24.32% in group A and 21.35% in group B (P = 0.82), and 6-week mortality were 10.81% and 33.71% in group A and B respectively (P = 0.00). Multivariate analysis was performed in 104 non-HCC patients, which found that TIPS (OR = 0.08, 95% CI: 0.01–0.86, P = 0.04), viral cirrhosis (OR = 8.72, 95% CI: 1.36–55.80, P = 0.02) and the 5-day treatment failure rate (OR = 19.54, 95% CI: 2.30–165.97, P = 0.00) were related to 6-week mortality.
Conclusion: The proportion of patients with high risk of treatment failure and mortality who received pre-emptive-TIPS was relatively low in our cohort and TIPS can improve short-term survival in non-HCC patients.

WED-165

Baveno VII algorithm was able to stratify the risk of portal hypertension-related events in patients with HBV-related cirrhosis

Haiyu Wang[1], Jinjun Chen. [1]*Nanfang Hospital, Southern Medical University, Guangzhou, China*
Email: 375612668@qq.com

Background and aims: Baveno VII algorithm has been proposed and validated for avoiding endoscopy screening in cirrhosis patients, however, its prognostic value lacks prospective validation.
Method: HBV-related compensated cirrhosis were prospectively enrolled from April 2019 to April 2022 and followed until July 2023. All patients underwent liver stiffness measurement (LSM), spleen stiffness measurement (SSM) and esophagogastroduodenoscopy (EGD) screening for esophageal varices (EV) and some were reassessed during follow-up.
Results: Overall 1253 patients were enrolled with a median follow-up of 29 months (IQR 20–42). One experienced decompensation from 667 patients identified as low-risk by the Baveno VII algorithm, compared to 31 cases among 586 high-risk patients (0.6 vs. 20.8 per 1,000 person-years, p = 0.0004). The Baveno VII algorithm identified more patients (53.2%) into low-risk for decompensation than Baveno VII single cutoff model (47.2%, p = 0.003) and than Baveno VI criteria (33.8%, p < 0.0001) did. Patients with high-risk varices diagnosed via endoscopy following Baveno VII algorithm assessment had greater probability of decompensation compared to those identified by the Baveno VII single cutoff model (43.2 vs. 21.3 per 1,000 person-years, p = 0.0093). Additionally, among the 499 patients who underwent endoscopic re-assessment, 242 consecutively identified as low-risk had much lower incidence of EV progression (2.6 vs. 106.3 per 1,000 person-years, p = 0.0003) and lower risk of decompensation compared to 144 consecutively identified as high-risk by the Baveno VII algorithm (0 vs. 33.5 per 1,000 person-years, p = 0.0266).
Conclusion: Baveno VII algorithm could identify HBV-related cirrhosis patients at low risk of decompensation, which was greatly improved upon Baveno VII algorithm reassessment.

WED-166

Prophylactic antibiotics cannot prevent infection in patients undergoing trans jugular intrahepatic portosystemic shunt or plug assisted retrograde transvenous obliteration electively for portal hypertension complications- a double-blind pilot randomized controlled trial

Aashika Bhashyakarla[1], Jagdish Singh[1], Vivek Sreekanth, Jignesh Reddy, Mithun Sharma[1], Shantan Venishetty[1], Manasa Alla[1], Sowmya Iyengar[1], Nageshwar Reddy[1], Manu Tandan[1], Anand Kulkarni[1]. [1]*Asian Institute of Gastroenterology, Hyderabad, India*
Email: aashika.006@gmail.com

Background and aims: Trans jugular (Direct) intrahepatic portosystemic shunt (T(D)IPSS) and Plug assisted retrograde transvenous obliteration (PARTO) are widely utilized interventional procedures to manage the complications of portal hypertension. The role of prophylactic intravenous antibiotics in patients undergoing these procedures electively is unclear, which we aimed to assess.
Method: In this double-blind, placebo-controlled, pilot randomized controlled trial, we included consecutive patients with portal hypertension undergoing T(D)IPSS or PARTO electively from 21/02/2024 to 15/11/2024. Patients were randomized to receive the drug (ceftriaxone 1 g twice daily till discharge) or placebo in a 1:1 ratio. The objectives were to assess the incidence of clinically significant infection (defined as fever >38C and quick SOFA $\geq$ 2) during the hospital stay, the duration of the hospital stay, in-hospital mortality, and adverse events related to the drug.
Results: Seventy patients (age 49.7 ± 15 years: women 32.9%; cirrhosis 85.7%; Among cirrhosis, Child Pugh class B 70% and MELD Sodium 12.4 ± 3.3) were included. 63% underwent PARTO, and 37% underwent T(D)IPSS, which were equally distributed between the two groups. The most common indication for PARTO was fundal varices and/or hepatic encephalopathy and the most common indication for T(D)IPSS was hepatic venous outflow tract obstruction. A total of 13% (9/70; 95% CI, 6–23) developed infection in hospital. The incidence was 11.4% (4/35; 95%CI, 3.2–26.7) in the antibiotic arm and 14.3% (5/35; 95% CI, 4.8–30.2) in the placebo arm (p = 0.72) in the hospital. However, only one patient in each group had a culture-positive infection with Gram-negative bacteria and one died in the hospital in the antibiotic group due to pneumonia. The duration of hospital stay was similar in both groups (Antibiotic: 4 ± 2.2 days vs. Placebo: 4.4 ±

1.7 days; p = 0.47). One patient in the placebo group complained of itching, while none in the drug arm had adverse events.
Conclusion: Prophylactic antibiotics cannot prevent infection in patients undergoing T(D)IPSS/PARTO electively for complications of portal hypertension.

WED-167
The efficacy of HCP407 in reducing dysphagia and chest pain following esophageal variceal ligation in patients with cirrhosis. Preliminary results of a prospective randomized study
Alejandro Fernandez-Simon[1], Joan Sampons[1], Clàudia García-Solà[1], Alex Bofill[1], Andres Cardenas[2]. [1]*Hospital Clinic, Barcelona, Spain;* [2]*Hospital Clinic, University of Barcelona, Institut d'Investigacions Biomèdiques August Pi-Sunyer (IDIBAPS), Barcelona Spain. Ciber de Enfermedades Hepáticas y Digestivas (CIBEREHD), Spain, Barcelona, Spain*
Email: acardena@clinic.cat

Background and aims: Endoscopic band ligation (EBL) is the preferred endoscopic treatment for esophageal varices (EV), owing to its effectiveness and safety profile. However, it often results in adverse effects such as dysphagia and chest discomfort. An over-the-counter medication containing hyaluronic acid, chondroitin sulfate, and poloxamer 407 (HCP407/ Esoxx One®), commonly used for treating gastroesophageal reflux, may offer therapeutic benefits in this context. This study aims to evaluate the efficacy of HCP407 in alleviating dysphagia and chest discomfort associated with EBL and to assess its effect on the healing of post-EBL ulcerations.
Method: All patients undergoing EBL at Hospital Clinic of Barcelona from October 2021 to May 2024 were prospectively included in this study. Participants were randomized into two groups: one group received HCP407 treatment following EBL, while the control group did not receive any treatment. Dysphagia was assessed using the validated Brief Esophageal Dysphagia Questionnaire (BEDQ) questionnaire on days 3 and 7 post-procedure. Baseline and follow-up endoscopies (conducted at 3–4 weeks) provided additional clinical data for analysis.
Results: Of the 31 patients initially enrolled and randomized, 29 completed the study and were analyzed. Most participants were male (82.8%), with a mean age of 63.3 years, and alcohol-related cirrhosis as the primary cause of EV. The HCP407-treated group reported lower dysphagia scores (mean BEDQ total score) on both day 3 (5 vs. 10.46 points) and day 7 (0.75 vs. 2.23 points) compared to the control group; however, these differences were not statistically significant. No significant differences were observed in the resolution rate of post-EBL ulcerations between groups.
Conclusion: Post-EBL treatment with HCP407 reduces the incidence and severity of dysphagia and chest discomfort, potentially benefiting patient comfort. However, a larger sample size is necessary to determine statistically significant effects.

WED-170
Descriptive study of the impact of using non-cardioselective beta-blockers in cirrhotic patients after a first episode of ascites
Alejandro Fernandez Soro[1], Victoria Lobo Antuña[1], Inmaculada Castello[1], Mercedes De La Torre Sanchez[1], Moises Diago[1], Carlos Alventosa-Mateu[1]. [1]*Hospital General de Valencia, Valencia, Spain*
Email: afdzsoro@gmail.com

Background and aims: Non-selective beta-blockers (NSBB) are the only non-etiological treatment with a proven positive impact on advanced chronic liver disease (ACLD). They are indicated in compensated ACLD with clinically significant portal hypertension and in decompensated ACLD with esophagogastric varices. However, their role in decompensated ACLD with ascites but no varices remains unclear. This study aimed to compare the progression of patients with ACLD treated or not treated with NSBB after a first ascitic episode.
Method: This retrospective single-center study included ACLD patients admitted to the General Hospital of Valencia for a first ascitic decompensation (2013–2023). Patients already on NSBB or with prior decompensation were excluded. Demographics, clinical progression, and mortality were compared between NSBB and non-NSBB groups using Chi-square, Mann-Whitney U, or Student's *t*-test. $P < 0.05$ was considered significant.
Results: We analyzed 92 patients (mean age 59.2 ± 9.9 years; 86% male). Predominant etiologies were alcohol-related liver disease (75%) and hepatitis C (16%). After the first ascitic episode, 54.9% did not initiate NSBB, while 45.1% did (56% propranolol, 44% carvedilol). No differences were found between groups in age, sex, ACLD etiology, or Child-Pugh/MELD scores. During follow-up, the non-NSBB group showed a higher probability of new hepatic decompensation (75% vs. 63%, $p = 0.25$), which occurred earlier (9.0 ± 10.7 vs. 13.2 ± 19.1 months, $p = 0.3$). They also experienced more recurrent events (67% vs. 49%, $p = 0.08$) and hospitalizations (2.3 ± 2.3 vs. 1.6 ± 1.8, $p = 0.14$). More patients in this group required therapeutic paracentesis (33% vs. 15%, $p = 0.039$). Mortality rates after the first ascitic event were similar (57% vs. 51%, $p = 0.66$), but death occurred earlier in the non-NSBB group (22.5 ± 23.2 vs. 37.7 ± 31.6 months, $p = 0.046$).
Conclusion: After a first ascitic decompensation, patients treated with NSBB had fewer hepatic decompensations, a reduced need for therapeutic paracentesis, and longer survival. NSBB may benefit patients following their first ascitic episode, regardless of varices.

WED-171
Safety of seladelpar in primary biliary cholangitis patients with cirrhosis and clinical signs of portal hypertension: data from the ENHANCE and RESPONSE studies
Aliya Gulamhusein[1], Michael K. Porayko[2], Andrea Galli[3], Francesca Carubbi[4], Xin Qi[5], Sarah Proehl[5], Daria Crittenden[5], Stuart C Gordon[6]. [1]*Division of Gastroenterology and Hepatology, Toronto Centre for Liver Disease, University of Toronto, Toronto, ON, Canada;* [2]*Department of Hepatology, Vanderbilt University, Nashville, TN, United States;* [3]*Azienda Ospedaliero Universitaria Careggi Gastroenterologia Clinica, Firenze, Italy;* [4]*Metabolic Medicine Unit, Azienda Ospedaliero Universitaria di Modena, University of Modena and Reggio Emilia, Modena, Italy;* [5]*Gilead Sciences, Inc., Foster City, CA, United States;* [6]*Division of Hepatology, Henry Ford Hospital, Wayne State University School of Medicine, Detroit, MI, United States*
Email: aliya.gulamhusein@uhn.ca

Background and aims: Primary biliary cholangitis (PBC) is a chronic, progressive, autoimmune, cholestatic liver disease that can cause cirrhosis and portal hypertension (PHT). Seladelpar is a first-in-class delpar (selective PPAR-delta agonist) approved for the treatment of PBC in combination with ursodeoxycholic acid (UDCA) in adults who have an inadequate response to UDCA, or as monotherapy in patients (pts) unable to tolerate UDCA. In two Phase 3, placebo-controlled studies (ENHANCE [NCT03602560] and RESPONSE [NCT04620733]), seladelpar significantly reduced cholestatic markers of disease and pruritus with a safety profile similar to placebo (primary analyses at month 3 in ENHANCE and month 12 in RESPONSE). Here, we present pooled safety data from these studies in a subgroup of patients with cirrhosis and clinical signs of PHT.
Method: Pts with PBC who received UDCA for ≥ 12 months or were UDCA intolerant with alkaline phosphatase (ALP) ≥ 1.67 × upper limit of normal (ULN) and total bilirubin (TB) ≤ 2 × ULN were randomised 1:1:1 to daily placebo, seladelpar 5 mg, or seladelpar 10 mg for up to 52 weeks in ENHANCE and 2:1 to daily seladelpar 10 mg or placebo for 52 weeks in RESPONSE. Cirrhosis was defined by medical history, liver biopsy, transient elastography, laboratory findings, radiological features, or clinical determination by the investigator. Pts with cirrhosis were identified as having signs of PHT at baseline (BL) if they had thrombocytopenia (platelet count < 140×10^3/μL), low albumin, elevated TB, or medical history of varices or ascites. Data are reported for the seladelpar (5 mg and 10 mg) and placebo groups.
Results: Among 56 pts with a diagnosis of cirrhosis at BL across the two studies, 27 had signs of PHT at BL (21 pts on seladelpar [15/21 on

10 mg] and 6 placebo). The majority of pts were female (85%) and White (89%), with a mean (range) age of 55.6 (33–74) years, and BL mean ALP and TB levels of 319.9 U/L and 1.2 mg/dL. Mean (SD) liver stiffness was 17.4 (3.5) kPa with placebo and 21.0 (11.8) kPa with seladelpar. In total, 5/6 (83%) pts on placebo and 15/21 (71%) pts on seladelpar experienced an adverse event (AE); 2/6 (33%) pts on placebo and 1/21 (5%) pts on seladelpar discontinued treatment due to AEs. Serious AEs occurred in 1/6 (17%) pts on placebo and 1/21 (5%) pts on seladelpar and deemed unrelated to study drug. Liver-related AEs by a predefined search strategy were similar across pts on placebo (2/6, 33%) or seladelpar (3/21, 14%) and included hepatomegaly, ascites, hyperbilirubinaemia, and portal hypertensive gastropathy. Liver-related laboratory abnormalities by predefined categories occurred in 2/6 (33%) placebo-treated pts and 1/21 (5%) seladelpar-treated pts.

Conclusion: In this pooled analysis of pts with PBC and cirrhosis with clinical signs of PHT from the ENHANCE and RESPONSE studies, safety outcomes were overall similar between seladelpar and placebo, with no new safety signals.

WED-172

Outcomes following transjugular intrahepatic portosystemic shunt in patients with hepatorenal syndrome and acute-on-chronic liver failure

Anand Kulkarni[1], Li Peng Margaret[2], Madhumita Premkumar[3], Karan Kumar[4], Akash Roy[5], Suprabhat Giri[6], Mithun Sharma[1], Daniel Huang[2], Sowmya Iyengar[1], Kamarjit Mangat[2], Swati Das[6], Manasa Alla[1], Shantan Venishetty[1], Jagdish Singh[1], Rajesh Gupta[1], Mark Muthiah[2], Nagaraja Padaki[1], Nageshwar Reddy[1]. *[1]AIG Hospitals, Hyderabad, India; [2]National University of Singapore, Singapore, Singapore; [3]PGIMER, Chandigarh, India; [4]Mahatma Gandhi Medical College, Jaipur, India; [5]Apollo Hospitals, Kolkata, India; [6]Kalinga Institute of Medical Sciences, Bhubaneshwar, India*
Email: anandvk90@gmail.com

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) has a proven role in the management of variceal bleeding and refractory ascites. However, the role of TIPS in special populations, i.e., patients with hepatorenal syndrome-acute kidney injury (HRS-AKI), acute-on-chronic liver failure (ACLF), and chronic kidney disease (CKD) is less known, which we aimed to assess.

Method: In this retrospective multicenter study from India and Singapore, we included patients who had undergone TIPS. We aimed to assess the transplant-free survival (TFS) of patients with HRS-AKI, ACLF, splenoportal (SP) axis thrombosis and CKD following TIPS. ACLF was defined as per APASL criteria.

Results: Two hundred and seven patients who underwent TIPS for various indications were included. Approximately 36.4% (71/195) had a history of HRS-AKI in the previous three months and had received vasoconstrictor with albumin for treatment. Patients with HRS-AKI had lower platelets (101.31 ± 57.7 vs. 129.5 ± 84.2; P = 0.01), indicating a greater degree of portal hypertension. Similarly, the portal pressure gradient was higher in HRS-AKI patients (25.35 ± 7.4 in HRS group vs 21.6 ± 6.3 mmHg in non-HRS group; P = 0.008). Most common indication was refractory ascites/hydrothorax (67%) in HRS-AKI group, while bleed (41.1%) was common indication in non-HRS group. On Kaplan Meier analysis, TFS was 52.1% (37/71; 95%CI, 40–64.1) in HRS group compared to 73.4% (91/124; 95%CI, 64.7–81) in non-HRS group (P < 0.001). Of the twelve patients with ACLF pre-TIPS, TFS was only 33.3% compared to 67.2% in those without ACLF (P < 0.001). Thirteen percent (27/207) of patients had SP axis thrombosis and seven percent (15/207) had CKD. TFS was similar among those with SP axis thrombosis (66.7%) and those without (65%). TFS was comparable among patients with CKD (53.3%) and those without CKD (66.1%; P = 0.31). However, the incidence of HE was 67% in CKD group compared to 34.4% in non-CKD group (P = 0.01).

Conclusion: TIPS may not be optimal therapy in improving survival in those with antecedent HRS-AKI or concomitant ACLF.

WED-173

Machine and deep learning for non-invasive detection of esophageal varices in hepatocellular carcinoma patients

Background and aims: Portal hypertension (PH) screening in advanced hepatocellular carcinoma (HCC) remains challenging. As current Baveno criteria lack sensitivity, endoscopy is required to detect esophageal varices (EV) to determine need for variceal bleeding prophylaxis. We aim to develop and validate a non-invasive classifier for EV status in HCC patients to avoid systematic endoscopy, utilizing deep learning (DL-imaging model) on contrast-enhanced CT scans (CECT) alongside clinical-biological data and imaging findings at baseline (baseline model).

Method: Data from 223 HCC patients eligible for Atezolizumab-Bevacizumab (AtezoBev) from three French hospitals with arterial phase CECT and no prior liver transplant were collected. Endoscopy for EV assessment was conducted within six months before starting AtezoBev. Patients were divided into training (AVC, PSL) and validation (SAT) cohorts. Abdominal axial CT features were extracted for DL-imaging model training and validation for EV classification. For the baseline model, a logistic regression model with LASSO-selected signature was trained and validated. Model performance was assessed by area under the receiver operator curve (AUROC).

Results: Median patient age was 65.6 years (84% male). Cirrhosis was present in 83.8% of patients, 49% had viral infection, alcohol consumption was present in 46% and metabolic syndrome in 37% (74% had mixed cause of liver disease). 74% were Child-Pugh A (MELD 8, 14% ALBI score 3). Median platelet count was 164,000/mm^3, total bilirubin was 14.0 uM/dL, INR was 1.14, albumin was 35.0 g/dL and creatinine was 72.0 uM. 53% had EV and 21% had history of ascites. Collaterals at imaging were present in 55%. HCC was multinodular in 77% of cases, with median size of 60 mm for largest lesion, 38% had infiltrating HCC and 41% vascular invasion, 60.5% were BCLC-C and 50% were treatment-naive for HCC. The DL-imaging model was able to classify EV status with AUROCs (median [95% confidence interval]) of 0.76 [0.57–0.91] in validation. For the baseline model, the signature was composed of 6 features: platelet count with log-odds ratio (LOR) of −0.22, total bilirubin (LOR: 0.40), presence of collaterals (LOR: 2.74), albumin (LOR: −0.19) and creatinine levels (LOR: −0.29) and INR (LOR: 0.09), showing an AUROC of 0.95 [0.84–1.00] in validation.

Conclusion: The baseline model classified EV status with very good performance, outperforming the DL-imaging model. High

importance for collateral vessel presence on CECT-scan was observed in the baseline model, suggesting that patients with collaterals may benefit from AVB prophylaxis with beta-blockers, potentially eliminating the need for endoscopy.

WED-174

Utility of spleen elastography in predicting transjugular intrahepatic porto-systemic shunt dysfunction in patients with liver cirrhosis

Asunción Ojeda[1], Lara Orts[2], Joana Codina Jane[2], M Àngels Falgà[3], Pamela Vizcarra[3], Anna Darnell[4], Ernest Belmonte[4], Alexandre Soler[4], Alba Cristina Igual[4], Valeria Perez[5], Sarah Shalaby[5], Wagner Ramirez[5], Sonia Torres[1], Anna Baiges[6], Virginia Hernández-Gea[7], Maria Ángeles García-Criado[4], Juan Carlos García-Pagán[5,6], Fanny Turon[6]. *[1]Barcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN-Rare Liver), Barcelona, Spain; [2]Arcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN- Rare Liver), CIBEREHD, Barcelona, Spain; [3]Arcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN- Rare Liver), Barcelona, Spain; [4]Servei de Radiologia, Hospital Clínic de Barcelona, Barcelona, Barcelona, Spain; [5]Arcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN-Rare Liver), Barcelona, Spain; [6]Barcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN- Rare Liver), CIBEREHD, Barcelona, Spain; [7]Barcelona Hemodynamic Lab, Liver Unit, Hospital Clínic de Barcelona, IDIBAPS, Universitat de Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN- Rare Liver), CIBEREHD, Barcelona, Spain*
Email: asunojedagomez@gmail.com

Background and aims: Transjugular Intrahepatic porto-systemic shunt (TIPS) dysfunction (defined as portocaval pressure gradient (PPG) > 12 mmHg) is a situation that can be associated with the recurrence of serious complications of portal hypertension (PHrC). The gold standard for its diagnosis is PPG measurement through TIPS catheterization. Doppler ultrasound (US) used as a screening test has a sensitivity of 90% but specificity of 45%, resulting in a significant number of normally functioning TIPS revisions. The aim of the study was to evaluate whether spleen stiffness measurement (SSM) by transient elastography, alone or in addition to US, is effective in detecting TIPS dysfunction.

Method: we retrospectively reviewed a prospective cohort of patients with liver cirrhosis treated with TIPS that underwent a routine/elective TIPS revision and SSM one month after TIPS, between 2019 and 2024. Patients with portal vein and/or TIPS thrombosis were excluded. US criteria considered indicative of TIPS dysfunction were the presence of echographic ascites, a mean of maximum portal flows velocities <28 cm/s together with hepatofugal flow at the intrahepatic portal vein branches or <39 cm/s if the flow at the intrahepatic portal vein branches was hepatopetal flow.

Results: 57 patients were included, 44 (75.9%) of them were men with a median age of 57.5 (49–66) years. At monthly catheterization, 12 (21%) patients had TIPS dysfunction and 45 (79%) did not. The mean SSM in patients with dysfunction was significantly higher than in patients without dysfunction (51 ± 14 Kpa vs 36 ± 10 KPa; p < 0.000). SSM has an AUROC of 0.805 to identify TIPS dysfunction. The most sensitive (sensitive 100%) cut-off point was 30 Kpa, although the specificity was low (36%). Thus, applying this value, 41 patients would have undergone TIPS revision but only 12 of them were dysfunctional. Of the entire cohort of 57 patients, 50 had screening US and 22 of them (38.6%) had US criteria suggesting TIPS dysfunction, which was only confirmed in 7 (all of them with an SSM >30 Kpa). The strategy of applying SSM to the 22 patients with US suggesting dysfunction and only reviewing those with SSM>30 Kpa (n = 15) would avoid unnecessary TIPS revision (reduction by 32% in the number of hemodynamic revisions; from 22 to 15 patients). We evaluated an additional group of 8 patients submitted to a TIPS revision due to a follow-up US suggesting TIPS dysfunction: 3 were dysfunctional and all of them had SSM > 30 KPa. Again, using SSM after US-Doppler would reduce from 8 to 4 patients (by 50%) the numer of TIPS revision for suspicion of TIPS dysfunction.

Conclusion: SSM alone appears to be less predictive of TIPS dysfunction than US-Doppler. However, the evaluation of SSM in the subgroup of patients in whom US suggests dysfunction allows avoiding unnecessary TIPS revisions (around 30–50% of patients), in patients with SSM < 30 KPa. These preliminary data must be confirmed in larger series of patients.

WED-175

Anemia following portal hypertension-related bleeding in liver cirrhosis: incidence and impact on prognosis

Email: asunojedagomez@gmail.com

Background and aims: Approximately 50% of patients with liver cirrhosis have anemia, usually multifactorial and its presence is associated with worse prognosis. Restrictive transfusion policies in the context of upper gastrointestinal bleeding (UGIB) could aggravate this anemia or determine its appearance if not previously present. The objective of the study was to evaluate the incidence of anemia at discharge after UGIB due to portal hypertension (PHT) in patients with cirrhosis and its impact on prognosis.
Method: Retrospective multicenter observational study of a prospective cohort of cirrhotic patients hospitalized for UGIB-PHT between 2017 and 2019. Patients were followed up to 1-year, death or liver transplant (LT) whatever occurred first.
Results: 844 episodes of UGIB-PHT were registered in 14 referral centers. 377 patients were excluded for different reasons (116 death during episode; 62 receiving TIPS, among other reasons) and finally 467 patients were included. 353 (75.6%) were men with a median age of 60 (IQR:52–69) years. The most frequent etiology was related to alcohol (42%). 62% of patients received red blood cell (RBC) transfusion during admission, with a median of 3 (2–5) units. At discharge, Child-Pugh score and MELDNa scores were 7 (6–8) and 13 (10–17) points. The median Hb at discharge was 9 (8.4–9.7) g/dl. 73 patients (15.6%) had Hb ≤ 12 g/dL (mild anemia); 310 (66.4%) Hb ≤ 10 (moderate) and 67 (14.8%) Hb ≤ 8(severe). In 373 patients (80%) an Hb value within the 6 previous months was available and 23% had moderate/severe anemia. At discharge, 81.2% of these patients had moderate/severe anemia. 259/467 (55.4%) patients received intravenous/oral iron during admission or at discharge (40% of those having mild anemia, 59% moderate and 60% severe). At 1 year, 69 (15%) patients died, 34 (7%) underwent LT, and 210 (44.9%) suffered PHC. The probability of LT-free survival without PHC was 85.6%, 72.6%, and 43.6% at 1, 3, and 12 months, and was associated at univariate analysis with male sex, older age, higher Child and MELDNa, lower Hb at discharge, and non being treated with iron. At multivariate analysis, male sex, higher MELDNa, and lower Hb at discharge were independently associated with this event. When analyzing those patients with moderate/severe anemia (Hb<10 g/dl), MELDNa and no receiving iron were independently associated with LT-free survival without PHC. Higher MELDNa and no receiving iron treatment were also independent predictive factors when survival without LT was considered (96.9%, 93.2%, and 67.5% at 1, 3, and 12 months).
Conclusion: Current transfusion-restrictive policies are associated with a high incidence of moderate/severe anemia at discharge of a UGIB-PHT, which is linked to a poor prognosis. Iron administration improves prognosis, but a high percentage of patients do not receive this treatment.

WED-176

Role of splenic stiffness in predicting outcomes in decompensated cirrhosis: an ambispective cohort study

Ayush Agarwal[1], Pavit Singh[1], Sinchana Lakshmi[1], Dhruv Advani[1], Akshay Sharma[2], Shekhar Swaroop[1], Arnav Aggarwal[1], Shubham Mehta[1], Sagnik Biswas[1], Samagra Agarwal[1], Shalimar Shalimar[1]. *[1]All India Institute of Medical Sciences, New Delhi, New Delhi, India; [2]Luminis Health Anne Arundel Medical Centre, Annapolis, Maryland, United States*
Email: drshalimar@gmail.com

Background and aims: Liver and splenic stiffness have emerged as promising non-invasive markers of portal hypertension. Studies have observed the utility of splenic stiffness in predicting high risk esophageal varices and decompensation in patients with compensated cirrhosis, but there is lack of data on its utility in predicting further decompensation and outcomes in more advanced stages of cirrhosis with pre-existing decompensation. This study evaluates the role of splenic stiffness measurement (SSM) in predicting outcomes in decompensated cirrhosis and compares its performance to liver stiffness measurement (LSM).
Method: This single center ambispective cohort study included consecutive adult patients with decompensated cirrhosis attending the liver clinic of a tertiary care hospital in India, whose liver and splenic stiffness values had been measured. Patients with valid measurements were included, while those with hepatic vein outflow tract obstruction, grade III ascites, or unreliable readings were excluded. Patients were followed up for further decompensation [new onset or refractory ascites, variceal bleed, hepatic encephalopathy, or acute-on-chronic liver failure (ACLF)]. Statistical analysis was done using Cox proportional regression analysis.
Results: Two hundred and fourteen patients were included: median age 46 years (IQR: 38–52) with 172 (80.37%) being male. The underlying etiology of cirrhosis was alcohol-related (83, 38.8%), chronic HBV (49, 22.9%), MASLD (24, 11.21%), chronic HCV (19, 8.9%), autoimmune hepatitis (20, 9.35%) and cryptogenic in the remaining patients. The most common pre-existing decompensation was ascites (90.1%) followed by variceal bleed (55.5%) and hepatic encephalopathy (25.3%). Baseline LSM and SSM values were 40.9 kPa (IQR: 22.7–63) and 58.1 kPa (IQR: 44.7–79.8), respectively. Further decompensation occurred on 41 (19.2%) patients over a follow up of 6 (3–16) months. The most common decompensation events were hepatic encephalopathy in 22 (10.3%) patients, ascites in 15 (7%), variceal hemorrhage in 9 (4.2%), and ACLF in 8 (3.7%) patients. Baseline Child-Turcotte-Pugh (CTP) score (HR 1.37, p 0.03), but not baseline SSM (HR 1.25, p 0.5), LSM (HR 1.01, p 0.06), change in SSM (HR 0.99, p 0.7), or SSM/LSM ratio (HR 0.88, p 0.2) was a significant predictor of further decompensation in survival analysis.
Conclusion: Splenic stiffness measurement does not predict further decompensation in decompensated cirrhosis.

Email: becchettichiara@tiscali.it

Background and aims: Cirrhotic cardiomyopathy (CCM) is a clinical syndrome characterized by functional and structural cardiac abnormalities in patients with cirrhosis, manly defined by the impaired ventricular relaxation (diastolic dysfunction - DD) in the absence of known cardiac disease. It is largely subclinical until significant haemodynamic stress, such as transjugular intrahepatic portosystemic shunt (TIPS), occurs. CCM criteria were recently refined and consisted of echocardiographic parameters. However, the clinical significance of these new criteria of DD in cirrhotic patients underwent TIPS is poorly understood.
Method: We conducted a retrospective, monocentric study aimed at evaluating the impact of DD, using 2005 and 2019 criteria for CCM and the Toulouse algorithm, on post-TIPS outcomes defined as major cardiovascular events (MACE) and liver transplant (LT) - free survival at 6-month after TIPS.
Results: Overall, 200 patients were included in the study. Of those, 144 (72%) were male and the median age at TIPS was 59 years (IQR 53–65). Considering only patients (127/200) with DD certainly definable through the 2019 CCM criteria, the prevalence of DD was 26%. These patients were significantly older (63 vs 57 years; p < 0.001) and with higher levels of N-terminal pro-B-type natriuretic peptide (NT-proBNP) (178 vs 90 pg/ml; p 0.04). With regards to 6-month outcomes after-TIPS, they did not show a higher rate of MACE (11% vs 3%; p = 0.29) nor of composite outcome LT and death (14% vs 18%; p = 0.55). We also observed that 2005 and 2019 DD criteria and Toulouse algorithm failed to predict MACE and LT – free survival at 6-month after TIPS. According to our results, only NT-proBNP value showed a significantly association with MACE (HR 1.07, CI 1.00–1.14, p 0.04) and severity of liver disease, defined by Model for End-Stage Liver Disease (MELD) and portal pressure gradient (PPG) pre-TIPS, was the only independent risk factor for mortality or LT (HR 1.32, CI 1.18–1.48, p < 0.001 and HR 1.12, CI 1.02–1.22, p 0.02, respectively).
Conclusion: Our findings suggest that while DD on echocardiography should not preclude the clinical benefits of TIPS, a comprehensive cardiac evaluation remains essential for patient selection. However, echocardiography parameters alone should not be used to predict cardiac decompensation or mortality risk after the procedure.

Dynamics in hepatic venous pressure gradient (HVPG) during the course of recompensated alcohol-related cirrhosis

Benedikt Hofer[1,2,3,4], Georg Semmler[1,2,3], Lorenz Balcar[1,2,3], Nina Dominik[1,2,3], Georg Kramer[1,2,3], Christian Sebesta[1,2,3], Paul Thöne[1,2,3], Benedikt Simbrunner[1,2,3,4], Albert Friedrich Stättermayer[1,2], Michael Trauner[1,3], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3,4]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [3]Clinical Research Group MOTION, Medical University of Vienna, Vienna, Austria; [4]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria*
Email: benedikt.s.hofer@meduniwien.ac.at

Background and aims: Alcohol abstinence may lead to recompensation in decompensated alcohol-related cirrhosis. However, the proportion of patients resolving clinically significant portal hypertension (CSPH) during recompensation and the utility of non-invasive tests for CSPH in this setting are unclear.
Method: Patients with recompensated alcohol-related cirrhosis and same-day hepatic venous pressure gradient (HVPG), liver stiffness (LSM) and spleen size (on ultrasound) measurement at the Vienna General Hospital were analysed. Recompensation was defined as resolution of all decompensation-defining complications and improvement in hepatic function following abstinence (Baveno VII criteria).
Results: Among 26 patients with recompensated alcohol-related cirrhosis undergoing HVPG measurement after a median of 3.5 months after recompensation (all Child-Pugh A5; median MELD: 9.5), median HVPG was 11 mmHg (IQR: 8–16) and CSPH resolved in 11 patients (42%). LSM was reliable (IQR/median < 30%) in 23/26 patients (median 20.7 kPa), performing well for diagnosing CSPH as a standalone marker (AUROC 0.833) and within the ANTICIPATE model (AUROC 0.788). Baveno criteria (LSM ≥ 25 kPa) showed excellent diagnostic accuracy for ruling-in CSPH (PPV and specificity 100%; CSPH in n = 8/8). In contrast, rule-out criteria (LSM ≤ 15 kPa & platelets ≥ 150 G/L) were less accurate (NPV 60% and sensitivity 84%; CSPH in n = 2/5), due to the limited diagnostic utility of platelet count (AUROC 0.461), with thrombocytopenia in 7/11 patients (64%) with resolved CSPH. In contrast, the AUROC of von Willebrand factor (vWF) antigen for CSPH was excellent (0.794) and applying a cut-off of < 170% to rule-out CSPH yielded an NPV and sensitivity of 100% (CSPH in n = 0/6). Splenomegaly (≥ 13 cm) persisted in 3/11 patients (27%) with resolved CSPH vs. 9/15 (60%) with CSPH persistence (p = 0.130). A paired prior HVPG in a decompensated stage was available in 17 patients (median 37 months between measurements). Median decompensated HVPG was 19 mmHg (IQR: 16–20), with a relative decrease of 44% (IQR: 19–53) following recompensation (p < 0.001). Similarly, MELD decreased by a median of 36%, C-reactive protein by 58%, interleukin-6 by 56% and von Willebrand factor (vWF) by 39% (p < 0.05 for all), with no significant change in platelets (–7%; p = 0.932) or spleen size (–5%; p = 0.210). While HVPG decrease showed no correlation with the increase in platelets (Spearman's r: 0.23; p = 0.381), its correlations with decreases in spleen size (r: 0.75; p = 0.001), vWF (r: 0.58; p = 0.025) and MELD (r: 0.50; p = 0.042) were statistically significant.
Conclusion: CSPH resolves in a considerable proportion of patients with alcohol-related cirrhosis achieving recompensation following abstinence. While Baveno criteria with LSM ≥ 25 kPa accurately ruled in CSPH persistence, rule-out criteria were inaccurate and may be improved by incorporating vWF.

WED-179
CT-based imaging indices predict hepatic encephalopathy after transjugular intrahepatic portosystemic shunt in cirrhotic patients

Xinyu Chen[1], Yicheng Lin[1], Jiajun Tian[2], Fenghui Li[2], Kefeng Jia[2], Rong Lv[2], Chao Yang[2], Jiayin Wang[2], Huiling Xiang[2]. *[1]The Third Central Clinical College of Tianjin Medical University, Tianjin Medical University, Tianjin, China; [2]Tianjin Third Central Hospital, Tianjin, China*
Email: chenxinyutmu@126.com

Background and aims: The transjugular intrahepatic portosystemic shunt (TIPS) is a critical therapeutic intervention for patients with

decompensated cirrhosis. Despite its benefits, hepatic encephalopathy (HE) is a prevalent postoperative complication that significantly impairs patients' quality of life and prognosis. Current research on imaging-based prediction models for HE development following TIPS is limited. This study aimed to determine the incidence of HE in patients with decompensated cirrhosis within six months post-TIPS and to evaluate the predictive value of liver volume and the third lumbar vertebral level skeletal muscle area (SMA) for the development of HE six months after TIPS.

Method: We enrolled 126 patients with decompensated cirrhosis treated at the Third Central Hospital of Tianjin, China, from April 2020 to July 2023, who underwent TIPS and had an enhanced computed tomography (CT) scan. These patients were followed for six months post-TIPS. Patients were stratified into two groups based on the development of HE within six months post-TIPS: those who developed HE and those who did not. The volumes of the liver and the L3 SMA were delineated using 3D Slicer software.

Results: We included 95 cirrhotic patients who met the inclusion criteria. The mean age of the patients was 57.7 ± 10.6 years, with 56 males (59.0%). The causes of cirrhosis were viral in 31 patients (32.6%), alcohol-related in 26 patients (27.4%), and other etiologies in 38 patients (40.0%). The median volumes of the liver lobes were as follows: left lobe 449.46 cm^3 (IQR 349.97, 540.22), right lobe 509.74 cm^3 (IQR 416.63, 679.80), and caudal lobe 26.60 cm^3 (IQR 21.55, 36.98). The median total hepatic volume was 1,000.94 cm^3 (IQR 843.81, 1284.77), and the median L3 SMA was 207.72 cm^2 (IQR 170.34, 243.46). Within six months post-TIPS, hepatic encephalopathy developed in 11 patients (11.58%). The left lobe volume, L3 SMA, and Child-Pugh scores significantly differed between groups ($p < 0.05$). Multivariate logistic regression analyses identified the left lobe liver volume (OR = 0.991, 95% CI 0.983–0.998) and the L3 SMA (OR = 0.979, 95% CI 0.959–0.999) as independent predictors of hepatic encephalopathy occurrence in cirrhotic patients within six months post-TIPS. A predictive model for hepatic encephalopathy within six months post-TIPS was developed, with the following characteristics: AUC = 0.839, sensitivity = 0.909, specificity = 0.774, and cutoff value = 0.161.

Conclusion: The incidence of HE among patients with decompensated cirrhosis within six months post-TIPS was 11.58%. The CT-derived volume of the left liver lobe and the L3 SMA were identified as independent predictors for the development of HE in these patients within six months post-TIPS. Consequently, a predictive model for HE development was established. A model score exceeding 0.161 indicated a lower likelihood of HE development in cirrhotic patients within six months following TIPS.

WED-180

Rate of recurrent gastrointestinal bleeding and outcomes in patients undergoing balloon-occluded retrograde obliteration (BRTO) versus transjugular intrahepatic portosystemic shunt (TIPS) for gastric variceal bleeding

Cristina Angelo[1], She-Yan Wong[1], Hope Kincaid[1], Kyle Shaak[1]. *[1]Lehigh Valley Health Network, Allentown, United States*
Email: cristina.angelo@lvhn.org

Background and aims: Gastroesophageal varices are a complication of cirrhosis and are associated with significant morbidity and mortality[1]. There is published guidance on the management of esophageal varices (EV), however less is known regarding the treatment of gastric varices (GV). Options are institution dependent and include transjugular intrahepatic portosystemic shunts (TIPS) or balloon-occluded retrograde transvenous obliteration (BRTO)[2]. The aim of our study is to compare outcomes for patients with GV bleeding treated with BRTO versus TIPS.

Method: This is a single center retrospective study conducted at a suburban health network in Pennsylvania. Patients older than 18 years with a diagnosis of cirrhosis and history of GV bleeding treated with BRTO or TIPS were included. The study time period was 2015 through 2022, with 1 year follow-up. Primary endpoint was rate of recurrent gastrointestinal bleeding (GIB). Secondary endpoints were rate of complications related to portal hypertension, time to recurrence of GIB, and overall mortality and survival.

Results: A total of 67 patients (n = 22 BRTO, n = 45 TIPS) were included. The average age was 58, 70% were male, and 92% were white. The etiology of cirrhosis was alcohol related in 58%, followed by metabolic dysfunction-associated steatohepatitis in 25%. The majority were Child-Pugh class B (72%) with a median MELD of 15. Recurrent GIB occurred in 10 patients with an overall incidence of 15% and a median length time of 3.5 days. The incidence of recurrent GIB for patients who had BRTO (n = 4) and TIPS (n = 6) was 18% and 13% respectively, and was not statistically significant ($p = 0.72$). Time to recurrent GIB was not statistically significant ($p = 0.75$). EV were found in 41 patients pre-procedurally (n = 8 BRTO, n = 33 TIPS) and 18 patients post-procedurally (n = 8 BRTO, n = 10 TIPS). The incidence of hepatic encephalopathy (HE) increased from 18% to 56% and ascites decreased from 64% to 56%, and this difference was not statistically significant ($p = 0.13$ and $p = 0.66$). Overall incidence of mortality was 46%, with median time to death of 131 days. 50% of patients in the BRTO group experienced death compared to 44% in TIPS group, and this was not statistically significant ($p = 0.67$). The median survival time was 2315 days versus 1931 days in the TIPS versus BRTO groups, and this was not statistically significant ($p = 0.71$).

Conclusion: TIPS and BRTO are performed for GV bleeding, and our study found that outcomes between the two groups were similar. The incidence of recurrent GIB was ~15%, occurred within one week of the procedure, and did not differ significantly between the groups. While a main concern with BRTO is worsening portal hypertension, our study did not show an increase in EV or ascites. Our data did not show a statistically significant difference in survival and overall mortality. Findings suggest that both treatments have comparable outcomes; therefore, the decision on procedure remains dependent on multiple factors including the patient, facility, and the expertise available.

WED-181-YI

Role of spleen stiffness measurement by vibration-controlled transient elastography at 100 Hz in guiding invasive hemodynamic reassessments after underdilated TIPS

Dario Saltini[1], Tomas Guasconi[1], Cristian Caporali[2], Marcello Bianchini[1], Federico Casari[2], Prampolini Francesco[2], Barbara Lei[3], Marco Scoppettuolo[3], Ascari Francesco[2], Andrea Salomè Velasco Mayorga[3], Antonio Piscopo[3], Antonio Colecchia[3], Filippo Schepis[1]. *[1]Severe Liver Disease Departmental Unit, AOU Policlinico di Modena, University of Modena and Reggio Emilia, Modena, Italy; [2]Division of Radiology, Interventional Radiology Unit, AOU Policlinico di Modena, Modena, Italy; [3]Gastroenterology Unit, Department of Specialistic Medicines, University of Modena and Reggio Emilia, Modena, Italy*
Email: dario.saltini@gmail.com

Background and aims: Underdilated Transjugular Intrahepatic Portosystemic Shunt (udTIPS) effectively manages portal hypertension complications while minimizing shunt-related adverse events. Spleen Stiffness (SS) measured by vibration-controlled transient elastography has shown high accuracy in detecting clinically significant portal hypertension when compared to the gold standard hepato-venous pressure gradient. The aim of this study is to evaluate SS as a non-invasive tool for identifying patients with Porto-Caval Pressure Gradient (PCPG) <12 mmHg after udTIPS.

Method: We prospectively enrolled patients with cirrhosis undergoing udTIPS at our referral center (January 2023–September 2024). Both invasive PCPG assessment and SS measurement with the spleen-dedicated 100 Hz probe by FibroScan® were performed at three time-points: before TIPS, immediately post-TIPS, and one-month after the procedure.

Results: The study included 51 patients (mean age 62 ± 12 years, 63% male) with preserved liver function [median Child-Pugh score 7 (IQR

3), MELD-Na 13 (IQR 6)]. TIPS indications were secondary prophylaxis for variceal bleeding (65%) and refractory ascites (35%). Median udTIPS dilation diameter was 6 (IQR 1) mm. PCPG progressively decreased from 22 (IQR 7) pre-TIPS to 15 (IQR 4) immediately post-TIPS and 11 (IQR 5) mmHg at one-month. Correspondingly, SS decreased from 74.5 (IQR 5) to 55.5 (IQR 21) and 41.6 (IQR 19) kPa. All SS measurements strongly correlated with PCPG values ($\rho = 0.72$, $p < 0.0001$). SS demonstrated an excellent diagnostic discrimination for PCPG <12 mmHg [AUC = 0.90 (95% CI 0.84–0.96)]. The cut-off of <35 kPa accurately ruled in patients with post-TIPS PCPG <12 mmHg (97.8% specificity, 88.2% PPV, 21.3 positive likelihood ratio).
Conclusion: SS measured with the spleen-dedicated 100 Hz probe strongly correlates with PCPG over time and reliably identifies patients achieving PCPG <12 mmHg after udTIPS. If validated in larger cohorts, SS may become a non-invasive tool for tailoring invasive hemodynamic reassessments in post-TIPS monitoring protocols.

WED-182
Predicting post-TIPS hepatic encephalopathy risk in patients with cirrhosis and refractory ascites: a proof-of-concept study using a 4D MRI perfusional model
Dario Saltini[1], Antonio Piscopo[2], Luca Nocetti[3], Stefano Colopi[4], Cristian Caporali[5], Marcello Bianchini[1], Tomas Guasconi[1], Federico Casari[5], Marco Scoppettuolo[2], Prampolini Francesco[5], Andrea Salomè Velasco Mayorga[2], Ascari Francesco[5], Antonio Colecchia[2], Filippo Schepis[1]. *[1]Severe Liver Disease Departmental Unit, AOU Policlinico di Modena, University of Modena and Reggio Emilia, Modena, Italy; [2]Gastroenterology Unit, Department of Specialistic Medicines, University of Modena and Reggio Emilia, Modena, Italy; [3]Medical Physics Unit, University Hospital Policlinico di Modena, Modena, Italy; [4]Division of Radiology, AOU Ospedale di Baggiovara, Modena, Italy; [5]Division of Radiology, Interventional Radiology Unit, AOU Policlinico di Modena, Modena, Italy*
Email: dario.saltini@gmail.com

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is a well-established treatment for refractory ascites (RA) in patients with cirrhosis. However, a major drawback is the development of post-procedural hepatic encephalopathy (HE), which results from the diversion of blood from the portal vein. According to the first-pass effect, this diversion reduces the liver's capacity to metabolize substances from the gut, leading to an accumulation of toxic compounds in the brain. Given that liver perfusion relies on arterial compensation (hepatic arterial buffer), it is plausible that effective compensation, which also depends on cardiac function, may reduce the risk of encephalopathy by detoxifying the blood during the second-pass metabolism. The aim of this study is to evaluate by Dynamic Contrast Enhanced-Magnetic Resonance Imaging (DCE-MRI) the changes in liver perfusion induced by TIPS in patients with RA and their relationship with the risk of HE.
Method: Twenty-nine consecutive patients underwent DCE-MRI, cardiac and hepatic hemodynamic evaluation before and after TIPS. MRI images were processed by a homemade software using the Dual Input Dual Compartment (DIDC) model, focusing on perfusion parameters.
Results: The DIDC model showed that total hepatic perfusion decreased by 24% after TIPS (248 ml/min/100 ml vs 189 ml/min/100 ml, p 0.095). As expected, a significant reduction in portal perfusion (decreased by 67%; 128.6 ml/min/100 ml vs 42.4 ml/min/100 ml, p 0.004) and an increase in hepatic arterial fraction post-TIPS (48% vs 77%, p 0.001) was observed. Post-TIPS residual total hepatic perfusion inversely correlated with one-year HE risk: patients with perfusion ≤130 ml/min/100 ml had a HE risk of 67.6% vs 36.4% for those >130 ml/min/100 ml (HR: 2.1, p 0.039).
Conclusion: Perfusion MRI is able to elucidate the impact of TIPS on liver perfusion, quantifying the extent of hepatic perfusion and its correlation with the development of post-TIPS HE.

WED-183
Cardiopulmonary hemodynamics and liver stiffness changes in predicting cardiac decompensation after TIPS: a prospective study
Dario Saltini[1], Tomas Guasconi[1], Cristian Caporali[2], Marcello Bianchini[1], Federico Casari[2], Prampolini Francesco[2], Barbara Lei[3], Marco Scoppettuolo[3], Ascari Francesco[2], Andrea Salomè Velasco Mayorga[3], Antonio Piscopo[3], Antonio Colecchia[3], Filippo Schepis[1]. *[1]Severe Liver Disease Departmental Unit, AOU Policlinico di Modena, University of Modena and Reggio Emilia, Modena, Italy; [2]Division of Radiology, Interventional Radiology Unit, AOU Policlinico di Modena, Modena, Italy; [3]Gastroenterology Unit, Department of Specialistic Medicines, University of Modena and Reggio Emilia, Modena, Italy*
Email: dario.saltini@gmail.com

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) can induce significant cardiovascular distress in patients with cirrhosis. Despite its therapeutic benefits, post-TIPS cardiac decompensation (CD) remains a serious concern, with early predictive factors still incompletely characterized. The aim of this study is to identify reliable predictive factors of post-TIPS symptomatic CD (AHA stage C-D).
Method: We prospectively enrolled consecutive patients with cirrhosis undergoing TIPS between May 2022 and May 2024 at our tertiary referral center. Baseline clinical and biochemical parameters were recorded. Right-heart catheterization was performed at three time points: pre-TIPS, immediately post-TIPS, and one-month post-procedure. Liver stiffness measurement (LSM) by vibration-controlled transient elastography was performed at corresponding intervals.
Results: Among 53 patients treated with TIPS for secondary prophylaxis of variceal bleeding (59%) or refractory ascites (41%), with a median Child-Pugh score of 7 (IQR 3) and a MELD-Na score of 12 (IQR 6), CD developed in 20% of patients, with a median onset of 3.3 months (IQR 5.8). At univariable Cox regression analysis, factors associated with CD were advanced age (71 vs. 59 years; HR 1.10, p = 0.010), presence of post-capillary pulmonary hypertension (pcPH) at one-month (82% vs. 26%; HR 6.33, p = 0.018), and the evidence of increased LSM at one-month follow-up (73% vs. 19%; HR 6.42, p = 0.006). The median LSM increased by +22% in patients who developed CD, in contrast to a – 23% decrease observed in those who did not (p = 0.012).
Conclusion: Presence of pcPH and increase of LSM at one-month follow-up are strongly associated with the development of post-TIPS CD. This is the first demonstration that gold-standard diagnosis of pcPH few weeks after TIPS can predict evolution towards CD. Further studies are required to investigate the relationship between LSM changes and cardiac adaptation following TIPS.

WED-184
Assessment of impact of ascitic fluid polymorphonuclear count on development of spontaneous bacterial peritonitis and survival in patients with liver cirrhosis and ascites
Sanjeev Jha[1], Ravikant Kumar[1], Saumyaleen Roy[1]. *[1]Indira Gandhi Institute of Medical Sciences, Patna, India*
Email: drsanjeevjha2010@gmail.com

Background and aims: Spontaneous bacterial peritonitis (SBP) is defined by ascitic fluid polymorphonuclear (A-PMN) cells count higher than 250 cells/microliter in the absence of an intraabdominal source of infection or any other explanation for an elevated A-PMN count. The clinical implications of SBP in terms of morbidity and mortality, have been well established however, knowledge about clinical implications of non SBP cirrhotic patients defined by A-PMN counts less than 250 cells/ microliter is limited. Aim of this study was to determine the development of SBP and survival in non–SBP cirrhotic patients with high A-PMN counts and compare it with low A-PMN count patients.

Method: In this prospective observational study, liver cirrhotic patients with ascites were stratified into 3 categories based on ascitic fluid PMN counts: 1) SBP group (PMN ≥ 250 cells/ microliter, number = 25 patients), 2) Intermediate ascitic fluid PMN group (I-PMN) (PMN counts in between 60 and 249 cells/ microliter, number = 50 patients), 3) Low ascitic fluid PMN group (L-PMN) (PMN counts less than 60 cells/ microliter, number = 81 patients). All patients were followed periodically up to 6 months for development of SBP and mortality.
Results: All the demographic profile of patients including Child Turcotte Pugh (CTP) and model for end stage liver disease sodium (MELD sodium) scores were similar among all the three groups. Median baseline PMN counts (25–75% IQR) was 819 cells/microliter (385–1490), 91 cells/microliter (76 – 110) and 24 cells/microliter (18–34) ($p < 0.001$) in SBP, I-PMN and L-PMN groups respectively. During follow up ascites resolved or reduced to become grade 1 ascites in 44%, 61% and 74% respectively in SBP, I-PMN and L-PMN group. Interval ascitic fluid examination was done in 59 patients (SBP group – 16 patients, I-PMN – 18 patients, L-PMN – 25 patients) during follow up period of 6 months. Respective median (IQR) interval PMN count in SBP, I-PMN and L-PMN group was 260 (142–397) cells/ microliter, 147 (88–256) cells/ microliter and 72 (47–88) cells/ microliter ($p < 0.001$). 11 patients (44%) in SBP and 5 patients (10.5%) in I-PMN group developed SBP whereas none of the patients in L-PMN group developed SBP ($p < 0.001$). 6 (24%), 4 (8.7%) and 5 (5.9%) patients died during follow up in SBP, I-PMN and L-PMN group respectively. Death in SBP group was significantly higher than L-PMN group, but difference of death rate between SBP and I-PMN group did not reach up-to statistical difference ($p = 0.08$). Death rate in I-PMN group was similar to L-PMN group.
Conclusion: Patients of I-PMN group are associated with significantly higher rate of development of SBP and rehospitalisation at month 6 as compared to L-PMN group. Both groups have similar mortality.

Email: drsuniltaneja@hotmail.com

Background and aims: Ascitic fluid examination is required to diagnose spontaneous bacterial peritonitis (SBP) in patients of decompensated cirrhosis. Being an invasive procedure, it is not only associated with a risk of bleeding in patients who often have coagulopathy, but may also introduce infection due to repeated need for paracentesis. Inflammation and transmigration of bacteria associated with SBP may lead to changes in peritoneum, omentum, bowel wall thickness and vascularity which if detected using ultrasonography, may help to diagnose SBP. We conducted this study to evaluate the utility of Ultrasonography (POCUS) as a non-invasive, point-of-care modality to diagnose SBP in patients of decompensated cirrhosis.
Method: Patients with decompensated cirrhosis with ascites were included. At baseline, all patients underwent ascitic fluid examination to diagnose SBP, as well as POCUS to assess bowel wall thickness, stratification, vascularity, peristalsis, peri-colonic and mesenteric lymph nodes and fat stranding. Amount of ascites, grading, internal echoes, septations, peritoneal and omental thickening and vascularity were also noted. POCUS findings were compared between SBP and no SBP groups.
Results: A total of 69 patients, aged 48 ± 13.8 years were included in the study of which 63 (91%) were males. The most common aetiology of cirrhosis was alcohol in 38 (55%) followed by metabolic dysfunction associated steatotic liver disease (MASLD) in 12 (18%) patients. SBP diagnosed on ascitic fluid examination was present in 34 (49.3%) patients. The SBP and no SBP patients were comparable in terms of age, gender distribution and aetiology of cirrhosis. The caecal bowel wall thickness ($p < 0.05$) and small bowel thickness ($p < 0.05$) were significantly higher in SBP group as compared to no SBP group. On logistic regression analysis increased caecal wall thickness (> 3 mm) had 3.1 times higher odds of having SBP in comparison to the thickness < 3 mm. The difference in bowel wall thickness at ascending, transverse, descending and sigmoid colon was statistically non-significant in SBP and no SBP group. There was no evidence of bowel wall five-layer stratification loss in any of the patients in both the groups. Increase in bowel wall vascularity was observed in SBP group, however it did not reach statistical significance as compared to the no SBP group ($p > 0.05$). There was a significant difference in internal echoes and septations in SBP versus no SBP group ($p < 0.05$). Peritoneal thickening, omental thickening and vascularity were comparable in both the groups.
Conclusion: This study demonstrates that POCUS can serve as a valuable diagnostic tool for the detection of SBP in patients of decompensated cirrhosis particularly in settings where rapid clinical decision-making is critical.

WED-186
TIPS for hydropic decompensation improves short-term outcome: a case-control study

Eduardo Cervantes-Alvarez[1], Wenyi Gu[1], Jonathan Byrtus[2], Carsten Meyer[3], Markus Treitl[4], Wulf Euringer[2], Alexander Gerbes[5], Tilman Sauerbruch[6], Joan Claria[7], Ferran Aguilar[7], Martin Roessle[2], Frank Erhard Uschner[1], Maximilian Joseph Brol[1], Markus Kimmann[1], Jörn Arne Meier[1], Kai-Henrik Peiffer[1], Martin Schulz[1], Vicente Arroyo[7], Michael Praktiknjo[1], Richard Moreau[7], Jonel Trebicka[1,7]. *[1]University Hospital Muenster. Email: eduardo.cervantesalvarez@ukmuenster.de

Background and aims: Portal hypertension characterizes decompensated cirrhosis and may trigger acute-on-chronic liver failure (ACLF) which carries the highest mortality. Transjugular intrahepatic portosystemic shunt (TIPS) is the most efficient therapy for portal hypertension-related complications including hydropic decompensation (HD) defined as refractory or recidivant ascites, hepatorenal syndrome and/or hydrothorax. However, TIPS for HD in ACLF is questioned.
Method: In this case-control study, patients from the prospective cohorts CANONIC (n = 1324) and German TIPS-Registry (n = 724) were screened for cases of HD and matched 1:1 by gender, age, MELD-score and presence and grade of ACLF. The total population was 118 ACLF patients of whom 59 received TIPS and 59 did not. Clinical parameters, ACLF status and mortality were assessed.
Results: There were no significant differences between the two groups regarding general characteristics. The main indication for TIPS was hepatorenal syndrome (61.0%). ACLF patients who did not receive TIPS had a higher 28-day cumulative mortality rate (22.0% vs. 5.1%, $p = 0.009$). At 28 days TIPS insertion in ACLF associated with a 78% mortality reduction (HR 0.22 [0.06–0.77]). It further led to improvement of ascites, hepatic encephalopathy, MELD and CLIF-C OF scores. Additionally, ACLF resolution occurred in 61% of TIPS ACLF patients.

The presence of coagulation and circulatory organ failures as well as higher bilirubin, INR, MELD and CLIF-C OF were associated with 28-day mortality. The survival benefit of TIPS was no longer observed after 90 days.
Conclusion: TIPS decreased the 28-day mortality of patients with hydropic decompensation and ACLF. Nevertheless, the role of TIPS is a bridging strategy to liver transplantation rather than a definitive therapy.

WED-187
Shunt cross-sectional area is a better predictor of overt hepatic encephalopathy than minimal hepatic encephalopathy
Elise Humerfelt[1], Elise Jonasson Nielsen[1], Bassam Mahdi[1], Birgitte Jacobsen[1], Lea Ladegaard Grønkjær[1], Mette Lauridsen[1].
[1]*University of Southern Denmark, Department for Regional Health Research, South Danish University Hospital Esbjerg, Esbjerg, Denmark*
Email: elise.jonasson.nielsen@rsyd.dk

Background and aims: Predicting overt hepatic encephalopathy (OHE) is critical. Psychometric tests for minimal hepatic encephalopathy (MHE) do not significantly increase post-test OHE probability. Portal hypertension causes spontaneous portosystemic shunts (SPSS), influencing OHE risk. This study investigates the link between SPSS total cross-sectional area (TCA), MHE, and OHE risk, hypothesizing that larger shunts prevalent in MHE patients may identify those at increased risk for OHE.
Method: We enrolled cirrhosis patients for contrast-enhanced abdominal CT and psychometric testing to identify MHE using a portosystemic hepatic encephalopathy score (PHES ≤−4 = MHE). Two hepatologists measured SPSS TCA, with discrepancies resolved by a senior radiologist. A large TCA was defined as >83 cm². We followed patients for 297 days (range 13–758), monitoring hospital admissions for OHE.
Results: The study included 102 patients (age 63, 68% male, 65% Child-Pugh A, 30% on lactulose and/or rifaximin). MHE patients (n = 34) had a mean shunt diameter twice that of non-MHE (261 cm² vs. 108 cm², p = 0.02), with higher ammonia (47 vs. 36, p = 0.02) and CRP levels (17 vs. 5, p = 0.002). Large-TCA patients (n = 27) showed higher ammonia (53 mg/L vs 35 mg/L, p = 0.003), with 40% having MHE. Sixteen patients (15%) developed OHE: 69% had MHE, 93% had large TCA, 55% had both, and 56% were on lactulose/rifaximin. OHE was more frequent in patients with both MHE and large TCA compared to MHE with smaller/no shunts (55% vs. 11%, p < 0.0001), and 73% (8/11) of MHE + large TCA patients developed OHE while on lactulose and/or rifaximin. Regression analysis showed Child-Pugh class, MELD, MHE status, and shunt TCA as risk factors (OR 2.6, 2.1, 5.7, 3.5; p < 0.001). MHE and SPSS TCA remained significant in multivariate analysis (OR 6.2, 1.1; p < 0.01). AUROC values for shunt diameter, CP class, and PHES were 0.71, 0.70, and 0.55, respectively.
Conclusion: MHE correlates with larger SPSS, significantly increasing OHE risk despite anti-HE treatment. Nearly all patients developing OHE had large SPSS TCA. Systematic SPSS assessment may be crucial for OHE prevention, potentially more so than MHE screening. Further research in larger cohorts is warranted.

WED-191
De novo decompensation and portal vein thrombosis are both linked to similar pathophysiologic alterations associated with advanced liver disease
Erica Villa[1], Rosina Maria Critelli[1], Davide Guido[2], Fabiola Milosa[1], Filippo Schepis[1], Marcello Bianchini[3], Dario Saltini[1], Grazia Serino[2], Antonio Piscopo[1], Gianluigi Giannelli[2]. [1]*University of Modena and Reggio Emilia, Modena, Italy;* [2]*IRCCS Saverio de Bellis, Castellana Grotte, Italy;* [3]*Azienda Ospedaliero-Universitaria, Modena, Italy*
Email: erica.villa@unimore.it

Background and aims: Portal vein thrombosis (PVT) and decompensation are major complications in chronic liver disease (CLD) but their temporal and pathophysiologic relationships remain poorly understood. We aimed to determine the sequence of these events and characterize their underlying pathophysiological patterns and to explore the overlap in the underlying mechanisms in a prospective cohort of patients with compensated advanced chronic liver disease (cACLD).
Method: From 2011 to 2021, we prospectively enrolled 545 patients with cACLD without HCC. At enrollment, these patients underwent upper gastrointestinal endoscopy, liver ultrasonography and elastography, hepatic venous pressure gradient measurement, and a series of laboratory tests, including 28 serum biomarkers related to inflammation, immunity, hypoxia, coagulation, and angiogenesis using the Ella ELISA method (Bio-Techne).
Results: At baseline, 45 patients (8.3%) had portal vein thrombosis (PVT) and 141 patients had experienced decompensation in the past despite being compensated at enrollment. Therefore, they were excluded from the prospective PVT and decompensation analysis. Over a median follow-up of 7 years, 58 patients (11.6%) developed PVT, corresponding to a yearly incidence of 1.16% and 131 (32.4%) developed decompensation, with a yearly incidence of 3.25%. Decompensation and PVT occurred concurrently in 7 of 131 cases (5.3%). In 12 cases (9.1%), PVT preceded decompensation, whereas in 16 cases (12.2%), PVT occurred afterward. In 98 cases (73.2%), decompensation was not associated with PVT. Median MELD was significantly higher in patients who developed decompensation with/without PVT than in 10 patients who developed PVT without decompensation. Baseline biomarkers associated with angiogenesis, inflammation, coagulation, and hypoxia were similarly and greatly altered in cases of newly developed decompensation, whether occurring alone or alongside PVT. However, inflammatory biomarkers were significantly more elevated in patients who experienced decompensation without PVT. In contrast, biomarkers in cases of isolated PVT primarily indicated endothelial alterations.
Conclusion: De novo decompensation and PVT both reflect similar pathophysiologic changes associated with advanced liver disease. They are linked to the extensive remodeling of liver tissue, representing two facets of the same underlying phenomenon. (supported by AIRC IG 2020-ID. 24858 project-P.I. Villa Erica).

Luther-University Halle-Wittenberg, Halle, Germany
Email: eva.schleicher@unimedizin-mainz.de

Background and aims: Real-world data on patients with the acute form of hepatorenal syndrome (HRS-AKI) are currently lacking, particularly taking into account the new diagnostic criteria (Acute Disease Quality Initiative (ADQI)-International Club of Ascites (ICA)). This multicenter, retrospective study aimed to evaluate treatment strategies and outcomes in patients with HRS-AKI.
Method: This study analyzed 490 patients with HRS-AKI treated with albumin/terlipressin at 12 tertiary care centers in Germany (2018–2022). The primary endpoint was a complete response to terlipressin treatment (ICA criteria). Baseline and follow-up data on HRS-AKI diagnosis, treatment initiation, duration, and response, as well as mortality, liver transplantation (LTX), and the need for renal replacement therapy were collected.
Results: The median age was 59 years and 62% of patients were male with a predominant etiology of alcohol-related liver disease (63%). Median duration of albumin therapy was 48 hours (IQR 0, 96) with a median albumin dose of 40 g/day (IQR 0, 100). Interestingly, terlipressin treatment was already initiated after 24 hours, instead of 48 hours in 194 (40%) patients. AKI-stages at time of treatment initiation with terlipressin were: AKI 1A 11%, AKI 1B 21%, AKI 2 31%, AKI 3 37% with a median serum creatinine (SCr) of 2.3 mg/dl, respectively. Overall, the mean initial dose of terlipressin was 2.6 mg/day, administered via continuous infusion in 85% of patients and was increased in 45% of patients to a maximum dose of 3.65 mg/day. 42% of patients showed complete response after a median of 11 days (IQR 9, 13). Partial and no response were achieved in 25% and 33% of patients, respectively. Interestingly, there was no difference in response rates when terlipressin was initiated after 24 hours compared to 48 hours (complete response: 41.8% vs. 42.5% ($p = 0.923$), partial response: 23% vs. 28% ($p = 0.280$), no response: 35% vs. 30% ($p = 0.263$)). Importantly, patients with AKI stage 3 had lower rates of treatment response (28.4% vs. 65.4% for AKI stage 1A, 47.6% for AKI stage 1B, and 46.7% for AKI stage 2, $p < 0.001$) but similar 12-month LTX-free survival ($p = 0.157$). Patients without treatment response to terlipressin, independent of AKI stage, had significantly lower 12-months LTX-free survival compared to patients with partial or complete response. In multivariable regression analysis, complete response to terlipressin therapy (HR 0.61 [0.48–0.77], $p < 0.001$), female sex (HR 0.74 [0.58–0.94], $p = 0.013$) and alcohol-related etiology (HR 0.70 [0.53–0.84], $p < 0.001$) were independently associated with better LTX-free survival.
Conclusion: Approximately two-thirds of patients with HRS-AKI responded to terlipressin in this real-world cohort, which is higher than in published clinical trials. However, the prognosis remains poor, especially in patients without any response to terlipressin at all.

WED-193

Resolution of portal hypertension by transjugular intrahepatic portosystemic shunt (TIPS) implantation reverses markers of gut-barrier dysfunction, systemic inflammation and anti-inflammatory monocyte alterations in patients with decompensated liver cirrhosis

Felix Piecha[1], Amirah Al-Jawazneh[2], Gustav Buescher[1], Aenne Harberts[1], Michael Spohn[1], Beatrice-Victoria Jahn[1], Johannes Köntopf[1], Anja Koop[1], Daniel Benten[1], Christoph Riedel[1], Peter Buggisch[3], Peter Huebener[1], Malik Alawi[1], Samuel Huber[1], Ansgar W. Email: f.piecha@uke.de

Background and aims: Decompensation of cirrhosis is accompanied by gut-barrier dysfunction, higher blood levels of *pathogen-associated molecular patterns* (PAMPs), *systemic inflammation* (SI), and functional immune cell alterations, leading to the syndrome of *cirrhosis associated immune dysfunction* (CAID). We hypothesize that *portal hypertension* (PH) is the functional driver of these immunological alterations, which can be reversed by its resolution via TIPS.
Method: 75 patients with ascitic decompensated cirrhosis undergoing TIPS-placement were included in our prospective cohort study, along with 15 patients with compensated cirrhosis as controls. The following markers were measured pre- and post-TIPS and once in controls: I-FABP (gut-barrier function), LBP (PAMP), sCD14 (monocyte activation), and 18 cytokines as a surrogate for SI. A phenotype profiling of monocytes was carried out by assessing the impact of patient serum on LPS-activated monocyte-derived macrophages from healthy donors using flow cytometry along with core monocyte/macrophage functions such as efferocytosis and cytokine secretion. RNA bulk sequencing analysis on CD14+ monocytes isolated from patients with compensated or decompensated cirrhosis pre- and post-TIPS was also carried out. Last, we analyzed the changes in all markers in correlation with the incidence of bacterial infections and transplant-free survival.
Results: Patients with decompensated cirrhosis pre-TIPS showed elevated levels iFABP, LPB and sCD14, as compared to controls. SI was present pre-TIPS, as indicated by elevated levels of e.g. IL-6 and C-reactive protein (CRP). Phenotypic profiling revealed a high expression of cell surface molecules normally associated to an anti-inflammatory monocyte/macrophage, resulting in an enrichment of a $MerTK^{high}CD163^{high}$ population. RNA bulk sequencing results further indicated the anti-inflammatory/suppressive signature in decompensated cirrhosis. Resolution of PH by TIPS lead to a decrease in all measured markers, finally reaching similar levels as in compensated controls. These changes were also observed at a transcriptional and phenotypic level in monocytes. Efferocytosis remained intact pre- and post-TIPS, whereas we observed an altered response to bacterial stimuli, as mirrored by an increased IL-6 secretion post-TIPS. The correlation with clinical data revealed that patients with further ascitic decompensation post-TIPS showed no improvement in SI or the monocyte phenotype, translating into a three-fold higher incidence of bacterial infections requiring hospitalization and a strongly decreased transplant-free survival.
Conclusion: Resolution of PH by TIPS is associated with a reversal of gut-barrier dysfunction, SI and monocyte alterations associated with a blunted immune response. Recompensation by TIPS translates into less bacterial infections and an improved transplant-free survival, most likely by altering the cytokine milieu and the macrophage polarization status.

WED-194-YI

Treatment response to terlipressin in patients with acute kidney injury - hepatorenal syndrome and preexisting chronic kidney disease – the german liver cirrhosis/CKD-Terli study group

Frank Erhard Uschner[1], Eva Maria Schleicher[2], Moritz Passenberg[3], Julian Pohl[4], Michael Praktiknjo[1], Anna Teresa Volk[5], Henrik Karbannek[6], Johannes Chang[7], Karsten Große[8], Charlotte Rohrer[9], Christian Labenz[2], Benjamin Maasoumy[10], Paul Jamme[11], Julian Cardinal von Widdern[12], Alexander Queck[5], Jonel Trebicka[1], Cornelius Engelmann[4], Jassin Rashidi-Alavijeh[3], Dominik Bettinger, Cristina Ripoll[6], German liver cirrhosis/Chronic Kidney Disease - Terli study group[13].

Email: frankerhard.uschner@ukmuenster.de

Background and aims: The previous definition of hepatorenal syndrome - acute kidney injury (HRS-AKI) excluded patients with signs of structural kidney injury. The recent update in the Acute Disease Quality Initiative (ADQI) - International Club of Ascites (ICA) consensus guidelines acknowledged that HRS-AKI might also occur in the presence of chronic kidney disease (CKD). However, no data are currently available on efficacy of treatment with terlipressin and its impact on outcome in patients with HRS-AKI and CKD. This multicenter, retrospective, observational study aimed to investigate treatment response of albumin and terlipressin in patients with HRS-AKI and CKD compared to patients without CKD.
Method: A total of 490 patients admitted between 2018 and 2022 with AKI-HRS who received albumin/terlipressin at 12 tertiary centers in Germany were retrospectively analyzed. Patients were stratified according to: (i) no CKD; (ii) suspected CKD: baseline glomerular filtration rate (GFR) < 60 ml/min *and* no evidence of structural kidney damage; (iii) proven CKD: GFR < 60 ml/min *and* history of primary nephropathy *or* evidence of structural kidney damage *or* known cardiovascular risk factors. The primary endpoint was a complete response to terlipressin treatment according to ICA recommendations (decrease of serum creatinine to a value within 0.3 mg/dl of baseline). Secondary endpoints included need for renal replacement therapy (RRT) and 12-month transplantation (LTx) - free survival.
Results: In total, 339 patients (69.2%) had no CKD, 35 patients (7.1%) suspected CKD and 116 patients (23.7%) proven CKD at baseline. 206 patients (42%) reached the primary endpoint of complete treatment response to terlipressin; 14 (40%) with suspected CKD, 43 (37.1%) with proven CKD and 149 patients without CKD at baseline (44%) (p = 0.435). The median time to partial or complete treatment response did not differ between patients without CKD or with proven CKD at baseline (6.0 [5.04–6.96] vs. 7.0 days [5.11–8.89], p = 0.775). Furthermore, the need for RRT during follow-up was similar between patients with or without CKD at baseline (31.4% vs. 24.1% vs. 25.1%, p = 0.408). The 12-month LTx-free survival was 35.2% (LTx in 17.5% and death in 47.3% of patients), with a median LTx-free survival time of 3 month (1.7–4.3) in the overall cohort. When adjusting for age, etiology, treatment response and liver function parameters (INR, bilirubin, albumin) with LTx as competing event, preexisting suspected and proven CKD did not impact survival in patients with AKI-HRS (sHR 1.40 [0.90–2.15], p = 0.132).
Conclusion: Suspicion or even presence of CKD does not seem to influence treatment response to terlipressin in patients with HRS-AKI and patients show comparable outcome irrespective of CKD. This study supports initiation of vasopressor treatment in patients with AKI-HRS independent of pre-existing structural kidney injury.

WED-195-YI
Frequency and impact of early and sustained hepatic recompensation after TIPS

Sophia Geißelbrecht[1], Martin Kabelitz[1], Jonna Friederike Zimmermann[1], Anja Tiede[1,2], Laura Buttler[1], Hannah Rieland[1], Jim Benjamin Mauz[1], Matti Peperhove[3], Christine Falk[4,5], Heiner Wedemeyer[1], Lisa Sandmann[1,2,6], Benjamin Maasoumy[1,2,6]. *[1]Department for Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover, Germany; [2]German Center for Infection Research (DZIF), Hannover/Braunschweig, Germany; [3]Department of Diagnostic and Interventional Radiology, Hannover Medical School, Hannover, Germany; [4]Department of Transplant Immunology, Hannover Medical School, Hannover, Germany; [5]German Center for Infection Research (DZIF), Hannover, Germany; [6]Excellence Cluster RESIST, Excellence Initiative Hannover Medical School, Hannover, Germany*
Email: Geisselbrecht.Sophia@mh-hannover.de

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is a highly effective treatment for patients with decompensated liver cirrhosis and may lead to recompensation in numerous cases. This study aimed to investigate determinants and clinical relevance of hepatic recompensation after TIPS insertion in a large prospective cohort.
Method: All consecutive patients with liver cirrhosis undergoing TIPS insertion between 07/2019 and 04/2024 at Hannover Medical School were prospectively enrolled. Prescheduled follow-ups were conducted at 1, 3, 6, 12, and 24 months post-TIPS. First and further decompensation were defined according to the Baveno VII criteria considering TIPS insertion as new baseline. For hepatic recompensation modified criteria were applied: Absence of any hepatic decompensating event until month 3 irrespective of the use of HE prophylaxis or diuretic treatment was considered as modified early recompensation (mER). Absence of hepatic decompensation until month 12 post-TIPS was defined as modified sustained recompensation (mSR). Competing risk analyses evaluated survival (with liver transplantation (LTx) as a competing event) and hepatic decompensation (with death and LTx as competing events). Landmark analyses at 3 and 12 months mitigated immortal time bias. All analyses were adjusted for MELD. Multivariable binary logistic regression analysis including age, MELD, CRP and IL-6 were performed to identify baseline predictors of mER and mSR.
Results: A total of 220 patients (median MELD: 12, 53% alcohol-related cirrhosis, 75% underwent TIPS for refractory ascites) were analysed. Overall, 38% and 23% achieved mER and mSR, respectively, while 1% of patients fulfilled the original Baveno VII criteria for hepatic recompensation. Only baseline IL-6 levels were significantly linked to mER (asHR: 0.93; p = 0.04) and mSR (asHR: 0.89; p = 0.03) in the multivariable analysis. Overall, mER (asHR: 0.41; p = 0.03) was linked to lower mortality. Of note, negative prognostic impact of early decompensation events was independent of fulfilling the first or further decompensation criteria. In contrast, mER was not associated with the risk of any hepatic decompensation (asHR: 0.83; p = 0.51), while there was a numerically lower risk for developing a further hepatic decompensating event thereafter (asHR: 0.55; p = 0.09). Surprisingly, achieving mSR did not lead to an improved survival (asHR: 1.13; p = 0.84). However, those with mSR after TIPS had a significantly lower risk of any decompensation (asHR: 0.13; p = 0.01) during longer follow-up and not a single mSR patient progressed to further hepatic decompensation (asHR: < 0.001; p < 0.001).
Conclusion: A significant number of patients achieve hepatic recompensation after TIPS. While mER indicates an improved survival, sustained recompensation month 12 after TIPS may identify patients with permanent symptom control.

WED-196-YI
Validation of the blood-based Vienna 3P/5P portal hypertension risk models in patients with compensated advanced chronic liver disease

Research Group MOTION, Medical University of Vienna, Vienna, Austria; [4]Christian-Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria; [5]CeMM Research Center for Molecular Medicine of the Austrian Academy of Sciences, Vienna, Austria; [6]Department of Laboratory Medicine, Medical University of Vienna, Vienna, Austria; [7]Ukrainian Institute for Systems Biology and Medicine, Kyiv, Ukraine
Email: georg.kramer@meduniwien.ac.at

Background and aims: Clinically significant portal hypertension (CSPH), defined as a hepatic venous pressure gradient (HVPG) ≥10 mmHg, identifies patients at risk for hepatic decompensation with risks escalating at HVPG ≥16 mmHg. While invasive HVPG measurement remains the gold standard for CSPH diagnosis, non-invasive alternatives are critically needed. We assessed the Vienna 3P and 5P models, machine learning tools based on three or five routine blood parameters, for non-invasive portal hypertension (PH) severity estimation as well as risk prediction and stratification capabilities in patients with compensated advanced chronic liver disease (cACLD). Their performance was benchmarked against HVPG, liver stiffness (LSM), and the ANTICIPATE ± NASH model, which incorporates LSM, platelet count ± body mass index (BMI).
Method: Patients with cACLD undergoing HVPG measurement, LSM and a blood withdrawal within the prospective VICIS study (NCT03267615) were included. Detection of CSPH and severe PH (i.e. HVPG ≥ 16 mmHg) were evaluated using area under the receiver operating characteristic curves (AUROC). Multivariate risk regression analysis was performed to predict hepatic decompensation (variceal bleeding, ascites, or hepatic encephalopathy), accounting for hepatocellular carcinoma (HCC) and non-liver-related death as competing risks. Additionally, the models' risk stratification capabilities were assessed.
Results: Among 266 patients with cACLD, the leading etiologies were viral hepatitis (27.8%) and alcohol-related liver disease (23.7%). The median HVPG was 11 mmHg (IQR: 8–16), with a prevalence of CSPH and severe PH of 62.8% and 25.6%, respectively. During a median follow-up of 23.9 months (IQR: 14.4–32.6), hepatic decompensation occurred in 48 patients (18%). The 3P and 5P models correlated with HVPG (p < 0.001), achieving AUROCs of 0.704 (5P) and 0.672 (3P) for CSPH, and 0.800 (5P) and 0.704 (3P) for severe PH prediction. The 5P model showed comparable time-dependent AUROCs to HVPG for predicting first hepatic decompensation at 6 months and 1 year (0.753–0.822), outperforming ANTICIPATE ± NASH (0.689–0.691) and LSM (0.621–0.636). In multivariate analysis, the 5P (adjusted subdistribution hazard ratio [aSHR]: 1.261, p = 0.002) and 3P (aSHR: 1.098, p = 0.032) models were independent risk factors for decompensation. Risk stratification by 3P/5P (<60%, 60–79%, ≥80%) effectively identified low- and high-risk patients (Gray's test p < 0.001), with the 5P model performing comparably to HVPG (<10, 10–15, ≥16 mmHg).
Conclusion: The blood-based 3P/5P models demonstrate strong prognostic value for predicting hepatic decompensation and stratifying cACLD patients in high and low risk groups. The 5P model performed comparably to invasive HVPG measurement, supporting its applicability in selecting "at-risk" cACLD patients for preventive therapies.

WED-197
Prognostic performance of the enhanced liver fibrosis (ELF) test in patients with advanced chronic liver disease in tertiary care

Georg Kramer[1,2,3], Benedikt Simbrunner[1,2,3,4], Benedikt Hofer[1,2,3,4], Nina Dominik[1,2,3], Lorenz Balcar[1,2,3], Lukas Hartl[1,2,3], Mathias Jachs[1,2,3], Michael Schwarz[1,2], Georg Semmler[1,2,3], Christian Sebesta[1,2,3], Paul Thöne[1,2,3], Philipp Schwabl[1,2,3,4], Michael Trauner[1,3], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3].
[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [3]Clinical Research Group MOTION, Medical University of Vienna, Vienna, Austria; [4]Christian-Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria
Email: georg.kramer@meduniwien.ac.at

Background and aims: The enhanced liver fibrosis test (ELF) is a blood-based biomarker developed for liver fibrosis staging but also reflects the dynamic process of matrix remodeling. We assessed the prognostic performance of ELF in a diverse cohort of patients with compensated (cACLD) and decompensated (dACLD) advanced chronic liver disease.
Method: Patients of the prospective VICIS (NCT03267615) study with measurements of hepatic venous pressure gradient (HVPG), liver stiffness (LSM) and ELF were included and grouped as cACLD and dACLD (ascites, overt hepatic encephalopathy, variceal bleeding). For cACLD patients, the event of interest was first decompensation (with HCC and non-liver-related death as competing events), for dACLD patients the liver-related events (LREs) of interest were either further decompensation, acute-on-chronic liver failure (ACLF) or liver-related death (with HCC, liver transplantation and non-liver-related death as competing risks). Multivariate competing risk regression models were adjusted for age, sex, HVPG and body-mass-index.
Results: Among 573 patients (n = 230 cACLD, n = 343 dACLD) alcohol-related liver disease (ALD) was the predominant etiology (44.7%). Median ELF (12.00 vs. 10.79; p < 0.001) and HVPG (19 vs. 11 mmHg; p < 0.001) were significantly higher in dACLD compared to cACLD. During a median follow-up of 18.7 months, first decompensation occurred in 51 (22.2%) cACLD and LRE in 168 dACLD patients (49.0%). In cACLD, ELF demonstrated time-dependent area under the receiver operating characteristic curves (td-AUROCs) of 0.765 and 0.754 for predicting first decompensation at 1 and 2 years, respectively, and was independently associated with first decompensation (adjusted subdistribution hazard ratio [aSHR]: 1.351; p = 0.002). Risk stratification was effective with balanced allocation in 3 distinct cACLD risk groups and robust identification of high-risk patients (high-risk ≥11.1 vs. low-risk <10.1, Gray's test p < 0.001; medium-risk: 10.1–11.09 vs ≥11.1, p = 0.006). In dACLD, ELF showed td-AUROCs of 0.585 and 0.649 for LREs at 1 and 2 years, comparable to HVPG (0.593 and 0.630, p = 0.886 and p = 0.712). ELF was an independent risk factor for LRE (aSHR: 1.150, p = 0.008) and effectively identified patients at high risk for LREs (high-risk: ≥14.0 vs. low-risk: <12.5, p < 0.001; medium-risk: 12.5–13.9 vs. ≥14.0, p = 0.004). However, risk group allocation was less balanced than in cACLD.
Conclusion: The ELF score demonstrates robust prognostic value in tertiary care cohorts, particularly in cACLD, where it effectively predicts first decompensation and stratifies risk. In dACLD, moderate predictive performance and less effective risk stratification reduce its clinical utility. Nevertheless, ELF remains an independent risk factor for LRE in dACLD and identifies high-risk patients who should be prioritized for intensified treatments.

WED-198
Incidence and clinical significance of recompensation after HCV-cure

Background and aims: Baveno VII has proposed criteria for cirrhosis recompensation. However, their prognostic significance in decompensated patients cured from hepatitis C virus (HCV) remains incompletely studied. Thus, we investigated the incidence and impact of recompensation after HCV-cure as well as its predictors.
Method: 2570 patients with advanced chronic liver disease (ACLD) from 10 European centers, including 2209 with compensated advanced chronic liver disease (cACLD) and 361 patients with decompensated cirrhosis, who achieved sustained virologic response to direct-acting antivirals (DAAs) were retrospectively included. The association between achieving recompensation according to Baveno VII and clinical outcomes (hepatocellular carcinoma [HCC], portal vein thrombosis [PVT], and [liver-related] death [LRD]) was investigated.
Results: 158 (43.8%) had a history of variceal bleeding and 330 (91.4%)/147 (40.7%) patients had previous or current ascites/hepatic encephalopathy; median MELD was 11 [IQR: 9–14] before DAA-treatment. During a median follow-up of 8.4 years, 132 patients (36.6%) achieved recompensation. Lower albumin levels and diabetes were negatively associated with achieving recompensation. The incidence-rates (IR) of LRD (4.2 vs. 8.8/100 patient-years) and PVT (2.7 vs. 5.4/100 patient-years) were substantially lower after recompensation vs. in the non-recompensated state, while HCC incidence remained high (3.9 vs. 5.5/100 patient-years). Compared to decompensated cirrhosis, achieving recompensation was independently associated with decreased risks of subsequent LRD (adjusted hazard ratio [aHR]: 0.38 [95%CI: 0.23–0.66]) and of PVT (aHR: 0.42 [95%CI: 0.22–0.76]), but both risks remained higher than in cACLD. Importantly, HCC incidence was not reduced as compared to decompensated cirrhosis.
Conclusion: Recompensation after HCV-cure is associated with substantially decreased risks of (liver-related) mortality and PVT, but not of HCC.

Email: georg.semmler@meduniwien.ac.at

Background and aims: Despite the recent introduction of further decompensation and recompensation in advanced chronic liver disease (ACLD), most research still relies on a unidirectional time to first event framework, which neglects the medical reality of a multidirectional patient journey. Notably, previous multistate analyses were based on historical natural history data, which may no longer be generalizable in the present era of effective etiological therapies. We aimed to investigate the multistate trajectories of ACLD in a contemporary prospectively characterized cohort.
Method: ACLD patients with portal hypertension (n = 464; hepatic venous pressure gradient [HVPG] >5 mmHg) were prospectively recruited from 2017 to 2021 (VICIS; NCT03267615). Clinical disease stages at baseline and during follow-up were defined as compensated (c)ACLD, first decompensation, further decompensation/ACLF (combined), liver-related death (LRD), and recompensation. A multistate model using Nelson-Aalen estimator of cumulative hazards was employed to study stage transitions. Recompensation and non-liver-related death were treated as absorbing states (i.e., patient censoring).
Results: The predominant etiologies were ALD/MetALD in 217 (46.8%), followed by viral hepatitis in 81 (17.5%), and MASLD in 40 (8.6%). At baseline, 179 (38.6%) were classified as cACLD, 168 (36.2%) as first decompensation, while 117 (25.2%) had further decompensation/ACLF. Median HVPG was 17 (12–21) mmHg. During a median follow-up of 28.8 months, 35 (19.6%) of cACLD patients developed first decompensation, 134 (28.9%) of all patients developed further decompensation/ACLF, and 83 (17.9%) experienced a LRD, while 75 (16.2%) achieved recompensation. For cACLD patients, the probability for remaining compensated at 24 months was 81.3% (95%CI: 75.0–87.6), for first decompensation 12.0% (7.4–16.7), further decompensation/ ACLF 2.8% (1.3–4.2), LRD 2.2% (0.3–4.1), and recompensation 1.7% (0.7–2.7). Among patients with first decompensation, 63.7% (56.2–71.3) remained decompensated at 12 months, 15.1% (10.4–19.8) transitioned to further decompensation/ ACLF, 6.3% (3.7–8.9) LRD, and 14.9% (10.0–19.8) achieved recompensation. In those with further decompensation/ACLF, 45.7% (37.4–54.1%) remained decompensated at 12 months, 32.2% (24.3–40.1%) had LRD, and 22.1% (15.1–29.0%) achieved recompensation.
Conclusion: In the era of etiological therapies, achieving recompensation is more likely than LRD after first hepatic decompensation. Further decompensation/ ACLF substantially worsens the prognosis, with a nearly five-fold increase in LRD risk, however, recompensation may still be achieved (similarly likely as after first decompensation), emphasizing the universal effectiveness of etiological therapies.

Non-invasive prediction of clinically significant portal hypertension in patients with compensated advanced chronic liver disease of different aetiologies

Giulia Francesca Manfredi[1,2], Davide Di Benedetto[1], Carla De Benedittis[2], Michela Burlone[2], Mattia Lotto[1,2], Angelo Strada[1,2], Rosalba Minisini[1], Mario Pirisi[1,2], Cristina Rigamonti[1,2]. *[1]Department of Translational Medicine, Università del Piemonte Orientale, Novara, Italy; [2]Division of Internal*

Medicine, AOU Maggiore della Carità, Novara, Italy
Email: gf.manfredi01@gmail.com

Background and aims: Patients with compensated advanced chronic liver disease (cACLD), defined according to the Baveno VI criteria based on a liver stiffness measurement (LSM) ≥10 kPa, are at risk of developing clinically significant portal hypertension (CSPH). Identifying cACLD patients with CSPH is essential for implementing personalized therapeutic strategies. We aimed to non-invasively stratify the CSPH risk in patients with cACLD of different etiologies and to predict the probability of liver decompensation (LD) using the Baveno VII criteria, the Baveno VII criteria implemented with spleen stiffness measurement (SSM), and the NICER model (PMID 39326431).
Method: Monocentric retrospective observational study including 191 consecutive cACLD patients, who underwent vibration-controlled transient elastography (VCTE) examination for LSM and SSM between December 2022 and April 2024. The Baveno VII criteria were applied, along with the Baveno VII-SSM criteria using a single cut-off (SSM ≤40 kPa and SSM >40 kPa) and dual cut-offs (SSM ≤25 kPa and SSM ≥55 kPa). Additionally, the NICER model was computed as published: Logit = –6.40032480 + ln(SSM) × 1.96952565 + ln(LSM) × 1.83093447 - BMI × 0.12882190 – platelets (PLT) × 0.01850461. Esophagogastroduodenoscopy (EGD) was performed per Baveno VI recommendations and proposed to all patients with SSM >40 kPa.
Results: Among the 191 patients (57.6% male, median age 65.87 years, median BMI 25.8 kg/m²), the median LSM was 19.1 kPa (IQR 13.4–32.2), SSM 42 kPa (IQR 28.1–52.8), PLT 139 × 10³/mmc (IQR 100–181). Applying the Baveno VII criteria: 36 patients (18.8%) were at low risk for CSPH (rule-out CSPH), 66 (34.5%) at high risk (rule-in CSPH), 89 (46.6%) in the grey zone. Using the Baveno VII-SSM criteria with a single cut-off: 71 patients (37.2%) were at low risk, 94 (49.2%) at high risk, 26 (13.6%) in the grey zone. Using the Baveno VII-SSM with dual cut-offs: 71 patients (37.2%) were classified as low risk, 66 (34.5%) as high risk, and 54 (28.3%) in the grey zone. Based on the NICER model, the median CSPH risk in the 191 patients was 65%. CSPH risk distribution was: <25% 80 patients (41.9%), >75% 92 patients (48.2%). Among the 152 patients who underwent EGD, esophageal varices were found in 11.5% of patients with a CSPH risk <25% and in 82% of patients with a CSPH risk >75% ($p < 0.0001$). During follow-up (median 8.4 months), 4 patients developed LD. In patients with CSPH risk >75% calculated using NICER, the probability of LD at 12 and 15 months was 2.5% and 7.6%, respectively, compared to 1.1% at both time points in patients with a CSPH risk ≤75% ($p = 0.27$).
Conclusion: The addition of SSM to the Baveno VII criteria reduces the diagnostic grey zone, enabling improved risk stratification for CSPH in cACLD patients. CSPH risk estimation using the NICER model provides additional non-invasive support for predicting CSPH.

Email: gff.mauro@gmail.com

Background and aims: Clinically significant portal hypertension (CSPH) is the main driver of complications in patients with advanced chronic liver disease (ACLD). While hepatic venous pressure gradient (HVPG) measurement remains the diagnostic gold standard, its invasiveness and limited availability hinder widespread use. Non-invasive tests such as liver (LSM) and spleen (SSM) stiffness measurement, and platelet count (PLT) are capable to reflect CSPH risk and are recommended by Baveno guidelines. However, they are limited by significant diagnostic gray zones and suboptimal performance in diverse etiologies and elastography modalities. This study aimed to develop a machine learning model (MLM) incorporating elastography and clinical parameters to predict CSPH across multiple elastography modalities.
Method: We analyzed 1,218 patients with ACLD across 17 Centers, who underwent HVPG and elastography with vibration-controlled transient elastography (n = 668), 2D-shear-wave elastography (n = 274) or point-shear-wave elastography (n = 276). Variables included LSM, SSM, PLT, age, gender, etiology, and Child-Pugh (CP) score (≤6 vs. >6). Elastography values were harmonized using Z-scores. We evaluated several MLMs with a 1,068–150 train-test split, targeting proportional representation across elastography modalities and balanced CSPH ratio. We evaluated MLM cut-offs for 100% Negative Predictive Values (NPV) in ruling-out CSPH and 100% Positive Predictive Values (PPV) in ruling-in CSPH (training set) and evaluated their performance in the test set. Clinical performance was evaluated against Baveno VII criteria, including standard (without SSM), dual (SSM<21 kPa/SSM>50 kPa), and single (SSM≤40 kPa/SSM>40 kPa) cut-off criteria.

Results: Random Forest (RF) outperformed other MLMs (AUC = 0.93, Brier Score = 0.11). Regarding CP score, only 2.6% of patients had CP>7 in test set. MLM output ranges 0.0–1.0. In test set, cut-offs of ≤0.45 for ruling-out and ≥0.60 for ruling-in CSPH achieved sensitivity of 0.97 (95%CI:0.95–1.00), NPV of 0.97(95%CI:0.93–1.00), specificity of 0.91 (95%CI:0.80–0.96), and PPV of 0.93(95%CI:0.87–0.97). The MLM significantly reduced the diagnostic gray zone to 10.6% versus 44.0%, 39.3%, and 23.3% for standard Baveno VII, dual cut-off, and single cut-off criteria (all $p < 0.001$). This improvement was consistent across all elastography techniques and etiologies. In patients with alcohol-related disease, the model reduced the gray zone to 6.9% compared to 48.2% with standard Baveno VII criteria ($p < 0.001$). Similarly, in metabolic dysfunction-associated steatotic liver disease the gray zone reached 2.1% from 51.3% ($p < 0.001$).
Conclusion: Our pan-elastography MLM based on LSM, SSM, PLT significantly improves CSPH prediction while reducing diagnostic uncertainty across liver disease etiologies and elastography techniques. This approach offers reliable tool for CSPH diagnosis and non-invasive guidance for non-selective beta-blocker treatment.

WED-206-YI
Influence of low-dose acetylsalicylic acid on renal function in patients with liver cirrhosis and ascites

Henrik Karbannek[1], Marina Reljic[1], Andreas Stallmach[1], Alexander Zipprich, Cristina Ripoll. [1]*Department of Internal Medicine IV, Jena University Hospital, Friedrich-Schiller University Jena, Jena, Germany*
Email: henrik.karbannek@uni-jena.de

Background and aims: Non-steroidal anti-inflammatory drugs are not recommended in patients with cirrhosis and ascites due to acute kidney injury (AKI) risk. Nowadays, with the increasing prevalence of metabolic dysfunction-associated steatotic liver disease, more patients require low-dose acetylsalicylic acid (ASA) for cardiovascular prophylaxis. This study aims to evaluate the impact of low-dose ASA on transplant (LT)-free survival, renal function, and further decompensation in patients with cirrhosis and ascites.
Method: This is a retrospective unicentric analysis of consecutive patients with cirrhosis and ascites from 01/2019 to 12/2022. Baseline data included medical history, liver disease severity, complications, cardiovascular comorbidities, co-medications, and laboratory values. Follow-up was extended until 12/2023. Endpoints were LT-free survival, changes in serum creatinine (sCr), incidence of AKI, and further decompensation. Variables were compared with T-student and Mann-Whitney U test. Propensity score matching (PSM), Cox regression analyses, and competing risk analyses were performed.
Results: 303 patients [194 (64%) men, median age 59 (53–66) years], of whom 53 (17.5%) were on low-dose ASA, were included and followed for a median of 350 (150–406) days. Thirteen (31.0%) ASA patients and 59 (29.1%) controls died or underwent LT. There was no difference in LT-free survival (HR 1.13, 95% CI 0.62–2.07) or death (HR 0.77, 95% CI 0.33–1.80) (with LT as competing risk) in patients who took ASA. Seven (16.7%) ASA patients developed AKI, of which three (42.9%) were hepatorenal syndrome (HRS-AKI), compared to 23 (11.4%) AKI cases [7 (30.4%) HRS-AKI] in controls, with no significant differences in their incidence (AKI: HR 1.47, 95% CI 0.63–3.42; HRS-AKI: HR 1.96, 95% CI 0.51–7.57). Although ASA patients had significantly higher sCr levels at baseline (100 µmol/l vs. 77 µmol/l, $p = 0.006$), they decreased slightly in ASA patients (−4 µmol/l) and worsened in controls (+10 µmol/l) during follow-up ($p = 0.052$). Further decompensation occurred in 14 (33.3%) ASA patients and 70 (34.5) controls, with no significant effect of ASA (HR 0.90, 95% CI 0.51–1.60). This observation was maintained in the competing risk analysis (death and LT as competing risks), (HR 0.85, 95% CI 0.36–2.02). After PSM (1:1), no differences were observed in LT-free survival (HR 1.18, 95% CI 0.52–2.64), the incidence of AKI/AKI-HRS (AKI: HR 1.83, 95% CI 0.53–6.29; AKI-HRS: HR 2.79, 95% CI 0.29–26.84), and further decompensation (HR 0.84, 95% CI 0.41–1.72).
Conclusion: Intake of low-dose ASA does not affect LT-free survival, renal function and the incidence of AKI or further decompensation in patients with cirrhosis and ascites.

WED-207-YI
Effectiveness of carvedilol plus variceal band ligation compared to carvedilol alone in primary prophylaxis of variceal bleed in cirrhosis with high-risk oesophageal varices

Jata Shankar Kumar[1], Premashis Kar[2], Pawan Sharma[2]. [1]*Max superspeciality hospital, Vaishali, Ghaziabad, India;* [2]*Max superspeciality hospital, Vaishali (India), Vaishali(Ghaziabad), India*
Email: jatashankar.dr@gmail.com

Background and aims: Portal hypertension is a major complication of liver cirrhosis, frequently leading to the development of oesophageal varices. Variceal bleeding accounts for significant morbidity and mortality among cirrhotic patients. Non-selective beta-blockers (NSBBs) and endoscopic variceal ligation (EVL) are commonly employed as prophylactic measures to prevent initial variceal bleeding. Aim of this study was to assess the effectiveness of combination therapy of carvedilol and EVL compared to carvedilol alone for primary prophylaxis of variceal bleed in cirrhosis with high-risk oesophageal varices.
Method: A randomized controlled trial was conducted in which 80 cirrhotic patients with high-risk oesophageal varices (large varices or varices with positive red color sign) without a prior history of variceal bleeding were prospectively enrolled. Participants were randomized into two groups: 40 received combination therapy of carvedilol plus EVL, and 40 received carvedilol alone. Patients were followed for one year, with regular clinical assessments, biochemical evaluations, and endoscopic surveillance. 8 Patients lost during follow up (4 in each group). Total 72 patients were analysed at the end of 1 year. The primary outcome was the incidence of first variceal bleed. Secondary outcomes included overall mortality, bleeding-related mortality and adverse events related to interventions.
Results: The mean age was slightly higher in the EVL plus carvedilol group (59.7 ± 12.9 years) compared to the carvedilol alone group (56.1 ± 11.9 years), with a p value = 0.222, indicating no significant difference. Gender distribution showed more males in both groups, with 63.9% in the EVL plus carvedilol group and 77.8% in the carvedilol alone group. Intention-to-treat analysis showed that the combination group had a significantly lower incidence of first variceal bleed compared to those in the carvedilol-alone group after 1 year (22.2% vs. 50%, $p = 0.014$). Overall mortality after 1 year was lower in combination group although without a statistically significant difference (11.1% vs. 19.4%, $p = 0.325$). Mortality due to bleeding after 1 year was also lower in combination group but without a statistically significant difference (5.6% vs. 13.9%, $p = 0.232$). Variceal bleeding was the most common cause of death in both group (5.6% vs. 13.9%, $p = 0.232$). Both groups had similar adverse event profiles. No significant differences were found in baseline demographic or clinical parameters, including age, ensuring comparability between the groups.
Conclusion: The combination of EVL and carvedilol is superior to carvedilol alone for primary prophylaxis of variceal bleeding in cirrhosis patients with high-risk oesophageal varices and there is no significant difference in adverse events between two groups.

WED-208
The GEMA score predicts mortality in patients undergoing TIPSS for ascites

Jemima Finkel[1], Silke François[2], Ioanna Papagiouvanni[2], Amine Benmassaoud[3], Louise China[2], Dominic Yu[2], David Patch[2], Emmanuel Tsochatzis[1]. [1]*Institute for Liver and Digestive Health, UCL, London, United Kingdom;* [2]*Royal Free Hospital, London, United Kingdom;* [3]*McGill University, Montreal, Canada*
Email: jfinkel@doctors.org.uk

Background and aims: The GEMA and GEMA-Na scores were recently derived in patients awaiting liver transplantation and performed better than MELD-Na and MELD 3.0 for predicting waiting list mortality [1]. We evaluated the predictive ability of GEMA and GEMA-Na in a cohort of patients who underwent transjugular intrahepatic portosystemic shunts (TIPSS) for the management of ascites.
Method: Data was collected for patients undergoing TIPSS procedures at the Royal Free between 2010 and 2022. Statistical analyses used included *t*-tests and Mann-Whitney tests for comparison of continuous variables and the Cox proportional hazards model to identify predictive factors for mortality. Patients were censored at the point of death, last known follow up or the date of transplantation.
Results: 279 TIPSS were performed. 62.7% of the patients were male with a mean age of 56.7 years. Alcohol was the most common aetiology (63.4%), followed by metabolic dysfunction- associated steatotic liver disease (14.3%) and hepatitis C infection (8.6%). The median baseline MELD was 11 (IQR 9–14). Following TIPSS, a total of 14% of patients were transplanted, 5 within 90 days and 24 within one year. Of the remaining patients, survival at 90-days and 12-months was 91.5% (237/259) and 74.5% (175/235) respectively. Of the documented causes of death, 68.1% were due to liver related causes and 13.9% due to sepsis. Baseline variables predictive at univariate analysis for 90-day mortality included hypertension, diabetes, previous cardiac history and smoking histories but only hypertension (aHR 3.780, 95% C.I. 1.628–8.776) remained so at multivariable analysis. MELD (aHR 1.083, 95% C.I. 1.022–1.148), MELDNa (aHR 1.056, 95% C.I. 1.008–1.106) and GEMA (aHR 1.071, 95% C.I 1.007–1.139) scores (in separate models) were independent predictors of 12-months mortality alongside previous cardiac disease (aHR 2.561, 95% C.I 1.206–5.437). For overall mortality, although all prognostic scores were significant at univariate analysis only MELD (aHR 1.073, C.I 1.025–1.122), MELDNa (aHR 1.043, 95% C.I. 1.007–1.079) and GEMA (aHR 1.050, 95% C.I. 1.004–1.099) remained independently predictive at multivariable analysis. Additional clinical factors included age (aHR 1.022, 95% C.I 1.004–1.041), diabetes (aHR 1.448, 95% C.I. 1.005–2.086) and platelet count (aHR 0.998, 95% C.I. 0.995–1.000).
Conclusion: In this cohort of patients undergoing TIPSS for ascites, GEMA (and other prognostic scores) were predictive of 12 month and overall mortality. This study provides proof-of-concept that GEMA has prognostic utility outside a transplant setting.

WED-209-YI
Early need for paracentesis after TIPS is linked to further ascitic decompensation and impaired survival

Martin Kabelitz[1], Lukas Hartl[2,3], Golda Schaub[4], Anja Tiede[1,5], Andrea Kornfehl[2,3], Hannah Schneider[1], Peter Huebener[4], Mathias Jachs[2,3], Jan Hinrichs[6], Sarah Lisa Schütte[1], Christoph Riedel[7], Jim Benjamin Mauz[1], Tammo Lambert Tergast[1], Bernhard Meyer[8], Peter Bannas[7], Julia Kappel[2,3], Heiner Wedemeyer[1,5,9], Johannes Kluwe[4,10], Lisa Sandmann[1,5], Felix Piecha[4], Thomas Reiberger[2,3], Benjamin Maasoumy[1,5]. *[1]Department for Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [2]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [3]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [4]I. Email: Kabelitz.Martin@mh-hannover.de

Background and aims: Clinically significant portal hypertension (CSPH) in cirrhosis can result in recurrent/refractory ascites (RA). Aside from liver transplantation (LT), a transjugular intrahepatic portosystemic shunt (TIPS) remains the most effective treatment for RA. However, some patients may still require large-volume paracentesis (LVP) after TIPS. An early need for LVP (i.e., within ≤30 days after TIPS) is often considered clinically insignificant, based on the assumption that TIPS requires some time to achieve adequate ascites control. We aimed to evaluate the impact and timing of post-TIPS LVP requirement on patient prognosis.
Method: A total of 1,509 patients undergoing TIPS implantation between 2000 and 2023 at three European centers (Hannover, Vienna, Hamburg) were screened. Patients with TIPS indication other than RA, vascular liver disease, hepatocellular carcinoma, or insufficient follow-up data were excluded. Outcomes were recorded until one year after TIPS. Competing risk analyses were performed, considering LT or death as competing events for LVP outcomes, and LT as a competing event for survival analysis. Cox proportional hazards regression with time-dependent covariates and landmark analyses at 30- and 90-days post-TIPS were utilized to mitigate immortal time bias.
Results: A total of 729 patients (median MELD: 13 [IQR 10–16], 66% male, 65% alcohol-related liver disease) were included in the final analysis. In the 30-day landmark analysis, patients requiring LVP within the first 30 days post-TIPS demonstrated an elevated risk of requiring LVP beyond 30 days (subdistribution hazard ratio (sHR): 2.95 [2.18–4.01]; $p < 0.001$) and worse LVP-free (sHR: 3.66 [2.82–4.76]; $p < 0.001$) as well as worse overall survival (sHR: 2.43 [1.74–3.39]; $p < 0.001$). Similarly, patients requiring LVP between 30–90 days post-TIPS exhibited a higher risk of requiring LVP after 90 days (sHR: 1.93 [1.42–2.63]; $p < 0.001$) worse LVP-free (sHR: 3.84 [2.84–5.2]; $p < 0.001$) and overall worse survival (sHR: 1.83 [1.24–2.71]; $p < 0.001$). Time-dependent analysis, treating LVP as a time-varying covariate, also showed significantly impaired survival of patients requiring LVP during follow-up (HR: 3.99 [2.86–5.12]; $p < 0.001$). These findings remained consistent after adjustment for MELD or the Freiburg Index of post-TIPS survival.
Conclusion: Early LVP – regardless if required within 30 or within 30–90 days – after TIPS is a strong predictor of survival, the need for subsequent post-TIPS LVP, and LVP-free survival – indicating that post-TIPS LVP requirement should not be dismissed as clinically insignificant. Caregivers should consider prompt and decisive action, such as optimizing diuretics or considering TIPS revision, whenever LVP occurs, regardless of the timing.

WED-210
Growth differentiation factor 11 increases after TIPS insertion, correlates with muscle mass and is an independent predictor of survival

Martin Kabelitz[1], Simon Johannes Gairing[2,3], Anja Tiede[1], Eva Maria Schleicher[2], Hannah Schneider[1], Falko Zucker-Reimann[2], Jim Benjamin Mauz[1], Julia Weinmann-Menke[2,3], Bernhard Meyer[4], Michael Bernhard Pitton[2,3], Heiner Wedemeyer[1,5], Peter Galle[2], Benjamin Maasoumy[1,5], Christian Labenz[2,3], Lisa Sandmann[1,5]. *[1]Department for Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [2]Department of Internal Medicine I, University Medical Center of the Johannes Gutenberg-University, Mainz, Germany; [3]Cirrhosis Center Mainz (CCM), University Medical Center of the Johannes Gutenberg-University, Mainz, Germany; [4]Department of Diagnostic and Interventional Radiology, Hannover Medical School, Hannover, Germany; [5]German Center for Infectious Research, Hannover/Braunschweig, Germany*
Email: Kabelitz.Martin@mh-hannover.de

Background and aims: Growth differentiation factor 11 (GDF11), a member of the TGF-beta family, has been implicated in tissue regeneration and fibrosis. Experimental studies suggest elevated GDF11 levels in patients with fibrosis, though its role in clinical outcomes and muscle mass remains controversial. Thus, we investigated GDF11 as a potential biomarker for sarcopenia and clinical outcomes following transjugular intrahepatic portosystemic shunt (TIPS).
Method: We prospectively recruited 199 consecutive patients with cirrhosis undergoing TIPS insertion at two German centers. Structured follow-up visits, including biosampling and frailty assessment using the liver frailty index (LFI), were conducted at one, three, six, and 12 months post-TIPS. GDF11 levels were measured pre-TIPS and at each follow-up using enzyme-linked immunosorbent assay. Analyses included Spearman rank correlation coefficients, competing risk analysis for outcome data with liver transplantation as competing event, and linear mixed models (LMM) to assess GDF11 kinetics after TIPS. Additionally, we used maximally selected rank statistics to determine a predictive GDF11 cut off for survival.
Results: Among the 199 patients, 54% had alcohol-related cirrhosis, median MELD score was 12 (IQR: 9–16), and 78% underwent TIPS for refractory ascites. Before TIPS, median GDF11 levels were 1,905 pg/mL (IQR: 893–3,158). GDF11 correlated significantly with muscle mass (skeletal muscle index, $r = 0.51$, $p < 0.001$) and frailty (LFI, $r = -0.31$, $p < 0.001$). GDF11 levels before TIPS were associated with reduced mortality (subdistribution hazard ratio (sHR): 0.34 [0.15–0.79]; $p = 0.012$) after TIPS, an association that remained significant after adjusting for MELD (adjusted sHR: 0.33 [0.14–0.76]; $p < 0.001$). Using maximally selected rank statistics, a GDF11 cutoff of 1,069 pg/mL stratified survival ($p = 0.03$), with patients below this threshold showing significantly increased mortality (sHR: 2.60 [1.41–4.67]; $p = 0.002$, MELD adjusted: $p = 0.002$, asHR: 2.64 [1.44–4.85]; $p = 0.002$). GDF11 levels increased significantly post-TIPS (LMM baseline vs. follow-ups: BL–FU1 $p = 0.15$; BL–FU3 $p < 0.001$; BL–FU6 $p < 0.001$; BL–FU12 $p < 0.001$). Notably, GDF11 levels did not correlate with MELD.
Conclusion: GDF11 levels increased significantly following TIPS and effectively stratified survival outcomes. Furthermore, GDF11 correlated with muscle mass and frailty and emerged as an independent predictor of post-TIPS survival, highlighting its potential utility for risk stratification.

WED-211

Non-invasive evaluation of portal hypertension in patients with advanced chronic liver disease undergoing major abdominal surgery

Lidia Canillas[1], Amalia Pelegrina[2], Fawaz León[3], Aina Salis[3], Elena Colominas-González[4], Antonia Caro[5], Juan Sánchez-Parrilla[6], Juan Álvarez[7], Fernando Burdio[2], Jose A. Carrión[1,8]. *[1]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, Liver Section, Gastroenterology Department, Hospital del Mar, Barcelona, Spain, IMIM (Hospital del Mar Medical Research Institute), Barcelona, Spain, Barcelona, Spain; [2]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, IMIM (Hospital del Mar Medical Research Institute), Barcelona, Spain, Department of Surgery, Hospital del Mar, Barcelona, Spain, Barcelona, Spain; [3]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, Department of Medicine, Universitat Autònoma de Barcelona, Barcelona, Spain, Barcelona, Spain; [4]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, Pharmacy Department, Hospital del Mar, Barcelona, Spain, Barcelona, Spain; [5]Liver Section, Gastroenterology Department, Hospital del Mar, Barcelona, Spain, Barcelona, Spain; [6]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, Abdomen Section, Radiology Department, Hospital del Mar, Barcelona, Spain, Barcelona, Spain; [7]Department of Medicine and Life Sciences, Universitat Pompeu Fabra, Barcelona, Spain, IMIM (Hospital del Mar Medical Research Institute), Barcelona, Spain, Anesthesia Department, Hospital del Mar, Barcelona, Spain, Barcelona, Spain; [8]Department of Medicine, Universitat Autònoma de Barcelona, Barcelona, Spain, Barcelona, Spain*
Email: jcarrion@psmar.cat

Background and aims: In patients with advanced chronic liver disease (ACLD) undergoing major surgery, the presence of clinical decompensation (Child-Pugh B/C) increases mortality. In patients with compensated disease, the presence of severe portal hypertension (SPH) defined by a hepatic venous pressure gradient of 16 and especially 20 mmHg [Reverter E (J Hepatology, 2019)], is associated with higher postoperative mortality. Studies are needed to evaluate the impact of this diagnosis using non-invasive techniques. The aim was to compare postoperative mortality based on the presence or absence of non-invasive variables suggestive of preoperative severe portal hypertension.
Method: A retrospective, single-center study was conducted on patients with ACLD undergoing major abdominal surgery between 2010 and 2019. ACLD was defined as: 1) transient elastography (TE) >15 kPa; 2) abdominal ultrasound with signs of chronic liver disease, 3) data on portal hypertension. The SPH was considered by non-invasive methods (ni-SPH) according to previously published parameters [Jindal (Am J Gastroenterol, 2020)]: 1) splenomegaly (>13 cm) and thrombocytopenia <100,000/uL; 2) TE >42.8 kPa; 3) large varices. Patients were categorized into 3 groups: without ni-SPH (group A), without ascites with ni-SPH (group B), and with ascites (group C). Baseline characteristics were compared using univariate analysis (X^2 and U-Mann Whitney) and survival using mortality curves (Kaplan-Meier) and proportional hazards model (Cox regression).
Results: A total of 197 patients were included: median age 65 years, 68% male, and 53% with ACLD due to alcohol. Abdominal surgery was open in 57% (n = 113). Emergency surgery was performed in 44.2% (n = 87). There were 111 (56.4%) patients in group A, 62 (31.5%) in group B, and 24 (12.2%) in group C. In the 181 patients with Child-Turcotte-Pugh (CTP), the prevalence of CTP ≥ B7 was 12.6% (13/103), 29% (16/55) and 100% (23/23), respectively ($p < 0.01$). Patients in Group B vs. A had a higher proportion of ASA-IV (12.9% vs. 9%; $p = 0.03$), and worse liver function according to CTP ≥ B7 (29.1% vs. 12.6%, $p = 0.01$); without differences in MELD-Na (12 vs. 11 points, $p = 0.14$). The 90-day postoperative mortality was 4.5% (5/111) in group A, 12.9% (8/62) in group B, and 41.7% (10/24) in group C, respectively ($p < 0.01$). The increase in mortality [HR (95% CI), p] associated with ni-SPH among compensated patients (B vs. A) was 3.0 (1.0–9.2), $p = 0.05$. Moreover, ascites compared to compensated patients (A+B vs. C) were associated with an increased mortality of 6.8 (3.0–15.5); $p < 0.01$. The greatest difference was observed between patients without ni-SPH and those with ascites of 11.5 (3.9–33.8), $p < 0.01$.
Conclusion: Patients without hepatic decompensation but with non-invasive parameters suggestive of severe portal hypertension have three times higher 90-day postoperative mortality. Preoperative identification of these parameters can facilitate early initiation of treatments and more selective perioperative management.

WED-212

Determining the optimal portal pressure gradient after small-diameter TIPS for ascites: a cohort study

Guofeng Liu[1], Luo Xuefeng. *[1]Department of Gastroenterology and Hepatology, Sichuan University-University of Oxford Huaxi Joint Centre for Gastrointestinal Cancer, West China Hospital, Sichuan University, Chengdu, China*
Email: liuguofeng543@163.com

Background and aims: The transjugular intrahepatic portosystemic shunt (TIPS) is a well-established therapeutic strategy for refractory and recurrent ascites. However, the optimal hemodynamic threshold for portal pressure gradient (PPG) following TIPS placement remains uncertain. This study aimed to elucidate the relationship between post-TIPS PPG and clinical outcomes in patients undergoing small-diameter (8-mm) cover TIPS for ascites.

Method: From July 2015 to June 2023, consecutive patients receiving small-diameter (8-mm) TIPS for ascites were considered for inclusion retrospectively. The impact of PPG on clinical outcomes—including ascites response, overt hepatic encephalopathy (OHE), further decompensation, and mortality—was evaluated using Fine and Gray competing risk regression models, both unadjusted and adjusted for potential confounders.
Results: A total of 143 patients were included in the analysis. Patients with persistent or recurrent ascites after TIPS exhibited significantly higher post-TIPS PPG than those without ($P < 0.001$). While patients who developed OHE had significantly lower post-TIPS PPG ($P < 0.001$). Receiver operating characteristic (ROC) curve analysis identified post-TIPS PPG as a reliable predictor of both ascites (AUC: 0.733, $P < 0.001$; cutoff: 10.5 mmHg) and OHE (AUC: 0.716, $P < 0.001$; cutoff: 7.5 mmHg). Univariate and multivariate Fine and Gray competing risk regression analyses further revealed that patients with PPG between 8 and 10 mmHg had favorable outcomes, including a lower incidence of ascites (>10 mmHg vs. 8–10 mmHg, adjusted SHR: 5.74, 95% CI: 1.11–15.58, $P < 0.001$), a reduced risk of OHE (<8 mmHg vs. 8–10 mmHg, adjusted SHR: 2.87, 95% CI: 1.29–6.35, $P = 0.010$), and a decreased risk of further decompensation after TIPS placement (>10 mmHg vs. 8–10 mmHg, adjusted SHR: 2.78, 95% CI: 1.43–5.41, $P = 0.003$; <8 mmHg vs. 8–10 mmHg, adjusted SHR: 2.42, 95% CI: 1.20–4.90, $P = 0.014$).
Conclusion: This study revealed post-TIPS PPG was associated with clinical outcomes in patients with refractory and recurrent ascites undergoing small-diameter TIPS. A post-TIPS PPG of 8–10 mmHg emerges as the optimal range, effectively controlling ascites without significantly increasing the risk of shunt-related hepatic encephalopathy, while also reducing the risk of further decompensation.

WED-213-YI
Right heart function on hemodynamic alterations and survival outcomes after transjugular intrahepatic portosystemic shunt

Yaozu Liu[1], Fangmin Meng[2], Jingqin Ma[1], Wen Zhang[1], Zhiping Yan[1], Cuizhen Pan[2], Jianjun Luo[1]. *[1]Department of Interventional Radiology, Zhongshan Hospital, Fudan University, Shanghai, China, shanghai, China; [2]Department of Echocardiography, Zhongshan Hospital, Fudan University, Shanghai, China, Shanghai, China*
Email: luo.jianjun@zs-hospital.sh.cn

Background and aims: To assess the right heart function in patients with decompensated cirrhosis and further analyze the impact of right heart function and right ventricular to pulmonary artery vascular coupling on hemodynamic regulation and prognosis after transjugular intrahepatic portosystemic shunt (TIPS).
Method: A prospective study included patients with decompensated cirrhosis underwent TIPS from January 2022 to January 2023. Patients underwent a comprehensive echocardiographic evaluation of cardiac function within 24 hours before the TIPS. The pressures of the portal vein, inferior vena cava, and right atrium were measured immediately before the TIPS, immediately after TIPS, and 2–4 days later. The primary endpoint of the study was all-cause mortality post-TIPS.
Results: Fifty-eight patients were enrolled, among which right heart dysfunction was primarily characterized by enlargement of the right atrial volume (RAV: 40.97 ± 13.19 ml). Nine patients (15.5%) exhibited right ventricular to pulmonary artery vascular uncoupling (TAPSE/PASP: 0.78 ± 0.13 vs 0.43 ± 0.16 mm/mmHg, $p < 0.001$), with worse right atrial strain and right ventricular free wall longitudinal strain (RVFWLS) indicating impaired right atrial and ventricular myocardial function in these patients. However, there were no significant differences in portal vein, inferior vena cava, right atrium pressures, and portal pressure gradients between the two groups at different measurement point. Additionally, patients with right ventricular to pulmonary artery vascular uncoupling showed more severe postoperative peripheral venous congestion at three months (71.4% vs 10.4%, $P < 0.001$) and six months (66.7% vs 6.4%, $P < 0.001$), with a poorer response to diuretic monotherapy. The median follow-up period was 11 months (range 1–17 months), during which six patients (10.3%) died. Elevated right atrial pressure (Log-rank test, $p = 0.0379$) and right ventricular to pulmonary artery vascular uncoupling (Log-rank test, $p = 0.007$) before TIPS significantly affected postoperative survival.
Conclusion: In patients with decompensated cirrhosis, the presence of right ventricular to pulmonary artery vascular uncoupling indicates relatively poorer overall right heart function which does not impair short-term post-TIPS hemodynamic regulation. But it significantly increased rate of postoperative lower extremities edema and mortality.

WED-214
The safety and efficacy of trans-splenic portal vein recanalization-assisted TIPS for the treatment of portal vein obliteration: a multicenter retrospective study

Yaozu Liu[1], Jingqin Ma[1], Wen Zhang[1], Zhiping Yan[1], Jianjun Luo[1]. *[1]Department of Interventional Radiology, Zhongshan Hospital, Fudan University, shanghai, China*
Email: luo.jianjun@zs-hospital.sh.cn

Background and aims: Trans-splenic portal vein recanalization-assisted transjugular intrahepatic portosystemic shunt (Trans-splenic PVR-TIPS) may be an effective treatment for patients with portal vein obliteration. However, due to the technological complexity, current studies are limited to case reports or small-sample research, and its safety and efficacy require further validation. In this context, we conducted a multicenter retrospective study to assess the safety and efficacy of Trans-splenic PVR-TIPS.
Method: We conducted a multicenter retrospective study of patients who underwent Trans-splenic PVR-TIPS from June 2018 to June 2023, including a total of 67 patients. The procedural success rate, complications, and long-term portal vein recanalization rate(percentage of remnant lumen of the main portal vein $\geq$ 50%) were evaluated. Patients were classified into two groups based on the assistance technique: the balloon-assisted Trans-splenic PVR-TIPS group and the snare-assisted Trans-splenic PVR-TIPS group. Radiation exposure and complications were analyzed to assess which guidance technique is more optimal for the procedure.
Results: In the 67 patients included in the study, the surgical success rate was 95.5% (n = 64). Apart from one case of sepsis due to bacterial colonization within the stent, no other severe surgery-related complications were observed. The median follow-up was 37 months, with a 1-year portal vein patency rate of 90.6% and an overall stent patency rate of 81.3% during the entire follow-up period. Among patients with portal vein occlusion, 75% occurred within the first 2 years after the procedure. Compared to the balloon-assisted group, the snare-assisted group had shorter overall procedure time (155.2 ± 32.8 min vs 134.0 ± 34.5 min, $p = 0.015$) and fluoroscopy time (68.9 ± 19.3 min vs 59.4 ± 17.95 min, $p = 0.045$), but no statistically significant difference was observed in the incidence of splenic-related complications(9.7% vs 3.0%, $p = 0.347$).
Conclusion: Trans-splenic PVR-TIPS appears to be a safe and effective approach for managing portal vein obliteration, demonstrated by its high success rate, low incidence of surgical complications, and favorable long-term portal vein patency. Furthermore, the application of a snare-assisted technique during the procedure may help reduce both complications and radiation exposure.

WED-215-YI
Factors associated with clinical deterioration in patients with ascites that may be preventable by TIPS

Lorenz Balcar, Marta Tonon, Joan Valls[1], Valeria Calvino[2], Lucie Simonis, Jan Embacher[3], Roberta Gagliardi[2], Christian Sebesta[3], Leonie Hafner[3], Antonio Accetta[2], Lukas Hartl[3], Mattias Mandorfer, Michael Trauner, Paolo Angeli[2], Thomas Reiberger, Juan Carlos García-Pagán[4], Georg Semmler, Salvatore Piano[2].

[1]Barcelona Clinical Coordinating Center, Barcelona, Spain; [2]University of Padova, Padova, Italy; [3]Medical University of Vienna, Vienna, Austria; [4]Universitat de Barcelona, Barcelona, Spain
Email: lorenz.balcar@meduniwien.ac.at

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is an effective treatment of cirrhotic patients with recurrent/refractory ascites. However, the benefit of TIPS may be more evident in patients with more preserved liver function, while poor liver function and refractory ascites reduced the disease-modifying effect. The aim of the current study was to identify risk factors for portal hypertension (PH)-related complications potentially preventable by TIPS occurring within 12 months in patients with cirrhosis who developed ascites as first decompensating event – to potentially prioritise them for TIPS.
Method: We included 451 patients from two tertiary care centres (Vienna and Padua) with ascites as single first decompensating event between 2003 and 2021 and who had no obvious contraindications for TIPS placement (age >75 years, heart failure, hepatic encephalopathy, hepatocellular carcinoma, MELD ≥20, bilirubin ≥5 mg/dL). Multivariable logistic regression analysis was used to identify variables independently associated with a composite endpoint of PH-associated complications (spontaneous bacterial peritonitis, refractory ascites, HRS-AKI, variceal bleeding), liver transplantation, or liver-related death – but excluding encephalopathy (that could be induced/aggravated by TIPS). Absolute risk was validated in a temporal validation cohort from Vienna (2021–2024, n = 84).
Results: Mean age in the derivation cohort was 56 ± 11years, 69% were male, and the most common aetiology of liver disease was alcohol-related (51.4%). While 252 (56%) presented with ascites grade 2, 199 (44%) presented with ascites grade 3. Median Child-Pugh-score was 8 (IQR: 7–9), and median MELD was 12 (IQR: 9–15). Within 12 months, 152 (34%) patients developed the composite endpoint. A model including ascites grade (odds ratio [OR]: 6.5 [95%CI, 4.12–10.41], p < 0.001), sodium (OR per mmol/L: 0.9 [95%CI, 0.85–0.95], p < 0.001) and MELD (OR per point: 1.1 [95%CI, 1.03–1.19], p = 0.007) predicted best the occurrence of the composite endpoint within 12 months (AUROC: 0.792 [95%CI: 0.748–0.836]). Applying a recursive partitioning classification tree, the following patients were selected with a high risk of PH-related complications potentially preventable by TIPS: ascites grade 3 with either sodium <135 mmol/L or MELD ≥12 points. These patients had an absolute risk of 64.3% (derivation cohort) and 68.9% (validation cohort) to develop the composite endpoint within the first 12 months.
Conclusion: Patients with first decompensation due to ascites grade 3 and either sodium <135 mmol/L or MELD ≥12 are at high risk for PH-related complications that can potentially be prevented by early TIPS placement without waiting for recurrent/refractory ascites. Prospective trials assessing the effectiveness of early TIPS placement in patients with 'high-risk' ascites index decompensation are encouraged.

WED-216
Inter-assay/inter-laboratory comparison of von Willebrand Factor antigen as diagnostic and prognostic biomarker in advanced chronic liver disease

Lorenz Balcar, Alberto Zanetto[1], Lorenzo Alberio[2], Jelle Adelmeijer[3], Benedikt Simbrunner[4], Cristiana Bulato[1], Elena Matthey[2], Maxime Zermatten[2], Kerstin Zinober[4], Georg Semmler, Bernhard Scheiner[4], Michael Trauner, Thomas Reiberger, Paolo Simioni[1], Francisco-Javier Gomez[2], Ton Lisman[3], Mattias Mandorfer. [1]University of Padova, Padova, Italy; [2]Université de Lausanne, Lausanne, Switzerland; [3]University of Groningen, Groningen, Netherlands; [4]Medical University of Vienna, Vienna, Austria
Email: lorenz.balcar@meduniwien.ac.at

Background and aims: Von Willebrand factor antigen (VWF:Ag) is an inexpensive lab test that is broadly available in routine laboratories, primarily due to its role in the diagnosis of VWD, the most common bleeding disorder. Moreover, VWF:Ag is the most promising blood-based NIT for CSPH in compensated advanced chronic liver disease (cACLD) and a prognostic biomarker in ACLD. The VITRO score (ratio of VWF:Ag and platelet count) may replace elastography as a NIT for CSPH or reduce the diagnostic grey zone of the Baveno VII criteria. However, the vast majority of published results are based on the Stago VWF:Ag assay. To allow widespread clinical application, we performed a comparative study with the other commonly applied assays (i.e., Werfen & Siemens).
Method: We included citrate plasma samples from 404 ACLD patients undergoing HVPG measurement at the Medical University of Vienna. Frozen samples were provided to centres with expertise in haemostasis/coagulation tests applying different VWF:Ag assays (Stago/Groningen, Werfen/Padua, Siemens/Lausanne). Respective assays were compared and evaluated for diagnostic (CSPH) and prognostic utility in cACLD (endpoint: first hepatic decompensation). Based on previous findings, patients on statins were excluded (n = 51).
Results: 353 patients who predominantly had steatotic liver disease (55%) were studied. Median VWF:Ag levels were: Stago 282 (IQR: 195–358)%, Werfen 256 (IQR: 193–325)%, and Siemens 215 (IQR: 148–298)%, which translated into VITRO values of 2.75, 2.48, and 2.2. Stago and Werfen (intraclass correlation [ICC] 0.911; Pearson's r 0.914) as well as Siemens (ICC 0.921; Pearson's r 0.922) showed near perfect correlation. While the mean difference between Stago and Werfen was small (12.1 [IQR: 5.7–18.5]), there was a substantial difference when comparing Stago with Siemens (49.6 [IQR: 43.9–55.3]), indicating systematically lower values with the Siemens assay. Among 121 compensated patients, the CSPH prevalence was 72.7%. While all assays yielded comparable AUCs, the Stago VWF:Ag assay had the highest discriminative ability for CSPH (0.737; Werfen: 0.719; Siemens: 0.689). When applying VWF:Ag to calculate the VITRO score, all AUCs were >0.8 (Stago: 0.836; Werfen: 0.849; Siemens: 0.817). Using the previously established VITRO score cut-off ≥2.5 to rule-in CSPH, PPV was >90% with all assays, however, the Siemens assay ruled-in CSPH in a lower proportion of patients. Similar findings were observed when applying the Baveno VII-VITRO sequence. VWF:Ag assays as well as respective VITRO scores yielded similar prognostic abilities, with a time-dependent AUC of ~0.65 at 1 & 2 years.
Conclusion: VWF:Ag & VITRO score showed a robust diagnostic and prognostic performance in this inter-assay/inter-laboratory comparison study. The Stago and Werfen assays can be used interchangeably applying established cut-offs. Approaches to incorporate the systematically lower VWF:Ag values of the Siemens assay will be presented at the EASL Congress.

WED-221
Copeptin decrease after TIPS is linked to portal pressure and kidney function

Lukas Hartl[1,2,3], Theresa Müllner-Bucsics[1,2,3], Julia Kappel[1,2,3], Marlene Hintersteininger[1,2], Nina Dominik[1,2,3], Benedikt Hofer[1,2,3,4], Lorenz Balcar[1,2,3], Georg Kramer[1,2,3,4], Christian Sebesta[1,2,3], Paul Thöne[1,2,3], Lukas Reider[5], Maria Schoder[5], Michael Trauner[1,3], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3,4]. Email: lukas.a.hartl@meduniwien.ac.at

Background and aims: Arginine-vasopressin (AVP) and the renin-angiotensin-aldosterone system (RAAS) are upregulated in patients

with decompensated cirrhosis (DC). A transjugular intrahepatic portosystemic shunt (TIPS) effectively decreases portal pressure and may impact on AVP and RAAS. We thus investigated plasma levels of copeptin (an AVP biomarker), plasma renin concentration (PRC) and plasma aldosterone concentration (PAC) before and after TIPS implantation.

Method: We assessed copeptin levels in consecutive patients with DC (included in the prospective AUTIPS registry; NCT03409263) undergoing covered TIPS implantation at the Vienna General Hospital between 04/2018–11/2024. Copeptin, PRC and PAC were measured before (i.e., baseline [BL]), as well as 1 (M1), 3 (M3), 6 (M6), 9 (M9) and 12 (M12) months after TIPS implantation.

Results: 96 patients (67.7% male, median age: 57 years) with predominantly alcohol-related liver disease (58.3%) and median MELD of 11 (IQR 9–17) were included. The indication for TIPS implantation was ascites in 68 patients (70.8%) and variceal bleeding in 28 patients (29.2%). Median portal pressure gradient (PPG) was reduced from 18 (IQR 15–22) mmHg to 8 (IQR 6–10) mmHg after TIPS implantation. At BL, copeptin levels were elevated (>11.4 pmol/L) in 57.3% (n = 55/96) of patients. Median copeptin levels significantly decreased from BL to M1 (paired in n = 77; BL: 12.1 pmol/L to M1: 8.8 pmol/L; p < 0.001), while median sodium concentration increased (BL: 136.0 mmol/L to M1: 138.0 mmol/L; p < 0.001). In patients with available copeptin levels at all time points (n = 34), median levels of copeptin showed a significant and sustained decrease after TIPS (from BL: 11.5 pmol/L to M12: 6.9 pmol/L; p = 0.041). In contrast, median PRC (BL: 135.8 µIU/mL to M1: 127.2 µIU/mL; p = 0.366) and median PAC (BL: 219.9 pg/mL to M1: 266.0 pg/mL; p = 0.419) did not decrease after TIPS implantation. Consistently, there was also no decrease of PRC and PAC at later timepoints (PRC n = 34; from BL: 130.3 µIU/mL to M12: 100.1 µIU/mL; p = 0.131/PAC n = 35; from BL: 249.4 pg/mL to M12: 311.0 pg/mL; p = 0.142). In multivariate linear regression analysis (corrected for bilirubin, albumin, sodium and leukocyte count at M1), plasma copeptin at M1 after TIPS implantation was independently linked to post-TIPS PPG (aB: 1.00; 95% CI: 0.24–1.77; p < 0.001) and creatinine at M1 (aB: 16.03; 95% CI: 10.26–21.81; p < 0.001).

Conclusion: The decrease in copeptin, an AVP biomarker, is independently linked to severity of portal hypertension (PPG) and kidney function after TIPS and is associated with improved serum sodium levels. Decreasing AVP activation after TIPS indicates an ameliorated hemodynamic state in patients with DC.

WED-222

Clinical outcomes of cirrhotic patients undergoing balloon-occluded retrograde transvenous obliteration for prevention of gastric variceal rebleeding

Luo Xuefeng[1]. [1]*Department of Gastroenterology and Hepatology, Sichuan University-University of Oxford Huaxi Joint Centre for Gastrointestinal Cancer, West China Hospital, Sichuan University, Chengdu, China*
Email: luo_xuefeng@wchscu.cn

Background and aims: Balloon-occluded retrograde transvenous obliteration (BRTO) is an established treatment for managing gastric varices (GVs). This study evaluated the clinical outcomes of BRTO in preventing rebleeding from gastric varices in patients with cirrhosis.

Method: From May 2015 to May 2024, cirrhotic patients who underwent BRTO at our institution to prevent gastric variceal rebleeding were considered for inclusion. Clinical outcomes, including gastric variceal rebleeding, new or worsening ascites, aggravation of esophageal varices (EV), hepatic encephalopathy (HE), and overall mortality, were assessed using univariate and multivariate logistic regression and Cox proportional hazards models.

Results: A total of 234 patients were included in the analysis. The predominant type of GV was gastroesophageal varices type 2 (GOV2) (51.3%), followed by isolated gastric varices type 1(IGV1) (39.8%). 49.8%/38.0%/12.2% had Child–Turcotte–Pugh A/B/C cirrhosis, respectively, with a median MELD score of 10. During a median follow-up of 31.9 months, worsening of esophageal varices was observed in 38 patients (16.2%), while 29 patients (12.4%) developed new or worsening ascites. Variceal rebleeding occurred in 36 patients (15.4%) (bleeding from GV in 3 and EV in 33). A total of 71 patients died during follow-up. The 1-, 2-, and 3-year survival rates were 91.5%, 86.8%, and 77.3%, respectively. Multivariate Cox regression analysis identified age (HR, 1.045, 95% CI, 1.023–1.066; P < 0.001), Child-Pugh score (HR, 1.306, 95% CI, 1.152–1.481; P < 0.001), and adherence to non-selective beta-blockers (NSBB) (HR, 0.308, 95% CI, 0.132–0.720; P = 0.007) as independent predictors of mortality.

Conclusion: This study demonstrates that BRTO effectively prevents gastric variceal rebleeding, with favorable survival rates. Age, Child-Pugh score, and NSBB adherence are critical predictors of mortality.

WED-223

Colonization with multidrug resistant organisms is associated with poor outcomes in patients with decompensated cirrhosis of liver: a tertiary care center experience

Manasa Alla[1], Ankit Mittal[1], Shantan Venishetty[1], Anand Kulkarni[1], Mithun Sharma[1], Sowmya Iyengar[1], Haripriya Reddy[1], Harshith Kadnur[1], Nagaraja Padaki[1], Nageshwar Reddy[1]. [1]*AIG Hospitals, Hyderabad, India*
Email: manasa1512@gmail.com

Background and aims: There is significant morality and morbidity associated with methicillin resistant Staphylococcus aureus (MRSA), carbapenem-resistant enterobacterales (CRE) and vancomycin resistant enterococcus (VRE) infections in patients with cirrhosis of liver. Colonization is associated with increased risk of infections in high risk patients including prolonged hospital stay and organ failures. However, there is limited data on effect of colonization with these organisms on outcomes in liver cirrhosis. We aimed to assess the effect of colonization with MDROs colonization on 28 day mortality in decompensated cirrhosis of liver.

Method: It was a retrospective data analysis done among admitted patients at a tertiary care center from February 2022–September 2024 in patients with decompensated cirrhosis of liver. Inclusion criteria were prior history of hospitalization in last 3 months, multiple co-morbidities, history of any surgeries in last 3 months, history of prolonged antibiotic use in the last 1 month, re-admission in the same hospital. Rectal swab to detect VRE & multi drug resistant organism (MRDO) colonization, CRE screening, nasal swab for MRSA colonization, and axilla and groin swab for candida auris were performed. Necessary contact precautions were taken for those patients positive and were categorized as colonizers.

Results: 240 patients with decompensated cirrhosis of liver were screened and 70 patients with mean age 48.42 ± 12.63 years were included. Mean CTP and MELD were 10.42 ± 2.56 and 21.86 ± 4.73 respectively. Alcohol {28/70 (40%)} was the most common etiology of liver cirrhosis followed by NASH {25/70 (35.7%)}. 37.1% (26/70) were colonizers and out of which 24.2% (17/70) were colonizers with more than one MDROs. MRSA colonization was seen in 14.2% (10/70) and VRE colonization 20% (14/70). The incidence of CRE colonization and candida auris positive screen was 21.4% (15/70) and 11.4% (8/70) respectively. Incidence of pneumonia was seen in {34.6%(9/26) vs 13.6% (6/44); p = 0.03}, urosepsis in {46.1%(12/26) vs 20.4%(9/44); p = 0.02 } in colonizers vs non-colonizers respectively. Mean days of hospitalization were {19.82 ± 5.63 vs 16.32 ± 4.98; p < 0.05}in colonizers vs non-colonizers respectively. 28-day mortality in colonizers was {76.9%(20/26) vs 50%(22/44); p = 0.02 } compared to non-colonizers.

Conclusion: Our study showed that colonization with MDRO is associated with increased incidence of pneumonia and urosepsis and a higher 28-day mortality. Rapid and prompt screening of colonizers is necessary for appropriate management and isolation practices in patients with cirrhosis of liver.

WED-224

The AMMON-OHE model predicts post-TIPS overt hepatic encephalopathy

María Pilar Ballester[1], Christian Labenz[2], Lisa Sandmann[3], Lukas Hartl[4], Jesus Donate[5], Simon Johannes Gairing[6], Lorenz Balcar[4], Luis Téllez[7], Mattias Mandorfer[4], Agustín Albillos[8], Juan Antonio Carbonell-Asins[9], Rajiv Jalan[10], Benjamin Maasoumy[11], Thomas Reiberger[12]. *[1]Clinic University Hospital of Valencia, Valencia, Spain; [2]I. Email: mapibafe@gmail.com

Background and aims: Overt hepatic encephalopathy (OHE) occurs in up to 50% of patients undergoing transjugular intrahepatic portosystemic shunt (TIPS), and potentially with recurrent episodes. Due to its impact on health-related quality of life and survival, accurate OHE risk prediction models are needed to allow for adequate management and to ensure favorable outcomes after TIPS. The AMMON-OHE model, a machine learning model that includes 5 clinical and biochemical variables, was recently developed and validated to predict the risk of OHE in outpatients with cirrhosis. The aim of this study was to evaluate the utility of the AMMON-OHE model to predict post-TIPS OHE.
Method: This is an observational cohort study of cirrhosis patients undergoing TIPS in 3 liver units in Europe. The AMMON-OHE model was measured at the time of TIPS insertion and patients were followed-up until OHE development, liver transplant or death, whichever came first. Patients were stratified into low, medium and high-risk groups according to the previously defined AMMON-OHE cut-offs and cumulative OHE incidence curves were constructed. Risk group comparisons were performed using Gray's test. Cox regression models were fitted to study independent risk factors for OHE.
Results: A total of 355 patients were included, 70% males with a median age of 57 (IQR 13) years. The most frequent etiology of cirrhosis was alcohol (54%) and the most common indication for TIPS was ascites (68%) and variceal bleeding (21%). A total of 90 (25%) patients had a history of pre-TIPS OHE episodes and 59 (23%) were on lactulose and 50 (19%) on rifaximin at TIPS implantation. Mean portosystemic gradient before and after TIPS was 18 (5) and 7 (3) mmHg, respectively. During a median of 5.6 (IQR 14) months, 160 (45%) patients developed OHE. There were significant differences in the cumulative OHE incidence between risk groups ($p = 0.022$). At one year, 91 events were observed in the high-risk group with a cumulative incidence of 46% (95% CI: 0.39–0.53), 40 events in the medium-risk group with a cumulative incidence of 40% (95% CI: 0.30–0.49) and 8 events in the low-risk group with a cumulative incidence of 24% (95% CI: 0.08–0.37). Age, diabetes, history of pre-TIPS OHE, MELD, MELD Na, MELD 3.0, Child-Pugh, and creatinine were independently associated with a shorter time to OHE development (all $p < 0.05$).
Conclusion: OHE remains a frequent complication in cirrhosis patients undergoing TIPS. Risk stratification of patients according to the AMMON-OHE model yielded significant differences in the risk of and time to OHE development post TIPS. This novel model could be easily adopted in clinical practice for the selection of candidates who may benefit from intensified OHE prophylaxis.

WED-225

Risk factors of post-banding ulcer bleeding in patients with cirrhosis at a large tertiary center in Switzerland

Maria De Brito Nunes[1], Matthias Knecht[2], Jonas Schropp[3], Reiner Wiest[2], Jaime Bosch[3], Annalisa Berzigotti[4]. *[1]department for biomedical research, visceral surgery and medicine, university of bern, department of internal medicine, hospital of fribourg, graduate school for health sciences, university of Bern, Bern, Switzerland; [2]department of visceral surgery and medicine, Inselspital, Bern University Hospital, University of Bern, Bern, Switzerland; [3]department for biomedical research, visceral surgery and medicine, University of Bern, Switzerland, Bern, Switzerland; [4]department of visceral surgery and medicine, Inselspital, Bern University Hospital, University of Bern, Switzerland, Bern, Switzerland*
Email: maria.debritorodriguesnunes@unibe.ch

Background and aims: Esophageal variceal bleeding is a major complication of liver cirrhosis and portal hypertension, and is related with significant mortality (10–15% at six weeks). Endoscopic band ligation (EBL) is the reference standard procedure for preventing or managing acute variceal bleeding. Post-banding ulcer bleeding (PBUB), which occurs at the sites where ligation bands are placed, is an understudied complication of EBL. This single-center retrospective cohort study, conducted at the University Hospital of Bern (Switzerland) aimed to determine the incidence rate and mortality rates of PBUB; identify factors associated with PBUB; and evaluate strategies used to control PBUB.
Method: The study included patients with cirrhosis who underwent EBL between January 2018 and December 2022. The primary outcome was the overall bleeding secondary to post-banding ulcer (PBU) and risks factors of PBUB. The cumulative incidence of PBUB was visualized for relevant covariates. Associations were assessed using the Cox proportional hazards model with cluster-robust standard errors, first via univariate analysis and then in a multivariate model.
Results: 203 patients underwent 600 endoscopic band ligation procedures, and 900 endoscopies. The main etiologies of cirrhosis were alcohol-related liver disease (59%) and metabolic dysfunction-associated steatotic liver disease (28%). The incidence rate of PBUB was 19% when considering the total number of patients. Several factors were significantly associated with PBUB in the univariate analysis, including the presence of infection (HR 5.26 [1.82; 15.2], $p = 0.002$), high INR (HR 6.25 [2.65; 14.71], $p < 0.001$), anticoagulation therapy (HR 2.21 [1.06; 4.6], $p = 0.035$), and acute variceal bleeding with urgent EBL (HR 3.58 [1.88; 6.83], $p < 0.001$). Treatment with non-selective beta-blockers (HR 0.48 [0.25; 0.93], $p = 0.03$) and platelet count (HR 0.95 [0.89; 1.00], $p = 0.047$) were associated with a reduced risk of PBUB. In the multivariate analysis, only creatinine (HR 1.07 [1.03; 1.11], $p < 0.001$) and anticoagulation therapy (HR 2.47 [1.3; 4.68], $p = 0.006$) were identified as risk factors for PBUB. Treatment for PBUB and refractory ulcer bleeding included pharmacological therapy with proton pump inhibitors and vasoactive drugs. Endoscopic interventions varied and included endoscopic band ligation, hemoclips, hemospray, and self-expandable metallic stents; other interventions included transjugular intrahepatic portosystemic shunt and liver transplantation. The 28-day and 90-day mortality rates after EBL were 6.1% (95% CI 4%–8.1%) and 12% (95% CI 8.3–15.5%).

Conclusion: Although infection, high INR, and urgent EBL were associated with PBUB on univariate analysis, they did not remain significant in the multivariate model. Only renal impairment and anticoagulation therapy were identified as significant independent risk factors for PBUB. The management of this complication was heterogeneous, underlining need of standardization.

WED-226

Unveiling the economic burden of decompensated cirrhosis: a comprehensive cost analysis

Mariana Esteves[1,2], Rita Bragança[1,2], Kohilan Gananandan[2], Glória Conceição[3], Rajiv Jalan[2], Julio Souza[4], Rajeshwar Prosad Mookerjee[2]. [1]*Internal Medicine Department, Unidade Local de Saúde de Trás-os-Montes e Alto Douro, Vila Real, Portugal;* [2]*Liver Failure Group, Institute for Liver and Digestive Health, University College London, Royal Free Campus, London, United Kingdom;* [3]*Centro Nacional de Investigaciones Cardiovasculares (CNIC), Madrid, Spain;* [4]*ISEP. Institute of Engineering – Polytechnic of Porto, Porto, Portugal*
Email: mariana.martins.esteves@hotmail.com

Background and aims: Decompensated cirrhosis has significant clinical and societal impacts, yet comprehensive data on the financial impact is lacking. This study provides in-depth assessment of costs, resource utilization, and outcomes for decompensated cirrhosis, including readmission analysis.
Method: We studied a tertiary-center, retrospective cohort of cirrhosis patients admitted with acute decompensation between October'18-February'21, with six-month follow-up data, extracted from electronic patient records, discharge summaries and clinic letters, capturing demographics, comorbidities, decompensation types and severity, intensive care unit (ICU) interventions, procedures, and outcomes. Follow-up data included readmissions, procedures, and outpatient visits. Costs were estimated using current, UK healthcare resource codes. Statistical analyses included descriptive statistics, multivariate linear regression, and Kaplan-Meier analysis.
Results: 387 patients were included (age 56.7 ± 13.4 years; 67% male); primary aetiology was alcohol (53%), followed by MASLD (11%) and viral hepatitis (10%). The median MELD-Na score at admission was 21, and Child-Pugh 10. Among 533 admissions, the most frequent decompensations were ascites (45%), variceal bleeding (27%), and hepatic encephalopathy (19%). The median length of stay (LOS) was 8 days. Key precipitating factors included alcohol (26%), infection (22%), and variceal bleeding (19%). Readmissions occurred in 100 patients; median time to first readmission of 27 days. Index admission mortality was 15%, increasing to 35% at 180 days. The total cost of inpatient care was £8.2M with a mean cost of £15,334 per admission. ICU stays accounted for £3.25M. Major costs included paracenteses (£1.3M), upper GI endoscopies (£723 K), and TIPS (£356 K). Albumin contributed notably, costing £161 K. Costs varied by decompensation type, with SBP admissions being the most expensive (£27,255/admission), followed by variceal bleeding (£19,838) and ascites (£13,615). Predictors of higher costs included longer LOS (2% increase /day, $p < 0.001$), multi-organ support (140% increase for 3 organs supported, $p < 0.001$), ICU admission (40% increase, $p = 0.014$), paracentesis (1 paracentesis increased costs by 14%, $p < 0.001$, while ≥ 5 led to a 75% increase, $p < 0.001$), TIPS (51% increase, $p < 0.001$), and 20% albumin (0.95% cost increase /100 g, $p < 0.001$). Total follow-up costs were £535 K, with consultant-led visits (£124,866), paracenteses (£121,854), and rifaximin (£120,435) as key contributors.
Conclusion: Cirrhosis acute decompensation imposes significant healthcare costs, especially ICU care, procedures, and albumin and rifaximin use. Mortality and readmission rates remain alarmingly high, underscoring the need for sustained post-discharge care strategies and early intervention, to optimize care and mitigate additional healthcare expenditure.

WED-227

Hormone dysregulation in young people with liver disease and portal hypertension: an unrecognised problem that requires attention

Marianne Samyn[1], David R Taylor[1], Ritika Kapoor[1], Jeremy Nayagam[1], Sophie Cant[1], Deepak Joshi[1]. [1]*King's College Hospital, London, United Kingdom*
Email: marianne.1.samyn@kcl.ac.uk

Background and aims: Hormone dysregulation is described in adults with advanced liver disease but poorly explored in in adolescents and young adults (AYA). The aim of this study was to analyse the hormone profile of AYA with chronic liver disease (CLD) and portal hypertension and its relationship with clinical phenotype, blood tests and radiological features.
Method: Observational study in 72 AYA (22 M), median age 19 (IQR 17–23) years attending a young adult liver clinic. Hormone profiles including serum and urine steroid profile (USP) were analysed and the USP compared with an age and gender matched cohort of healthy controls (n = 67).
Results: 57 AYA had a diagnosis of CLD [20 M] with autoimmune liver disease [n = 24] and biliary atresia [n = 13] were most common; 15 [2 M] were diagnosed with extrahepatic portal vein obstruction (EHPVO). Platelet count $<150 \times 10^9$/l [PLT<150], in keeping with portal hypertension was present in 49 [68%]. Compared to healthy controls, 50% had an abnormal USP and more commonly observed in EHPVO [87%] vs CLD [40%, $p < 0.001$] and in PLT<150 vs PLT>150 group [61% vs 26%, p.005] with no gender difference. An abnormal compared to normal USP was characterised by higher serum bilirubin [23 [14–34] vs 11 [7–19] umol/l, $p < 0.001$], testosterone [4.6 [1.9–16.5] vs 1.2 [0.4–6.7] nmol/l, $p = .011$] and INR [1.1 [1.0–1.3] vs 1.0 [1.0–1.1], $p = .004$] and lower white cell [4.1 [3–5, vs 5.4 [4.0–6.8] $\times 10^9$/l, $p = .011$] and platelet [96 [67–127] vs 150 [89–244] $\times 10^9$/l, $p = .007$] count. The frequency of radiological features in CLD and EHPVO were liver nodules (70%), varices (69%), right lobe atrophy (65%), lieno-renal shunting (45%), umbilical vein patency (34%) and splenic artery aneurysms (20%). The presence of varices, lieno-renal shunting and right lobe atrophy was more common in EHPVO vs CLD [93% vs 62%, $p = .022$, 80% vs 36%, $p = .002$ and 87% vs 59%, $p = .020$ respectively], PLT<150 vs PLT>150 [87% vs 30%, $p < 0.001$, 60% vs 13%, $p < 0.001$, 79% vs 35%, $p < 0.001$ respectively] and abnormal vs normal USP profiles [86% vs 51%, $p = .002$, 64% vs 26%, $p = .001$, 78% vs 51%, $p = .020$ respectively]. Menstrual irregularities including irregular menses ± menorrhagia [n = 22,45%], amenorrhoea [n = 6,12%, primary n = 3] and polycystic ovary syndrome/premature pubarche [n = 7, 14%] were reported by 71% of females. Menstrual irregularities were associated with elevated serum testosterone levels [86% vs 50%, $p = 0.044$] and the presence of varices on imaging [86% vs 51%, $p = .047$]. Nine AYA [8F,1M] had undetectable testosterone levels [<0.4 nmol/l] whilst 11/20 males were had testosterone deficiency [Free androgen index <35]. This group was less likely to have PLT<150 but more likely to have patency of the umbilical vein on imaging when compared with AYA with normal/high testosterone levels.
Conclusion: Hormone dysregulation is prevalent in AYA with EHPVO and CLD and relates to features of portal hypertension and extrahepatic porto-systemic shunting.

WED-228

Frailty, malnutrition, and sarcopenia are prevalent among patients with liver disease and are associated with worse health-related quality of life and complications of cirrhosis

Maria Dezan[1], Caio da Hora[1], Isadora Almeida[2], Victor Santos[2], Jessica Dutra[2], Bruno Mendes[2], Arthur Lima[3], Andrezza Magalhães[3], Lucas Souza[3], Amanda Nascimento[1], Ana Batista[1], Lourianne Cavalcante[1], Rosângela de Jesus[1], Helma Pinchemel Cotrim[1], Andre Lyra[4]. [1]*Federal University of Bahia, Salvador, Brazil;* [2]*São Rafael Hospital, Salvador, Brazil;* [3]*University Hospital Professor Edgard Santos, Salvador, Brazil;* [4]*Federal University of*

Bahia, University Hospital Professor Edgard Santos, São Rafael Hospital, Salvador, Brazil
Email: marigabi_dezan@hotmail.com

Background and aims: Chronic liver disease (CLD) has high morbidity and clinical and nutritional complications that affect health-related quality of life (HRQoL). We aimed to quantify HRQoL in patients with CLD and correlate it with clinical and nutritional complications.
Method: Cross-sectional study, response to the Chronic Liver Disease Questionnaire (CLDQ) and nutritional assessment for sarcopenia (bioimpedance – BIA and arm muscle circumference – AMB), frailty (liver frailty index) and malnutrition (subjective global assessment – SGA and specific nutritional assessment for chronic liver disease – SNA-CLD). Statistical analysis used the Mann-Whitney, Kruskal-Wallis, and Chi-square tests.
Results: So far, 277 individuals were included (235 outpatients; 42 inpatients); the mean age was 55.7 ± 13.4 years, 52% women; 62.5% with liver cirrhosis (60% Child A; mean MELD Na 13 ± 5.5). Alcohol-related liver disease was the most prevalent in the total and in-hospital populations (28% and 43%, respectively), and metabolic dysfunction-associated steatotic liver disease among outpatients (29%). Outpatients and inpatients had CLDQ scores of 5.4 ± 1.2 and 4.6 ± 1.1, respectively; $p < 0.000$; the domains with the lowest scores were, respectively, fatigue (5.1 ± 1.7) and activities (4.5 ± 1.6) and worry (4.5 ± 1.7). Patients with more advanced cirrhosis had worse scores than those with Child A, MELD Na < 15, no portal hypertension (PH), and ascites: 4.7 ± 1.2 x. 5.6 ± 1.1 ($p = 0.006$); 4.8 ± 1.3 × 5.5 ± 1.1 ($p < 0.001$); 5.2 ± 1.2 × 5.6 ± 1.1 (p 0.01) and 4.9 ± 1.2 × 5.7 ± 1.1 ($p =$ 0.00), respectively. We detected frailty in 21% of the cases. Sarcopenia (by BIA and AMB) and malnutrition (by SGA and SNA-CLD) were detected in 24.6%, 13.9%, 46.2%, and 53% of cases, respectively. Cirrhosis, its complications, and the use of beta-blockers were associated with frailty ($p < 0.01$). Sarcopenia by AMB was associated with Child B/C, MELD Na ≥ 15, and ascites. More severe degrees of malnutrition by SNA-CLD and SGA were associated with cirrhosis, Child B/C, MELD Na ≥ 15, PH, ascites, and use of beta-blockers ($p <$ 0.001). The HRQoL scores in those with and without sarcopenia by AMB and BIA were 4.6 ± 1.3 × 5.4 ± 1.1 ($p < 0.001$) and 4.6 ± 1.3 × 5.5 ± 1.1 ($p < 0.001$), respectively. The frail and pre-frail groups had lower HRQoL scores when compared to the robust group of individuals: 4.6 ± 1.2 × 5.5 ± 1.1 × 5.6 ± 1.0 ($p < 0.001$). By SGA, severely malnourished patients had worse HRQoL when compared to those moderately malnourished and well-nourished: 4.7 ± 1.0 × 5.0 ± 1.3 × 5.0 ± 1.1 ($p <$ 0.001). According to SNA-CLD, the HRQoL worsened as the patients became increasingly malnourished ($p < 0.001$).
Conclusion: In this population, there was an association between the severity of liver disease (assessed by Child B/C, MELD Na ≥15, PH, and ascites), worse HRQoL, and a higher prevalence of frailty, malnutrition, and sarcopenia (AMB). These nutritional complications were also associated with worse HRQoL.

Background and aims: The MELD score was initially developed as a means of predicting mortality in patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) placement. In 2022, MELD 3.0 was introduced with the objective of improving mortality prediction in patients with liver cirrhosis. Despite having been validated in a number of cohorts, its prognostic value in patients undergoing TIPS remains elusive, particularly in Western cohorts. The objective of this study is to compare the accuracy of MELD 3.0 in predicting mortality with that of the established scores FIPS, MELD-Na and MELD.
Method: This retrospective multicentre study evaluated MELD 3.0 in two cohorts of patients with liver cirrhosis undergoing TIPS placement. Cohort 1 was derived from a single German tertiary hospital, while a multicentre validation cohort 2 included patients from seven German tertiary hospitals. The primary outcome measure was one-year mortality following TIPS placement. The prognostic performance of each score was evaluated using receiver operating characteristic (ROC) analysis and the concordance index (c-index). Furthermore, the c-indices were compared using DeLong's tests. In order to identify risk groups for TIPS placement in each cohort, patients were defined as belonging to a high-risk group if they were above the 85th percentile for each score, and as not belonging to a high-risk group if they were below the 85th percentile. Subsequently, one-year mortality was assessed using log-rank tests and Kaplan-Meier survival curves.
Results: A total of 1828 patients were included in the study (cohort 1: n = 412, cohort 2: n = 1416). The primary indication for TIPS placement in both cohorts was refractory ascites. In cohort 1, the ROC analysis demonstrated a c-index for one-year mortality of 0.701 (MELD 3.0), 0.704 (FIPS), 0.712 (MELD-Na), and 0.670 (MELD). In cohort 2, the corresponding c-indices were 0.633 (MELD 3.0), 0.670 (FIPS), 0.626 (MELD-Na) and 0.629 (MELD). DeLonǵs test revealed no statistically significant differences between MELD 3.0 and the other scores in cohort 1. However, in cohort 2, MELD 3.0 demonstrated superior performance in comparison to MELD-Na ($p = 0.0475$), while FIPS demonstrated superior performance in comparison to MELD 3.0 ($p = 0.0033$). The log-rank tests demonstrated that each high-risk group showed a significantly higher one-year mortality compared to the respective non-high-risk group ($p < 0.05$), with the exception of the patients in cohort 1 stratified by MELD ($p = 0.063$).
Conclusion: The findings of this study indicated that MELD 3.0 demonstrated comparable prognostic accuracy to MELD and MELD-Na in predicting one-year mortality in patients undergoing TIPS placement at high-volume tertiary centres. However, the results also suggested that FIPS might perform slightly better.
